Evidence from measuring eye movements in reading led to a similar conclusion (see *Eye Movements in Reading*). For instance, if a person reads 'While Mary was mending the sock fell off her lap,' the reader's eyes are likely to fixate a long time on the word 'fell' or to regress from that word to an earlier point in the sentence. This happens because the verb 'fell' is grammatically inconsistent with the normally preferred structural analysis of '…mending the sock'; 'the sock' must be the subject of 'fell,' not the object of 'mending.' Similarly, a person who reads 'When the car stopped the moon came up' is likely to fixate a longer than normal time on 'moon.' Here, 'moon' is simply implausible as the direct object of 'stop,' not ungrammatical. This pattern of results indicates that readers (and presumably listeners) create and evaluate grammatical and meaning relations word by word, without waiting for a clause boundary.

It is tempting to hypothesize that readers and listeners always perform a full semantic analysis of sentences word by word, with never a delay. This 'immediacy hypothesis' may be too strong. Some evidence indicates that, while true lexical ambiguities (e.g., the difference between the bank of a river and a bank for money) may be resolved word by word, sense ambiguities (e.g., the difference between a newspaper as something to read and a newspaper as an institution) may not be (Frazier and Rayner 1990). Similarly, determining the antecedent of a pronoun may be a task that readers do not always complete at the first opportunity. Nonetheless, one secure conclusion is that readers and listeners generally understand a great deal of what a sentence conveys with little or no lag.

3.3 Garden-pathing

Another much-studied phenomenon is 'garden-pathing.' When readers and listeners construct word-by-word interpretations of sentences, they sometimes make mistakes. Bever (1970) initiated the study of garden-pathing with his infamous sentence 'The horse raced past the barn fell' (compare 'The car driven into the garage caught fire' if you doubt that the former sentence is actually possible in English). Readers are 'led down the garden path' by their preference to take 'horse' as the agent of 'race,' and is disrupted when the final verb 'fell' forces a revision so that 'raced past the barn' is taken as a relative clause that modifies 'horse,' and 'horse' is taken to be the theme of 'race' and the subject of 'fell.'

The mistakes readers and listeners make can be extremely diagnostic of the decision rules they follow. A simple empirical generalization (which may or may not describe the cognitive process a reader or listener is engaging in; see below) is that when a choice between two analyses has to be made, the reader/listener initially favors (a) the choice that is simpler in terms of grammatical structure, or (b) in the absence of complexity differences, the choice that permits new material to be related to the most recently processed old material. In the 'horse raced' sentence, the main verb analysis is simpler than the relative clause analysis. In 'While Mary was mending the sock fell off her lap,' a reader/listener prefers to relate 'the sock' to the recently processed verb 'mending' rather than to material that has not yet been received. In both cases, these preferences are disconfirmed by material that follows, resulting in a garden-path.

A great deal of experimental work using techniques of self-paced reading and eye movement measurement has indicated that reading is slowed (and regressive eye movements are encouraged) at points where garden-paths occur. Similarly, experimental research using ERPs has indicated the existence of distinct patterns of neural response to being garden-pathed. Research using these, and other, techniques has gone further and demonstrated the existence of subtle garden-paths that may not be apparent to conscious introspection (e.g., the temporary tendency to take 'the article…' as the direct object of 'understand' in 'I understood the article on word recognition was written by a real expert'). Normally, it appears that the rules readers and listeners use to decide on the grammatical structures of sentences function so smoothly that their operation cannot be observed. But just as the analysis of visual illusions allows insight into the normal processes of visual perception by identifying when they go astray, identifying when a rule for analyzing sentence structure gives the wrong answer can go far in determining what rule is actually being followed.

3.4 Lexical and Frequency Effects

Once the existence and basic nature of garden-paths were discovered, researchers realized that garden-paths did not always occur. The sentence presented earlier, 'The car driven into the garage caught fire' does not seem to lead to a garden-path. This may be due in part to the fact that the verb 'driven' is unambiguously a participle, not a main verb, and the normally preferred simpler analysis is grammatically blocked. However, other cases indicate that more subtle effects exist. Sentences with verbs that are obligatorily transitive are relatively easy (e.g., '*The dictato*r captured in the coup was hated' is easier than 'The dictator fought in the coup was hated'). Sentences with verbs like 'cook,' whose subject can take on the thematic role of theme/affected object, are particularly easy ('The soup cooked in the pot tasted good').

Sentences in which the subject is implausible as agent of the first verb but plausible as its theme are easier than sentences in which subject is a plausible agent (e.g., 'The evidence examined by the lawyer was unreliable' is easier than 'The defendant examined by the lawyer was unreliable,' although this difference may depend on a reader being able to see the start of the disambiguating 'by' phrase while reading the first verb). Consider a different grammatical structure, prepositional phrase attachment. It is easier to interpret a prepositional phrase as an argument of an action verb than as a modifier of a noun (e.g., 'The doctor examined the patient with a stethoscope' is easier than 'The doctor examined the patient with a broken wrist'), which is consistent with a grammatical analysis in which the former sentence is structurally simpler than the latter. However, this difference reverses when the verb is a verb of perception or a 'psychological' verb and the noun that may be modified is indefinite rather than definite (e.g., 'The salesman glanced at a customer with suspicion' is harder than 'The salesman glanced at a customer with ripped jeans') (Spivey-Knowlton and Sedivy 1995; see also Frazier and Clifton 1996, Mitchell 1994, Tanenhaus and Trueswell 1995, for further discussion and citation of experimental articles).

These results indicate that grammatical structure is not the only factor that affects sentence comprehension. Subtle details of lexical structure do as well. Further, the sheer frequency with which different structures occur and the frequency with which particular words occur in different structures seems to affect sentence comprehension: For whatever reason, more frequent constructions are easier to comprehend. For example, if a verb is used relatively frequently as a participle compared to its use as a simple past tense, the difficulty of the 'horse raced' type garden-path is reduced. Similarly, the normal preference to take a noun phrase following a verb as its direct object (which leads to difficulty in sentences like 'I understood the article on word recognition was written by an expert') is reduced when the verb is more often used with sentence complements than with direct objects. MacDonald et al. (1994) review these findings, spell out one theoretical interpretation which will be considered shortly, and discuss the need to develop efficient ways of counting the frequency of structures and to decide on the proper level of detail for counting structures.

3.5 *Effects of Context*

Sentences are normally not interpreted in isolation, which raises the question of how context can affect the processes by which they are understood. One line of research has emphasized the referential requirements of grammatical structures. One use of a modifier, such as a relative clause, is to select one referent from a set of possible referents. For instance, if there are two books on a table, you can ask for the 'book that has the red cover.' Some researchers (e.g., Altmann and Steedman 1988) have suggested that the difficulty of the relative clause in a 'horse raced' type garden-path arises simply because the sentence is presented out of context and there is no set of referents for the relative clause to select from. This suggestion entails that the garden-path would disappear in a context in which two horses are introduced, one of which was raced past a barn. Most experimental research fails to give strong support to this claim (cf. Mitchell 1994, Tanenhaus and Trueswell 1995). However, the claim may be correct for weaker garden-paths, for example the prepositional phrase attachment discussed above ('The doctor examined the patient with a broken wrist'), at least when the verb does not require a prepositional phrase argument. And a related claim may even be correct for relative clause modification when temporal relations, not simply referential context, affect the plausibility of main verb vs. relative clause interpretations (cf. Tanenhaus and Trueswell 1995).

3.6 *Effects of Prosody*

Most research on sentence comprehension has focused on reading. However, some experimental techniques permit the use of spoken sentences, which raises the possibility of examining whether the prosody of a sentence (its rhythm and melody) can affect how it is comprehended. The presence of a prosodic boundary (marked in English by a change in pitch at the end of the prosodic phrase, elongation of its final word, and possibly the presence of a pause) can affect the interpretation of a sentence. It can even eliminate the normal preferences that result in garden-paths. For example, Kjelgaard and Speer (1999) showed that the proper pattern of prosodic boundaries can eliminate the normal difficulty of sentences like 'Whenever Madonna sings a song is a hit.' As these authors emphasize, though, there is more to prosody than just putting in pauses. The entire prosodic pattern of an utterance (including the presence and location of 'pitch accents'; Schafer et al. 1996) can affect how it is interpreted.

4. *Psychological Models of Sentence Comprehension*

Psycholinguists have learned a great deal about the phenomena of sentence comprehension. This does not mean that they agree about the cognitive processes of readers and listeners that produce these phenomena.

Early theories of how people understand sentences claimed that the rules that make up a linguistic theory of a language are known (implicitly) to language users,

who use the rules directly in comprehending language (see Fodor et al. 1974). This did not work with the rules provided by early transformational grammars. Their rules operated on domains as large as a clause, and it soon became clear that people did not wait for the end of a clause to understand a sentence.

These early direct incorporation theories were replaced by what can be called 'detective-style' theories. Readers and listeners were presumed to search for clues of any kind to the relations among words in a sentence. Psycholinguistic theorizing became little more than listing cues that people used.

In the 1970s, as grammars changed to use more restrictive types of rules (especially emphasizing phrase-structure rules), a new breed of grammar-based theories developed. These theories added descriptions of decision strategies to the claim that people use the rules provided by the grammar, focusing on how they choose among various alternative rules in analyzing a sentence (Frazier 1987; cf. Frazier and Clifton 1996, Mitchell 1994, for further discussion of these theories). They claimed, for instance, that readers and listeners incorporate each new word into a sentence structure in the simplest and quickest possible way. This led to compelling accounts of garden-path phenomena, and the theories under discussion are often referred to as 'garden-path' theories.

In the 1970s and 1980s, linguistic theory moved away from positing broad, generally applicable rules to making claims about information contained in individual lexical items (constrained by some extremely broad general principles). This encouraged the development of 'lexicalist' theories of sentence comprehension (see MacDonald et al.1994, for the most completely developed statement of such a theory). These theories emphasize the specific contribution of individual words, rather than the effects of conformity to generally applicable word configurations. An individual word can provide a variety of kinds of information, including the possible and preferred thematic roles for its arguments, the frequency with which it is used in various constructions, and the entities it can refer to, as well as information about the phrase structure configurations it can appear in. Lexicalist theories propose that all these kinds of information are available and are used in deciding among alternative analyses.

It is clear that contemporary theories of sentence comprehension differ in the range of information that they claim guides sentence analysis. Garden-path theories are 'modular' (cf. Fodor 1983) in that they claim that only certain necessarily relevant types of information affect initial decisions about sentence structure. Lexicalist theories are generally non-modular in allowing many different kinds of information to affect these decisions. The theories also differ in what can be called depth-first vs. breadth-first processing (see Clifton 2000, for discussion). Garden-path theories are typically depth-first (although logically they need not be); they typically claim that a single analysis is built initially and then evaluated. Lexicalist theories are typically breadth-first; they claim that several different analyses are activated in parallel (generally being projected from the head of a phrase), and that all available types of information are used to choose among them. Experimental data have thus far not been able to settle the debate between theorists favoring depth-first models and theorists favoring breadth-first ones.

Garden-path theories explain garden-paths elegantly, and provide a more adequate account of how sentence structures are created than lexicalist theories do. On the other hand, they are forced to ascribe the effects of lexical structure, frequency, and context described above to a 'reanalysis' stage, which follows discovery that the initially preferred analysis is incorrect. Lexicalist theories, on the other hand, provide a natural account of effects of lexical structure, frequency, and context, especially when implemented as connectionist constraint-satisfaction models. But they have not yet been developed in a way that adequately explains where sentence structures come from (it is unappealing to say that the large parts of the grammar are stored with each lexical entry) or that explains why structurally complex sentences are overwhelmingly the ones that lead to garden-paths.

5. *Beyond Parsing*

This article has focused on how readers and listeners use their knowledge of language to compose sentence meanings from words. While much of the power of language comes from readers' and listeners' abilities to 'follow the rules' and arrive at grammatically licensed interpretations of sentences, it is also clear that people have the ability to go beyond such literal interpretation. The context in which an utterance is heard or a sentence is read can influence its interpretation far more profoundly than the context effects discussed above. The meaning of words can be altered depending on the context in which they occur (consider 'bank' in the context of a trip to the river to fish vs. a purchase of a house, or 'red' in the context of a fire truck vs. a red-haired woman). The reference of a definite noun phrase can depend the discourse context. A listener can determine whether a speaker who says 'Can you open this door?' is asking about the adequacy of a job of carpentry vs. requesting some assistance. Speakers can rely on listeners to get their drift when they use figurative language such as metaphors and possibly irony ('My copy editor is a butcher'). And very generally, what a listener or reader takes a speaker or writer to mean may depend on their shared goals and mutual knowledge (cf. Clark 1996).

Nonetheless, all these varied uses of language depend on the listener/reader's ability to put words

together into sentence meanings, which makes the study of the topics considered in this article an important branch of cognitive psychology.

C. Clifton, Jr.

Sequential Decision Making

Sequential decision making describes a situation where the decision maker (DM) makes successive observations of a process before a final decision is made, in contrast to dynamic decision making (see *Dynamic Decision Making*) which is more concerned with controlling a process over time.

Formally a sequential decision problem is defined, such that the DM can take observations $X_1, X_2, \ldots$ one at a time. After each observation X_n the DM can decide to terminate the process and make a final decision from a set of decisions D, or continue the process and take the next observation X_{n+1}. If the observations $X_1, X_2, \ldots$ form a random sample, the procedure is called sequential sampling.

In most sequential decision problems there is an implicit or explicit cost associated with each observation. The procedure to decide when to stop taking observations and when to continue is called the *stopping rule*. The objective in sequential decision making is to find a stopping rule that optimizes the

decision in terms of minimizing losses or maximizing gains including observation costs. The optimal stopping rule is also called the optimal strategy or the optimal policy.

A wide variety of sequential decision problems have been discussed in the statistics literature, including search problems, inventory problems, gambling problems, and secretary-type problems, including sampling with and without recall. Several methods have been proposed to solve the optimization problem under specified conditions, including dynamic programming, Markov chains, and Bayesian analysis.

In the psychological literature, sequential decision problems are better known as *optional stopping problems*. One line of research using sequential decision making is concerned with seeking information in situations such as buying houses, searching for a job candidate, price searching, or target search. The DM continues taking observations until a decision criterion for acceptance is reached. Another line of research applies sequential decision making to account for information processing in binary choice tasks (see *Diffusion and Random Walk Processes*; *Stochastic Dynamic Models (Choice, Response, and Time)*), and hypothesis testing such as in signal detection tasks (see *Signal Detection Theory: Multidimensional*). The DM continues taking observations until either of two decision criteria is reached. Depending on the particular research area, observations are also called offers, options, items, applicants, information, and the like. Observation costs include explicitly not only possibly money, but also time, effort, aggravation, discomfort, and so on.

Contrary to the objective of statisticians or economists, psychologists are less interested in determining the optimal stopping rule, and more interested in discussing the variables that affect human decision behavior in sequential decision tasks. Optimal decision strategies are considered as normative models, and their predictions are compared to actual choice behavior.

1. Sequential Decision Making with One Decision Criterion

In sequential decision making with one decision criterion the DM takes costly observations X_n, $n = 1,\ldots$ of a random process one at a time. After observing $X_n = x_n$ the DM has to decide whether to continue sampling observations or to stop. In the former case, the observation X_{n+1} is taken at a cost of c_{n+1}; in the latter case the DM receives a net payoff that consists of the payoff minus the observation costs. The DM's objective is to find a stopping rule that maximizes the expected net payoff.

The optimal stopping rule depends on the specific assumptions made about the situation: (a) the distribution of X is known, not known or partly known, (b) X_i are distributed identically for all i, or have the similar distribution but with different parameters, or have different distributions, (c) the number of possible observations, n, is bounded or unbounded, (d) the sampling procedure, e.g., it is possible to take the highest value observed so far when stopping (sampling with recall) or only to take the last value when stopping (sampling without recall), and (e) the cost function, c_n, is fixed for each observation or is a function of n. Many of these problems have been studied theoretically by mathematicians and experimentally by psychologists. Pioneering experimental work was done in a series of papers by Rapoport and colleagues (1966, 1969, 1970, 1972).

1.1 Unknown Sample Distribution: Secretary-type Problems

Kahan et al. (1967) investigated decision behavior in a sequential search task where the DM had to find the largest of a set of $n = 200$ numbers, observed one at a time from a deck of cards. The observations were taken in random order without replacement. The DM could only declare the current observation as the largest number (sampling without recall), and could compare the number with the previous presented numbers. No explicit cost for each observation was taken, i.e., $c = 0$. The sample distribution was unknown to the DM. A reward was paid only when the card with the highest number was selected, and nothing otherwise. This describes a decision situation that is known as *the secretary problem* (a job candidate search problem; for various other names, see, e.g., Freeman 1983) which, in its simplest form, makes explicit the following assumptions (Ferguson 1989): (a) only one position is available, (b) the number n of applicants is known, (c) applicants are interviewed sequentially in random order, each order being equally likely, and (d) all applicants can be ranked without ties—the decision to reject or accept an applicant must be based only on the relative ranks of the applicants interviewed so far, (e) an applicant once rejected cannot later be recalled, and (f) the payoff is 1 when choosing the best of the n applicants, 0 otherwise.

The optimal strategy for this kind of problem is to reject the first $s-1$, $s \geqslant 1$, items (cards, applicants, draws) and then choose the first item that is best in the relative ranking so far. With

$$a_s \equiv \frac{1}{s} + \frac{1}{s+1} + \cdots + \frac{1}{n-1} \tag{1}$$

the optimal strategy is to stop if $a_s < 1$ and to continue if $a_s > 1$, which can easily be determined for small n. For large n, the probability of choosing the best item is

approximated by $1/e$ and the optimal s by n/e. ($e = 2.71\ldots$). (For derivations, see, e.g., DeGroot 1970, Freeman 1983, Gilbert and Mosteller 1966).

Kahan et al. (1967) reported that about 40 percent of their subjects did not follow the optimal strategy but stopped too late and rejected a card that should have been accepted. The failure of the strategy for describing behavior was assigned to its inadequacy for the described task. Although at the beginning of the experiment the participants did not know anything about the distribution (requirement), they could learn about the distribution by taking observations (partly information). To guarantee ignorance of the distribution, Gilbert and Mosteller (1966) recommended supplying only the rank of the observation made so far and not the actual value. Seale and Rapoport (1997) conducted an experiment following this advice. They found that participants (with $n = 40$ and $n = 80$) stopped earlier than prescribed by the optimal stopping rule. They proposed simple decision rules or heuristics to describe the actual choice behavior. Using a cutoff rule, the DM rejects the first $s-1$ applicants and then chooses the next top-ranked applicant, i.e., the candidate. The DM simply counts the number of applicants and then stops on the first candidate after observing $s-1$ applicants. Under a candidate count rule, the DM counts the number of candidates and chooses the jth candidate. A successive non-candidate rule requires the DM to choose the first candidate after observing at least k consecutive noncandidates following the last candidate.

The secretary problem has been extended and generalized in many different directions within the mathematical statistics field. Each of the above assumptions has been relaxed in one way or another. (Ferguson 1989, Freeman 1983). However, the label of secretary problem tends to be used only when the distribution is unknown and the decision to stop or to continue depends only on the relative ranking of the observations taken so far and not on their actual values.

1.2 Known Sample Distribution

Rapoport and Tversky (1966, 1970) investigated choice behavior when the mean and the variance of the distribution was known to the DM. The cost for each observation was fixed but the amount varied across experimental conditions, and the number of possible observations n was unbounded (1966) or bounded and known (1970). Behavior for sampling with and without recall was compared. When sampling is without recall only the value of the last observation, $X_n = x_n$, can be received, and the payoff is this value minus the total sampling cost, i.e, $x_n - cn$. The optimal strategy is to find a stopping rule that maximizes the expected payoff $E(X_N - cN)$. When sampling is with recall, the highest value observed so far can be selected and the payoff is $\max(x_1,\ldots, x_n) - cn$ and the optimal strategy is to find a stopping rule that maximizes $E(\max(X_1,\ldots, X_N) - cN)$. In the following, v with subscripts and v^* denote the expected gain from an (optimal) procedure.

1.2.1 Number of Observations Unbounded. If n is unbounded, i.e., if the number of observations that can be taken is unlimited, and X_1, $X_2\ldots$ are sampled from a known distribution function $F(x)$, the optimal strategy is the same for both sampling with and without recall. In particular, the optimal strategy is to continue to take observations whenever the observed value $x_j < v^*$, and to stop taking observations as soon as an observed value $x_j \geqslant v^*$, where v^* is the unique solution of

$$\int_{v^*}^{\infty} (x - v^*)\, dF(x) = c \quad -\infty < v^* < \infty. \tag{2}$$

When the observations are taken from a standard normal distribution with density functions $\phi(x)$ and distribution function $\Phi(\mathrm{x})$, we have that

$$v^* = \frac{\phi(v^*) - c}{1 - \Phi(v^*)}. \tag{3}$$

Although sampling with and without recall have the same solution, they seem to be different from a psychological point of view. Rapoport and Tversky (1966) found that the group sampling without recall took significantly fewer observations than the participants sampling with recall. The mean number of observations for both groups decreased with increasing cost c, and the difference with respect to the number of observations taken was diminished. However, the participants in both groups took fewer observations than prescribed by the optimal strategy. This nonoptimal behavior of the participants was attributed to a lack of thorough knowledge of the distributions.

1.2.2 Number of Observations Bounded. If n, $n \geqslant 2$, is bounded, i.e., if not more than n observations can be taken, the optimal stopping rules for sampling with and without recall are different. For sampling without recall, an optimal procedure is to continue taking observations whenever $x_j < v_{n-j} - c$ and to stop as soon as $x_j \geqslant v_{n-j} - c$, where $j = 1, 2\ldots n$ indicates the number of observations which remain available and

$$v_{j+1} = (v_j - c) - \int_{v_j - c}^{\infty} (x - (v_j - c))\, dF(x). \tag{4}$$

With $v_1 = E(X) - c$, the sequence can be computed successively. Again, assuming a standard normal distribution $v_{j+1} = \phi(v_j - c) + \Phi(v_j - c)$.

For sampling with recall, the optimal strategy is to continue the process whenever a value $x_j < v^*$ and to stop taking observations as soon as an observed value $x_j \geqslant v^*$, where v^* is as in Eqn. (2), which is the same solution as for n unbounded. (For derivations of the strategies, see DeGroot 1970, Sakaguchi 1961.)

Rapoport and Tversky (1970) investigated choice behavior within this scenario. Sampling was done both with and without recall. The number of observations that could be taken as well as observation cost varied across experimental groups. One third of the participants did not follow the optimal strategy. Under both sampling procedures and all cost conditions, they took on average fewer observations than predicted by the corresponding optimal stopping rules. There were no systematic differences due to cost, as observed in their previous study. They concluded that 'the optimal model provides a reasonable good account of the behavior of the subjects' (p. 119).

1.3 Different Sample Distributions for Each Observation

Most research concerned with sequential decision making assumes that the observations are sampled from the same distribution, i.e., X_i are distributed identically for all i. For many decision situations, however, the observations may be sampled from the same distribution family with different parameters, or from different distributions. Especially in economic areas, such as price search, it is reasonable to assume that the distributions from which observations are taken change over time. The sequence of those samples has been called *nonstationary series*. Of particular interest are two special nonstationary series: *ascending* and *descending* series. For ascending series, the observations are drawn from distributions, usually from normal distributions, with increasing mean as i increases; for descending series the mean of the distribution decreases as i increases, i indicating the sample index. For both cases, experiments have been conducted to investigate choice behavior in a changing environment. Shapira and Venezia (1981) compared choice behavior for ascending, descending and constant (identically distributed X_i) series. In one experiment (numbers from a deck of cards), the distributions were known to the DM; no explicit observation costs were imposed; sampling occurred without recall; and the number of observations that could be taken was limited to $n = 7$. The variance of the distributions varied across experimental groups. An optimal procedure was assumed to continue taking observations whenever $x_j < v_{n-j}$, and to stop as soon as $x_j \geqslant v_{n-j}$, where $j = 1, 2 \ldots n$ indicates the number of observations which remain available. $k = 1, \ldots, n$ indicates the specific distribution for the jth observation. Thus

$$v_{j+1} = v_j - \int_{v_j}^{\infty} (x - v_j)\, dF_k(x). \tag{5}$$

With $v_1 = E(X_1)$ the sequence can be computed successively. Assuming a standard normal distribution $v_{j+1} = \phi_k(v_j) + \Phi_k(v_j)$.

Across all conditions, 58 percent of the participants behaved in an optimal way. The proportion of optimal stopping did not depend on the type of series but on the size of the variance. Nonoptimal stopping (24 percent stopped too early; 18 percent too late) depended on the series and on the size of the variance. In particular, participants stopped too early on ascending and too late on descending series. A similar result was observed by Brickman (1972). In this study, departing from the optimal stopping rule was attributed to an inadequacy of the stopping rule taken for the particular experimental conditions (assuming complete knowledge of the distributions). In a secretary problem design (see Sect. 1.1), Corbin et al. (1975) were less concerned with optimal choice behavior than with the processes by which the participants made their selections, and with factors that influenced those processes. The emphasis of the investigation was on decision making heuristics rather than on the adequacy of optimal models. With the same optimal stopping rule for all experimental conditions, they found that stopping behavior depended on contextual variables such as the ascending or descending trend of the inspected numbers of the stack.

2. Search Problems—Multiple Information Sources

In a sequential decision making task with multiple information sources, the DM has the option to take information sequentially from different sources. Each information source may provide valid information with a particular probability and at different cost. The task is not only to decide to stop or to continue the process but also, if continuing, which source of information to consult.

Early experimental studies were done by Kanarick et al. (1969), Rapoport (1969), Rapoport et al. (1972). A typical task is to find an object (e.g., a black ball) which is hidden in one of several possible locations (e.g., in one of several bins containing white balls). The optimal search strategy depends on further task specifications, such as whether the object can move from one location to another, how many objects are to be found, and whether the search process may stop before the object has been found. Rapoport (1969)

investigated the case when a single object that could not move was to be found in one of r, $r \geqslant 2$, possible locations. The DM was not allowed to stop the process before the target was found. All of the following were known to the DM: the a priori probability p_i, $p_i > 0$ that the object is in location i, $i = 1, 2, \ldots, r$, with $\sum_{i=1}^{r} p_i = 1$; a miss probability α_i, $0 < \alpha_i < 1$, that even if the object is in location i it will not be found in a particular search of that location ($1-\alpha_i$ is referred to the respective detection probability); and a cost, c_i, for a single observation at location i. The objective of the DM is to find a search strategy that minimizes the expected cost. For $i = 1, \ldots, r$ and $j = 1, 2, \ldots$ let Π_{ij} denote the probability that the object is found at location i during the jth search and the search is terminated. Then

$$\Pi_{ij} = p_i \alpha_i^{j-1} (1-\alpha_i), \quad i = 1, \ldots, r, \; j = 1, 2, \ldots \tag{6}$$

If all values of Π_{ij}/c_i for all values of i and j are arranged in order of decreasing magnitude, the optimal strategy is to search according to this ordering (for derivations, see DeGroot 1970). Ties may be ordered arbitrarily among themselves. The optimal strategy is determined by the detection probabilities and observation costs, and optimal search behavior implies a balance between maximizing the detection probability and minimizing the observation cost. Rapoport (1969) found that participants did not behave optimally. They were more concerned with maximizing the probability of detecting the target than with minimizing observation cost. Increasing the difference of observation cost c_i among the $i = 1, 2, 3, 4$ locations showed that the deviation from the optimal strategy even increased. Rapoport et al. (1972) varied the search problems by allowing the DM to terminate the search at any time; adding a terminal reward, R, for finding the target; and a terminal penalty, B, for not finding the target. Most participants showed a bias toward maximizing detection probability vs. minimizing search cost per observation, similar to the previous study.

3. *Sequential Decision Making with Two or More Possible Decisions*

A random sample $X_1, X_2, \ldots$ is generated by an unknown state of nature, Θ. The DM can take observations one at a time. After observing $X_n = x_n$ the DM makes inferences about Θ based on the values of $X_i, \ldots, X_n$ and can decide whether to continue sampling observations or to stop the process. In the former case, observation X_{n+1} is taken; in the latter, the DM makes a final decision $d \in D$. The consequences to the DM depend on the decision d and the value θ.

The statistical theory for this situation was developed by Wald during the 1940s. It has been used to test hypotheses and estimate parameters. In psychological research, sequential decision making of this kind is usually limited to two decisions $D = \{d_1, d_2\}$, and applied to binary choice tasks (see *Diffusion and Random Walk Processes*; *Stochastic Dynamic Models (Choice, Response, and Time)*; *Bayesian Theory: History of Applications*).

The standard theory of sequential analysis by Wald (1947) does not include considerations of observation costs $C(n)$, losses for terminal decisions $L(\theta, d)$, and *a priori* (subjective) probabilities π of the alternative states of nature. *Deferred decision theory* generalizes the original theory by including these variables explicitly. The objective of the DM is to find a stopping rule that minimizes expected loss (called risk) and expected observation cost. The form of that optimal stopping rule depends mainly on the assumptions about the number of observations that can be taken (bounded or unbounded), and on the assumption of cost per observation (fixed or not) (see DeGroot 1970). Birdsall and Roberts (1965), Edwards (1965), and Rapoport and Burkheimer (1971) introduced the idea of deferred decision theory as normative models of choice behavior to the psychological community. Experiments investigating human behavior in deferred decision tasks have been carried out by Pitz and colleagues (e.g., Pitz et al. 1969), and by Busemeyer and Rapoport (1988). Rapoport and Wallsten (1972) summarize experimental findings.

For illustration, assume the decision problem in its simplest form. Suppose two possible states of nature θ_1 or θ_2, and two possible decisions d_1 and d_2. Cost c per observation is fixed and the number of observations is unbounded. The DM does not know which of the states of nature, θ_1 or θ_2 is generating the observation, but there are a priori probabilities π that it is θ_1 and $(1-\pi)$ that it is θ_2. Let w_i denote the loss for a terminal decision incurred by the DM in deciding that θ_i is not the correct state of nature when it actually is ($i = 1, 2$). No losses are assumed when the DM makes a correct decision. Let π_n denote the posterior probability that θ_1 is the correct state of nature generating the observations after n observations have been made. The total posterior expected loss is $r_n = \min\{w_1\pi_n, w_2(1-\pi_n)\} + nc$. The DM's objective is to minimize the expected loss. An optimal stopping rule is specified in terms of decision boundaries, α and β. If the posterior probability is greater than or equal to α, then decision d_1 is made; if the posterior probability is smaller than or equal to β, then d_2 is selected; otherwise sampling continues.

Sequential Statistical Methods

Statistics plays two fundamental roles in empirical research. One is in determining the data collection process: the experimental design. The other is in analyzing the data once it has been collected. For the purposes of this article, two types of experimental designs are distinguished: *sequential* and *nonsequential*. In a sequential design the data that accrue in an experiment can affect the future course of the experiment. For example, an observation made on one experimental unit treated in a particular way may determine the treatment used for the next experimental unit. The term 'adaptive' is commonly used as an alternative to sequential. In a nonsequential design the investigator can carry out the entire experiment without knowing any of the interim results.

The distinction between sequential and nonsequential is murky. An investigator's ability to carry out an experiment exactly as planned is uncertain, as information that becomes available from within and outside the experiment may lead the investigator to amend the design. In addition, a nonsequential experiment may give results that encourage the investigator to run a second experiment, one that might even simply be a continuation of the first. Considered separately, both experiments are nonsequential, but the larger experiment that consists of the two separate experiments is sequential.

In a typical type of nonsequential design, 20 patients suffering from depression are administered a drug and their improvements are assessed. An example sequential variation is the following. Patients' improvements are recorded 'in sequence' during the experiment. The experiment stops should it happen that at least nine of the first 10 patients, or no more than one of the first 10 patients improve(s). On the other hand, if between two and eight of the first 10 patients improve then sampling continues to a second set of 10 patients, making the total sample size equal to 20 in that case. Another type of sequential variation is when the dose of the drug is increased for the second 10 patients should it happen that fewer than four of the first 10 improve.

Much more complicated sequential designs are possible. For example, the first patient may be assigned a dose in the middle of a range of possible doses. If the patient improves then the next patient is assigned the next lower dose, and if the first patient does not improve then the next patient is assigned the next higher dose. This process continues, always dropping the dosage if the immediately preceding patient improved, and increasing the dosage if the immediately preceding patient did not improve. This is called an 'up-and-down' design.

Procedures in which batches of experimental units (such as groups of 10 patients each) are analyzed before proceeding to the next stage of the experiment

are called 'group-sequential.' Designs such as the up-and-down design, in which the course of the experiment can change after each experimental unit responds are called 'fully sequential.' So a fully sequential design is a group-sequential design in which the group size is one. Designs in which the decision of when to stop the experiment depends on the accumulating results are called 'sequential stopping.' Using rules to determine which treatments to assign to the next experimental unit or batch of units is called 'sequential allocation.'

Designs of most scientific experiments are sequential, although perhaps not formally so. Investigators usually want to conserve time and resources. In particular, they do not want to continue an experiment if they have already learned what they set out to learn, and this is so whether their conclusion is positive or negative, or if finding a conclusive answer would be prohibitively expensive. (Where the investigator discovers that the standard deviation of the observations is much larger than originally thought is an example of an experimental design that would be prohibitively expensive to continue because the required sample size would be large.)

Sequential designs are difficult or impossible to use in some investigations. For example, results might take a long time to obtain, and waiting for them would mean delaying other aspects of the experiment. Suppose one is interested in whether grade-schoolers diagnosed with attention deficit hyperactivity disorder (ADHD) should be prescribed Ritalin. The outcome of interest is whether children on Ritalin will be addicted to drugs as adults. Consider assigning groups of 10 children to Ritalin and 10 to a placebo, and waiting to observe their outcomes before deciding whether to assign an additional group of 10 patients to each treatment. The delay in observation means that it would probably take hundreds of years to get an answer to the overall question. The long-term nature of the endpoint means that any reasonable experiment addressing this question would necessarily be nonsequential, with large numbers of children assigned to the two groups before any information at all would become available about the endpoint.

1. *Analyzing Data from Sequential Experiments—Frequentist Case*

Consider an experiment of a particular type, say one to assess extrasensory perception (ESP) ability. A subject claiming to have ESP is asked to choose between two colors. The *null hypothesis* of no ability is that the subject is only guessing, in which case the correct color has a probability of 1/2. Suppose the subject gets 13 correct out of 17 tries. How should these results be analyzed and reported? The answer depends on one's statistical philosophy. Frequentists and Bayesians take different approaches. Frequentist analyses depend on whether the experiment's design is sequential, and if it is sequential the conclusions will differ depending on the actual design used.

In the nonsequential case the subject is given exactly 17 tries. The frequentist P-value is the probability of results as extreme as or more extreme than those observed. The results are said to be 'statistically significant' if the P-value is less than 5 percent. A convention is to include both 13 or more successes and 13 or more failures. (This 'two-sided' case allows for the possibility that the subject has ESP but has inverted the 'extrasensory' signals.) Assuming the null hypothesis and that the tries are independent, the probabilities of the number of successes is binomial. Binomial probabilities can be approximated using the normal distribution. The z-score for 13 out of 17 is about 2, and so the probability of 13 or more successes or 13 or more failures is about 0.05 (the exact binomial probability is 0.049), and so the results are statistically significant at the 5 percent level and the null hypothesis is rejected.

Now suppose the experiment is sequential. The frequentist significance level is now different, and it depends on the actual design used. Suppose the design is to sample until the subject gets at least four successes and at least four failures—same data, different design. Again, more extreme means more than 13 successes (and exactly four failures) or more than 13 failures (and exactly four successes). The total probability of these extreme values is 0.021—less than 0.049—and so the results are now more highly significant than if the experiment's design had been nonsequential.

Consider another sequential design, one of a type of group-sequential designs commonly used in clinical trials. The experimental plan is to stop at 17 tries if 13 or more are successes or 13 or more are failures, and hence the experiment is stopped on target. But if after 17 tries the number of successes is between five and 12 then the experiment continues to a total of 44 tries. If at that time, 29 or more are successes or 29 or more are failures then the null hypothesis is rejected. To set the context, suppose the experiment is nonsequential, with sample size fixed at 44 and no possibility of stopping at 17; then the exact significance level is again 0.049. When using a sequential design, one must consider all possible ways of rejecting the null hypothesis in calculating a significance level. In the group-sequential design there are more ways to reject than in the nonsequential design with the sample size fixed at 17 (or fixed at 44). The overall probability of rejecting is greater than 0.049 but is somewhat less than $0.049 + 0.049$ because some sample paths that reject the null hypothesis at sample size 17 also reject it at sample size 44. The total probability of rejecting the null hypothesis for this design is actually 0.080. Therefore, even though the results beyond the first 17 observations are never observed, the fact that they might have been observed makes 13 successes of 17 no

Table 1
Summary of experimental designs and related significance levels

Stopping rule	Significance level
After 17 observations (nonsequential)	0.049
After at least 4 successes and 4 failures	0.021
After 17 or 44 observations, depending on interim results	0.08
Stop when 'you think you know the answer'	Undefined

longer statistically significant (since 0.08 is greater than 0.05). The three designs above are summarized in Table 1. The table includes a fourth design in which the significance level cannot be found.

To preserve a 0.05 significance level in group-sequential or fully sequential designs, investigators must adopt more stringent requirements for stopping and rejecting the null hypothesis; that is, they must include fewer observations in the region where the null hypothesis is rejected. For example, the investigator in the above study might drop 13 successes or failures in 17 tries and 29 successes or failures in 44 tries from the rejection region. The investigator would stop and claim significance only if there are at least 14 successes or at least 14 failures in the first 17 tries, and claim significance after 44 tries only if there are at least 30 successes or at least 30 failures. The *nominal significance levels* (those appropriate had the experiment been nonsequential) at $n = 17$ and $n = 44$ are 0.013 and 0.027, and the overall (or adjusted) significance level of rejecting the null hypothesis is 0.032. (No symmetric rejection regions containing more observations allow the significance level to be greater than this but still smaller than 0.05.) With this design, 13 successes out of 17 is not statistically significant (as indicated above) because this data point is not in the rejection region. The above discussion is in the context of significance testing. But the same issues apply in all types of frequentist inferences, including confidence intervals.

The implications of the need to modify rejection regions depending on the design of an experiment are profound. In view of the penalties that an investigator pays in significance level that are due to repeated analyses of accumulating data, investigators strive to minimize the number of such analyses. They shy away from using sequential designs and so may miss opportunities to stop or otherwise modify the experiment depending on accumulating results.

What happens if investigators fail to reveal that other analyses did occur, or that the experiment might have continued had other results been observed? Any frequentist conclusion that fails to take the other analyses into account is meaningless. Strictly speaking, this is a breach of scientific ethics when carrying out frequentist analyses. But it is difficult to find fault with investigators who do not understand the subtleties of frequentist reasoning and who fail to make necessary adjustments to their inferences.

For more information about the frequentist approach to sequential experimentation, see Whitehead (1992).

2. *Analyzing Data from Sequential Experiments—Bayesian Case*

When taking a Bayesian approach (see *Bayesian Statistics*) (or a likelihood approach), conclusions are based only on the observed experimental results and do not depend on the experiment's design. So the murky distinction that exists between sequential and nonsequential designs is irrelevant in a Bayesian approach. In the example considered above, 13 successes out of 17 tries will give rise to the same inference in each of the designs considered. Bayesian conclusions depend only on the data actually observed and not otherwise on the experimental design (Berger and Wolpert 1984, Berry 1987).

The Bayesian paradigm is inherently sequential. Bayes's theorem prescribes the way learning takes place under uncertainty. It specifies how an observation modifies one's state of knowledge (Berry 1996). Moreover, each observation that is planned has a probability distribution. After 13 successes in 17 tries, the probability of success on the next try can be found. This requires a distribution, called a 'prior distribution,' for the probability of success on the first of the 17 tries. Suppose the prior distribution is uniform from zero to one. (This is symmetric about the null hypothesis of 1/2, but it is unlikely to be anyone's actual prior distribution in the case of ESP because it gives essentially all the probability to *some* ESP ability.) The predictive probability of a success on the 18th try is then $(13+1)/(17+2) = 0.737$, called 'Laplace's rule of succession' (Berry 1996, p. 204). Whether to take this 18th observation can be evaluated by weighing the additional knowledge gained (having 14 successes out of 18, with probability 0.737, or 13 successes out of 18, with probability 0.263) with the costs associated with the observation.

Predictive probabilities are fundamental in a Bayesian approach to sequential experimentation. They indicate how likely it is that the various possibilities for future data will happen, given the data currently available. Suppose that after 13 successes of 17 tries one is entertaining taking an additional 27 observations. One may be interested in getting at least 30 successes out of the total of 44 observations—which means at least 17 of the additional 27 observations are successes. The predictive probability of this is about 50 percent. Or one may be interested in getting successes

in at least 1/2 (22) of the 44 tries. The corresponding predictive probability is 99.5 percent.

The ability to use Bayes's theorem for updating one's state of knowledge and the use of predictive probabilities makes the Bayesian approach appealing to researchers in the sequential design of experiments. As a consequence, many researchers who prefer a frequentist perspective use the Bayesian approach in the context of sequential experimentation. If they are interested in finding the frequentist operating characteristics (such as significance level and power), these can be calculated by simulation.

The next section (Sect. 4) considers a special type of sequential experiment. The goals of the section are to describe some of the calculational issues that arise in solving sequential problems and to convey some of the interesting aspects of sequential problems. It takes a Bayesian perspective.

3. *Sequential Allocation of Experiments: Bandit Problems*

In many types of experiments, including many clinical trials, experimental units are randomized in a balanced fashion to the candidate treatments. The advantage of a balanced design is that it gives maximal information about the differences between treatments. In some types of experiment, including some clinical trials, it may be important to obtain good results on the units that are part of the experiment. Treatments—or *arms*—are assigned based on accumulating results; that is, assignment is sequential. The goal is to maximize the overall effectiveness—of those units in the experiment, but also, perhaps, including those units not actually in the experiment but whose treatment might benefit from information gained in the experiment.

Specifying a design is difficult. The first matter to be considered is the arm selected for the initial unit. Suppose that the first observation is X_1. The second component of the design is the arm selected next, given X_1 and also given the first arm selected. The third component depends on X_1 and the second observation X_2, and on the corresponding arms selected. And so on. A design is *optimal* if it maximizes the expected number of successes. An arm is optimal if it is the first selection of an optimal design.

Consider temporarily an experiment with n units and two available arms. Outcomes are dichotomous: arm 1 has success probability p_1 and arm 2 has success probability p_2. The goal is to maximize the expected number of successes among the n units. Arm 1 is standard and has known success proportion p_1. Arm 2 has unknown efficacy. Uncertainty about p_2 is given in terms of a prior probability distribution. To be specific, suppose that this is uniform on the interval from 0 to 1.

Table 2
Possible designs and associated expected number of successes

Design	Expected number of successes
{1; 1, 1}	$\mathbf{2p_1}$
{1; 1, 2}	$p_1+p_1^2+(1-p_1)/2$
{1; 2, 1}	$p_1+p_1/2+(1-p_1)p_1$
{1; 2, 2}	$p_1+1/2$
{2; 1, 1}	$1/2+p_1$
{2; 1, 2}	$1/2+(1/2)p_1+(1/2)(1/3)$
{2; 2, 1}	$\mathbf{1/2+(1/2)(2/3)+(1/2)p_1}$
{2; 2, 2}	$\mathbf{2(1/2)=1}$

If $n=1$ then the design requires only an initial selection, arm 1 or arm 2. Choosing arm 1 has expected number of successes p_1. Choosing arm 2 has conditional expected number of successes p_2, and an unconditional expected number of successes, the prior probability of success, which is 1/2. Therefore arm 1 is optimal if $p_1 \geqslant 1/2$ and arm 2 is optimal if $p_1 \leqslant 1/2$. (Both arms—and any randomization between them—are optimal when $p_1 = 1/2$.)

The problem is more complicated for $n \geqslant 2$. Consider $n=2$. There are two initial choices and two choices depending on the result of the first observation. There are eight possible designs. One can write a design as $\{a; a_S, a_F\}$, where a is the initial selection, a_S is the next selection should the first observation be a success, and a_F is the next selection should the first observation be a failure. To find the expected number of successes for a particular design, one needs to know such quantities as the probability of a success on arm 2 after a success on arm 2 (which is 2/3) and the probability of a success on arm 2 after a failure on arm 2 (which is 1/3). The possible designs and their associated expected numbers of successes are given in Table 2.

It is easy to check that only three of these expected numbers of successes (shown in bold) are candidates for the maximum. If $p_1 \geqslant 5/9$ then {1; 1, 1} is optimal; if $1/3 \leqslant p_1 \leqslant 5/9$ then {2; 2, 1} is optimal; and if $p_1 \leqslant 1/3$ then {2; 2, 2} is optimal. For example, if $p_1 = 1/2$ then it is optimal to use the unknown arm 2 initially. If the outcome is a success, then a decision is made to 'stay with a winner' and use arm 2 again. If a failure occurs, then the decision is made to switch to the known arm 1.

Enumeration of designs is tedious for large n. Most designs can be dropped from consideration based on theoretical results (Berry and Fristedt 1985). For example, there is a breakeven value of p_1, say p_1^*, such that arm 1 is optimal for $p_1 \geqslant p_1^*$. Also, one need consider only those designs that continue to use arm 1 once it has been selected. But many designs remain. Backward induction can be used to find an optimal design (Berry and Fristedt 1985).

Table 3
The optimal expected proportion of successes for selected values of n and for fixed $p_1 = 1/2$

n	1	2	5	10	20	50	100	200	500	1,000	10,000
Proportion of successes	0.500	0.542	0.570	0.582	0.596	0.607	0.613	0.617	0.621	0.622	0.624

Table 4
The breakeven values of p_1* for selected values of n

n	1	2	5	10	20	50	100	200	500	1000	10,000
p_1*	0.500	0.556	0.636	0.698	0.758	0.826	0.869	0.902	0.935	0.954	0.985

Table 3 gives the optimal expected proportion of successes for selected values of n and for fixed $p_1 = 1/2$. Asymptotically, for large n, the maximal expected proportion of successes is 5/8, which is the expected value of the maximum of p_1 and p_2. Both arms offer the same chance of success on the current unit, but only arm 2 gives information that can help in choosing between the arms for treating later units.

Table 4 gives the breakeven values of p_1^* for selected values of n. This table shows that information is more important for larger n. For example, if $p_1 = 0.75$ then arm 1 would be optimal for $n = 10$, but it would be advisable to test arm 2 when $n = 100$; this is so even though arm 1 has probability of 0.75 of being better than arm 2.

When there are several arms with unknown characteristics, the problem is still more complicated. Optimal designs may well indicate selection of an arm that was used previously and set aside in favor of another arm because of inadequate performance. For the methods and theory for solving such problems, see Berry (1972), and Berry and Fristedt (1985). The optimal designs are generally difficult to describe. Berry (1978) provides easy to use sequential designs that are not optimal but that perform reasonably well.

Suppose the n units in the experiment are a subset of the N units on which arms 1 and 2 can be applied. Berry and Eick (1995) consider the case of two arms with dichotomous response and show how to incorporate all N units into the design problem. They find the optimal Bayes design when p_1 and p_2 have independent uniform prior distributions. They compare this with various other sequential designs and with a particular nonsequential design: balanced randomization to arms 1 and 2. The Bayes design performs best on average, of course, but it is robust in the sense that it outperforms the other designs for essentially all pairs of p_1 and p_2.

4. Further Reading

The pioneers in sequential statistical methods were Wald (1947) and Barnard (1944). They put forth the sequential probability ratio test (SPRT), which is of fundamental importance in sequential stopping problems. The study of the SPRT dominated the theory and methodology of sequential experimentation for decades.

For further reading about Bayesian vs. frequentist issues in sequential design, see Berger (1986), Berger and Berry (1988), Berger and Wolpert (1984), and Berry (1987, 1993). For further reading about the frequentist perspective, see Chow et al. (1971) and Whitehead (1992). For further reading about Bayesian design issues, see Berry (1993), Berry and Stangl (1996), Chernoff and Ray (1965), Cornfield (1966), and Lindley and Barnett (1965). For further reading about bandit problems, see Berry (1972, 1978), Berry and Eick (1995), Berry and Fristedt (1985), Bradt et al. (1956), Friedman et al. (1964), Murphy (1965), Rapoport (1967), Rothschild (1974), Viscusi (1979), and Whittle (1982/3). There is a journal called *Sequential Analysis* that is dedicated to the subject of this article.

Serial Verb Constructions

1. Definition and Importance

The term 'serial verb construction' (SVC) is usually applied to a range of apparently similar syntactic constructions in different languages, in which several verbs occur together within one clause or unit, without evidence of either subordination or coordination of the verbs. For example, sentences like (1), from the West African language Twi, are typical of what most scholars would regard as an SVC:

(1) Kofi de pono no baae
Kofi take-PAST table the come-PAST
'Kofi brought the table' or more literally,
'Kofi took the table and came with it'

SVCs have attracted attention from linguists for three main reasons. First, syntacticians have found them interesting because the possibility of having more than one main (i.e., nondependent, nonauxiliary) verb within a clause or clause-like unit challenges traditional assumptions that a clause contains exactly one predicate (see Foley and Olson 1985, pp. 17, 57). Second, because of their prevalence both in languages of West Africa and in certain Creole languages, they have become central to debates among Creole language researchers, being seen either as evidence for the importance of substrate (i.e., African mother-tongue) influence on the Creole, or as deriving from universal properties of human language which are manifested in the creolization process (see *Pidgin and Creole Languages*. Third, serial verbs show a tendency to be reanalyzed as other grammatical categories (complementizers and prepositions), with implications for the processes of historical change (see *Historical Linguistics*: *Overview*).

While different researchers use different criteria for defining serial verbs, the following set would probably be accepted by most and is based on one described by McWhorter (1997, p. 22) as a 'relatively uncontroversial distillation of the conclusions of various scholars':

(2) (a) an SVC contains only one overt subject;
(b) it contains no overt markers of coordination or subordination;
(c) it expresses concomitant actions (either simultaneous or consecutive) or a single action;
(d) it falls under one intonational contour;
(e) it has tense–modality–aspect marking on none of the verbs, or on one only (usually the first or last in the series) or on all of them; and
(f) it contains a second verb which is not obligatorily subcategorized for by the first verb.

Even the above six conditions leave it unclear where exactly to draw the line around SVCs, particularly in languages which have little morphology. In some cases of what may appear to be SVCs, we may be dealing simply with unmarked coordination of verb phrases expressing simultaneous actions.

2. Serial Verb Types

Serial constructions can be classified into different types on the basis of the functions of the verbs in the series relative to one another.

The sentences in (3) provide examples of different functional types of SVC which have been discussed in the literature.

(3) (a) *Directional complements*: V_2 is *go*, *come*, or another common intransitive motion verb which functions to indicate the directionality of the action denoted by V_1.
Olú gbé àga wá
Olu take chair come
'Olu brought a chair' (Yoruba, West African)
(b) *Other motion verb complements*: similar to type (a), but V_2 may be transitive motion verb with its own object expressing the goal of the action denoted by V_1
Kofi tow agyan no wɔɔ Amma
Kofi throw-PAST arrow the pierce-PAST Amma
'Kofi shot Amma with the arrow'
(c) *Instrumental constructions*: V_1 is *take* or a semantically similar common verb, while V_2 denotes an action performed with the aid of the object of V_1.
Kofi teki a nefi koti a brede
Kofi take the knife cut the bread
'Kofi cut the bread with a knife' (Sranan, Caribbean Creole)
(d) *Dative constructions*: V_2 is usually *give*, with an object which denotes the (semantic) indirect object of V_1.
Ogyaw ne sika mãã me
he-leave-PAST his money give-PAST me
"He left me his money" (Twi, West African)
(e) *Comparative constructions*: a verb meaning *pass* or *surpass* is used with an object to express comparison. In this case 'V_1' is often in fact an adjective.
Amba tranga pasa Kofi
Amba strong pass Kofi
'Amba is stronger than Kofi' (Sranan, Caribbean Creole)
(f) *Resultative constructions*: V_2 denotes the result or consequence of an action denoted by V_1.
Kofi naki Amba kiri
Kofi hit Amba kill
'Kofi struck Amba dead' (or more literally,
'Kofi hit Amba and killed her') (Sranan, Caribbean Creole)
(g) *Idiomatic constructions (lexical idioms)*: These are cases where the meaning of the verbs together is not derivable from the meanings of the verbs separately. They are not found in all serializing languages, but some of the West African group are particularly rich in them.
Anyi-Baule (West African):
bɔ 'hit' nĩã 'look' bɔ…nĩã 'say, tell'
Yoruba (West African):
là 'cut open' yé… 'understand' là…yé'explain'

3. Distribution in the World's Languages

Serial verb constructions have been identified in many languages but it is clear that they occur in areal clusters and are not spread evenly among the languages of the world. So far serializing languages have been identified in the following areas: West Africa (Kwa and related language families), the Caribbean (Creole languages which have a historical relationship with Kwa languages), Central America (e.g., Misumalpan), Papua New Guinea (Papuan languages and Tok Pisin—Melanesian Pidgin English), South-east Asia (e.g., Chinese, Vietnamese, Thai). There are isolated reports of SVC-like constructions from elsewhere. How credible these are depends on which criteria are adopted to define SVCs.

4. Grammatical Analyses

Numerous researchers have put forward proposals for grammatical analyses of SVCs. The analyses may be classified into two types, with some degree of overlap. *Semantic* analyses typically seek to account for SVCs in terms of how they break down verbal concepts into more basic semantic components (take–carry–come for *bring*, for example). *Syntactic* analyses differ mainly according to whether they treat SVCs as a phrase structure phenomenon (usually under a version of X-bar theory), as a form of complementation, subordination, or secondary predication (i.e., involving more than one clause-like unit), or as a lexical phenomenon (e.g., as single but disjoint lexical items (see *Syntax*)).

The following phrase structure (4) proposed for SVCs in the literature is typical of those advocated by a number of researchers:

(4) $VP \rightarrow V\ XP\ VP$ where X is N or P

This produces a right-branching tree with a theoretically infinite number of verbs in a series. Such a structure would allow lexical relations and relations like 'subject-of' and 'object-of' to hold between verbs in the series, and captures the intuition that verbs (or verb phrases) function as complements to verbs earlier in the sequence.

Some researchers have treated SVCs as involving complementation or subordination, with clauses or clause-like units embedded within the VP and dependent on a higher verb. For example, Larson (1991, pp. 198–205) has argued in favor of analyzing serial constructions as a case of 'secondary predication.' A structure similar to that for *Carol rubbed her finger raw* in English can also, he says, account for serial combinations of the *take… come* and *hit… kill* types (a) and (f) above).

Foley and Olson (1985) propose a distinction between 'nuclear' and 'core' serialization. In nuclear serialization the serial verbs all occur in the nucleus of the clause, in other words the verbs form a single unit which must share arguments and modifiers. The core layer of the clause consists of the nuclear layer plus the

core arguments of the verb (Foley and Olson 1985, p. 34). In 'core' serialization two cores, each with own nucleus and arguments, are joined together. Languages may exhibit both kinds of serialization or just one. Examples (a) and (b) below (Foley and Olson 1985, p. 38) illustrate this difference; (a) is an example of core, and (b) of nuclear, serialization:

(5) (a) fu fi fase isoe
he sit letter write
'He sat down and wrote a letter'
(Barai, Papuan)

(b) Fu fase fi isoe
He letter sit write
'He sat writing a letter'

This evidence suggests that 'serialization' may not be a unitary phenomenon, and although a single account which explains the two or more different construction types (such as Foley and Olson's) would be welcome, it may be that separate analyses may be needed as more different types of SVC come to light.

5. *The Creolists' Debates*

SVCs are among the most salient grammatical features of many Creoles of the Caribbean area which distinguish them grammatically from their European lexifier languages. As such they have attracted attention from creolists, who, finding similar structures in West African languages which historically are connected with the Creoles in question, have claimed SVCs are evidence of substrate influence on the grammar of the Creoles concerned.

An alternative view has been offered by Bickerton (1981) and Byrne (1987), who regard the similarities between SVCs in the Creole and West African languages as coincidental. Instead, they argue, SVCs result in Creoles from universal principles of grammar, and are a consequence of the rudimentary verbal structure (V but not VP) which exist, they say, in a Creole at the earliest stage of development. They point out the existence of SVCs or serial-like structures in other pidgins and Creoles such as Tok Pisin (New Guinea Pidgin) and Hawaiian Creole English, which have no historical connections with West Africa.

McWhorter (1997) argues against Bickerton and Byrne, claiming that the Caribbean Creoles not only share SVCs with West African languages, but that their SVCs are structurally similar to each other in ways that SVCs from other areal language groupings are not. Using the nuclear/core distinction proposed by Foley and Olson (see above), he argues that Papuan languages serialize at the nuclear level, while Kwa languages, Caribbean Creoles, Chinese, and other Southeast Asian languages serialize at the core level. Considering also the range of pidgins and Creoles which lack SVCs altogether, he concludes that 'SVCs have appeared around the world in precisely the creoles which had serializing substrata' (1997, p. 39).

SVCs have thus become a major site of contention between 'substratists' and 'universalists' in Creole studies, with both sides remaining committed to their own positions (see *Pidgin and Creole Languages*).

6. *SVCs and Language Change*

Particular verbs which participate in serial constructions in some cases appear to have been reanalyzed as members of another syntactic category, e.g., from verb to preposition (*give*→*for*) or complementizer (*say*→*that*). In such cases, the position of the verb usually makes it amenable to such a reanalysis (e.g., if it typically occurs immediately before its objects, it may be reanyalzed as a preposition if the semantics encourage this interpretation). Reanalyzed serial verbs lose, to varying degrees, their verbal properties and take on, again to varying degrees, the morphological characterisics of their new category. Lord (1973) describes cases of reanalysis of verbs as prepositions, comitative markers, and a subordinating conjunction in Yoruba, Gã, Ewe, and Fon. Verbs with the meaning '*say*' are susceptible to reinterpretation as complementizers (introducing sentential clauses), while those with the meaning '*finish*' have a tendency to be interpreted as completive aspect markers (see *Grammaticalization*).

7. *Related Constructions*

Lack of a satisfactory definition of 'serial verb construction' makes it difficult to decide what may count as a related kind of structure. Chinese has a range of verbal structures which bear resemblances to SVCs. One of these, the class of *co-verbs*, is widely believed to be the result of the reanalysis of serial verbs as prepositions. Others, so-called *resultatives*, resemble secondary predications.

The Bantu languages, though related to the serializing languages of West Africa, do not seem to have SVCs. However, some have verbal chains where the second and subsequent verb have different marking from the first. In many Bantu languages, the verb meaning *say* is homophonous with a complementizer. These phenomena remain to be explained by a general theory.

Service Economy, Geography of

Producer services are types of services demanded primarily by businesses and governments, used as inputs in the process of production. We may split the demand for all services broadly into two categories: (a) demands originating from household consumers for services that they use, and (b) demands for services originating from other sources. An example of services demanded by household consumers is retail grocery services, while examples of producer services are management consulting services, advertizing services, and computer systems engineering.

1. *Development of the Term 'Producer Services'*

Producer Services have emerged as one of the most rapidly growing industries in advanced economies, while the larger service economy has also exhibited aggregate growth in most countries. In the 1930s, Fisher (1939) observed the general tendency for shifts in the composition of employment as welfare rose, with an expanding service sector. Empirical evidence of this transformation was provided by Clark (1957), and the Clark–Fisher model was a popular description of development sequences observed in nations that were early participants in the Industrial Revolution. However, this model was criticized as a necessary pattern of economic development by scholars who observed regions and nations that did not experience the pattern of structural transformation encompassed in the Clark–Fisher model. Moreover, critics of the Clark–Fisher model also argued that the size of the service economy relative to that of goods and primary production required efforts to classify the service economy into categories more meaningful than Fisher's residual category 'services.'

The classification of service industries based upon their nature and their source of demand was pioneered in the 1960s and 1970s. The classic vision of services developed by Adam Smith ('they perish the very instant of their performance') was challenged as scholars recognized that services such as legal briefs or management services can have enduring value, similar to investments in physical capital. The term producer services became applied to services with 'intermediate' as opposed to 'final' markets.

While this distinction between intermediate or producer services and final or consumer services is appealing, it is not without difficulties. Some industries do not fit neatly into one category or another. For example, households as well as businesses and governments demand legal services, and hotels—a function generally regarded to a consumer service—serve both business travelers and households. Moreover, many of the functions performed by producer service businesses are also performed internally by other businesses. An example is the presence of in-house accounting functions in most businesses, while at the same time there are firms specializing in performing accounting services for their clients. Notwithstanding these difficulties of classification, there is now widespread acceptance of the producer services as a distinctive category of service industry. However, variations in the classification of industries among nations, as well as differences in the inclusion of specific industries by particular scholars leads to varying sectoral definitions of producer services. Business, legal, and engineering and management services are included in most studies, while the financial services are often considered to be a part of the producer services. It is less common to consider services to transportation, wholesaling, and membership organizations as a component of the producer services.

Table 1 documents for the US economy growth in producer services employment between 1985 and 1995 by broad industrial groups. The growth of producer services over this time period was double the national rate of job growth, and this growth rate was almost identical in metropolitan and rural areas. While financial services grew relatively slowly, employment growth in business and professional services was very strong. Key sectors within this group include temporary help agencies, advertizing, copy and duplicating, equipment rental, computer services, detective and protective, architectural and engineering, accounting, research and development, and management consulting and public relations services.

2. *Early Research on the Geography of Producer Services*

Geographer's and regional economist's research on producer services only started in the 1970s. Pioneering

Table 1
US employment change in producer Services, 1985–95

Sector	Job growth (thousands)	Percentage growth
Finance, insurance, and real estate	994	16.6
Business and professional services	4,249	79.2
Legal services	275	40.0
Membership organizations	599	38.6
Total, producer services	6,117	45.0
Total, all industries	19,039	23.4

research includes the investigations of office location in the United Kingdom by Daniels (1975), and the studies of corporate control, headquarters, and research functions related to corporate headquarters undertaken in the United States by Stanback (1979). Daniels (1985) provided a comprehensive summary of this research, distinguishing between theoretical approaches designed to explain the geography of consumer and producer services. The emphasis in this early research focused on large metropolitan areas, recognizing the disproportionate concentration of producer services employment in the largest nodal centers. This concentration was viewed as a byproduct of the search for agglomeration economies, both within freestanding producer services and in the research and development organizations associated with corporate headquarters. This early research also identified the growth of international business service organizations that were concentrated in large metropolitan areas to serve both transnational offices of home-country clients and to generate an international client base.

Early research on producer services also documented tendencies for decentralization from central business districts into suburban locations, as well as the relatively rapid development of producer services in smaller urban regions. In the United States, Noyelle and Stanback (1983) published the first comprehensive geographical portrait of employment patterns within the producer services, differentiating their structure through a classification of employment, and relating this classification to growth trends between 1959 and 1976. While documenting relatively rapid growth of producer services in smaller urban areas with relatively low employment concentrations, this early research did not point towards employment decentralization, although uncertainties related to the impact of the development of information technologies were recognized as a factor that would temper future geographical trends.

The geography of producer services was examined thoroughly in the United Kingdom through the use of secondary data in the mid-1980s (Marshall et al. 1988). This research documented the growing importance of the producer services as a source of employment, in an economy that was shedding manufacturing jobs. It encouraged a richer appreciation of the role of producer services by policy-makers and scholars and called for primary research to better understand development forces within producer service enterprises.

While many scholars in this early period of research on producer services emphasized market linkages with manufacturers or corporate headquarter establishments, other research found industrial markets to be tied broadly to all sectors of the economy, a fact also borne out in input-output accounts. Research also documented geographic markets of producer service establishments, finding that a substantial percentage of revenues were derived from nonlocal clients, making the producer services a component of the regional economic base (Beyers and Alvine 1985).

3. *Emphasis in Current Research on the Geography of Producer Services*

In the 1990s there has been an explosion of geographic research on producer services. Approaches to research in recent years can be grouped into studies based on secondary data describing regional patterns or changes in patterns of producer service activity, and studies utilizing primary data to develop empirical insights into important theoretical issues. For treatment of related topics see *Location Theory*; *Economic Geography*; *Industrial Geography*; *Finance, Geography of*; *Retail Trade*; *Urban Geography*; and *Cities: Capital, Global, and World.*

3.1 *Regional Distribution of Producer Services*

The uneven distribution of producer service employment continues to be documented in various national studies, including recent work for the United States, Canada, Germany, and the Nordic countries. While these regions have exhibited varying geographic trends in the development of producer services, they share in common the relatively rapid growth of these industries. They also share in common the fact that relatively few regions have a concentration of or a share of employment at or above the national average.

In Canada, the trend has been towards greater concentration, a pattern which Coffey and Shearmur

(1996) describe as uneven spatial development. Utilizing data for the 1971 to 1991 time period, they find a broad tendency for producer service employment to have become more concentrated over time.

The trend in the United States, Germany, and the Nordic countries differs from that found in Canada. In the Nordic countries producer service employment is strongly concentrated in the capitals, but growth in peripheral areas of Norway and Finland is generally well above average, while in Denmark and Sweden many peripheral areas exhibit slow growth rates (Illeris and Sjøholt 1995). In Germany, the growth pattern exhibits no correlation between city size and the growth of business service employment (Illeris 1996). The United States also exhibits the uneven distribution of employment in the producer services. In 1995 only 34 of the 172 urban-focused economic areas defined by the US Bureau of Economic Analysis had an employment concentration in producer services at or above the national average, and these were predominately the largest metropolitan areas in the country. However, between 1985 and 1995 the concentration of employment in these regions diminished somewhat, while regions with the lowest concentrations in 1985 tended to show increases in their level of producer services employment. Producer service growth rates in metropolitan and rural territory have been almost identical over this same time period in the United States. There is also considerable evidence of deconcentration of employment within metropolitan areas from central business districts into 'Edge Cities' and suburban locations in Canada and the United States (Coffey et al. 1996a, Coffey et al. 1996b, Harrington and Campbell 1997). Survey research in Montreal indicates that this deconcentration is related more strongly to new producer service businesses starting up in suburban locations than to the relocation of existing establishments from central city locations (Coffey et al. 1996b).

3.2 Producer Services and Regional Development

Numerous studies have now been undertaken documenting the geographic markets of producer service establishments; for summaries see Illeris (1996) and Harrington et al. (1991). Illeris' summary of these studies indicates typical nonlocal market shares at 35 percent, but if nonlocal sales are calculated by weighting the value of sales the nonlocal share rises to 56 percent. In both urban and rural settings establishments are divided into those with strong interregional or international markets, and those with primarily localized markets. Over time establishments tend to become more export oriented, with American firms tending to have expanded interregional business, while European firms more often enter international markets (O'Farrell et al. 1998). Thus, producer services contribute to the economic base of communities and their contribution is rising over time due to their relatively rapid growth rate.

Growth in producer service employment in the United States has occurred largely through the expansion in the number of business establishments, with little change in the average size of establishments. Between 1983 and 1993 the number of producer service establishments increased from 0.95 million to 1.34 million, while average employment per establishment increased from 11 to 12 persons. The majority of this employment growth occurred in single unit establishments, nonpayroll proprietorships, and partnerships. People are starting these new producer service establishments because they want to be their own boss, they have identified a market opportunity, their personal circumstances lead them to wish to start a business, and they have identified ways to increase their personal income. Most people starting new companies were engaged in the same occupation in the same industry before starting their firm, and few report that they started companies because they were put out of work by their former employer in a move designed to downsize in-house producer service departments (Beyers and Lindahl 1996a).

The use of producer services also has regional development impacts. Work in New York State (MacPherson 1997) has documented that manufacturers who make strong use of producer services as inputs are more innovative than firms who do not use these services, which in turn has helped stimulate their growth rate. Similar positive impacts on the development of clients of producer service businesses has been documented in the United Kingdom (Wood 1996) and more broadly in Europe (Illeris 1996).

3.3 Demand Factors

Considerable debate has raged over the reasons for the rapid growth of the producer services, and one common perception has been that this growth has occurred because of downsizing and outsourcing by producer service clients to save money on the acquisition of these services. However, evidence has accumulated that discounts the significance of this perspective. Demand for producer services is increasing for a number of reasons beyond the cost of acquiring these services, based on research with both the users of these services and their suppliers (Beyers and Lindahl 1996a, Coffey and Drolet 1996). Key factors driving the demand for producer services include: the lack of expertise internal to the client to produce the service, a mismatch between the size of the client and the volume of their need for the service, the need for third-party opinions or expert testimony, increases in government regulations requiring use of particular services, and the need for assistance in managing the complexity of firms or to stay abreast of new technologies.

Evidence also indicates that producer service establishments often do business with clients who have in-house departments producing similar services. However, it is rare that there is direct competition with these in-house departments. Instead, relationships are generally complementary. Current evidence indicates that there have been some changes in the degree of in-house vs. market acquisition of producer services, but those selling these services do not perceive the balance of these in-house or market purchases changing dramatically (Beyers and Lindahl 1996a).

3.4 Supply and Competitive Advantage Considerations

The supply of producer services is undertaken in a market environment that ranges from being highly competitive to one in which there is very little competition. In order to position themselves in this marketplace, producer service businesses exhibit competitive strategies, and as with the demand side, recent evidence points towards the prevalence of competitive strategies based on differentiation as opposed to cost (Lindahl and Beyers 1999, Hitchens et al. 1996, Coffey 1996). The typical firm tries to develop a marketplace niche, positioning itself to be different from competitors though forces such as an established reputation for supplying their specialized service, the quality of their service, their personal attention to client needs, their specialized expertise, the speed with which they can perform the service, their creativity, and their ability to adapt quickly to client needs. The ability to deliver the service at a lower cost than the client could produce it is also a factor considered important by some producer service establishments.

3.5 Flexible Production Systems

The flexible production paradigm has been extended from its origin in the manufacturing environment in recent years into the producer services (Coffey and Bailly 1991). There are a variety of aspects to the issue of flexibility in the production process, including the nature of the service being produced, the way in which firms organize themselves to produce their services, and their relationships with other firms in the production and delivery process. The labor force within producer services has become somewhat more complex, with the strong growth of the temporary help industry that dispatches a mixture of part-time and full-time temporary workers, as well as some increase in the use of contract or part-time employees within producer service establishments. However, over 90 percent of employment remains full-time within the producer services (Beyers and Lindahl 1999).

The production of producer services is most frequently undertaken in a manner that requires the labor force to be organized in a customized manner for each job, although a minority of firm's approach work in a routinized manner. Almost three-fourths of firms rely on outside expertise to produce their service, and half of producer service firms engage in collaboration with other firms to produce their services to extend their range of expertise or geographic markets. The services supplied by producer service establishments are also changing frequently; half of the establishments interviewed in an US study had changed their services over the previous five years. They do so for multiple reasons, including changing client expectations, shifts in geographic or sectoral markets, changes in government regulations, and changes in information technologies with their related changes on the skills of employees. These changes most frequently produce more diversified service offerings, but an alternative pathway is to become more specialized or to change the form or nature of services currently being produced (Beyers and Lindahl 1999).

3.6 Information Technologies

Work in the producer services typically involves face to face meetings with clients at some point in the production process. This work may or may not require written or graphical documents. In some cases the client must travel to the producer service firm's office, and in other cases the producer service staff travels to client. These movements can be localized or international in scale. However, in addition to these personal meetings, there is extensive and growing use of a variety of information technologies in the production and delivery of producer services work. Computer networks, facsimile machines, telephone conversations, courier services, and the postal system all play a role, including a growing use of the Internet, e-mail, and computer file transfers between producers and clients. Some routine functions have become the subject of e-commerce, but much of the work undertaken in the producer services is nonroutine, requiring creative interactions between clients and suppliers.

3.7 Location Factors

The diversity of market orientations of producer service establishments leads to divergent responses with regard to the choice of business locations (Illeris 1996). Most small establishments are located convenient to the residential location of the founder. However, founders often search for a residence that suits them, a factor driven by quality of life considerations for many rural producer service establishments (Beyers and Lindahl 1996b). Businesses with spatially dispersed markets are drawn to locations convenient to travel networks, including airports and the Interstate Highway System in the US. Businesses

with highly localized markets position themselves conveniently to these markets. Often ownership of a building, or a prestigious site that may affect trust or confidence of clients is an influencing factor. Establishments that are part of large multi-establishment firms select locations useful from a firm-network-of-locations perspective, which may be either an intra- or interurban pattern of offices.

4. Methodological Considerations

Much of the research reported upon here has been conducted in the United States, Canada, or the United Kingdom. While there has been a rapid increase in the volume of research reported regarding the themes touched upon in the preceding paragraphs, the base of field research is still slender even within the nations just mentioned. More case studies are needed in urban and rural settings, focused on marketplace dynamics, production processes, and the impact of technological development on the evolution of the producer services. The current explosion of e-commerce and its use by producer service firms is a case in point. Recent research has tended to be conducted either by surveying producer service enterprises or their clients, but only rarely are both surveyed to obtain answers that can be cross-tabulated. Individual researchers have developed their protocol for survey research, yielding results that tend to be noncomparable to other research. Means need to be developed to bring theoretical and empirical approaches into greater consistency and comparability.

There are variations in the organization of production systems related to the producer services among countries. Some countries internalize these functions to a relatively high degree within other categories of industrial activity, and there needs to be greater thought given to ways in which research on these functions within these organizations can be measured.

5. Future Directions of Theory and Research

Research on the producer services will continue at both an aggregate scale, as well as at the level of the firm or establishment. Given the recent history of job growth in this sector of advanced economies, there will certainly be studies documenting the ongoing evolution of the geographical distribution of producer services. This research needs to proceed at a variety of spatial scales, ranging from intrametropolitan, to intermetropolitan or interregionally within nations, and across nations. International knowledge of development trends is currently sketchy, especially in developing countries where accounts may be less disaggregate than in developed countries with regard to service industries.

Research at the level of the firm and establishment must continue to better understand the start-up and evolution of firms. While there is a growing body of evidence regarding motivations and histories of firm founders, there is currently little knowledge of the movement of employees into and among producer service establishments. There is also meager knowledge of the distribution of producer service occupations and work in establishments not classified as producer services. Case studies are needed of collaboration, subcontracting, client-seller interaction, processes of price formation, the interplay between the evolution of information technologies and service-product concepts, and types of behavior that are related to superior performance as measured by indicators such as sales growth rate, sales per employee, or profit. There is also a pressing need for international comparative research, not just in the regions that have been relatively well researched (generally the US, Canada, and Europe), but also in other parts of the planet. There is also a pressing need for the development of more robust models and theory in relation to the geography of producer services.

Services Marketing

Marketing, as a philosophy and as a function, has already reached the maturity stage. In the 1950s, the basic emphasis was on consumer goods and the mass marketing approach; in the 1960s, it was the marketing potentiality of durable goods; and in the 1970s; the emphasis was on industrial goods.

Only in the 1980s did service organizations start to take a professional interest in marketing approaches and tools. More recently also, the public services, and the nonprofit services in general, have begun to participate in marketing. Despite its recent arrival, services marketing is undoubtedly the most innovative and, thanks to new technology, seems as though it may change the old approach completely. The trend is moving from mass marketing to one-to-one marketing, a typical feature of services promotion.

1. *Peculiarities of Services Marketing*

If services marketing is becoming so important, it is necessary to understand its peculiarities. Everything is related to the *intangibility of services*: they are 'events' more than 'goods,' and as a consequence it is impossible to store them. They are 'happenings,' where it is difficult to forecast what will be produced and what the consumer will get. The relationship becomes increasingly important, especially when the consumer becomes a 'part-time producer'—a 'pro-sumer' (producer + consumer).

Interaction with people is very important in many services, such as restaurants, air transportation, tourism, banking, and so on. The interaction is not only between producer and consumer, but also among the users, as happens in schools among students.

Because of these elements there is another very important aspect: in services marketing it is difficult to standardize performance, and quality can be very different from one case to another. Quality control ahead of the event is impossible, because nobody knows in advance the service that will actually be provided to the customer. Many external factors can affect the level of quality, e.g., the climate, or the unpredictable behavior of customers. Consequently, it is not always possible to fulfill promises at the point of delivery, even if the organization does its best to deliver the required level of quality.

Another peculiarity is that services are not 'visible' and so cannot represent a 'status symbol,' unless the service can be matched with tangible objects, such as credit cards, university ties, football scarves, etc. But the most important aspect is that services cannot be stored, and therefore production and use are simultaneous. This creates problems in terms of production capacity, because it is difficult to match fluctuations in demand over seasons, weeks, or days.

It is possible to synchronize production and use by means of different tools. The most used approach is pricing, because varying service prices may be applied at different periods of time (e.g., telephone charges, or airline tickets). There are other tools, such as 'user education,' implemented by the service producer. In this case, the producer tries to 'educate' the consumer to ask for a particular, better-quality, service during the so-called 'valley periods' when sales are slow.

Other solutions involve the employment of part-time workers during 'peak periods,' or the implemen-

tation of maintenance activity in the 'valley periods'; making reservations is a typical approach in the case of theatres or in the health care service. In all cases it is necessary to overcome fluctuating demand with a 'synchromarketing activity.'

2. Critical Success Factors in Services Marketing

Because of the peculiarities of the services, there are many critical success factors in services marketing: (a) service industrialization, (b) strategic image management, (c) customer satisfaction surveys, (d) operations, personnel, and marketing interaction, (e) internal marketing, (f) user education, and participation, (g) managerial control of costs, and investments, (h) relationship with the public authorities, (i) quality control, and (j) synchromarketing.

Of these, further comment can be devoted to internal marketing, whose goal is 'to create an internal environment which supports customer consciousness and sales mindedness among the personnel' (Gronroos 1990). 'Internal marketing means applying the philosophy and practices of marketing to people who serve the external customers, so that the best possible people can be employed and retained, and they will do the best possible work' (Berry and Parasuraman 1991).

Another point to emphasize is quality control, because, as has been said, the quality of the service is perceived to be more than objective. Many studies say that the focal point in services is the perceived quality, as a result of a comparison between the expected quality and the image of the service really provided. As a consequence, it is very important to survey customer opinion on a regular basis, and to check whether, via this opinion, service is becoming better or worse. A further point is related to the importance of a company's image as a factor affecting, positively or negatively, customers' judgment. This is why it is necessary to manage a company's image with a strongly strategic approach, outlining what the company is, what people think it is, and how it wants people to think of it. Image improvement is not only a matter of communication; it also involves personnel behavior, services provided, and material facilities.

3. Future Perspectives

At the start of the twenty-first century, services marketing is very important in the developed countries, because of the relevance of services in terms of GNP, employment, etc., and we can predict that it is going to increase further in importance, thanks to new technologies that facilitate the relationship between producer and customer. There will be an increasing amount of one-to-one marketing, which is particularly suitable for services. Another important development will concern the internationalization of services (e.g., McDonald's, Club Med, Manchester United, Hertz, etc.), where the critical success factors will be related to the improvement of 'high tech' in the back office and 'high touch' in the front line: Industrialization and personalization at the same time, to achieve high customer satisfaction in every country. Sales of products now often include the offer of some services, as, for example, in the automotive industry, where this is represented by the after sales service, a very important aspect affecting the buyer decision process. Offers such as this are the key issues that, in most cases, actually make the difference, given the fact that the basic product is very frequently similar to other products, and the difference is provided by the service included in the product.

Settlement and Landscape Archaeology

For contemporary archaeology, settlement and landscape approaches represent an increasingly important focus that is vital for a core mission of the discipline to describe, understand, and explain long-term cultural and behavioral change. Despite this significance, few syntheses of this topic have been undertaken (cf. Parsons 1972, Ammerman 1981, Fish and Kowalewski 1990, Billman and Feinman 1999). Yet settlement and landscape approaches provide the only large-scale perspective for the majority of premodern societies. These studies are reliant on archaeological surface surveys, which discover and record the distribution of material traces of past human presence/habitation across a landscape (see *Survey and Excavation (Field Methods) in Archaeology*). The examination and analysis of these physical remains found on the ground surface (e.g., potsherds, stone artifacts, house foundations, or earthworks) provide the empirical foundation for the interpretation of ancient settlement patterns and landscapes.

1. Historical Background

Although the roots of settlement pattern and landscape approaches extend back to the end of the nineteenth century, archaeological survey has only come into its own in the post World War II era. Spurred by the analytical emphases of Steward (1938), Willey's Virú Valley archaeological survey (1953) provided a key impetus for settlement pattern research in the Americas. In contrast, the landscape approach, which has a more focal emphasis on the relationship between sites and their physical environments, has its roots in the UK. Nevertheless, contemporary archaeological studies indicate a high degree of intellectual cross-fertilization between these different surface approaches.

1.1 Early Foundations for Archaeological Survey in the Americas and England

The American settlement pattern tradition stems back to scholars, such as Morgan (1881), who queried how the remnants of Native American residential architecture reflected the social organization of the native peoples who occupied them. Yet the questions posed by Morgan led to relatively few immediate changes in how archaeology was practiced, and for several decades few scholars endeavored to address the specific questions regarding the relationship between settlement and social behavior that Morgan posed. When surface reconnaissance was undertaken by archaeologists, it tended to be a largely unsystematic exercise carried out to find sites worthy of excavation.

In the UK, the landscape approach, pioneered by Fox (1922), was more narrowly focused on the definition of distributional relationships between different categories of settlements and environmental features (e.g., soils, vegetation, topography). Often these early studies relied on and summarized surveys and excavations that were carried out by numerous investigators using a variety of field procedures rather than more uniform or systematic coverage implemented by a single research team. At the same time, the European landscape tradition generally has had a closer link to romantic thought as opposed to the more positivistic roots of the North American settlement pattern tradition (e.g., Sherratt 1996).

1.2 The Development of Settlement Archaeology

By the 1930s and 1940s, US archaeologists working in several global regions recognized that changing patterns of social organization could not be reconstructed and interpreted through empirical records that relied exclusively on the excavation of a single site or community within a specific region. For example, in the lower Mississippi Valley, Phillips et al. (1951) located and mapped archaeological sites across a large area to analyze shifting patterns of ceramic styles and settlements over broad spatial domains and temporal contexts.

Yet the most influential and problem-focused investigation of that era was that of Willey in the Virú Valley. Willey's project was the first to formally elucidate the scope and potential analytical utility of settlement patterns for understanding long-term change in human economic and social relationships. His vision moved beyond the basic correlation of environmental features and settlements as well as beyond the mere definition of archtypical settlement types for a given region. In addition to its theoretical contributions, the Virú program also was innovative methodologically, employing (for the first time in the Western Hemisphere) vertical air photographs in the location and mapping of ancient settlements. Al-

though Willey did not carry out his survey entirely on foot, he did achieve reasonably systematic areal coverage for a defined geographic domain for which he could examine changes in the frequency of site types, as well as diachronic shifts in settlement patterns.

Conceptually and methodologically, these early settlement pattern projects of the 1930s and 1940s established the intellectual underpinnings for a number of multigenerational regional archaeological survey programs that were initiated in at least four global regions during the 1950s and 1960s. In many ways, these later survey programs were integral to the theoretical and methodological re-evaluations that occurred in archaeological thought and practice under the guise of 'the New Archaeology' or processualism. The latter theoretical framework stemmed in part from an expressed emphasis on understanding long-term processes of behavioral change and cultural transition at the population (and so regional) scale. This perspective, which replaced a more normative emphasis on archtypical sites or cultural patterns, was made possible to a significant degree by the novel diachronic and broad scalar vantages pieced together for specific areas through systematic regional settlement pattern fieldwork and analysis.

1.3 Large-scale Regional Survey Programs

During the 1950s through the 1970s, major regional settlement pattern programs were initiated in the heartlands of three areas where early civilizations emerged (Greater Mesopotamia, highland Mexico, and the Aegean), as well as in one area known for its rich and diverse archaeological heritage (the Southwest USA). The achievements of the Virú project also stimulated continued Andean settlement pattern surveys, although a concerted push for regional research did not take root there until somewhat later (e.g., Parsons et al. 1997, Billman and Feinman 1999).

Beginning in 1957, Robert M. Adams (e.g., 1965, 1981) and his associates methodically traversed the deserts and plains of the Near East by jeep, mapping earthen tells and other visible sites. Based on the coverage of hundreds of square kilometers, these pioneering studies of regional settlement history served to unravel some of the processes associated with the early emergence of social, political, and economic complexity in Greater Mesopotamia. Shortly thereafter, in highland Mexico, large-scale, systematic surveys were initiated in the area's two largest mountain valleys (the Basin of Mexico and the Valley of Oaxaca). These two projects implemented field-by-field, pedestrian coverage of some of the largest contiguous survey regions in the world, elucidating the diachronic settlement patterns for regions in which some of the earliest and most extensive cities in the ancient Americas were situated (e.g., Sanders et al. 1979, Blanton et al. 1993). After decades, about half of the Basin of Mexico and almost the entire Valley of Oaxaca were traversed by foot.

In the Aegean, regional surveys (McDonald and Rapp 1972, Renfrew 1972) were designed to place important sites with long excavation histories in broader spatial contexts. Once again, these investigations brought new regional vantages to areas that already had witnessed decades of excavation and textual analyses. Over the same period, settlement pattern studies were carried out in diverse ecological settings across the US Southwest, primarily to examine the differential distributions of archaeological sites in relation to their natural environments, and to determine changes in the numbers and sizes of settlements across the landscape over time. In each of the areas investigated, the wider the study domain covered, the more diverse and complex were the patterns found. Growth in one part of a larger study area was often timed with the decrease in the size and number of sites in another. And settlement trends for given regions generally were reflected in episodes of both growth and decline.

Each of these major survey regions (including much of the Andes) is an arid to semiarid environment. Without question, broad-scale surface surveys have been most effectively implemented in regions that lack dense ground cover, and therefore the resultant field findings have been most robust. In turn, these findings have fomented long research traditions carried out by trained crews, thereby contributing to the intellectual rewards of these efforts. As Ammerman (1981, p. 74) has recognized, 'major factors in the success of the projects would appear to be the sheer volume of work done and the experience that workers have gradually built up over the years.'

1.4 Settlement Pattern Research at Smaller Scales of Analysis

Although settlement pattern approaches were most broadly applied at the regional scale, other studies followed similar conceptual principles in the examination of occupational surfaces, structures, and communities. At the scale of individual living surfaces or house floors, such distributional analyses have provided key indications as to which activities (such as cooking, food preparation, and toolmaking) were undertaken in different sectors (activity areas) of specific structures (e.g., Flannery and Winter 1976) or surfaces (e.g., Flannery 1986, pp. 321–423). In many respects, the current emphasis on household archaeology (e.g., Wilk and Rathje 1982) is an extension of settlement pattern studies (see *Household Archaeology*). Both household and settlement pattern approaches have fostered a growing interest in the non-elite sector of complex societies, and so have spurred the effort to understand societies as more than just undifferentiated, normative wholes.

At the intermediate scale of single sites or communities, settlement pattern approaches have compared the distribution of architectural and artifactual evidence across individual sites. Such investigations have clearly demonstrated significant intrasettlement variation in the functional use of space (e.g., Hill 1970), as well as distinctions in socioeconomic status and occupational history (e.g., Blanton 1978). From a comparative perspective, detailed settlement pattern maps and plans of specific sites have provided key insights into the similarities and differences between contemporaneous cities and communities in specific regions, as well as the elucidation of important patterns of cross-cultural diversity.

2. *Contemporary Research Strategies and Ongoing Debates*

The expansion of settlement pattern and landscape approaches over the last decades has promoted the increasing acceptance of less normative perspectives on cultural change and diversity across the discipline of archaeology. In many global domains, archaeological surveys have provided a new regional-scale (and in a few cases, macroregional-scale) vantage on past social systems. Settlement pattern studies also have yielded a preliminary means for estimating the parameters of diachronic demographic change and distribution at the scale of populations, something almost impossible to obtain from excavations alone. Nevertheless, important discussions continue over the environmental constraints on implementation, the relative strengths and weaknesses of different survey methodologies, issues of chronological control, procedures for population estimation, and the appropriate means for the interpretation of settlement pattern data.

2.1 *Environmental Constraints*

Although systematic settlement pattern and landscape studies have been undertaken in diverse environmental settings including heavily vegetated locales such as the Guatemalan Petén, the eastern woodlands of North America, and temperate Europe, the most sustained and broadly implemented regional survey programs to date have been enacted in arid environments. In large part, this preference pertains to the relative ease of finding the artifactual and architectural residues of ancient sites on the surface of landscapes that lack thick vegetal covers. Nevertheless, archaeologists have devised a variety of means, such as the interpolation of satellite images, the detailed analysis of aerial photographs, and subsurface testing programs, that can be employed to locate and map past settlements in locales where they are difficult to find through pedestrian coverage alone. In each study area, regional surveys also have to modify their specific field methodologies (the intensity of the planned coverage) and the sizes of the areas that they endeavor to examine to the nature of the terrain and the density of artifactual debris (generally nonperishable ancient refuse) associated with the sites in the specified region. For example, sedentary pottery-using peoples generally created more garbage than did mobile foragers; the latter usually employed more perishable containers (e.g., baskets, cloth bags). Consequently, other things being equal, the sites of foragers are generally less accessible through settlement and landscape approaches than are the ancient settlements that were inhabited for longer durations (especially when ceramics were used).

2.2 *Survey Methodologies and Sampling*

Practically since the inception of settlement pattern research, archaeologists have employed a range of different field survey methods. A critical distinction has been drawn between full-coverage and sample surveys. The former approaches rely on the complete and systematic coverage of the study region by members of a survey team. In order to ensure the full coverage of large survey blocks, team members often space themselves 25–50 m apart, depending on the specific ground cover, the terrain, and the density of archaeological materials. As a consequence, isolated artifact finds can occasionally be missed. But the researchers generally can discern a reasonably complete picture of settlement pattern change across a given region. Alternatively, sample surveys by definition are restricted to the investigation of only a part of (a sample of) the study region. Frequently such studies (because they only cover sections of larger regions) allow for the closer spacing of crew members.

Archaeologists have employed a range of different sampling designs. Samples chosen for investigation may be selected randomly or stratified by a range of diverse factors, including environmental variables. Nevertheless, regardless of the specific sampling designs employed, such sample surveys face the problem of extrapolating the results from their surveyed samples to larger target domains that are the ultimate focus of study. Ultimately, such sample surveys have been shown to be more successful at estimating the total number of sites in a given study region than at defining the spacing between sites or at discovering rare types of settlement. The appropriateness of sample design can only be decided by the kinds of information that the investigator aims to recover. There is no single correct way to conduct archaeological survey, but certain methodological procedures have proven more productive in specific contexts and given particular research aims.

2.3 *Chronological Constraints and Considerations*

One of the principal strengths of settlement pattern research is that it provides a broad-scale perspective

on the changing distribution of human occupation across landscapes. Yet the precision of such temporal sequences depends on the quality of chronological control (see *Chronology, Stratigraphy, and Dating Methods in Archaeology*). The dating of sites during surveys must depend on the recovery and temporal placement of chronologically diagnostic artifacts from the surface of such occupations. Artifacts found on the surface usually are already removed from their depositional contexts. Finer chronometric dating methods generally are of little direct utility for settlement pattern research, since such methods are premised on the recovery of materials in their depositional contexts. Of course, chronometric techniques can be used in more indirect fashion to refine the relative chronological sequences that are derived from the temporal ordering of diagnostic artifacts (typically pottery).

In many regions, the chronological sequences can only be refined to periods of several hundred years in length. As a result, sites of shorter occupational durations that may be judged to be contemporaneous in fact could have been inhabited sequentially. In the same vein, the size of certain occupations may be overestimated as episodes of habitation are conflated. Although every effort should be made to minimize such analytical errors, these problems in themselves do not negate the general importance of the long-term regional perspective on occupational histories that in many areas of the world can be derived from archaeological survey alone. Although the broad-brush perspective from surveys may never provide the precision or detailed views that are possible from excavation, they yield an encompassing representation at the population scale that excavations cannot achieve. Adequate holistic perspectives on past societies rely on the multiscalar vantages that are provided through the integration of wide-ranging archaeological surveys with targeted excavations.

2.4 Population Estimation

One of the key changes in archaeological thought and conceptualization over the past half-century has been the shift from essentialist/normative thinking about ancient societies to a more populational perspective. But the issue of how to define past populations, their constituent parts, and the changing modes of interaction between those parts remains challenging at best. Clearly, multiscalar perspectives on past social systems are necessary to collect the basic data required to estimate areal shifts in population size and distribution. Yet considerable debate has been engendered over the means employed by archaeologists to extrapolate from the density and dispersal of surface artifacts pertaining to a specific phase to the estimated sizes of past communities or populations.

Generally, archaeologists have relied on some combination of the empirically derived size of a past settlement, along with a comparative determination of surface artifact densities at that settlement, to generate demographic estimates for a given community. When the estimates are completed for each settlement across an entire survey region, extrapolations become possible for larger study domains. By necessity, the specific equations to estimate past populations vary from one region to another because community densities are far from uniform over time or space. Yet due to chronological limitations, as well as the processes of deposition, disturbance, and destruction, our techniques for measuring ancient populations remain coarse-grained. Although much refinement is still needed to translate survey data into quantitative estimates of population with a degree of precision and accuracy, systematic regional surveys still can provide the basic patterns of long-term demographic change over time and space that cannot be ascertained in any other way.

2.5 The Interpretation of Regional Data

Beyond the broad-brush assessment of demographic trends and site distribution in relation to environmental considerations, archaeologists have interpreted and analyzed regional sets of data in a variety of ways. Landscape approaches, which began with a focused perspective on humans and their surrounding environment, have continued in that vein, often at smaller scales. Such studies often examine in detail the placement of sites in a specific setting with an eye toward landscape conservation and the meanings behind site placement (Sherratt 1996). At the same time, some landscape studies have emphasized the identification of ancient agrarian features and their construction and use.

In contrast, the different settlement pattern investigations have employed a range of analytical and interpretive strategies. In general, these have applied more quantitative procedures and asked more comparatively informed questions. Over the last 40 years (e.g., Johnson 1977), a suite of locational models derived from outside the discipline has served as guides against which different sets of archaeological data could be measured and compared. Yet debates have arisen over the underlying assumptions of such models and whether they are appropriate for understanding the preindustrial past. For that reason, even when comparatively close fits were achieved between heuristically derived expectations and empirical findings, questions regarding equifinality (similar outcomes due to different processes) emerged. More recently, theory-building efforts have endeavored to rework and expand these locational models to specifically archaeological contexts with a modicum of success. Continued work in this vein, along with the integration of some of the conceptual strengths from both landscape and settlement pattern approaches are requisite to under-

standing the complex web of relations that govern human-to-human and human-to-environment interactions across diverse regions over long expanses of time.

3. Looking Forward: The Critical Role of Settlement Studies

The key feature and attribute of archaeology is its long temporal panorama on human social formations. Understanding these formations and how they changed, diversified, and varied requires a regional/populational perspective (as well as other vantages at other scales). Over the last century, the methodological and interpretive toolkits necessary to obtain this broad-scale view have emerged, diverged, and thrived. The emergence of archaeological survey (and settlement pattern and landscape approaches) has been central to the disciplinary growth of archaeology and its increasing ability to address and to contribute to questions of long-term societal change. At the same time, the advent of settlement pattern studies has had a critical role in moving the discipline as a whole from normative to populational frameworks.

Yet settlement pattern work has only recently entered the popular notion of this discipline, long wrongly equated with and defined by excavation alone. Likewise, many archaeologists find it difficult to come to grips with a regional perspective that has its strength in (broad) representation at the expense of specific reconstructed detail. Finally, the potential for theoretical contributions and insights from settlement pattern and landscape approaches (and the wealth of data collected by such studies) has only scratched the surface. In many respects, the growth of regional survey and analysis represents one of the most important conceptual developments of twentieth-century archaeology. Yet at the same time, there are still so many mountains (literally and figuratively) to climb.

Sex Differences in Pay

Differences in pay between men and women remain pervasive in late twentieth-century labor markets, with women's average earnings consistently below men's

even when differences in hours of work are taken into account. This 'gender pay gap' may result from unequal pay within jobs, but is also related to the different types of jobs occupied by men and women. Considerable debate has arisen over the extent to which it is evidence of discrimination in labor markets or simply a result of the individual attributes and choices of men and women. The size of the pay gap may also be influenced by the institutional framework of pay bargaining and regulation in different countries. The article reviews a range of factors thought to contribute to the gender pay gap, and the strategies designed to eradicate it. It draws primarily on evidence from affluent industrialized nations.

1. *The Gender Pay Gap: Trends and Comparisons*

While the gap between men's and women's average earnings has narrowed in most countries in the late twentieth century, significant inequality remains. Moreover, substantial cross-national differences are apparent. Table 1 illustrates some of these variations in selected countries. To enhance comparison, the data are drawn as far as possible from one source (International Labour Office [ILO] *Yearbook of Labour Statistics*). Where available, the figures are for hourly earnings, as data for longer periods produce deflated estimates of women's relative earnings due to the tendency for women to work fewer hours than men. Also, while the most widely available and reliable data are for manufacturing, women's employment in industrialized nations tends to be concentrated more in service industries. Thus earnings in the ILO's more inclusive category of 'non-agricultural activity' are also reported where available, although these are less satisfactory for cross-national comparison due to variations in the range of industries included. Even within countries, series breaks in data collection may limit the accuracy of comparisons over time. Some caution is therefore needed in interpreting cross-national differences and trends. Nevertheless, a number of broad observations can be made on the basis of the data presented in Table 1.

Looking first at trends within countries, an increase in women's average earnings relative to men's since 1970 is evident in all of the countries listed except Japan. In many cases this has occurred mainly in the 1970s, although some countries (for example, Belgium, Canada, and the USA) show marked improvement since 1980. In several cases, however, closing of the gender pay gap has slowed in the 1990s.

The table also provides some indication of cross-national variation in the size of the gender pay gap. Figures for Canada and the USA are from different sources and not strictly comparable with data from the other countries. Among the others listed, the picture of cross-national variance appears broadly similar for manufacturing and 'non-agricultural' data. On the basis of the hourly manufacturing data, which are the most reliable for comparative purposes, Sweden stands out having the narrowest gender pay gap in the mid-1990s. The large gap in Japan reflects the use of monthly rather than hourly earnings, and thus the impact of different working hours between men and

Table 1
Women's earnings as a percentage of men's[i], selected countries and years[ii]

i. Percentages are based on hourly earnings except for Canada and Japan. ii. Countries have been selected on the basis of data availability and to provide a span across continents. iii. ILO 'non-agricultural' activity groups. Data for Canada and the USA are from different sources and are based on all industries. iv. For Canada, percentages are based on yearly earnings for full-year, full-time workers. The use of yearly wages deflates the figures as women work fewer hours than men on average, even when the comparison is limited to full-time workers. v. For Japan, percentages are based on monthly earnings. vi. For the USA, percentages are based on hourly earnings, but these are for workers paid an hourly wage and are not directly comparable with hourly data for other countries. vii. 1972. viii. 1974. ix. 1992. x. 1993 — Data unavailable.

women. However, OECD approximations of hourly earnings in manufacturing in Japan still show a very large pay gap (OECD 1988, p. 212), and ILO data indicate that on this issue Japan looks more like other East Asian countries (for example, South Korea and Singapore) than the other countries listed in the table.

Overall, the data raise several questions. Why is there a gender pay gap? What accounts for its variation over time and across nations? What can, or should, be done to eradicate it? These questions are addressed in the following sections which examine possible explanations for the gender pay gap, the effect of institutional factors on its variation across countries, and the strategies most likely to assist in its elimination.

2. *Explaining the Gender Pay Gap*

One of the most direct ways in which sex differences in pay have arisen historically is through the establishment of different rates of pay for men and women in wage-setting processes. The assumption that men, as 'breadwinners,' should be entitled to higher pay than women underpinned pay determination in many countries until well into the twentieth century. In some countries this was institutionalized in the form of a 'family wage' for men. While early challenges to these assumptions were made in several countries, equal pay rates for men and women were usually only achieved where men's jobs were threatened by cheaper female labor (see, for example, Ryan and Conlon 1989, pp. 99–100). In most countries it was not until the 1960s and 1970s, following the growth of second wave feminism and increasing involvement of women in paid employment, that the inequity of different rates of pay for men and women was responded to directly through policies of equal pay for equal work.

However, much of the pay difference between men and women results not from different pay rates in the same jobs, but from the location of men and women in different jobs. This sex segregation of the labor market has proved remarkably resistant to change, and in Walby's (1988) view, accounts for the persistence of the gender pay gap since World War II in spite of the increasing human capital (i.e., education and labor market experience) of women over that time period (see *Sex Segregation at Work*).

Segregation is significant for pay inequality to the extent that female-dominated sectors of the labor market deliver lower pay. Female-dominated occupations, for example, may be low-skilled or involve skills that have been undervalued. They may also be less likely to provide discretionary payments such as overtime or bonuses. Empirical studies demonstrate that the proportion of women in an occupational group is negatively associated with wage levels, with typically around one-third of the gender pay gap shown to be due to occupational segregation by sex (Treiman and Hartmann 1981). Results for this type of analysis are highly dependent on the level of disaggregation of occupations applied. Finer disaggregation uncovers greater inequality, as vertical segregation exists within broad occupational groups, with men more likely to be in the higher status, higher paid, jobs.

Concentration of women in a small number of occupational groups is also significant for pay outcomes. Grimshaw and Rubery (1997), for example, demonstrate that in seven OECD countries around 60 percent of women are concentrated in just 10 occupational groups out of a total of between 50 and 80, with little change in this situation since the mid-1980s. Moreover, their analysis shows a wage penalty associated with this concentration of employment. Women within these occupations, on average, earn less than the all-occupation average.

Another form of labor market division potentially affecting pay differences is the distribution of men and women between firms. Blau (1977) has shown that in the USA women and men are differently distributed among firms, with women more likely to be employed in comparatively low-paying firms. These sorts of divisions may contribute to sex differences in earnings within occupations.

A further type of division that has become of increasing significance is that between full-time permanent and other, less regular, types of employment. Part-time work is highly female dominated in most countries, and on average tends to be less well remunerated per hour than full-time work. Waldfogel (1997, p. 215), for example, shows that part-time work carries a wage penalty for the women in her sample. Thus, although part-time positions may assist women to retain careers by facilitating the combination of work and family responsibilities, the concentration of women in this type of work may contribute to the gender pay gap.

In sum, sex differences in pay can arise from different pay rates in particular jobs or the distribution of female employment into lower paying jobs. In both cases, pay differences may be due to forms of discrimination or to non-discriminatory influences. Non-discriminatory influences include the individual attributes and choices of men and women, and although these may reflect broader social inequities, they can be distinguished from overt forms of discrimination within the labor market. Both areas are considered below.

2.1 *Individual Attributes and Choices*

A wide body of literature has addressed the extent to which the gender pay gap can be explained by individual attributes and choices. Human capital theory suggests that productivity related differences between men and women, such as education, skill, and labor market experience, may account for sex differ-

ences in earnings. Typically, analyses decompose earnings differences between men and women into a component that can be 'explained' by productivity factors, and another that represents the 'unexplained' elements of the gender pay gap that are ascribed to labor market discrimination (Oaxaca 1973). Whether human capital differences themselves might be evidence of social inequality (for example, reflecting differential access to training or restricted choices about labor force attachment) has not been an explicit part of this analytical approach.

Numerous studies have been conducted for different countries, and although there are difficulties of measurement and interpretation that complicate such analyses, human capital variables typically account for less than half, and often considerably smaller proportions, of the gender pay gap (Treiman and Hartmann 1981, p. 42). The studies which explain most have been those including detailed estimates of employment experience or labor force attachment (for example, Corcoran and Duncan 1979). Where women's more intermittent labor force attachment has been captured effectively, as in longitudinal surveys or work histories, the negative effect on wages has been clearly demonstrated (Waldfogel 1997, pp. 210–11).

Alongside intermittent labor force attachment, several studies show a wage penalty for women associated with the presence of children. In a regression model utilizing data from 1968–88, Waldfogel (1997, p. 212) identifies a penalty in hourly wages associated with having a child, and a larger penalty for two or more children, even after controlling for actual employment experience and factors such as education. The effects of family and domestic labor responsibilities are thus likely to be cumulative, lowering women's earnings through reducing employment experience and the capacity to retain career paths. While some may interpret such findings as evidence that a proportion of the gender pay gap is non-discriminatory and simply due to individual choices, others may observe that women's disproportionate responsibility for family care affects the range of choices available (see *Motherhood: Economic Aspects*).

2.2 Discrimination in Employment

There are several types of labor market discrimination with implications for sex differences in pay. For example, employers may discriminate against women when recruiting and promoting staff, preferring to hire men for higher status positions, and investing more in training and career support for men. This may be 'statistical discrimination,' reflecting assumptions that women will be more likely than men to leave work, or have lower levels of commitment to it, once they have family responsibilities. However, it is not clear that women leave jobs more frequently than men (see England 1992, p. 33), hence the rationality of this type of discrimination is questionable. Less direct forms of discrimination may be the result of customary practice, with long-standing procedures and organizational cultures effectively hindering the advancement of women (see Cockburn 1991).

Discrimination may also be evident in the way pay rates are established. While the overt use of different rates of pay for men and women discussed earlier is no longer widespread, female-dominated areas of employment may be relatively underpaid. England's (1992) analysis provides some evidence for this by showing that the sex composition of an occupation explains between 5 percent and 11 percent of the gender pay gap even when factors such as different types of demands for skill and effort, and industrial and organizational characteristics are controlled for. Undervaluation could be the result of women's comparatively low bargaining power, and could also reflect gender-biased estimations of the value of skills in female-dominated occupations. England (1992), for example, shows that 'nurturing' skills carry a wage penalty, thus suggesting that this type of work is devalued because of its association with typical 'women's work.' Such findings indicate that policies of 'comparable worth' or 'equal pay for work of equal value'—that is, comparisons of dissimilar jobs to produce estimations of job value free of gender-bias—have an important role to play.

3. The Role of Institutions

While the factors considered thus far contribute to an understanding of the gender pay gap in a general sense, they are frequently less useful in explaining differences between countries. For example, differences between countries in the level of occupational segregation appear to be unrelated to performance on sex differences in pay. In Japan, the combination of low levels of occupational segregation and a large gender pay gap may be explained partly by women's relative lack of access to seniority track positions in large firms (Anker 1997, p. 335)—that is, by other types of segregation. However, a different type of explanation is necessary to understand why some countries that are highly sex-segregated by occupation (such as Sweden and Australia) have comparatively narrow gender pay gaps. This anomaly suggests the importance of institutional factors in influencing the gender pay gap.

Blau and Kahn (1992), for example, point out that the effect of occupational concentration on sex differences in pay will be influenced by the overall wage distribution in any country—where wages are relatively compressed, the effect of segregation on earnings will be minimized. Wage distribution is in turn likely to be a product of the institutional framework for wage bargaining, with more centralized and regulated systems conducive to lower levels of wage dispersion,

and, therefore, a narrower gender pay gap. Cross-national statistical evidence supports these links, showing association between centralized wage fixation and high levels of pay equity (Whitehouse 1992, Gunderson 1994). This relationship is likely to result not only from wage compression, but also from an enhanced capacity to implement equal pay measures in more centralized systems. Rubery (1994) notes that the degree of centralization has implications for several matters of relevance to pay equity outcomes, including the maintenance of minimum standards and the scope for equal value comparisons. Decentralized pay systems tend to provide more limited scope for comparisons to support equal pay for work of equal value cases, and results may be limited to specific enterprises, or to individuals. Overall, trends in wage bargaining arrangements may be more influential on pay equity outcomes than specific gender equity measures (Rubery 1994, Rubery et al. 1997, Whitehouse 1992). Wage bargaining systems are, however, country-specific, and embedded in national employment systems (Rubery et al. 1997). Translation of institutional structures across countries is therefore unlikely to be a viable proposition.

4. *Policy options*

As the gender pay gap cannot be attributed to one type of cause, a number of strategies will be necessary to attempt its elimination. While addressing pre-market impediments to women's advancement (such as sex-role stereotypes and their impact on educational and employment choices) is part of this agenda, the main strategies are those designed to remove barriers within the labor market. International conventions such as the ILO's Equal Remuneration Convention (No. 100) and the United Nations' Convention on Elimination of all forms of Discrimination Against Women have provided some impetus for action, and most countries have now implemented some form of equal pay legislation or prohibition against discrimination in employment. However, the efficacy of such measures is highly variable.

The most direct strategies are legislative provisions requiring the payment of equal pay for equal work, and equal pay for work of equal value. Equal pay for equal work provisions have been most effective where they have included a requirement to remove differential pay rates for men and women in industrial agreements. The rapid narrowing of the gender pay gap in Australia and the UK in the 1970s, for example, demonstrates the effectiveness of measures that removed direct discrimination in collective agreements (Gregory et al. 1989, Zabalza and Tzannatos 1985). Improvements in Sweden in the same decade also reflect the advantage of widespread coverage by collective agreements, and in that case predate the introduction of equal pay legislation. However, while equal pay requirements may be quite effective initially where they equalize minimum rates between men and women across a comprehensive set of collective agreements, the level of segregation in the labor market means that most provisions for equal pay for equal work apply to only a small proportion of women, as few men and women are in fact doing the same work.

Provisions for equal pay for work of equal value (comparable worth) open up a wider field for contestation, but this strategy has proved difficult to implement. Historical bias in the way 'female' jobs are valued has not been easy to eradicate as even quite detailed job evaluation methods retain aspects of gender bias and may in fact perpetuate existing hierarchies (Steinberg 1992). Moreover, cases have proved complex and time consuming. Comparable worth does permit reconsideration of the valuation of work, however, and is particularly important given the apparent resistance of patterns of occupational segregation to change. It will be most effective where the scope for comparison is wide, and results apply collectively to types of jobs rather than to individuals.

Apart from strategies that deal directly with pay, provisions to prohibit discrimination in employment have been adopted in most countries. Anti-discrimination legislation and equal employment opportunity or affirmative action measures aim to prevent sex discrimination in hiring and placement, and in some cases seek to correct for past sex discrimination by requiring attention to the unequal distribution of men and women within organizations. While it is difficult to estimate the impact of such measures on the gender pay gap, they have no doubt restricted the scope for overt discrimination and contributed to a gradual change in customs and attitudes.

Given the impact of family responsibilities on women's earnings noted earlier, erosion of the gender pay gap will also require the use of strategies to assist in the combination of work and family responsibilities. Ultimately this also requires a more even division of domestic labor between men and women to assist women to retain career progression and employment experience. Paid parental and family leave, and measures to deliver flexibility with job security while combining employment and caring responsibilities will be part of this agenda, although experience thus far suggests that encouragement to fathers to share these types of provisions will also be necessary.

Finally, it must be emphasized that the gender pay gap is dependent on a wide range of policy and institutional factors, most of which are not designed with gender equity goals in mind. In particular, wage bargaining arrangements and employment policies may affect the size of the gender pay gap by affecting outcomes such as wage dispersion. Trends away from centralized and regulated forms of pay bargaining are therefore of some concern as they may increase dispersion, which in turn may erode gains made

through equal pay or comparable worth strategies. In short, the pursuit of pay equity cannot be limited to a single agenda, but requires multiple policy measures, and—like most endeavors attempting significant social change—will require a long period of time to achieve.

Sex Hormones and their Brain Receptors

Nerve cells react not only to electrical and chemical signals from other neurons, but also to a variety of steroid factors arising from outside the brain. Steroids, particularly gonadal steroids, have profound effects on brain development, sexual differentiation, central nervous control of puberty, the stress response, and many functions in the mature brain including cognition and memory (Brinton 1998, McEwen 1997).

The brain contains receptors for all five classes of steroid hormones: estrogens, progestins, androgens, glucocorticoids, and mineralocorticoids. Steroid hormone receptors are not uniformly distributed, but occupy specific loci within the brain (McEwen 1999, Shughrue et al. 1997). As expected the hypothalamus has a rich abundance of steroid receptors, particularly receptors for the sex hormones estrogen, progesterone, and testosterone. Remarkably, the limbic system is also a site for steroid action and contains estrogen, androgen, and glucocorticoid receptors. The cerebral cortex is also a site of steroid action and expresses receptors for estrogens and glucocorticoids. Some of these receptors arise from separate genes while others arise from alternative splicing of a single gene. For example the progesterone receptor exists in multiple isoforms derived from the alternative splicing of one gene (Whitfield et al. 1999) whereas estrogen receptors have multiple receptor subtypes (ERα and ERβ) that originate from separate genes, as well as multiple isoforms (Warner et al. 1999, Keightley 1998).

1. Structure of Steroid Receptors

All genomic steroid hormone receptors are composed of at least three domains: the N-terminal (or A/B) region, the DNA binding domain containing two zinc-fingers (region C), and the ligand-binding domain to which the hormone binds (region E). Select steroid receptors, such as the estrogen receptors, have an additional C-terminal (or F) region, which serves to modify receptor function (Tsai and O'Malley 1994, Warner et al. 1999) (Fig. 1A).

The amino-terminal A/B region of steroid receptors is highly variable and contains a transactivation domain, which interacts with components of the core transcriptional complex. Region C of these receptors contains a core sequence of 66 amino acids that is the most highly conserved region of the nuclear hormone receptor family. This region folds into two structures that bind zinc in a way characteristic of type II zinc

Figure 1
Structural aspects of Steroid Receptors. A. The steroid receptors can be divided into 6 functional domains A, B, C, D, E, and F. The function of each domain is indicated by the solid lines. B. Ribbon representation of the ligand binding domain of estrogen receptor α indicating the ligand binding pocket. Upon ligand binding the receptor dimerizes and then can act as a transcription factor (adapted from Brzozowski et al. 1997). C. Ribbon representation of ERα demonstrating the conformational alterations induced by 17β-estradiol. Upon binding estradiol, helix 12 folds to cover the ligand binding pocket leaving the coactivator binding site free. D. Ribbon representation of ERα demonstrating the conformational alterations induced by raloxifene. Upon binding raloxifene, helix 12 is displaced obscuring the coactivator binding site (adapted from Brzozowski et al. 1997)

fingers. These two type II zinc clusters are believed to be involved in specific DNA binding, thus giving the C regions its designation as the DNA binding domain. In addition, the C region plays a role in receptor dimerization (Fig. 1A and B). The D region contains a hinge portion that may be conformationally altered upon ligand binding. The E/F-region is functionally complex since it contains regions important for ligand binding and receptor dimerization, nuclear localization, and interactions with transcriptional co-activators and corepressors (Horwitz et al. 1996). It has been observed that a truncated receptor lacking regions A/B and C can bind hormone with an affinity similar to that of the complete receptor suggesting that region E is an independently folded structural domain. Amino acids within region E that are conserved amongst all members of the nuclear receptor family are thought to be responsible for the conformation of a hydrophobic pocket necessary for steroid binding whereas the non-conserved amino acids may be

important for ligand specificity. The conserved amino acid sequences within the ligand binding domain of the nuclear receptors make up a common structural motif, which is composed of 11–12 individual α helices with helix 12 being absent in some members of the superfamily of steroid receptors. Although domain F is not required for transcriptional response to hormone, it appears to be important for modulating receptor function in response to different ligands.

Of prime importance in estrogen receptor function is helix 12 (Fig. 1C), found in the most carboxyl region of the ligand-binding domain, which is thought to be responsible for transcriptional activation function (AF-2) activity (Warner et al. 1999). This region realigns over the ligand-binding pocket when associated with agonists, but takes on a different conformation with antagonists (Fig. 1). Such conformational changes are thought to affect interactions with coactivators, since helix 12 is required for interaction with several of the coactivator proteins and mutations that are known to abolish AF-2 transcriptional activity also abolish the interaction of the nuclear receptors with several of their associated proteins (McKenna et al. 1999, Warner et al. 1999). The ability of different ligands to determine the conformational state of the receptor has profound consequences on the ability of the steroid receptor to drive gene transcription.

2. *Classical Mechanism of Sex Steroid Action*

Classically, sex steroids exert their effects by binding to intracellular receptors and modifying gene expression (Tsai and O'Malley 1994). Steroid receptors are ligand-activated transcription factors that modulate specific gene expression. In the presence of hormone, two receptor monomers dimerize and bind to short DNA sequences located in the vicinity of hormone-regulated genes (Fig. 2). These specific DNA sequences, or hormone response elements (HRE), contain palindromic or directly repeating half-sites (Tsai and O'Malley 1994). Since an HRE exerts its action irrespective of its orientation and when positioned at a variable distance upstream or downstream from a variety of promoters (Tsai and O'Malley 1994), it is an enhancer. Steroid receptors represent inducible enhancer factors that contain regions important for hormone binding, HRE recognition, and activation of transcription.

The mechanism of transactivation by nuclear receptors has recently achieved further complexity by the discovery of an increasing number of coregulators. Coregulator proteins can modulate the efficacy and direction of steroid-induced gene transcription. Coregulators include coactivators ERAP160 and 140, and RIP160, 140, and 80 which were biochemically identified by their ability to specifically interact with the hormone binding domain of the receptor in a ligand-dependent manner (McKenna et al. 1999) (Fig. 2). For example, the interaction between estrogen receptors and coregulators was promoted by estradiol whereas antiestrogens did not promote this interaction. Further studies led to the identification of many other co-activators including glucocorticoid receptor interacting protein 1 (GRIP 1), steroid receptor coactivator 1 (SRC 1), and transcriptional intermediary factor 2 (TIF 2). When cotransfected with nuclear receptors, including estrogen receptor, these coactivators are capable of augmenting ligand-dependent transactivation. In addition, the phospho-CREB-binding protein (CBP) and the related p300 have been demonstrated to be estrogen receptor-associated proteins and involved in ligand-dependent transactivation. It has also been shown that co-activator RIP140 interacts with the ER in the presence of estrogen, and this interaction enhances transcriptional activity between 4- to 100-fold, depending on promoter context.

3. *Rapid Signaling Effects of Sex Steroids*

Although steroids induce many of their effects in the brain through activation of genomic receptors, non-transcriptional actions of estrogens, progestins, glucocorticoids, and aldosterone have been observed in a variety of tissues, including the brain (Brinton 1993, 1994, Watson et al. 1995, Pappas et al. 1995). These nontranscriptional actions are characterized by short-term effects that range from milliseconds to several minutes. Additionally, these effects still occur in the presence of actinomycin D or cyclohexamide, known transcriptional blockers. The first suggestion of the non-transcriptional actions of steroids came when it was observed that progesterone induced rapid anesthetic and sedative actions when injected subcutaneously (Brinton 1994). Then in the 1960s and 1970s numerous studies suggested that estrogen modulated the electrical activity of a variety of nerve cells (Foy et al. 1999). Subsequent studies utilizing various techniques and preparations have shown that these effects occur too rapidly to be genomic in nature (Foy and Teyler 1983).

Morphological studies of neuronal development conducted *in vitro* have shown that estrogenic steroids exert a growth-promoting, neurotrophic effect on hippocampal and cortical neurons via a mechanism that requires activation of NMDA receptors (Brinton et al. 1997). *In vivo* studies have revealed a proliferation of dendritic spines following 17β-estradiol treatment that can be prevented by blockade of NMDA receptor-channels, though not by AMPA or muscarinic receptor antagonists (Woolley 1999). Other reports have provided evidence that chronic 17β-estradiol treatment increases the number of NMDA receptor binding sites, and NMDA receptor-mediated responses (Woolley 1999).

Figure 2
Classical mechanism of steroid action. Upon binding of steroid (S) to an inactive steroid receptor, the receptor is activated and two receptor-ligand monomers dimerize and bind to the hormone response element (HRE). Coactivators such as RIP140, CBP, and SRC-1 bind to and link the hormone receptor with the general transcription factors (GTF) and RNA polymerase of the transcription machinery to alter transcription

Recent studies suggest a direct link between the estrogen receptor and the mitogen-activated protein kinase (MAPK) signaling cascade (Singh et al. 2000). MAPKs are a family of serine-threonine kinases that become phosphorylated and activated in response to a variety of cell growth signals. In neuronal cells, estrogen resulted in neuroprotection that was associated with a rapid activation of the MAPK

Figure 3
Rapid signaling effects of sex steroids. Estradiol, acting through a possible membrane bound or cytoplasmic receptor, causes the transient activation of c-src-tyrosine kinase. Activated c-src can potentiate the glutamate response through the NMDA receptor. Additionally, c-src can cause the phosphorylation of p21 (ras)-guanine nucleotide activating protein leading to the activation of MAP Kinase, which has many downstream effects on cell survival and growth

signaling pathway (Singh et al. 2000). These neuroprotective effects, which occurred within 5 minutes of estrogen exposure are thought to occur through the transient activation of c-src-tyrosine kinases and tyrosine phosphorylation of p21(ras)-guanine nucleotide activating protein (Fig. 3). Additionally, the potentiation of the NMDA receptor mediated neuronal response by estrogen is thought to be mediated by c-src-tyrosine kinases (Bi et al. 2000). It is not yet clear whether these effects require the classical estrogen receptor (ERα/β) or if there is an as of yet undiscovered membrane receptor that mediates these rapid effects of estrogen (Razandi et al. 1999). Thus, while steroid receptors are ligand-induced transcriptional enhancers, they are also activators of intracellular signaling pathways that can profoundly influence neuronal function and survival.

Challenges remain in our understanding of steroid action and sites of action in brain. Remarkably, our knowledge of genomic sites of steroid action has greatly expanded in the past decade while the membrane sites of steroid action remain a challenge to fully characterize. Our understanding of steroid effects in brain has led to the expansion of the role of steroid receptors beyond sexual differentiation and reproductive neuroendrocrine function to regulators of nearly every aspect of brain function including cognition. The full range of mechanisms by which steroids influence such a wide array of brain functions remains to be discovered.

Sex Offenders, Clinical Psychology of

The clinical psychology of sex offenders involves assessment, treatment, and prevention. Clinical assessment involves the careful description of the problem and an estimation about the risk for recidivism, or re-offense. Clinical treatment involves interventions to reduce the risk of recidivism. Clinical prevention involves interventions before a person becomes a sex offender to reduce the risk of recidivism. There is much more research on assessment and treatment of sex offenders than there is on prevention of sex offending.

1. *Who are Sex Offenders?*

A sex offender is anyone who has forced another person to engage in sexual contact against their will. Sex offending may or may not involve physical force. For example, a person can use psychological force to get another person to have sex, as in the case of a power differential between two persons (e.g., employer–employee). However, coercive sex that involves physical force is more likely to be regarded as sex offending than coercive sex that does not. Another issue is the ability of the victim to give consent. Minors and developmentally disabled persons are usually considered to lack the ability to give consent. A person's ability to give consent may also become impaired, such as in the case of substance abuse. Thus, a person engaging in sex with a person who is unable to consent or whose ability to give consent is impaired might be considered a sex offender.

The term sex offender usually is associated with a person who has been apprehended in a legal context for their coercive sexual behavior. Nevertheless, not all persons who engage in sexually coercive behaviors are caught. Thus, two persons could engage in the same sexually coercive behavior, but the one who is caught would be considered a sex offender and the one who is not caught would not. Moreover, legal statutes

vary from jurisdiction to jurisdiction. For example, sexual penetration may be required to be considered a sex offender in some jurisdictions, while other jurisdictions may have broader definitions that include nonpenetrative forms of sexual contact. Legal jargon may obscure the meaning and impact of sexually coercive behavior, as well. For example, terms such as 'indecent liberties' and 'indecent assault' may both refer to rape, as defined as forced sexual intercourse. However, indecent liberties or indecent assault charges carry very different legal meanings and punishments than does rape. Similarly, rape committed by a stranger is more likely to be prosecuted than rape committed by someone known to the victim. Nevertheless, the behavior in both instances is rape. Because of these inconsistencies and vagaries in legal definitions of sex offending, the current article will adopt a broad approach to sexual aggression, focusing on coercive sexual behavior whether or not the perpetrator has been apprehended.

There is often disagreement between perpetrators and victims on whether sexual aggression actually occurred, or the seriousness of it. A comprehensive discussion of the veracity of perpetrator and victim reports is beyond the scope of this article. However, current definitions of sexual aggression give more weight to victims' perceptions of the occurrence of sexual aggression, given perpetrators' tendencies to defend and minimize aggressive behavior and the inherent power differential between victims and offenders. It is usually disadvantageous to bring the negative attention to oneself that accompanies accusing someone of sexually victimizing them. In courtroom settings, victims' personal and sexual histories are examined in cases of sexual abuse in a manner that is unparalleled for other types of offenses. Nevertheless, child custody disputes appear to be one context in which there may be some risk, albeit small, for false accusations of sexual abuse on the part of a parent seeking to disqualify the parenting fitness of the other parent.

The Diagnostic and Statistical Manual (*DSM*) of the American Psychiatric Association includes several sexual disorders, or paraphilias, that sex offenders may have. These include fetishism (sexual arousal associated with nonliving objects), transvestic fetishism (sexual arousal associated with the act of cross-dressing), voyeurism (observing unsuspecting nude individuals in the process of disrobing or engaging in sexual activity), exhibitionism (public genital exposure), frotteurism (touching a nonconsenting person's genitalia or breasts, or rubbing one's genitals against a nonconsenting person's thighs or buttocks), pedophilia (sexual attraction or contact involving children), sexual masochism (sexual arousal associated with suffering), and sexual sadism (sexual arousal associated with inflicting suffering). Although the fetish disorders do not involve contact with an actual person, these disorders can result in arrest when a fetishist steals the fetish items (e.g., undergarments). Rape often does not involve sexual arousal directly associated with suffering and is more commonly classified in *DSM* as a component of antisocial personality disorder than as a sexual disorder. Such a classification appears justified, in that many rapists engage in both sexual and nonsexual forms of aggression and other rule-violating behaviors. The focus of this article will be on rape and child molestation because there exists more research on these topics than on any of the other types of sexual offenses. The emphasis in the literature on these two sex offenses reflects the fact that these may create more harm to victims than the other disorders.

2. *History*

The clinical study of sex offenders had its beginnings in research on sexuality. Some of the earliest scholarly writings on sexual deviance were detailed case studies by psychiatrist Krafft-Ebing (1965/1886). Krafft-Ebing postulated that all sexual deviations were the result of masturbation. The case study method focused exclusively on highly disturbed individuals without matched control cases, which precluded objective considerations of etiology (Rosen and Beck 1988).

Kinsey and colleagues (1948) conducted large-scale normative surveys of sexual behavior, resulting in major works on male and female sexuality. Because adult–child sexual contact was relatively common in his samples, Kinsey underplayed the negative effects of such behavior (Rosen and Beck 1988). Work on sexual deviance continued at the Kinsey Institute after Kinsey's death (Gebhard et al. 1965).

A major advance in the assessment of sexual arousal was the development of the laboratory measures of penile response by Freund (1963). Freund's measure, known as the penile plethysmograph, involved an inflatable tube constructed from a condom, by which penile volume change in response to erotic stimuli (e.g., nude photographs) was measured by air displacement (Rosen and Beck 1988). Less intrusive penile measures to assess circumference changes were later developed (Bancroft et al. 1966; Barlow et al. 1970). Among behaviorists, penile response to deviant stimuli (e.g., children, rape) became virtually a gold standard of measurement for sexual deviance (e.g., Abel et al. 1977).

The emphasis of behaviorists on the role of sexual arousal in sex offending came under criticism from feminist theories. Rape was conceptualized as a 'pseudosexual' act of anger and violence rather than as a sexual disorder. This approach was popularized by Groth (1979). More recent conceptualizations have incorporated sexual, affective, cognitive, and developmental motivational components of sex offending (Hall et al. 1991).

3. *Risk Factors for Sex Offending*

One major risk factor for being a sex offender is being male. Less than 1 percent of females perpetrate any form of sexual aggression, whereas the percentage of men who are rapists ranges from 7 to 10 percent, and the percentage of men who admit to sexual contact with children is 3 to 4 percent. Evolutionary psychologists suggest that mating with multiple partners provides males with a reproductive advantage. Thus, sexually aggressive behavior may be a by-product of evolutionary history. Nevertheless, most men are not sexually aggressive. Thus, being a male may be a risk factor for being sexually aggressive, but certain environmental conditions may be necessary for someone to become sexually aggressive. For example, aggressive behavior, including sexually aggressive behavior, is accepted and socialized among males more than females in most societies.

Another risk factor for males becoming sexually aggressive, particularly against children, is personal sexual victimization. Boys who have been sexually victimized are more likely to engage in sexualized behaviors (e.g., sexual touching) immediately following sexual victimization than boys who have not. Moreover, in recent studies, over half of adult sex offenders have reported being sexually abused during childhood. However, the sexual abuse of males is not invariably associated with becoming sexually abusive, as the majority of males who are sexually abused do not become abusers.

The single best predictor of sex offending is past sex offending. Persons who have sexually offended multiple times in the past are more likely to sexually offend in the future than those who have limited histories of sex offending. Recidivism rates for child molesters and rapists are similar at 25 to 32 percent. Persons who have committed multiple sex offenses have broken the barriers against offending and have lowered the threshold for re-offending by developing a pattern of behavior. Thus, sex offenders having multiple offenses are the group that poses the greatest risk to community safety. Moreover, the predictive utility of past sex offending suggests that interventions with first-time offenders and interventions to prevent sex offending from starting are critical to avoid the establishment of an ingrained pattern of behavior.

4. *Motivational Factors for Sexual Offending*

What causes men to become sex offenders? One common explanation has been the sexual preference hypothesis that sex offenders are more sexually aroused by coercive than by consenting sexual activity. Learning theories posit that sexual arousal to coercive sexual activity is conditioned (see *Classical Conditioning and Clinical Psychology*). For example, a pedophile may have had sexually arousing experiences during childhood with peers and may never have outgrown these experiences. The fusion of violent and sexual images in the media may influence some men to associate sexual arousal with aggressive activity. The sexual preference hypothesis appears to be most appropriate for some sex offenders against children, particularly those who offend against boys. For many men who molest children, their sexual arousal to children exceeds their sexual arousal to adults, as assessed by genital measures. However, some child molesters, particularly incestuous offenders, may be more sexually aroused by adults than by children. The sexual preference hypothesis is less applicable to men who rape adults. Most rapists' sexual arousal is greatest in response to adult consenting sexual activity and less in response to sexual activity that involves physical force. However, a minority of rapists do exhibit a sexual preference for rape over consenting adult sexual activity. These rapists would be considered sexual sadists.

Another common explanation of sex offending has been anger and power. Some feminist scholars have gone as far as to say that sex offending is a 'pseudo-sexual' act and that it is not about sex. However, recent feminist scholarship recognizes the sexual and aggressive aspects of sex offending. If sex offending is a violent, rather than a sexual, act, why does the perpetrator not simply assault the victim rather than sexually assaulting the victim? Anger and power are most relevant in explaining the rape of women by males. Adversarial relationships with women may cause some men to attempt to enforce their sense of superiority over women via rape. Some child molesters may also have anger and power motives for their offending. However, depression is a more common precursor to child molesting than anger. One source of depression may be perceived or actual social incompetence in peer relationships. Sexual contact with children may represent a maladaptive method of coping with this depression.

Excuses to justify sexually aggressive behavior may be the motivation for some forms of sex offending. Such excuses deny or minimize the impact of sexual aggression and are known as cognitive distortions. Cognitive distortions are common in acquaintance rape situations and in incest. An acquaintance rapist may contend that rape cannot occur in the context of a relationship or that the existence of a relationship justifies any type of sexual contact that the rapist desires. Common cognitive distortions among incest offenders are that sexual contact with their child is a form of affection, or sexual education, or that it merely amounts to horseplay. Thus, the motivation for a person employing cognitive distortions is that the sexual contact is 'normal' and is not aggressive.

It is likely that these different types of motivation for sex offending may interact for many sex offenders. Sexual arousal to coercive sexual behavior, emotional problems, and cognitive distortions may coexist for

some sex offenders, and a singular explanation of the basis of the problem may be inadequate. Nevertheless, complex explanations of sex offending are less likely to result in treatment interventions than are explanations that identify the major motivational issues.

5. *Treatment Interventions for Sex Offenders*

The most common forms of treatment for sex offenders have been behavioral, cognitive-behavioral, and psychohormonal interventions. Behavioral methods have typically involved interventions to reduce sexual arousal to inappropriate stimuli (e.g., children, rape) (see *Behavior Therapy: Psychiatric Aspects*). Aversive conditioning, which pairs sexual arousal to the inappropriate stimulus with an aversive stimulus (e.g., foul odor, thoughts about punishment for sex offending) is perhaps the most widely used behavioral treatment with sex offenders. Cognitive-behavioral methods focus on the influence of cognitive factors, including individual beliefs, standards, and values, on sex-offending behavior (see *Cognitive Therapy*). Common cognitive-behavioral treatments often involve cognitive restructuring, empathy enhancement, social skills training, and self-control techniques. Relapse prevention, which has been adapted from the treatment of addictive behaviors, has gained relatively wide acceptance in the treatment of sex offenders. This cognitive-behavior method involves self-control via anticipating and coping with situations following treatment that create high risk for relapse (e.g., social contact with potential victims) (see *Relapse Prevention Training*). Psychohormonal treatments involve the use of antiandrogen drugs to reduce the production of testosterone and other androgens. Such androgen reduction suppresses sexual arousal. The antiandrogen that has been most commonly used is medroxyprogesterone (Depo Provera).

Evidence across recent studies of rapists, child molesters, and exhibitionists suggests that cognitive-behavioral and psychohormonal interventions may be more effective than no treatment or behavioral treatments. Recidivism rates among sex offenders, as measured by arrests for sex offenses, are 25–32 percent. Sex offender recidivism rates in studies of behavioral treatments have been approximately 40 percent. Both cognitive-behavioral and psychohormonal treatments have yielded recidivism rates of 13 percent. Why is there such a high rate of recidivism in studies of behavioral treatments? It could be contended that behavioral treatments are too narrowly focused on sexual arousal and ignore other motivational issues (e.g., emotional, cognitive). However, psychohormonal treatments also primarily focus on sexual arousal reduction and result in relatively low recidivism rates. Thus, it is possible that any positive effects of behavioral treatments may 'wear off' over time. It is also possible that the sex offenders in the behavioral treatment studies were at higher risk for recidivism, although the recidivism rates for all forms of treatment are based on both inpatient and outpatient samples. Thus, there is support for cognitive-behavioral and psychohormonal treatments being the most effective treatments with sex offenders. Nevertheless, the evidence of this treatment effectiveness is somewhat limited.

A major limitation of psychohormonal treatments is compliance. These treatments usually involve intramuscular injections and are effective only as long as they are complied with. Sex offender refusal and dropout rates with psychohormonal treatments range from 50 to 66 percent. Moreover, a study directly comparing the relative effectiveness of cognitive-behavioral vs. antiandrogen treatments within the same population of sex offenders is needed. Such a study could clarify whether the effective suppression of sexual arousal achieved by antiandrogen treatments is sufficient to reduce recidivism or whether the more comprehensive aspects of cognitive-behavioral treatments offer necessary adjuncts. Also unknown is whether a combined cognitive behavioral plus antiandrogen approach would be superior to either approach alone.

An encouraging development is evidence of effectiveness of cognitive-behavioral methods in reducing recidivism among adolescent sex offenders. Interventions with adolescents may prevent the development of a history of sex offending that is associated with reoffending. However, there are extremely few outcome studies of adolescent sex offender treatment.

Most of the available treatment research on sex offenders has been conducted with European American populations. It is unknown whether these treatments are equally effective with other groups. For example, cognitive-behavioral methods are individually based. However, individually-based interventions may not be as effective in cultures in which there is a strong group orientation. Thus, individual change might be offset by group norms. For example, in some patriarchal groups, misogynous attitudes may be normative and sexual aggression permissible. Conversely, there may be protective cultural factors that could be mobilized to prevent sex offending. Thus, the context in which interventions are used needs to be examined in future research.

6. *Prevention*

There have been virtually no prevention studies that have examined perpetration of sex offending as an outcome measure. Yet the costs to society of sex offending, in terms of damage to and rehabilitation of victims and of incarceration and rehabilitation of offenders, implore us to seek ways to prevent the problem before it occurs. The recidivism rates of the most effective treatments are at 13 percent, which is

significantly better than other forms of treatment or no treatment. Yet, it could be contended that a 13 percent recidivism rate is unacceptably high. Perhaps the effective components of cognitive-behavioral interventions could be adapted for proactive use in prevention programs.

Most sexual abuse prevention programs have focused on potential victims for interventions. However, perpetrators, not victims, are responsible for sex offenses. A completely effective sex offense prevention program would eliminate the need for victim programs. Prevention programs for potential victims are critically important in terms of empowerment. However, there has been a disproportionate amount of attention in sexual abuse prevention to victims. Relatively simple modifications of existing victim prevention programs could potentially go a long way toward preventing perpetration of sex offenses. For example, most children's sexual abuse prevention programs present the concept of 'bad touch,' which usually is instigated by someone else. Missing from most of these programs, however, is the idea that not only should someone else not 'bad touch' you, but you also should not 'bad touch' someone else. Such an intervention could reach many potential perpetrators who would not otherwise receive this information. The impact of efforts to prevent sex offense perpetration is unknown. Thus, there is a great need for the development and evaluation of interventions to prevent sex offending.

Sex Preferences in Western Societies

Since 1950, a great number of authors working in the field of anthropology, demography, sociology, and psychology in North America and Europe have tried to determine parental sex preferences. The authors have used various approaches and samples, but in general results are relatively consistent. In this entry, the four methods most frequently used in this field will be reviewed: (a) first-child preference, (b) only-child preference, (c) sex preference for the next child, and (d) the parity-progression ratio technique.

1. First-child Preference

Many authors have tried to determine the sex preference of adult individuals with regard to their firstborn child with a question such as 'For your first child would you prefer a girl or a boy?' More than 30 studies

conducted in North America, for the most part with samples of college students or respondents recruited for fertility studies, have indicated that most women and men prefer a boy rather than a girl for their firstborn child. These findings give the strong impression that the preference for a boy as a firstborn has been universal among people in Western societies since 1950.

Since these results are based on a hypothetical situation that might not happen in the respondent's life, Steinbacher and Gilroy (1985) have argued that an assessment of sex preference when the women are pregnant would be more valid. A review of the literature in English and French found 16 empirical investigations in which it was possible to identify the maternal sex preference of *pregnant* women. In eight of these studies, the information concerning the expectant father's preference was also available, either from the fathers themselves (in three studies) or from their pregnant wives (in five studies).

These studies clearly indicate that first-time pregnant women more often prefer a *girl* than a boy, especially after 1981, when a preference for a girl is shown in six out of seven studies. The data concerning expectant fathers are different; in fact, in seven out of the eight studies, men preferred a boy rather than a girl for a first child.

Concerning the variables associated with the sex preference for a first child, two studies have presented data on pregnant women (Uddenberg et al. 1971, Steinbacher and Gilroy 1985). First, Uddenberg et al. (1971) found that women who grew up with only female siblings more often preferred a son first in a small sample of 81 first-time pregnant women in Sweden. (Some other studies showed the opposite: namely, that the more sisters a woman has, the greater her preference for a girl.) In addition, women who desire a girl are psychologically more autonomous than women who desire a boy. Interestingly, Uddenberg et al. (1971) also found no significant difference between the age or the social classes of the women who preferred a girl or a boy, or who expressed no specific preference. Second, the study by Steinbacher and Gilroy (1985), which dealt with 140 first-time pregnant women in the USA, reported that older women more often chose the no-preference category, and that those who agreed strongly with the women's movement preferred a girl rather than a boy. Otherwise, they did not find any significant relationship in variables such as race, income, marital status, or religion.

Interestingly, in this type of literature, the no-preference percentage has varied from 25 percent to 59 percent since 1981. An important point is to determine whether in fact many of the women who claim to have no preference use this answer to hide a preference, as has been suggested by Pharis and Manosevitz (1980). Marleau et al. (1996) consequently checked the validity of this traditional sex preference question by comparing the answers to that question with the answers to a 'feminine/masculine' scale which assessed how pregnant women imagined the sex of their future baby. It was shown that women having expressed no sex preference on a direct question had in fact no explicit image of their baby as male or female on the 'feminine/masculine' scale. This experiment seems to confirm the validity of the classical direct question.

2. *Only-child Preference*

In reviewing the literature relative to only-child preference, Marleau and Maheu (1998) identified many studies in which it was possible to identify women's and/or men's sex preference(s). Two subgroups of studies are found. The first one consists of 11 studies in which the subjects were forced to select the sex of a child on the basis of the hypothetical situation that they would have only one child in their whole lives. In the second subgroup, five studies were designed to elicit the number of children the subjects desired in their lives. Some subjects declared that they wanted only one child, and it was possible from these answers to determine the sex of this child for further analysis. The results of these two subgroups of studies were collapsed together for the final analysis. It should be noted that all of these studies were made in the USA between 1951 and 1991, and that in the majority of studies the samples consisted of college or university students.

The mains results indicate that women, in general, prefer a boy to a girl for an only child. However, in three of the five most recently published studies, women more often prefer a *girl* rather than a boy for an only child. Results for men show that in nearly all studies, at least 70 percent prefer a boy.

Some of these authors have tried to determine whether any variables are related to the sex preference. The most frequently found connection has been to education; in the two most recent decades, the data indicate that women who have reached university level more often prefer a girl than a boy for an only child. Men, whether they have an university education or not, prefer a boy more often. Pooler (1991) has identified two other variables: the variable 'wife retaining her own name' and the variable 'religion.' Female students who agree with the idea of retaining their own name after marriage more often prefer a girl. In addition, Jewish students prefer a girl whereas Catholics and Protestants prefer a boy.

Some authors have hypothesized that the women's preference for a female only child could be attributed to the fact that the perceived traditional female role disadvantage appears now to be significantly diminishing in Western societies. For example, Hammer and McFerran (1988) showed, significantly, that all subgroups of females (except unmarried noncollege females) would prefer to be reborn as a female.

3. The Preference for Sex of the Next Child

Another method consists in asking individuals their sex preference for a next child, based on the existing family composition. This type of question is found habitually in fertility surveys. In general, the data indicate that women with only one child more often prefer a child of the opposite sex. Moreover, a high percentage of women prefer a child of the opposite sex when they already have two or three children of the same sex. (Men rarely participate in these fertility surveys.)

For example, Marleau and Saucier (1993) showed that almost half of the women who already had a child hoped that their second child would be of the opposite sex in data from the Canadian Fertility Survey of 1984. Nearly 80 percent of women who already had two boys desired a girl for their next child, whereas nearly 50 percent of those with two girls preferred a boy.

Some authors have worked with other measures, especially with the mean number of desired children. Here the results are mixed. Some studies have found that women with a boy and a girl intend to have the same mean number of children as those who have two children of the same sex, but other studies have found that the mean number of children desired is higher for the latter group.

Other authors have worked with a measure such as the use of contraception by women who have already had children. A study done by Krishnan (1993) with the Canadian Fertility Survey of 1984 on women aged between 18 and 49 showed a son preference: the women who already had two sons were more likely to use contraception than those who had two girls.

4. Parity Progression Ratio

A method used by many authors is the parity-progression ratio. This technique consists in observing real behavior rather than being satisfied with verbal statements of attitude as in the methods mentioned above.

The parity progression ratio is the proportion of couples at a given parity who have at least one additional child. If certain sex compositions of existing children are associated with a lower than average progression ratio, the inference is made that the predominant sex in those compositions is preferred. More than 30 studies were identified in the literature. In general, the data indicate that couples with one child continue to bear children regardless of the sex of the first child. Parents with two children of the same sex are more likely to go on than those with one child of each sex.

For example, it was shown (Marleau and Saucier 1996) in a large sample from the Canadian General Social Survey of 1990 that 58 percent of the couples with two children of the same sex were more likely to have another child as compared with 53 percent of couples with two children of both sexes. On the other hand, those who stopped childbearing the more often were those with a boy first and a boy second. No such differences in behavior occurred in couples with three children.

This method is interesting because it can be computed from large databases collected for other purposes. But, it remains a weakness of this method that it gives good results only if sex preferences are relatively homogeneous in the population studied.

5. Conclusion

When we compare the findings reviewed above, we note that a global tendency is revealed by the first three, namely the increasing preference among women for a girl over a boy since 1980. More research will be needed to verify whether this trend will continue and to understand the reasons for this recent shift. A further trend is revealed by the first method, namely the increasing proportion of women who have chosen the no-preference option since 1980. This trend is visible for both pregnant and nonpregnant women.

Sex-role Development and Education

Today's debate on sex or gender is dominated by two antagonistic paradigms: sociobiology and constructivism. On evolutionary terms man's characteristics are determined by natural selection operating at the level of genes. Man has survived millions of years of competitive struggle for existence. This by definition implies egotism as a core feature of his genes, i.e., a readiness to maximize own reproductive chances at the cost of others. Egotistic genes may produce 'altruistic' behavior in case the net reproductive success of own genes (embodied in close relatives) can be increased (kinship altruism) or future repayments in emergencies can be secured (reciprocal altruism). Gene egotism has implications for sex differences. Across all species females' investment in reproduction is greater: they produce fewer and larger, i.e., more costly gametes; among mammals they invest time in carrying and nursing the young and among humans in taking care of them during an extended phase of dependency. Both sexes—being but vehicles of egotistic genes—strive to maximize reproductive success. Different strategies, however, will be efficient. In view of their high pre-investment, taking care of the young pays for females and given that females will take care, it pays better for males to spread their genes as widely as possible. For females sexual reserve is the better strategy—it allows them to test a male's fidelity and increase his investments; and it pays to select high status males, since their greater resources increase chances of survival for the few young a female will be able to bear. In contrast, males profit from quick seductions and from selecting females according to beauty and youthfulness—criteria that indicate high reproductive capacity. Further assumptions are needed: given that genes happen to reside half of the time of their existence in male, the other half in female bodies, they have to be assumed to operate differently in different environments. Also, the adaptive value of present characteristics can be justified only by reference to life conditions of our ancestors—of which we know little. Constructivism draws a contrary picture. Sex differences—so its core claim—are but social constructions. In fact, the classificatory system itself is a modern Western design stipulating the following features (see Tyrell 1986). (a) Reference to physical aspects, i.e., the presence/absence of a penis (some cultures focus more on social activities like childcare or warfare). (b) Binary, i.e., a strictly exclusive categorization (some cultures allow for or even ascribe a positive status to hermaphrodites). (c) Inclusive, i.e., all individuals are classified even those with unclear genetic make-up (using an operation to improve outward appearance if necessary). (d) Irreversible (except via operation) (some cultures allow for social sex role changes). (e) Ascriptive from birth on (some cultures define children as neutrals and ascribe sex role membership only in initiation rituals). The very assumption of large sex differences is a modern idea that from the constructivist perspective is mistaken: it is an essentialist reification of what in fact is but a cooperative interactive achievement. Humans—so the basic tenet—don't 'have' a sex and they 'are' not males or females, rather they 'act' and 'see' each other as such. Studies on transsexuality analyze the ways in which individuals perform and recognize gender. The two paradigms are based on opposite assumptions. In sociobiology man is but a vehicle for powerful genes, in constructivism he is an omnipotent creator. In sociobiology he is a lone wolf entering social relations only for reproductive concerns, in constructivism he is a social being whose very (even sexual) identity is dependent on interactive co-construction. Nevertheless, both paradigms concur in their ahistorical approach. In sociobiology genes that survived under the living conditions of our ancestors determine human dispositions forever—across all periods and societies. In constructivism man is created ever anew in each interaction situation. Both approaches simply ignore the power of history—consolidated in collective traditions and reproduced in biographical learning processes. These will come to the fore in the following analysis of present sex role understanding. Three aspects will be discussed: its empirical description, historical emergence, and ontogenetic development.

1. *Sex Differences—a Descriptive Perspective*

Sex differences can be analyzed on various levels: on the level of the individual, the culture, the social structure.

1.1 *Psychological Level*

Recent meta-analyses of US data show that with greater educational equality sex differences in cognitive performance have largely disappeared over the past few decades except for a slight overrepresentation of males at the very top of mathematical and the very bottom of verbal abilities and an average higher male performance in spatial ability tasks. Male spatial superiority is even greater among

Mexicans but has not been found among Eskimos. These latter findings suggest a connection between the development of spatial understanding and cultural differences in degree of supervision and control exerted upon young girls.

It has been claimed that morality is gendered: women are maintained to be more flexible and care-oriented, men to be more rigidly oriented to abstract principles and more autonomous. These differences are seen to arise from differences in the structure of self shaped by the early experience of female mothering. Girls can maintain the primary identification with the first caretaker (relational self), while boys—in order to become different—have to distance themselves (autonomous self) (Gilligan and Wiggins 1988).

Neither flexibility nor care, however, are specific to women. Flexibility is a correlate of a modern moral understanding. Kant had still ascribed exceptionless validity to negative duties given that God—not man—was held responsible for any harm resulting from compliance. On innerwordly terms, however, impartially minimizing harm is given priority over strict obedience to rules. If exceptions are at all deemed justifiable they will more likely be conceded by those who are aware of possible costs incurred by anyone affected. Individuals who are personally involved will be more knowledgeable of such costs. This may explain why women—in agreement with Gilligan—were found to judge more flexibly with respect to abortion, yet at the same time more rigidly with respect to the issue of draft resistance than men (Döbert and Nunner-Winkler 1985). Besides, those in power can insist more rigidly on their convictions, thus flexibility might be the virtue of subordinates. Care is not part of a relational self-structure produced in early childhood—rather it is part of the female role obligation. Indeed, preschool girls showed no more empathic concerns than boys (Nunner-Winkler 1994), but a majority of (especially older) German subjects more often justified strictly condemning working mothers by referring to their dereliction of duty and to their egotistic strivings for self-fulfillment than to the harm their children might suffer.

1.2 Cultural Level

Two aspects—although empirically concurring—need to be distinguished: gender stereotypes and gender-role obligations.

Gender stereotypes are collectively shared assumptions about the different 'nature' of men and women. Across cultures men are assumed to be aggressive, independent, and assertive, women to be emotional and sensitive, emphatic, and compliant. Contradictory evidence does not detract from such persuasions—immunity to empirical refutation is the very core of stereotypes and there are mechanisms to uphold them. Expectations guide the way observations are perceived, encoded, and interpreted, e.g., noncompliance is perceived as a sign of strength if shown by a man, of dogmatism if shown by a woman. Behavior that conforms to expectations is encoded on abstract terms, discrepant behavior with concrete situational details. This eases making use of the 'except clause' when interpreting deviant cases (e.g., for a woman she is extraordinarily assertive). Thus, suitably framed and interpreted even conflicting observations can stabilize stereotypes.

With gender-role obligations, women are assigned to the private sphere, men to the public realm. Thus, taking care of children and household chores is seen to be primarily women's task, breadwinning men's. These roles are defined by contrasting features. Family roles are ascribed, diffuse, particularistic, affective and collectivity-oriented; occupational roles are achieved, specific, universalistic, affectively neutral, and self-oriented (Parsons 1964). Identifying and living in agreement with one's gender role will influence ways of reacting, feeling, and judging. Thus, gender differences might be understood as a correlate not primarily of genetic dispositions or of a self-structure shaped in infancy, but rather of the culturally institutionalized division of labor between the sexes.

1.3 Sociostructural Level

Gender stereotypes and role obligations influence career choice and commitment to the occupational sphere. In consequence, there is a high gender segregation of the workforce. The proportion of women is over 90 percent in some fields (e.g., secretary, receptionist, kindergarten-teacher) and less than 5 percent in others (e.g., mechanic, airplane pilot). Jobs that are considered women's work tend to offer fewer opportunities for advancement, less prestige, and lower pay than jobs occupied primarily by men. Worldwide the gender gap in average wage is 30–40 percent and it shows little sign of closing. Top positions in economy, politics, and sciences are almost exclusively filled by men, and part-time working is almost exclusively a female phenomenon. Both men and women tend to hold negative attitudes towards females in authority. Women entering male occupations are critically scrutinized, males entering female occupations (e.g., nursing) in contrast easily win acceptance and promotion.

2. The Historical Emergence of Gender Differences

There are two (partly independent) dimensions implied in the debate on gender roles: the hierarchical one of equality vs. inequality of rights and the horizontal one of difference vs. sameness in personality

make-up. We begin with equality. According to medieval understanding individuals find themselves in different social positions by the will of God and it is God who commanded that women obey men. Enlightenment declared all men to be equal—irrespective of gender (or race). Thus, a new justification was needed if the subordination of women (or black slaves) was to be maintained. This instigated a search for 'natural' differences between women and men (between blacks and whites) that soon succeeded in specifying differences in brain size or the shape and position of sexual organs (in IQ)—much to the detriment of women (or blacks). Legal discrimination has largely discontinued. Women (and blacks) are granted full rights to vote or to participate in the educational system.

The assumption of gender differences, however, is still prevalent. It arose in consequence of the industrialization process. In agricultural economies women had their own sphere of control (house, garden, cattle, commercialization of surplus products) and their contribution was essential for subsistence: 'These women in no way resemble the 19th century image of women as chaste, coy, demure … Peers describe them as wild, daring, rebellious, unruly' (Bock and Duden 1977). Industrialization led to a separation of productive and reproductive work, i.e., to the contrast between familial and occupational roles described above. With rapid urbanization and increasing anonymity around the turn of the twentieth century, antimodernist discontent grew. Increasingly, female 'complementary virtues,' e.g., empathy, emotionality, sensitivity came to be seen as bulwark against the cold rationality of the structure of capitalist economy and bureaucratic administration. This sentiment was (and partly still is) shared even by feminists deeply committed to secure legal, political, and social equality for women.

3. *Ontogenetic Development*

Each generation of newborns is an invasion of barbarians—nonetheless, within a decade or two most turn into useful members of their specific society. How is this effected? Education is too narrow a term in that it refers primarily to methods purposefully applied in order to produce desired results. Children, however, are influenced not primarily by planned educational actions, but rather by the entirety of their life conditions. They are not merely passive objects to social instruction, rather—in mostly implicit learning processes—they actively reconstruct the basic rule systems underlying their experiences. This way they acquire knowledge systems, value orientations, action dispositions. In this (self-)socialization process different learning mechanisms are at work: classical and instrumental conditioning produce response tendencies; through bestowal and withdrawal of love a conformity disposition is shaped; through parental authority and firmness the internalization of values is furthered; children imitate behavior of models they deem interesting and they implicitly recognize regularities and rule structures. With increasing cognitive and ego development reflexive self-distancing from and consciously taking a stance towards one's previous learning history becomes possible.

How are sex roles acquired? Increasingly parents advocate identical educational goals for boys and girls. Nevertheless, unwittingly, especially fathers tend to treat them differently—handling male infants more roughly and disapproving of sissy behavior (Golombok and Fivush 1994). Also, from early on, children prefer same-sex playmates (Maccoby 1990). Such early experiences may leave some traces. More direct sex role learning, however, seems to depend on sociocognitive prerequisites. A change has been documented to occur in children's understanding of concepts. They shift from focusing on externally observable surface features to basic definitional criteria (in the case of nominal terms) or to the assumption of stable and essential inner characteristics that all members of a given category share (in the case of natural kind terms). Sex is treated like a natural kind term, i.e., sex is understood to remain constant despite outward changes, to denote some 'essential' even if unobservable commoness, and to allow for generalizing new information across all members of the same category (Gelman et al. 1986). This constitutes a universal formal frame of reference (that makes stereotypical thinking so irresistible). It needs to be filled with content. Children learn what is typical and appropriate for men and women in their culture by beginning to selectively observe and imitate exemplary same-sex models (Slaby and Frey 1975). Largely, this learning process is intrinsically motivated (Kohlberg 1966), i.e., by the desire to be a 'real boy/girl' and become a 'real man/woman.' It proceeds by (mostly implicitly) reconstructing those gendered behavioral, expressive, and feeling rules that are institutionalized in the given culture. In our culture there are many cues from which children will read what constitutes sex-appropriate demeanor. The sexual division of labor is seen already in the family: women are more likely to sacrifice their career for the family (and men their family-life for their career) and even full-time-employed mothers spend considerably more time on childcare and housework than fathers. In the school, teachers tend to give more attention to boys and praise them for the quality of their work (while praising girls for neatness). Curricula may segregate the sexes, offering home economics to girls, contact sport or mechanic training to boys. The social structure of the school impresses the idea of male authority over women with most principals in elementary school being male although most teachers are female. In fact, it has been found that first-graders attending schools

with a female principal display less stereotypical views on gender roles than children in schools with a male principal. These early lessons on sex differences are reinforced in public: in politics and business top positions are mostly filled by men and books, films, TV, and advertisements depict men as dominant, powerful, and strong, women as beautiful, charming, and yielding. Thus, consciously treating boys and girls alike in family and kindergarten will be of little avail in counterbalancing the impressive overall picture of structural sexual asymmetry and alleged personality differences between the sexes in personality characteristics and behavioral dispositions.

4. *The Future of Sex Roles*

With modernization, ascriptive categories lose importance. Social systems increasingly come to be differentiated in subsystems each fulfilling a specific function and operating according to its own code (Luhmann 1998). Gender is the code of the family; it cannot substitute for the codes of other subsystems, e.g., in science it is the truth of a statement, on the market it is the purchasing power, in court it is the lawfulness of the sentence that counts; the gender of the author, the customer, the judge are (or should be) irrelevant. True, there still exists inequality between the genders. Nevertheless, all over the world it has been drastically reduced over the past few decades. In all countries women have profited more by the educational expansion of the 1960s and 1970s; while at the beginning of the twentieth century in less than 1 percent of 133 countries analyzed voting rights were conceded to women, today all of them with male franchise (over 90 percent) have extended suffrage to women (Ramirez et al. 1997). Many countries have inserted a clause concerning equal social participation rights for women in their constitution and set up special institutions; also some have introduced affirmative actions. Increasingly, women come into prestigious positions which will improve chances for succeeding women who now meet with role models and old girls' networks. Nevertheless, merely increasing the proportion of women on top will not suffice. It may only increase the tendency of a split up of female biographies with women opting for either family or career (while men can have both). A real change requires a more equal distribution of productive and reproductive work between the genders. In this respect Sweden has been quite successful by institutionalizing an egalitarian welfare regime (e.g., providing publicly financed daycare centers across the whole country; granting a generous leave of absence to both parents at child birth, and offering a specific paternity leave to fathers which 83 percent make use of). In Sweden we find a high birthrate (1.8) along with a high rate of female employment (75.5 percent). This stands in contrast to the situation in Germany where both rates are low (1.3; 59.7 percent). The German welfare system is described as paternalistic (e.g., women are offered extended publicly financed maternity leaves yet there are hardly any daycare centers for infants or all-day schools and the disapproval of working mothers is especially high (Garhammer 1997). Such differences between countries may indicate that social policy does have an important part to play in reducing or reproducing gender inequalities.

Sex Segregation at Work

All societies organize work through a sexual division of labor in which women and men typically perform different tasks. These tasks may also depend as well on people's age, race, ethnicity, nativity, and so forth. Although this sexual division of labor divides market and non market work by sex, sex segregation usually refers to the sexual division of labor among paid workers. Thus, sex segregation is the tendency for the sexes to do different kinds of paid work in different settings.

Customarily, 'segregation' denotes physical separation, as in school segregation by race. However, the term 'sex segregation' refers to physical, functional, or nominal differentiation in the work that women and men do. 'Men's work' does not simply differ from 'women's work,' however; predominantly male jobs tend to be better and more highly valued. This occurs both in vertical segregation which assigns men higher-level jobs than women in the same occupation, and in horizontal segregation in which the sexes pursue different occupations.

1. *Sex Segregation and Sex Inequality*

Segregation—whatever its form—is a key engine of inequality. The domains reserved for members of dominant and subordinate groups are not just different, they are unequal, with the more desirable domains reserved for members of dominant groups. Because economic, social, and psychological rewards are distributed through people's jobs, segregation both facilitates and legitimates unequal treatment. Sex segregation reinforces sex stereotypes, thereby justifying the sexual division of labor it entails, and it reduces equal-status cross-sex contacts that could precipitate challenges to differentiation. In sum, workplace segregation benefits men and harms women (Cotter et al. 1997).

1.1 *Consequences of Sex Segregation*

Job, establishment, and occupational segregation account for most of the differences in the rewards that men and women garner from employment. The most important of these differences is earnings. Estimates of the importance of occupational segregation for the pay gap between the sexes vary widely, depending on the analytic approach. An estimated one-third of the earnings gap results from occupational segregation in the USA and abroad (Anker 1998). Establishment-level data for the USA, Norway, and Sweden by Petersen and his colleagues attribute about three-quarters of the gap to occupational segregation (Petersen and Morgan 1995). This approach may still underestimate the effect of occupational segregation on the pay gap: the amount of sex segregation in metropolitan labor markets affects how much segregation affects women's and men's earnings with all women losing pay and all men gaining in highly segregated markets, and no pay gap if occupational segregation were very low (Cotter et al. 1997, p. 725).

Men dominate the more lucrative jobs partly because employers reserve such jobs for men and partly because female work is devalued (England 1992). The under-valuation of female activities not only shrinks women's pay, it also reduces their economic independence, familial power, and sense of entitlement.

Sex segregation also creates disparities in the sexes' authority, mobility opportunities, working conditions, and chance to acquire skills. Segregation disproportionately relegates women to dead-end jobs or jobs on short career ladder, thus reducing their aspirations and opportunity for mobility ladders (Baron et al. 1986). This vertical segregation creates a 'glass ceiling' that concentrates women in the lower level positions and reduces their authority.

2. *Theories of Segregation*

The most common theories of sex segregation emphasize the preferences of workers and employers. Hypothetically, gender-role socialization or a sexual division of domestic labor that encourages men to pick jobs that maximize earnings and women to select jobs that facilitate child-rearing lead to sex-differentiated preferences (England 1992). Men's vested interests also hypothetically prompt them to exclude women from 'men's jobs.' The universality of the assumed sex-specific preferences limits the value of preference explanations: because preferences theoretically vary between, not within the sexes, the sexes should be completely segregated. Empirical evidence casts doubt on preference theories: youthful occupational preferences only loosely related to the sex composition of adults' occupation (see Jacobs 1989, 1999). Moreover, the sexes similarly value high pay, autonomy, prestige, and advancement opportunities, which should minimize between-sex differences.

Explanations focusing on employers' preferences stemming from sex biases and attempts to minimize employment costs through statistical discrimination are limited by their emphasis on hard-to-measure motives. Although it stands to reason that employers influence job-level segregation because they assign workers to jobs, it is difficult to learn why. However, by examining the effects of training and turnover costs and skill on women's exclusion and sex segregation, Bielby and Baron (1986) showed that employers discriminated statistically against women by imputing to individuals stereotypical characters of their sex, but contrary to neoclassical economic theory, this practice was neither efficient nor rational.

In sum, standard theoretical approaches to segregation predict universally high segregation rather than explaining variation in its level. Although these theories have stimulated considerable research, it is difficult to directly test them, so the importance of women's and employers' 'choices' remains a matter of debate. More fruitful explanations (summarized later) try to explain variation in segregation across aggregates or over time.

3. Measuring Segregation

Segregation is a property of aggregates, not individuals. Its measurement depends on how it is conceptualized. The most common conceptualization—the sexes' different representation across work categories—is measured by the index of dissimilarity, D, whose formula is $\Sigma\, f_i - m_i/2$ (f_i and m_i represent the percentages of female and male workers in each work entity). D is the percentage of either female or male workers who would have to change to a work category in which they are underrepresented for the sexes' distributions across categories to be identical. The size of D depends both on the extent of segregation and the relative sizes of the work entities (e.g., occupation) so it is unsuitable for comparing segregation across populations with work entities of different relative sizes. A size-standardized variant of D which holds entity size constant permits comparing levels of segregation across populations.

Segregation is also conceptualized as the concentration of the sexes in work entities dominated by one sex. This conception is relevant to the thesis that women are disproportionately crowded into relatively few occupations. A simple measure of concentration is the proportion of each sex in the n occupations that employ the most men or women. (For an index of concentration, see Jacobs (1999) who warns that concentration measures assume that female and male occupations are aggregated to the same degree.)

A third conception of segregation is each sex's probability of having a coworker in their job or occupation of the same or the other sex, designated as P* (Jacobs 1999). The value of P* depends on both the extent of segregation and the sex composition of the population.

Occupations can be described in terms of their sex composition, and are sometimes characterized as 'integrated' or 'segregated' or 'female- or male dominated' based on whether one sex is disproportionally represented. For example, in the USA, billing clerk is a segregated occupation because 89 percent of its incumbents are female, whereas women are just 47 percent of the labor force. The individual-level experience of segregation is the sex composition of her or his job or occupation, so a billing clerk holds a predominantly female occupation.

In 1992, Charles proposed using log linear methods to study sex segregation. Because log linear methods adjust for both the varying sizes of work entities and the sexes' respective shares of the labor force they are useful for studying why the extent of segregation varies cross-nationally and over time. They also allow researchers to estimate the impact of independent variables on a sex's representation in specific occupations or occupational categories, net of the occupational structure (Charles 1992, p. 488, 1998).

All measures of segregation are sensitive to the level of aggregation of the work units of interest. If segregation exists within units—which it usually does—the more aggregated the units, the less segregation will be observed. Although fully disaggregated data, such as establishment-level data, are preferable, they are hard to come by. Cross-national data are particularly likely to be aggregated because researchers need to make work units comparable across countries and because the data some countries collect are broadly aggregated.

4. The Extent of Segregation

Most research on segregation focuses on the sexes' concentration in different occupations. (An occupation comprises jobs that involve similar activities within and across establishments.) In a 'typical' country in the early 1990s about 55 percent of workers held either 'male' or 'female' jobs (Anker 1998, p. 5). Although countries vary considerably in the extent to which the sexes are segregated occupationally, in the 1990s most developed nations had segregation indices between 50 and 70 (Anker 1998). In 1997, the segregation index for detailed occupations in the USA was 53.9 (Jacobs 1999).

The sexes are most segregated in the Middle East and Africa. In the early 1990s, segregation indices across detailed occupations were at least 70 for Tunisia, Kuwait, and Jordan, largely because of Muslim proscriptions against contact between the sexes. Most of the EU societies and 'transition economies' (former Soviet satellites) had indices in the mid-50s. Segregation was lowest in Asian/Pacific nations, with indices ranging from 36 (China) to 50 (Japan). China's low segregation level results from its large, sex-integrated agricultural sector.

Among the Western developed countries, Italian and US workers were least segregated, and Scandinavians most segregated. In these countries, occupational segregation is positively related to women's labor force participation; indeed the same factors facilitate women's labor force participation and encourage sex segregation—paid parental leave and part-time work which lead to statistical discrimination against women and the shift of customarily female domestic tasks into the market economy (Charles 1992). Also contributing to cross-national differences in segregation is the relative sizes of manufacturing and service sectors, since men tend to dominate the

former and women the latter (Charles 1998). Variation in national commitment to gender ideology also explains cross-national differences in segregation (Charles 1992).

4.1 Segregation Across Jobs

Much higher levels of sex segregation exist in establishment-level studies of job segregation (a job is a position in an establishment whose incumbents perform particular tasks) because people in the same occupation work in different establishments or different jobs (Bielby and Baron 1984; Tomaskovic-Devey 1993). For example, male lawyers are more likely than female lawyers to work for law firms, and within law firms men dominate litigation. Organizations' characteristics and personnel practices affect how segregated they are. Small and large establishments are the most segregated. Small establishments are segregated because they employ workers of only one sex; whereas large bureaucracies have segregative personnel practices, such as sex segregated job ladders (Bielby and Baron 1984).

5. Trends in Segregation

In the last quarter of the twentieth century segregation fell in most of the world, although women continued to dominate clerical and service occupations, and most customarily male production jobs remained inaccessible to women (Charles 1998). Segregation increased during the 1970s and 1980s in Asian/Pacific countries; remained constant in Southern and Central European countries; and declined in the USA, Western Europe, the Middle East and North Africa, and other developing countries (Anker 1998, p. 328). In most countries declines reflected increased occupational integration as well as shifts in the occupational structure in which heavily segregated occupations shrank.

In the USA, increased integration resulted primarily from women's movement into customarily male occupations. The higher pay in customarily male jobs draw women. Large numbers of men enter customarily female occupations only when they become much more attractive, and such changes are rare. The size-standardized index was stable between 1990 and 1997, indicating that after 1990 real occupational integration halted, although fewer persons worked in heavily segregated occupations (Jacobs 1999).

5.1 Explaining the Decline in Segregation

According to the theoretical framework summarized above, the more similar the sexes become in their preferences and skills, the less segregated they will be. According to cross-national research, the narrowing of the education gap between the sexes has contributed to integration. In the USA, for example, as fewer women majored in education and more majored in business, educational segregation declined and occupations integrated. The shrinking experience gap between the sexes may also reduce segregation if it relieves employers' misgivings over hiring women for jobs that involve firm-specific skills.

However, employers' hiring and job-assignment practices are the proximate determinants of the level of segregation. Many establishments employ women in customarily male jobs only when there are not enough qualified men. Thus, organizational and occupational growth both foster integration if they cause a shortfall of male labor. Shortages have also brought about integration when occupations deteriorated in their pay, autonomy, or working conditions (e.g., pharmacist, typesetter; Reskin and Roos 1990) and thus became less attractive to men.

Employers who face economic penalties for segregating and whose job assignments are monitored are more likely than are others to integrate jobs (Baron et al. 1991). Thus, anti-discrimination and affirmative action regulations have fostered integration by making it illegal for employers to exclude workers from jobs on the basis of their sex. These rules have made a difference largely through 'class-action' lawsuits against employers. Anti-discrimination laws are ineffective in reducing segregation when regulations are not enforced and when class-action lawsuits are not permitted.

Finally, according to development theory, modernization replaces ascription with achievement in filling social positions. However, modernization is associated with the growth of economic sectors that most societies label as 'women's work.' Thus, the net effect of modernization, as measured by GNP, has been segregative because it expands female dominated clerical and sales occupations (Charles 1992).

5.2 Nominal Integration

What appears to be genuine integration may be a stage in a process of re-segregation in which women are replacing men as the predominant sex. In the USA, for example, insurance adjusting and typesetting re-segregated over a 20-year period when these occupations changed from male to female dominated. For individual women, the corresponding process is the 'revolving door' through which women in male occupations pass back into customarily female occupations (Jacobs 1989).

5.3 Explaining Stability

Because the amount of sex segregation has changed so little, scholars have devoted as much attention to explaining stability as to explaining change. Unchanging levels of segregation may result from stability in

the causal variables or from processes whose opposing effects cancel out each other.

Gender ideology strongly favors stability. Many occupations are sex-labeled, representing a cultural consensus that they are appropriate for one sex but not the other (e.g., childcare worker, automobile mechanic). Although these labels are not deterministic (indeed they sometimes vary across societies), they predispose employers to prefer sex-typical workers and workers to prefer sex-typical jobs. Although state policies have altered gender ideology, it is usually a conservative force.

Work organizations also resist change in customary business practices. Organizations' structures and practices reflect the cultural environment present when they were founded, and inertia preserves these structures and practices. Such practices include sex-segregated promotion ladders, credentials that are required for jobs, and the use of workers' informal networks to fill jobs. For example, recruitment through networks perpetuates the sex composition of jobs because people's acquaintances tend to be of their same sex. Statistical discrimination or stereotype-based job assignments perpetuate the sex composition of jobs because they prevent employers from discovering that their stereotypes are unfounded. Thus, barring external pressures to alter job assignments, job segregation is unlikely to change.

Of course, stable levels of segregation may be misleading if they are the result of counteracting forces that have opposing effects on the level of sex segregation. For example, in the 1980s Japan's occupations became slightly more integrated, but this was offset by the increased number of workers employed in occupations that were either male or female dominated. The net effect of the growth of female dominated clerical and service sectors in most economically advanced countries will cancel out some shift toward greater integration within occupations.

Sex Therapy, Clinical Psychology of

Sex therapy is an approach to the treatment of sexual problems. Results of psychophysiological studies of sexual responses in sexually functional subjects, in the 1960s, allowed gynecologist William Masters and psychologist Virginia Johnson to develop a therapeutic format for the treatment of sexual inadequacy. Apart from organic causes, sexual problems may be attributed to interpersonal difficulties and to problems with emotional functioning. Masters and Johnson were convinced that 'adequate' stimulation would result in sexual response in an engaged partner. Adequate stimulation feels good, is rewarding, and facilitates focus of attention on those feelings. Orig-

inally, adequate stimulation in therapies was restricted to behaviors comprising the classical heterosexual foreplay, coitus, and orgasm sequence. This criterion for adequate stimulation has been abandoned because of the rich diversity in sexual practices that exist in the real world.

Masters and Johnson hypothesized that fear of failure, and as a consequence becoming a spectator of one's own feelings, is the most important cause for sexual inadequacy. They devised a very ingenious procedure to assist people in becoming engaged in feelings of sexual excitement. Three important steps were specified. In the first step people learn to accept that mutual touching feels good. In this step demands for sexual performance, and anxieties related to such demands, are precluded by an instruction not to touch genitals or secondary sex characteristics (e.g., breasts). When the first step leads to acceptance of positive bodily feelings, the second step demands including genitals and breasts in mutual touching and caressing. Masters and Johnson have suggested some variations to accommodate specific sexual problems (e.g., premature ejaculation, erectile problems). The second step has to result in the physiological signs of sexual excitement—vaginal lubrication in women and erection of the penis in men. In the classical sequence the first and second step prepared for the third step which consisted of coital positions, again with variations, and stimulation through coitus to orgasm. Although coitus may be relevant from a reproductive point of view, it is not always and certainly not the only way to experience the ultimate pleasures of sex.

1. *Desire, Excitement, and Orgasm*

Masters and Johnson, on the basis of their psychophysiological studies, proposed a model of sexual response consisting of three phases: an excitement phase, an orgasm phase, and a resolution phase. The excitement phase and orgasm phase may be recognized as the second and third step of the classic treatment format. When other therapists began to apply Masters and Johnson's format it became clear that many patients do not easily engage in interactions prescribed by the sex therapy format. Apparently, an initial motivational step was missing. People who hesitate or avoid intimate interactions may lack desire, which often means that they do not expect the interaction to be rewarding. In 1979 Helen Kaplan proposed adding a desire phase, preceding the three phases specified by Masters and Johnson. Since Kaplan's proposal it has become clear that the prevalence of lack of desire is considerable. With hindsight most people accept that lack of desire must be the most important sexual problem. It is a problem for the individual who does not arouse desire in his or her partner. In most instances, not feeling desire is in itself unproblematic, but lack of sexual desire may become a problem in the relationship.

Sex therapy was a fresh and new treatment. Sexual problems were openly discussed, there was no time-consuming delving into past conflicts, and there were suggestions for a direct reversal of symptoms of sexual failure. Masters and Johnson preferred working with couples because the interaction within the couple often contributes in important ways to the sexual difficulties. Other therapists have offered treatment to individuals and to groups of individuals or couples.

An alternative to Masters and Johnson's therapy format is the mimicking of normal sexual development through the use of masturbation. This has been an important step for many women, especially those who missed this aspect of discovery of their own sexuality. In this approach people learn to induce sexual excitement through masturbation to eventually apply this 'skill' in interaction with a partner.

Some approaches developed from behavior therapy and rational emotive therapy focused on performance anxiety and fear of failure. Others used interventions from couple and group therapy. It is fair to say that nowadays almost all approaches to sexual difficulties incorporate elements from the Masters and Johnson sex therapy format.

2. *Sexual Dysfunctions in Men*

2.1 *Diagnostic Procedures*

The aim of the initial clinical interview is to gather detailed information concerning current sexual functioning, onset of the sexual complaint, and the context in which the difficulty occurred. This information gathering may be aided by the use of a structured interview and paper-and-pencil measures regarding sexual history and functioning. An individual and conjoint partner interview, if possible, can provide additional relationship information and can corroborate data provided by the patient. The initial clinical interview should help the clinician in formulating the problem. It is important to seek the patient's agreement with the therapist's formulation of the problem. When such a formulation is agreed upon, the problem may guide further diagnostic procedures.

Many men with erectile dysfunction may be wary of psychological causes of their problem. Psychological causes seem to imply that the man himself is responsible for his problem. This may add to the threat to his male identity that he is already experiencing by not being able to function sexually. Considering the way a man may experience his problem, it can be expected that it will not be easy to explain to him the contribution of psychological factors. A clinician knowledgeable in biopsychosocial aspects of sexual functioning should be able to discuss the problem openly with the patient. Dysfunctional performance is meaningful performance in the sense that misinformation, emotional states, and obsessive concerns about performance provide information about the

patient's 'theory' of sexual functioning. When contrasting this information with what is known about variations in adequate sexual functioning, it is often clear that one cannot but predict that the patient must fail. For the clinician a problem arises when, even with adequate stimulation and adequate processing of stimulus information according to the clinician's judgment, no response results, either at a physiological or a psychological level.

At this point, a number of assessment methods aimed at identifying different components or mechanisms of sexual functioning may be considered. In principle, two main strategies may be followed: In the first, although a psychological factor interfering with response cannot be inferred from the report of the patient, one can still suspect some psychological factor at work. Possibly the patient is not aware of this factor, thus he cannot report on it. Eliminating this psychological influence may result in adequate response. The second strategy applies when even with adequate (psychological) stimulation and processing, responding is prevented by physiological dysfunction. Physiological assessment may then aid in arriving at a diagnostic conclusion. The biopsychosocial approach predicts that it is inadequate to choose one of these strategies exclusively. The fact that sexual functioning is always psychophysiological functioning means that there may always be an unforeseen psychological or biological factor.

2.2 Psychological Treatments of Sexual Dysfunctions in Men

2.2.1 Approaches to treatment. The most important transformation of the treatment of sexual dysfunctions occurred after the publication of Masters and Johnson's (1970) *Human Sexual Inadequacy*. First of all, they brought sex into the treatment of sexual problems. Before the publication of their seminal book, sexual problems were conceived as consequences of (nonsexual) psychological conflicts, immaturity, and relational conflicts. In most therapies for sexual problems sex was not a topic in the therapeutic transactions. There were always things 'underlying,' 'behind,' and 'besides' the sexual symptoms that deserved discussion. Masters and Johnson proposed to attempt directly to reverse the sexual dysfunction by a kind of graded practice and focus on sexual feelings. If sexual arousal depends directly on sexual stimulation, that very stimulation should be the topic of discussion. Here the second important transformation occurred: A sexual dysfunction was no longer something pertaining to an individual; rather, it was regarded as a dysfunction of the couple. It was assumed they did not communicate in a way that allowed sexual arousal to occur when they intend to 'produce' it. Masters and Johnson thus initially considered the couple as the 'problem' unit. Treatment goals were associated with the couple concept: The treatment goal was orgasm through coital stimulation. This connection between treatment format and goals was lost once Masters and Johnson's concept was used in common therapeutic practice. People came in for treatment as individuals. Male orgasm through coitus adequately fulfills reproductive goals, but it is not very satisfactory for many women because they do not easily achieve orgasm through coitus. What has remained over the years, since 1970, is a direct focus on dysfunctional sex and a focus on sexual sensations and feelings as a vehicle for reversal of the dysfunction.

What Masters and Johnson tried to achieve in their treatment model is a shift in their patients' focus of attention. Let us look at one of Masters and Johnson's interventions to elucidate this point. People with sexual dysfunctions tend to wait and look for the occurrence of feelings, instead of feeling what occurs—hence, the spectator role. Their attention is directed towards something that is not there or does not exist, which is frustrating. In simplest form, Masters and Johnson propose to redirect attention by using the following steps: first of all they manipulate expectations by instructing the patient about what is allowed to occur and what is not. It is explained to the patient that nonsexual feelings are to be accepted as a way to accept sexual feelings later on, and therefore sexual areas are excluded in the initial homework tasks. From a psychological point of view this manipulation is ingenious; it directs attention away from sex—when you feel a caress on your arm it may be pleasant but (now) it is not sexual—however, at the same time, it defines sexual feelings as feelings in 'sexual areas.'

To attain a direct approach of sexual function numerous variants of couple, communication, and group therapy have been used. Rational emotive therapy has been used to change expectation and emotions (see *Behavior Psychotherapy: Rational and Emotive*). To remedy biographical memories connected with sexual dysfunction, psychoanalytic approaches have been used as well as cognitive behavior therapy approaches (see *Behavior Therapy: Psychological Perspectives*) . There are specific interventions for some dysfunctions; for example, premature ejaculation has been treated with attempts at heightening the threshold for ejaculatory release (stop–start or squeeze techniques).

Recently, as a spin-off of research into cardiac vascular smooth muscle pharmacology, drugs have become available which act by relaxing smooth muscles in the spongiose and cavernous structures in the penis. This relaxation is necessary to allow blood flow into the penis, thus causing an erection. Some of these drugs (e.g., sildenafil—Viagra®) support the natural neurophysiological reaction to sexual stimuli. Others act locally in the penis without sexual stimu-

lation. To slow down speed of ejaculation in men with premature ejaculation SSRIs (serotonin selective reuptake inhibitors) seem to be helpful.

Smooth muscle relaxants like sildenafil are helpful in older men when less naturally occuring transmitters are available. Men with vascular or neurodegenerative diseases (e.g., diabetes, multiple sclerosis) may also benefit from the use of smooth muscle relaxants. Although these drugs are very effective, they do not help every man with erectile problems.

Pharmacological treatment for erectile disorder may be an important step in restoring sexual function. Most couples will need information and advice to understand what they may expect from this treatment. For many it will not bring the final resolution of their relationship problems. In addition to drug treatment they will need some form of sex therapy or psychotherapy.

2.2.2 Validated treatments for male sexual dysfunctions. It has been difficult to get an overview of treatments for sexual dysfunctions because any proposal about how to approach dysfunctions was valid. This has changed through the introduction of criteria for validated or evidence-based practice by the American Psychological Association (APA). From the timely review by O'Donohue et al. (1999) of psychotherapies for male sexual dysfunctions it appears that the state-of-the-art is far from satisfactory. Following the criteria of APA's Task Force, they found no controlled outcome studies for male orgasmic disorder, sexual aversion disorder, hypoactive sexual desire disorder, and dyspareunia in men. For premature ejaculation and for erectile disorder there is evidence for the usefulness of psychological treatment. But effects are limited and often unstable over time.

Although the evidence-based practice movement should be firmly supported, unqualified support would be disastrous for the practice of the treatment of sexual problems. The care for patients with sexual problems must be continued even without proof according to the rules of 'good clinical practice.' The sensible clinician will learn to be very careful about any claims concerning either diagnostic procedures or treatments.

3. Sexual Dysfunctions in Women

3.1 Diagnostic Methods

Similar to the procedures in men, initial interviews should help the clinician in formulating the problem and in deciding whether sex therapy is indicated. Since sexual problems can be a consequence of sexual trauma it is necessary to ask if the woman ever experienced sexual abuse. An important issue is the agreement between therapist and patient about the formulation of the problem and the nature of the treatment. To reach a decision to accept treatment, the patient needs to be properly informed about what the diagnosis and the treatment involve. Dependent on the nature of the complaint, the initial interviews may be followed by medical assessments. In contrast to the assessment of men, the psychobiological assessment of women's sexual problems is not well developed.

3.2 Psychological Treatments of Sexual Dysfunctions in Women

3.2.1 Approaches to treatment. Similar to men, the treatment of sexual dysfunction in women contains many elements from Masters and Johnson sex therapy. As noted before, an important addition, especially in women, is the use of masturbation to discover their own sexuality.

Low sexual desire is generally treated with sensate focus exercises to minimize performance pressure, and communication training. In the treatment of sexual aversion the focus is on decreasing anxiety, the common core of sexual aversions. Behavioral techniques, like exposure, are most commonly used.

Treatment of sexual arousal disorder generally consists of sensate focus exercises and masturbation training, with the emphasis on becoming more self-focused and assertive in asking for adequate stimulation.

For the treatment of primary (lifelong) anorgasmia there exists a well-described treatment protocol. Basic elements of this program are education, self-exploration and body awareness, and directed masturbation. Because of the broad range of problems behind the diagnosis of secondary (not lifelong) and situational anorgasmia, there is no major treatment strategy for this sexual disorder. Dependent on the problem, education, disinhibition strategies, and assertiveness training are used. It is important to identify unrealistic goals for treatment like achieving orgasm during intercourse without clitoral stimulation.

For dyspareunia (genital pain often associated with intercourse), there are multiple possible somatic and psychological causes. A common picture is vulvar vestibulitis, pain at small inflamed spots at the lower side of the vaginal opening. However, often there is no clear organic cause for the pain. Treatment should be tuned to the specific causes diagnosed and can vary from patient to patient. Behavioral interventions typically include prohibition of intercourse, finger exploration of the vagina, first by the woman, then by her partner. Sensate-focus exercises may be used to increase sexual arousal and sexual satisfaction. Pelvic floor muscle exercises and relaxation training can be recommended in case of vaginismus or a high level of muscle tension in the pelvic floor.

Treatment of vaginismus commonly involves exposure to vaginal penetration by using dilators of increasing size or the women's fingers. Pelvic floor muscle exercises may be used to provide training in discrimination of vaginal muscle contraction and relaxation, and to teach voluntary control over muscle spasm.

Pharmacological treatment of sexual disorders of women is just beginning. Smooth muscle relaxants have been used in women to ameliorate sexual arousal and as a consequence hypoactive sexual desire. It appears that drugs like sildenafil produce smooth muscle relaxation and increased genital blood flow, but they have no effect on the subjective experience of sexual response. In women with subphysiological levels of testosterone—mainly in the postmenopause—testosterone patches appear to have an effect on mood, energy, and libido.

3.2.2 Validated treatments for women's sexual dysfunctions. Reviews of treatments for sexual dysfunctions in women following the criteria for validated or evidence-based practice have been published (O'Donohue et al. 1997, Heiman and Meston 1997, Baucom et al. 1998). Heiman and Meston conclude that treatments for primary anorgasmia fulfil the criteria of 'well-established,' and secondary anorgasmia studies fall into the 'probably efficacious' group. They conclude with some reservations that vaginismus appears to be successfully treated if repeated practice with vaginal dilators is included in the treatment. Their reservations are due to a lack of controlled or treatment comparison studies of vaginismus. All authors conclude that adequate data on the treatment of sexual desire disorder, sexual arousal disorder, and dyspareunia is lacking.

Although the evidence-based practice movement deserves support, care for patients with sexual problems must be continued even without proof according to the rules of 'good clinical practice.'

4. Future Directions

Sex therapy bloomed in the 1970s and 1980s, but reviews of evidence-based treatments suggest that developments stagnated and very few new studies have been undertaken. The recent shift to biological approaches will continue, at least for a while. Viagra and testosterone patches will shortly be followed by more centrally acting drugs (e.g., dopamine agonists). The search for drugs has provoked a wide range of studies into the biological basis of sexual function. This work inspires behavioral and cognitive neuroscience studies, which may provide a framework and new tools to better understand sexual emotions and sexual motivation.

Sexual Attitudes and Behavior

The focus in this article is on changes in premarital, homosexual, and extramarital sexual attitudes and behaviors as revealed in nationally representative surveys during the second half of the twentieth century. Attention will be mainly on shared sexual attitudes and behaviors in various societies. A shared attitude is a cultural orientation that pressures us to have positive or negative feelings toward some behavior, and to think about that behavior in a particular way.

1. Sexual Attitudes: Premarital Sexuality

Findings from various countries will be examined and compared but because of the large number of national surveys conducted in the USA, we will start there. The first national representative sample of adults in the USA that used a series of scientifically designed questions to measure premarital sexual attitudes was completed in 1963 (Reiss 1967). The National Opinion Research Center (NORC) at the University of Chicago was contracted to do the survey. Reiss composed 24 questions about premarital sexual relationships that

formed two unidimensional scales and several subscales (Reiss 1967, Chap. 2). The highest acceptance was to the question asking about premarital coitus for a man when engaged. Even on this question only 20 percent (30 percent of males and 10 percent of females) said they agreed that such premarital coitus was acceptable (Reiss 1967, p. 31). The date of this survey (early 1963) was strategic because it was at the start of the rapid increase in premarital sexuality that came to be known as the sexual revolution, and which soon swept the USA and much of the western world.

Two years later, in 1965, NORC fielded a national survey that contained four questions on premarital sexual attitudes. One of the questions also asked about the acceptance of premarital coitus for males when engaged. Scott (1998) reports an average acceptance rate of 28 percent, consisting of 37 percent of males and 21 percent of females in this survey. Acceptance was designated by a person checking either of the last two categories ('wrong only sometimes' and 'not wrong at all'), and disapproval was indicated by a person checking either of the first two categories ('always wrong' and 'almost always wrong'). The 20 percent acceptance rate in the 1963 national survey and the 28 percent rate in this 1965 survey lends credence to a rough estimate that at the start of the sexual revolution in premarital sex (1963–5), about one quarter of adults in the USA accepted premarital coitus while three quarters disapproved of it.

In 1970 Albert Klassen and his colleagues at the Kinsey Institute conducted the next nationally representative survey (1989). Klassen also used the NORC to conduct his survey. He used four questions and asked about the acceptability of premarital intercourse for males and females, when in love and when not in love. Reiss reported that the responses to questions about males specifying love and those specifying engagement, were less than 2 percent apart, and so the Klassen question about premarital sex for males in love can be compared to the two previous surveys. Klassen reports that 52 percent (60 percent of males and 45 percent of females) chose the two acceptant categories of 'wrong only sometimes' or 'not wrong at all' (Klassen et al. 1989, p. 389). In just seven years acceptance of coitus rose from 20 percent in 1963, 28 percent in 1965, to 52 percent in 1970. The questions used in all three national surveys seem comparable and, most importantly, the size of the difference from 1963 to 1970 is so large, that it is hard not to conclude that in those seven years, something that can be called a revolution began to evidence itself in American attitudes toward premarital coitus.

Reiss considered the increased autonomy of females and young people as the key factor in the increase of premarital sexual attitudes and developed the *Autonomy Theory* explanation of the sexual revolution around this concept (Reiss 1967, Chap. 10, Reiss and Miller 1979). In the l960s a higher percentage of females were employed than ever before and this meant more autonomy for them, and more autonomy for their children from parental controls and indoctrination. Females more than males were impacted by this increased autonomy and the three studies show much greater proportionate changes in female attitudes than in males. Adult males' acceptance doubled from 30 percent in 1963 to 60 percent in 1970, whereas adult females' acceptance increased 3.5-fold from 10 percent to 45 percent during the same period. The autonomy theory predicted that since female autonomy was increasing the most, female premarital permissiveness would increase the most. This is precisely what happened.

Starting in 1972 the NORC introduced the General Social Survey (GSS) to gather national data annually or biennially on adults in the USA concerning premarital sexuality and a wide range of other nonsexual attitudes and behaviors. These data afford a basis here to examine the change in premarital sexual attitudes from 1972 to 1998. Unfortunately, the GSS researchers did not ask a question modeled after that in the l963, 1965, and 1970 surveys, which all specified gender and the presence of love or engagement. The GSS question basically taps a respondent's global response to the acceptability of premarital coitus. It asked: 'If a man and a woman have sex relations before marriage, do you think it is always wrong, almost always wrong, wrong only sometimes or not wrong at all' (Davis and Smith 1999, p. 235). The 'always wrong' response to the GSS question is the only response that clearly excludes acceptance of coitus even for an engaged or in love male and so it will be considered as the response indicating rejection of such behavior.

The 1972 GSS survey reported that 63 percent accepted premarital coitus under some condition and 37 percent checked the 'always wrong' category. That was a significant growth from the 52 percent acceptance reported by Klassen for 1970. By 1975 the GSS surveys reported that acceptance had risen to 69 percent. The rise was small after 1975 and acceptance was 74 percent in 1998 (Davis and Smith 1999, p. 235). Looking at all the national surveys in the USA from 1963 to 1998 the evidence is that the period of most rapid change in acceptance of premarital coitus was from 1963 to 1975, with an overall increase from 20 percent to 69 percent. That is the period that we can most accurately label as a premarital sexual revolution. In all the surveys discussed the data showed that females, much more than males, increased their acceptance of premarital coitus and this led to more gender equality in attitudes towards premarital coitus. The gender comparisons in 1963 were 10 percent female acceptance to 30 percent male acceptance. By 1975 the comparisons were 65 percent female acceptance to 74 percent male acceptance.

Studies in a number of European societies indicate that even after the increased acceptance of premarital coitus in the USA, many Western countries were still more acceptant than the USA. For example, using

data from the International Social Survey Program (ISSP) of 1994, comparing the USA to five other societies, Scott reports that only Ireland was less acceptant of premarital coitus than the USA. Germany and Sweden were much more acceptant, and even Britain and Poland were significantly more acceptant (Scott 1998, p. 833). Unlike in the USA, Scott reports increases in acceptance of premarital coitus continuing in Britain during the 1980s and 1990s.

There are other national surveys that can be studied such as the 1971 and 1992 national surveys in Finland that show similar trends to what was found in the USA (Kontula and Haavio-Mannila 1995, Chap. 12). Frequent mention of comparable changes in premarital sexual attitudes can be found in the *International Encyclopedia of Sexuality* in its accounts of 31 societies (Francoeur 1997). There are also a number of other European countries with national surveys taken in the 1980s and 1990s but lacking earlier national surveys for comparison. Nevertheless, what evidence we have on these other societies seems to support a significant increase in the acceptance of premarital coitus similar to what was happening in the USA, although not necessarily in the exact same years.

2. *Sexual Attitudes: Homosexuality*

In 1973, a question on homosexual behavior was first asked in the GSS national survey in the USA. No distinction was made between male and female homosexuality. Nineteen percent accepted homosexual behavior as 'wrong only sometimes' or 'not wrong at all.' That did not vary a great deal until the 1993 GSS survey where acceptance jumped to over 29 percent. It then rose to 34 percent in 1996 and to 36 percent in 1998 (Davis and Smith 1999). One can only speculate as to why in the early 1990s this change accelerated in the USA. Perhaps the changes in the 1980s toward greater civil rights for homosexuals encouraged the increase in acceptance of homosexual behavior itself. However changes in the intensity of feelings cannot be indicated by the simple percent distribution on the GSS question on homosexuality. Clearly, using just one question to measure a sexual attitude, while useful, does not afford us sufficient information.

There are national data on homosexuality from other countries. Inglehart, using his two World Value Surveys, compared 20 societies in 1981 and 1990 on the question of homosexuality. He reported that in all but three of the 20 (Ireland, Japan, South Africa) there was an increase in acceptance of homosexuality between 1981 and 1990 (Inglehart 1997, p. 279). In addition, the ISSP (1994) reported that Poland and Ireland were less acceptant of homosexuality than the USA, whereas Britain, West Germany, East Germany, and Sweden were more acceptant (Scott 1998, p. 833).

When we compare changes in males and females in the USA using the GSS data we find that females changed more than males in accepting homosexuality. Homosexual attitudes have traditionally been one of the very few sexuality areas where females equal or exceed males in the acceptance of a sexual behavior. This type of male/female difference was commonly found also in Western European countries studied in the World Values Surveys. But this higher female level of acceptance of homosexuality was not typically found in Eastern European or Asian countries (Inglehart 1997).

3. *Sexual Attitudes: Extramarital Sexuality*

Extramarital sexual attitudes present a very different trend from either premarital or homosexual attitudes. The GSS data for the USA show that the acceptance of extramarital sexuality fell significantly between 1973 and 1988. Acceptance of extramarital sexuality (answering 'wrong only sometimes' and 'not wrong at all') in 1973 was 16 percent but by 1988 this had dropped to only 8 percent. Although male acceptance stayed higher than that of females, both genders showed close to a 50 percent decrease in acceptance over that period. The fear of HIV/AIDS may have played a role. Negative experiences with extramarital sexuality during the era of rapidly increasing divorce rates in the 1970s may also have contributed to this conservative trend.

This more conservative shift in extramarital attitudes was seen in only a minority of the 20 countries on which Inglehart presents data for the period 1981–90 (Inglehart 1997, p. 367). France, Northern Ireland, Sweden, Argentina, and South Africa showed the sharpest decreases in their acceptance of extramarital sexuality. Meanwhile, Mexico, Italy, Finland, and Hungary evidenced the strongest changes toward greater acceptance of extramarital sex. This finding presents a most interesting puzzle as to why some countries changed to be more restrictive while others became more acceptant of extramarital sexuality.

Adding more to this puzzle is the finding by Inglehart that from 1981 to 1990, 16 (of 19) countries increased their belief that a child needs two parents to be happy (1997, p. 287). Thus, there was clearly more agreement in most of these countries on the importance of the two-parent family than on extramarital sexuality. It must be that in some countries, extramarital sexuality was not seen as a challenge to the stability of the two-parent family. There is a need here to also study the various types of extramarital coital relationships to distinguish the impact on stable relationships of having a casual vs. a love affair and/or a consensual vs. a nonconsensual affair (Reiss 1986, Chap. 3). These sexual complexities are but one of the many sexual conundrums waiting to be deciphered by more detailed research that can clarify and elaborate the survey research data presented here.

4. Relation of Sexual Behaviors and Sexual Attitudes

The relation of sexual behavior to the attitude changes we have noted can be explored in several national studies in the USA. The 1982 National Survey of Family Growth (NSFG) interviewed females 15 to 44 years old. These 15–44 year old females were asked about their first coitus, and from this we can obtain retrospective reports for those in this sample who were teenagers in the early 1960s. Hopkins reports that the average percent nonvirginal for 15–19 year old females in 1962 was 13 percent and this rose to 30 percent by 1971 (Hopkins 1997). Zelnik and Kantner (1980) undertook three nationally representative samples of teenage females in the USA during the 1970s. They report that the percentage of 15–19 year old females who had experienced coitus rose from 30 percent in 1971 to 43 percent in l976, and finally to 50 percent in 1979 (Zelnik and Kantner 1980). The 50 percent rate dropped to 45 percent in 1982 and rose back to about 50 percent in 1988 and has stayed close to that level since then (Singh and Darroch 1999, Reiss 1997, Chap. 3). There were many other changes in teenage sexual relationships, such as improved contraception, that cannot be discussed here. Finally, it should be noted that premarital coital behavior, just like premarital attitudes, changed much more for females than for males (Laumann et al. 1994).

When we compare these behavioral changes with the attitudinal changes discussed above, it is apparent that the large increase in the acceptance of premarital coitus starting in the 1960s was very much in line with the contemporaneous increases in teenage coital behavior. Using the GSS surveys allows one to compare attitudes with behavior in all three areas of premarital, homosexual, and extramarital for specific years. These data show a relatively close relationship between attitudes and behaviors in all three areas. For example, among those who said premarital sex is 'always wrong' 32 percent had premarital coitus in the last year, while among those who said premarital coitus was 'not wrong at all,' 86 percent had premarital coitus in the last year (Smith 1994, p. 89). The comparable figures for homosexuality are 1 percent vs. 15 percent, and for extramarital sex 2 percent vs. 18 percent. These are very large differences and they support the interactive relationship of attitudes and behavior in our sexual lives which others have commented upon (Reiss 1967 Chap. 7, Klassen et al. 1989, p. 253).

Many of the same countries that were noted for increases in sexual attitudes since the 1960s also have national data supporting changes in sexual behavior, particularly in premarital sexuality (Inglehart 1997). A large national survey in England presents data supporting a very close association of attitudes and behaviors in premarital, homosexual, and extramarital sexuality (Johnson et al. 1994, p. 245). Also, in the area of homosexuality, Laumann reports similarities in his 1992 American data concerning homosexuality with data from other national surveys (Laumann et al. 1994). Finally, Francouer's encyclopedic work written by experts from 31 societies also supports a close connection between attitude changes and behavior changes in many of the countries studied (Francoeur 1997). The puzzle concerning how, and in what temporal sequences attitudes and behavior influence each other is one that requires careful research and theoretical attention.

5. Conclusions

The representative national surveys examined leads to several important conclusions about sexual attitudes and behaviors in the post Kinsey era. It seems clear that there has been a sexual revolution in the area of premarital sexuality in the USA and in a large number of other Western countries. This is evidenced in both attitudes and behaviors and more strongly on the part of females than males. There has also been a more moderate increase in the acceptance of homosexuality. Finally, it was found that the acceptance of extramarital sexuality has actually decreased in the USA and elsewhere while increasing in a few other countries.

There is a dearth of theories regarding why such sexual changes have occurred. The autonomy theory argues that the key variable in premarital sexual attitude change is the rise in autonomy (Reiss 1967, Reiss and Miller 1979). Such a change is also part of increased social acceptance of gender equality and of premarital sexuality, particularly in a gender equal relationship. The extensive examination by Hopkins of national data in the USA to test the autonomy theory's ability to explain premarital sexuality trends from 1960–90, strongly supports the increases in female gender equality as a key determinant of changes in autonomy, which in turn produced changes in premarital sexual attitudes and behaviors (Hopkins 1997, Chap. 6).

6. Future Directions

Reiss has delineated the nature of a new sexual ethic that he finds is increasingly popular in many countries in the Western world. He calls this new ethic, *HER Sexual Pluralism*, meaning that the moral yardstick in a sexual relationship is now the degree of *Honesty*, *Equality*, *and Responsibility* present. The older norms that judged people by whether they had performed a specific sexual behavior, have increasingly been replaced by focusing on the HER relationship parameters (Reiss 1997, Chaps. 1 and 10). This new ethic fits with the increased acceptance of premarital and homosexual sexuality, for the HER ethic does not use

marriage as the Rubicon of good and bad sexuality. The drop in the acceptance of extramarital sexuality in many countries may reflect the difficulty in carrying out two HER relationships simultaneously. HER sexual pluralism is well integrated with the more gender equal type of evolving Western society and is predicted to become the dominant sexual ethic of the twenty-first century.

One other theoretical explanation of sexual trends comes from Inglehart (1997). He postulates that as capitalist societies become more affluent and increasing numbers of their citizens feel secure, there has occurred a rise in 'non materialist' values. These new values stress well being and quality of life, over accumulation of more economic wealth. Inglehart argues that as part of this major emphasis on quality of life, we are witnessing a liberation and pluralization of sexual values, particularly in the premarital and homosexual areas. Inglehart's thesis is quite compatible with the autonomy theory because both theories are placing the birth of the changes in sexuality as a key part of the development of a new type of society; a society that is more autonomous and more concerned with the quality of life, than with economic survival. The fact that young people in these societies evidence these sexuality trends more than older people lends further support to the future growth of these changes. There appears to be a change in our basic social institutions in much of the world, and with that, a change in sexual relationships is occurring in line with the emerging HER sexual pluralism ethic.

Many aspects of sexual attitudes and behaviors could not be discussed in this article. Even the surveys in the three areas examined illustrate the need for a more detailed examination of the many nuances of sexuality in each area. In addition, sexual science requires better coverage of peoples outside the Western World (Barry and Schlegel 1980, Reiss 1986). We can make progress by combining qualitative and quantitative methods in our work and linking those many disciplines that study sexuality. One way that significant progress can be encouraged is by the establishment of a multidisciplinary Ph.D. degree in sexual science, and in the Spring of 1999 the Kinsey Institute started work to produce just such a degree program (Reiss 1999). This program will be immensely helpful in expanding sexual science's ability to explain our sexual lives. Theory is explanation, and science without theory is just bookkeeping. In all science we need to know why something is the way we find it, not just describe what is found. With the growth of our scientific explanations we will be better able to contain the myriad of sexual problems that plague sexual relationships worldwide.

Sexual Behavior and Maternal Functions, Neurobiology of

During the second half of the twentieth century, interdisciplinary research efforts have generated considerable information about the physiological mechanisms that control mammalian reproductive behaviors. The approach has used field and laboratory studies with animals to elucidate general principles that are beginning to be assimilated by the social sciences as they toil to understand the sexual and parental behaviors of our own species. What follows is a review of basic research on sexual behavior, sexual differentiation, and maternal functions in mammals including humans.

1. *Sexual Behavior*

Mammalian sexual behavior is facilitated in males and females by the hormonal secretions of the testes and ovaries, respectively. In females the display of sexual behavior shows cycles closely associated with fluctuations in the hormonal output of the ovaries. In many species, including rodents commonly used in laboratory experiments, the cyclic display of behavior includes both changes in the ability of the female to copulate as well as her motivation or desire to engage in sexual behavior. In these species intercourse is often physically impossible except during a brief period of optimal hormonal stimulation of central and peripheral tissues. The central effects of ovarian hormones (i.e., estrogen (E) and progesterone (P)) in the facilitation of female sexual behavior are mediated by receptors found in several brain regions including the ventromedial nucleus of the hypothalamus (VMH), the preoptic area, and the midbrain central gray. The effects of E and P on neurons of the VMH appear to be sufficient to facilitate the display of the postural adjustment necessary for copulation in female rats (i.e., the lordosis reflex), and the display of lordosis is prevented by lesions of the VMH (Pfaff et al. 1994). Female rats with VMH lesions can show lordosis if other neural systems that normally inhibit the display of lordosis are also surgically removed (Yamanouchi et al. 1985). The rewarding or reinforcing aspects of female copulation are likely to be mediated by dopaminergic systems that include the nucleus accumbens. The rewarding aspects of female sexuality appear to be activated only when the female can control when and how often she has contact with the male during mating, i.e., when the female can 'pace' the copulatory encounter (Erskine 1989).

In sharp contrast with nonprimate species, female monkeys are capable of engaging in sexual behavior at all phases of the ovulatory cycle and after ovariectomy. This fact which of course also applies to women, has been often used to question the importance of ovarian hormones in the modulation of female sexuality in primates. Other work, however, has shown that in spite of having the ability to copulate throughout the menstrual cycle, female monkeys show fluctuations in sexual motivation that are predictable from the pattern of ovarian E production across the cycle. For the behavioral effects of E to be evident, female monkeys must be tested in situations in which they are given the opportunity to choose between avoiding contact with the male or alternatively to approach the male and solicit his attention. In a series of elegant experiments conducted under naturalistic conditions Wallen and associates (Wallen 1990, 2000) have shown that in rhesus females, the willingness to leave an all-female group in order to approach a sexually active male peaks at the time of maximal E production at the end of the follicular phase. Further, under the same conditions, females never approach the male if their ovarian functions are suppressed by pharmacological manipulations. As argued by Wallen, in rhesus females and perhaps also in women, ovarian hormones do not determine the ability to engage in sexual behavior but have salient effects on sexual desire. Almost nothing is known about where E acts in the brain to facilitate sexual motivation in female primates.

In male mammals, castration results in a reduction in sexual behavior and replacement therapy with testosterone (T) or its metabolites restores the behavior to pre castration levels. In nonprimate species both the motivational and performance aspects of male sexuality are affected by lack of T. In men and possibly other primates, lack of T seems to affect sexual motivation more than sexual ability (Wallen 2000). Thus, men with undetectable circulating levels of T can reach full erections when shown visual erotic materials, but report little sexual interest in the absence of T replacement. In men, erectile dysfunction is often due to non endocrine causes such as vascular pathologies or damage to peripheral nerves. In the brain T seems to act primarily in the medial preoptic area (MPOA) to facilitate male sexual behavior, but it is evident that other brain regions as well as the spinal cord and other peripheral sites need hormonal stimulation for the optimal display of sexual behavior in males. Lesions of the MPOA have immediate and profound disruptive effects on male sexual behavior and these effects are remarkably consistent across species. Lesions of the MPOA however do not equally affect all components of male sexual behavior and some of the effects of the lesions are paradoxical. For example, in male rats lesions of the MPOA that virtually abolish male sexual behavior do not seem to affect willingness to work on an operant task when the reward is access to a receptive female. Similarly, male mice continue to show courtship behavior directed to females after receiving large lesions of the MPOA. It has been suggested that lesions of the MPOA selectively affect consummatory aspects of male behavior leaving appetitive or motivational components intact. Not all the data fit this proposed dichotomy. For

example rhesus monkeys that show copulatory deficits after MPOA damage do not lose all the consummatory aspects of male behavior; after the lesions the animals are capable of achieving erections and they frequently masturbate to ejaculation (Nelson 2000).

The view that male sexual behavior results primarily from T action in the MPOA and female sexual behavior from E and P action in the VMH is not without detractors. In a recent study of male sexual behavior in the rat, it was found that androgen antagonists implanted directly into the MPOA did block male sexual behavior as would be expected. However, the most effective site for androgen antagonist blockade was in the VMH! (McGinnis et al. 1996). There is also considerable overlap between the neural systems that are active during female sexual behavior and those that are active in the male during copulation. These studies may indicate that the appetitive aspects of sexual behavior, seeking out a partner, courtship, etc. are under the control of similar neural systems in both sexes (Wersinger et al. 1993).

2. *Sexual Differentiation*

In addition to the activational effects gonadal hormones have on adult sexual behavior, there is an extensive literature base to show that gonadal hormones also affect the development of brain systems that regulate male and female sexual behavior. These long-lasting effects are often referred to as 'organizational effects' to distinguish them from the concurrent facilitative actions that gonadal hormones have in the adult. Organizational hormone actions are thought to occur primarily during the period of sex differentiation of the nervous system. In species with short gestation, such as rats and hamsters, this developmental period occurs around the time of birth, whereas in those species with longer gestation times, such as primates, sex differentiation of the nervous system takes place during fetal development (Nelson 2000).

Normal males are exposed to androgens throughout this early developmental period as a result of the testes becoming active during fetal development. When genetic female rats were treated with T throughout this time they showed significant masculinization of behavior and genital morphology. As adults, these experimental females displayed most of the elements of male sexual behavior including the ejaculatory reflex. When males were deprived of androgens during this time they were less likely to show the consummatory responses associated with masculine copulation. Further, in the absence of androgens during early development, male rodents develop into adults who show most of the elements of female sexual behavior if treated with ovarian hormones. For many laboratory rodents the behavioral masculinizing effects of T treatment result from metabolites of T, namely estradiol and reduced androgens such as dihydrotestosterone. There is good evidence that for some species it is the estrogenic metabolite that is essential for behavioral masculinization.

Ovarian hormones do not appear to play a role in the development of the neural systems that underlie feminine sexual behavior in mammals. When female laboratory rodents, such as the golden hamster, are treated with estrogen during early development they actually show reduced levels of female sexual behavior as adults. However, their levels of male-like behavior, such as mounting receptive females, are increased, findings that are consistent with the concept that estrogen is a masculinizing metabolite of T in males.

The findings on the effects of gonadal hormones during early development of the female are not easily interpreted, because an independent definition of just what is feminine and what is masculine is not available. On the one hand it is clear that if a female rodent is exposed to high levels of androgen throughout early development she will develop a male-like anatomy and will, as an adult, show all the elements of male sexual behavior. On the other hand, female rodents are often exposed to low levels of androgens normally during gestation as a result of developing next to a male in the uterus. These females are often more dominant than other females and less attractive to males (VomSaal 1989). But they still copulate as females and reproduce, suggesting that normal variations in female phenotype may result from normal variation in androgen exposure during development. This variability in female behavior and attractiveness may be an important part of any normal female population. The problem lies in defining the limits of normal female variation resulting from androgen (or estrogen) exposure, as opposed to what androgen effects might be interpreted as masculinization (Fang and Clemens 1999). The criteria for making this distinction have not yet been defined.

Numerous sex differences have been reported for the mammalian nervous system and most of these probably result from the differential exposure to gonadal hormones that occurs during sex differentiation. It also presumed that the sex differences in behavior that we have noted result from these differences in the nervous system of males and females, but few models are available to show a strong correlation between sex differences in the CNS and sex differences in behavior (but see Ulibarri and Yahr 1996). Gonadal hormones can influence the development of the nervous system in a number of ways such as altering anatomical connectivity, neurochemical specificity, or cell survival. For example, while both male and female rats have the same number of nerve cells in the dorsomedial nucleus of the lumbosacral cord prior to sex differentiation, in the absence of androgen many of these cells die in the female, a normal process referred to as 'apoptosis.' This differential cell-death rate leaves the adult male rat with a larger dorsomedial nucleus than the female. In some brain regions it is suspected that hormones may actually promote cell death result-

ing in nuclei that are larger in the female than in the male. There are also numerous examples of sex differences in the peripheral nervous system as well.

For many years sex differences in human behavior were regarded as reflections of differences in how male and female children are reared. However, the accumulation of volumes of work showing that sex differences in non humans are strongly influenced by differential hormone exposure has forced scientists from many fields to re-evaluate the nurture hypothesis. Most would probably now agree to several general statements. 1. The brains of male and female humans are structurally very different. 2. These differences may reflect, at least in part, the different endocrine histories that characterize the development of men and women. 3. Some of the behavioral differences between males and females may result from these differences in their nervous systems. Disagreement occurs when we try to specify how much of one trait or another is due to biological factors and how much to experience, and it must be recognized at the outset that a clean separation of nature from nurture is not possible.

Most of the evidence for biological factors operating to produce sex differences in human behavior comes from clinical or field psychology studies. A number of syndromes involve variation in androgen or estrogen levels during early development: congenital adrenal hyperplasia (CAH) is a syndrome in which the adrenal gland produces more androgen than normal. Turners Syndrome is characterized by regression of the ovaries and reduced levels of androgen and E from an early age. Hypogonadism is a condition where boys are exposed to lower than normal levels of androgen. There are also populations of girls and boys who were exposed to the synthetic estrogen, diethylstilbestrol (DES) during fetal development as well as populations whose mothers were treated with androgenic-like hormones during pregnancy. A number of studies point to a change in girls play behavior as a result of exposure to androgens during fetal development. CAH girls or girls exposed to exogenous androgenic compounds are often found to show an increased preference for playing with toys preferred by boys and less likely to play with toys preferred by untreated girls. These androgen-exposed girls also are more likely to be regarded as 'tomboys' than their untreated sibs or controls and engage in more rough and tumble play than controls (Hines 1993). Some have argued that variation in androgen or E levels during early development may affect sexual orientation, but a general consensus on this point has not been reached at this time.

3. *Maternal Functions*

For rodents, especially in the case of the laboratory rat, the endocrine and neural mechanisms responsible for the onset and maintenance of maternal behavior are relatively well understood (Numan 1994). This understanding has stemmed to a large extent from the careful description of behaviors shown by maternal rats; these behaviors are easy to identify and to quantify in the laboratory. Such a rich and objective behavioral description is often lacking for other species including our own. In rats, all components of maternal care of the young (except milk production) can be induced in the absence of the hormonal changes that normally accompany pregnancy, parturition, and lactation. Thus, virgin female rats become maternal if they are repeatedly exposed to pups of the right age, a process referred to as sensitization. Hormones, nevertheless, play a critical role in the facilitation of maternal behavior and are necessary for the coordination of maternal care and the arrival of the litter. Using different experimental paradigms, several laboratories have identified E as the principal hormone in the facilitation of maternal behavior. When administered systemically or when delivered directly into the MPOA, E triggers the display of maternal behavior under many experimental conditions. Prolactin from the anterior pituitary or a prolactin-like factor from the placenta also play a role, albeit secondary, in the facilitation of maternal functions; administration of prolactin or analogs of this hormone enhances the activational effects of E on maternal behavior. Also, mice lacking functional prolactin receptors show poor maternal care. Other peptides and steroids have been implicated in the support of maternal functions (Nelson 2000). For example, central infusions of oxytocin facilitate maternal behavior under some conditions and the effects of P on food intake and fuel partitioning are crucial to meet the energetic challenges of pregnancy and lactation (Wade and Schneider 1992).

The integrity of the MPOA is necessary for the display of normal maternal behavior. Damage of the MPOA using conventional lesions or chemical lesions that spare fibers of passage interferes with normal maternal behavior under several endocrine conditions. Similar behavioral deficits are seen after knife cuts that interrupt the lateral connections of the MPOA. Cuts that interrupt other connections of the MPOA do not reproduce the behavioral deficits seen after complete lesions (Numan 1994). Normally, male rats do not participate in the care of the young, but exposing males to pups for several days can induce components of maternal behavior. Compared to females, adult males require more days of sensitization with pups and tend to show less robust maternal behavior. This sex difference is not evident before puberty (Stern 1987) suggesting that sexual differentiation of behavior may not be completed until after sexual maturation. When males are induced to care for the pups, the behavior is sensitive to the disruptive effects of lesions of the MPOA. Since MPOA damage affects both male sexual behavior and the display of maternal care, it is possible that there is partial overlap between the neural circuits

that support these two behavioral functions. Alternatively, MPOA lesions may affect more fundamental aspects of the behavioral repertoire of the animals, and such a deficit then becomes evident in different ways under different social conditions. The effects of MPOA lesions in females are also complex and not fully understood. In addition to affecting maternal functions MPOA damage results in a facilitation of the lordosis reflex concurrently with a reduction in the females' willingness to approach a sexually active male in testing situations that permit female pacing. Fine-grained analyses of the functional anatomy of the MPOA are needed to further elucidate the precise role of this area in mammalian reproductive functions.

Studies of monogamous mammalian species where males and females remain together after mating offer the opportunity to study paternal care as well as social bonding between parents and between parents and offspring. One promising model is that of the prairie vole in which both the female and the male care for the young (DeVries and Villalba 1999). Studies of these monogamous rodents suggest that bonding of the female to the male and to her young may be enhanced by oxytocin, a peptide hormone synthesized in the hypothalamus and secreted by the posterior pituitary. In the male, paternal care appears to result, not from oxytocin, but from another hypothalamic hormone, vasopressin. In addition to these posterior pituitary hormones investigators have found evidence for a role of the endogenous opiates in strengthening the bond between mother and offspring (Keverne et al. 1999).

Sexual Behavior: Sociological Perspective

This article considers social science research in the field of human sexual behavior since the start of the nineteenth century. Sexual behavior is understood here in a broad sense to include not just sexual acts but

also the associated verbal interactions and emotions (most notably love), as well as sexual desires, fantasies, and dysfunctions.

1. Overview

The main disciplines considered here are the sociology and anthropology of sexuality, the psychology and psychopathology of sexual behavior, and sexology. These disciplines began to take form in the nineteenth century, and were influenced by other intellectual currents and areas of knowledge which, though not discussed in this article, need to be indicated:

(a) Eugenics, in the form given it by Francis Galton from the 1860s. Eugenicist preoccupations were shared by most of the leading sexologists of the late nineteenth and early twentieth centuries (notably Havelock Ellis and Auguste Forel).

(b) The history of sexuality. This developed in the nineteenth century, initially as the history of erotic art and practices, and of prostitution; and later as the history of sexuality in the ancient world and in other cultural contexts.

(c) The ethology of sexuality. This emerged at the end of the nineteenth century, and has grown in influence since the 1960s, related partly to the development of sociobiology.

Three phases can be identified in the development of social science research on sexuality: the nineteenth century (when the emphasis was on the study of prostitution and the psychopathology of sexual behavior); the period 1900–45 (that of the great sexological syntheses, the pioneering anthropological monographs and the first sex surveys); and the period beginning in 1946 (marked in particular by an expansion of quantitative research on the general population).

2. 1830–99: From the 'Pathological' to the 'Normal'

It would be inaccurate to portray the nineteenth century in the industrialized countries as uniformly puritanical. The period was, of course, characterized by a widespread double standard in sexual morality (much less restrictive for young men than for young women), repression of masturbation, hypocrisy over the expression of love and sexual desires, censorship of literature and erotic art, and so on. But the nineteenth century also saw the development of feminism, the struggle for the civil rights of homosexuals, and the introduction of contraceptive methods in many countries. It was in the nineteenth century also that sexual behavior emerged as a major subject of scientific study.

A characteristic of much work on sexuality in this period is how a concentration on the 'pathological' and 'deviant' was used to cast new light on the 'normal'; that is, on the behavior most widespread in the population. For example, the quantitative study of prostitution preceded that of sexuality in marriage; the 'perversions' (referred to today as 'paraphilias') were examined before heterosexual intercourse between married couples; and the first scientific description of the orgasm (in 1855 by the French physician, Félix Roubaud) actually appeared in a study on impotence.

The first quantitative research on sexual behavior was conducted in the 1830s, much of it using the questionnaire technique being developed at this time. The first major empirical study in this field, based on quantification and combining sociological and psychological perspectives, was the investigation of prostitution in Paris conducted by the physician Alexandre Parent-Duchâtelet (1836).

The second main current of research in the nineteenth century was concerned with the psychopathology of sexuality. The years 1886 and 1887 were a decisive period. In 1886 was published the first edition of Richard von Krafft-Ebing's *Psychopathia sexualis* which presented a systematic classification of 'sexual perversions.' In 1887, the psychologist Alfred Binet (Binet 2001) published an article with the title 'Le fétichisme dans l'amour' ('Erotic fetishism'). Binet's text was the origin of an intellectual fashion for labeling the various 'sexual perversions' as 'isms' (the psychiatrist Charles Lasègue had coined the term 'exhibitionists' in 1877 but not the word 'exhibitionism'). By 'fetishism,' Binet referred to the fact of being particularly—or indeed exclusively—sexually excited by one part of the body or aspect of character, or by objects invested with a sexual significance (for example, underwear or shoes). He argued that the fetishism of any given individual was usually formed in childhood or adolescence, through a psychological process of association, during or after an experience that stirred the first strong sexual feelings. For Binet, many 'sexual perversions' as well as homosexuality should be considered as different forms of 'erotic fetishism.' Finally, he asserted that 'pathological' fetishism (such as obsessional fetishism for certain objects) was merely an 'exaggerated' form of the fetishism characteristic of 'normal' love (that of the majority of people). For a time this notion provided the unifying perspective for the psychopathology of sexuality, beginning with that elaborated by Krafft-Ebing in successive editions of his *Psychopathia sexualis*.

The years that followed saw the generalization of the terms 'sadism' and 'masochism' (popularized by Krafft-Ebing), 'narcissism' (invented by Havelock Ellis and Paul Näcke in 1898–99), 'transvestism' (introduced by Magnus Hirschfeld around 1910). The psycho-analysis of Sigmund Freud integrated these various expressions and, most importantly, Binet's

ideas about the lasting influence of childhood sexual impressions. This period also saw the development—encouraged by Alfred Binet and Pierre Janet—of the analysis of the sexual content in ordinary daydreams. The first questionnaire-based surveys of what in the twentieth century came to be referred to as sexual fantasies were carried out in the United States in the 1890s, in the context of research on adolescence led by G. S. Hall.

3. *1900–45: Large-scale Sexological Syntheses, Pioneering Anthropological Monographs and the First Sex Surveys*

The large volume of research conducted between 1900 and the end of World War II can be divided into three main currents (for a general view of the most significant contributions from this period, see E. Westermarck (1936).

The first current is that of sexological research. It was in this period that sexology acquired an institutional status. The first sexological societies were set up in Germany in the years after 1910, and in 1914 Albert Eulenburg and Iwan Bloch founded the period's most important journal of sexology (the *Zeitschrift für Sexualwissenchaft*). The first Institute for Sexual Science was opened by Magnus Hirschfeld in Berlin in 1919. In the 1920s the first international conferences of sex research were held. This period also saw publication of large-scale works of synthesis, in particular those by Auguste Forel (Swiss), Albert Moll, Hermann Rohleder, Magnus Hirschfeld (German), followed later by René Guyon (French) and Gregorio Marañon (Spanish). In the 1920s and 1930s, sexology became more self-consciously 'political.' A stated aim was to advance the 'sexual liberation' of young people and women, a cause advocated in influential books by B. Lindsey and W. Evans, Bertrand Russell, and Wilhelm Reich. Also published in these years were a number of extremely successful works popularizing sexological questions (the best known being those of the Englishwoman, Marie Stopes, and of the Dutch gynecologist, Th. H. Van de Velde). The aim of these manuals was to promote an enjoyment of marital sex, and the emphasis was accordingly on sexual harmony, orgasm, sexual dysfunctions, and no longer—as had been the case at the end of the nineteenth century—on 'sexual perversions.' The most representative and influential expression of the various tendencies in sexology at this time were the seven volumes of *Studies in the Psychology of Sex* (1900–28) by the Englishman, Havelock Ellis.

The second current of research is in sexual anthropology. Broadly speaking these were either comparative studies of marriage and sexual life (E. Crawley, W. I. Thomas, W. G. Sumner, A. Van Gennep, R. Briffault, K. Wikman and, foremost, E. Westermarck) or anthropological monographs, in particular those by B. Malinowski, M. Mead and G. Gorer. The most important of these monographs is that of Bronislaw Malinowski (1929) on the natives of the Trobriand Islands in New Guinea: topics examined include prenuptial sexuality, marriage and divorce, procreation, orgiastic festivals, erotic attraction, sexual practices, orgasm, the magic of love and beauty, erotic dreams and fantasies, as well as the morals of sex (decency and decorum, sexual aberrations, sexual taboos).

The third and final current from this period is quantitative studies of sex behavior. Before 1914 this research was conducted mainly in Russia, Germany and Scandinavia. Between the wars, it developed primarily in the United States (R. Pearl, G. V. Hamilton, K. B. Davis, R. L. Dickinson, and L. Beam). These works prepared the way for and in many respects prefigured the research conducted by Kinsey and his co-workers from 1938.

4. *Post-1946: Empirical Research in the Age of Sexual Liberalization*

In many countries, the second half of the twentieth century was a period of sexual liberalization. The improved status of women was reflected in a greater recognition of their rights in sexual matters (with implications for partner choice, use of contraception and abortion, as well as sexual pleasure). One consequence of this change was to encourage research into contraception: the contraceptive pill became available from 1960, and sterilization for contraceptive purposes was the most widely used means of birth control in the world by the end of the 1970s. Research was also encouraged into the physiology of the orgasm, and particularly the female orgasm, in the 1950s and 1960s (E. Gräfenberg, A. M. Kegel, A. C. Kinsey, W. H. Masters and V. E. Johnson, etc.). Another important factor of change was the arrival at adolescence in the 1960s of the postwar baby boom generation; economic affluence was the context for their demands for greater sexual freedom. This aspiration was reflected in a fall in age of first intercourse, especially for young women, and, related to this, a decline in the norm of female virginity at first marriage (or formation of first stable union). This liberalization reached its peak in the developed countries at the end of the 1970s and was brought to an abrupt halt by the AIDS epidemic, awareness of which began to develop, first in the United States, from 1981.

In the course of the last fifty years of the twentieth century, the social sciences have made a major contribution to the understanding of human sexuality. Special mention must be made of the contributions from historical demography, history (R. Van Gulik, K. J. Dover, M. Foucault, P. Brown, and others),

ethnology (V. Elwin, G. P. Murdock, C. S. Ford and F. A. Beach), the psychology of sexuality (see Eysenck and Wilson 1979), but also research originating in gay and lesbian studies conducted from a perspective of 'social constructionism' (sexuality is not a biological given but is socially constructed), as well as research on sexual identity, transsexualism, pornography and fantasies (for a general overview of the research mentioned above see: Ariès and Béjin (eds.) 1982, Allgeier and Allgeier 1988, McLaren 1999). Many of the new insights into sexual behavior acquired in this period have come from quantitative-based empirical research.

The most influential of this research in the 1940s and 1950s was that directed in the United States by Alfred Kinsey. Between 1938 and 1954, Kinsey and his co-researchers interviewed more than 16,000 volunteers. While the personal information they collected was probably reliable, the sample constructed by Kinsey's team was not representative of the US adolescent and adult population. Kinsey et al. (1948, 1953) distinguished the following 'sources of sexual outlet': masturbation, nocturnal emissions (or sex dreams), premarital heterosexual petting, premarital coitus (or intercourse), marital coitus, extramarital coitus, intercourse with prostitutes, homosexual responses and contacts, animal contacts. They established that the sexual history of each individual represents a unique combination of these sources of outlet and showed that between individuals there could be wide variation in 'total sexual outlet' (the sum of the orgasms derived from the various sources of sexual outlet). They also identified a number of sociological patterns. For example, compared with less educated people, better educated men and women had first heterosexual intercourse later, but had greater acceptance and experience of masturbation, heterosexual petting, foreplay and orogenital sexual practices. Also, according to these researchers, people with a premarital petting experience were more likely to have a stable marriage. In these two volumes there were curious omissions, the most striking being the almost total neglect of the emotions, notably love. And the interpretations given by the authors were sometimes debatable, such as the presentation of premature ejaculation as almost 'normal' because it happened to be widespread in the United States, or in considering women's erotic imagination to be much less developed than men's on the grounds that it seemed less responsive to sexually explicit images.

It was in large part because of these two volumes that sexology between the 1950s and the end of the 1970s often resembled little more than what has been described as 'orgasmology' (see Ariès and Béjin (eds.) 1982, pp. 183 et seq.). However, they do represent an important stage in the development of the sociology of sexuality.

A large number of quantitative surveys on sexuality were conducted in the 1960s and 1970s, influenced in part by Kinsey's research, but which gave much greater attention to the sexual attitudes, personality, family background, feelings and even fantasies of the people being interviewed. It has also to be noted that this research was increasingly based on representative samples.

These surveys were conducted on adult populations (Sweden, England, France, Finland, United States) but also on adolescents (England, United States, Denmark), young students and workers (West Germany) and homosexuals (United States, West Germany, in particular). They were conducted in a climate of increased politicization of sexuality that recalled the 1920s and often had utopian aspirations. The adoption of alternative sexual lifestyles (exemplified by the 'communes') was advocated by some; others celebrated the revolutionary potential of the (chiefly clitoral) orgasm.

But this climate changed rapidly in the 1980s with the emergence of AIDS. This epidemic, for which no vaccine existed, demonstrated the need for up-to-date empirical data on sexual behavior as a basis for encouraging prevention behaviors by the population (more careful partner selection, and the use of HIV testing and condoms, etc.). In response, large-scale surveys of the general population, often using probability samples, were carried out in the 1990s, in Europe and the United States (see Wellings et al. 1994, Laumann et al. 1994, Kontula and Haavio-Mannila 1995, Béjin 2001) and in the developing world (Cleland and Ferry (eds.) 1995).

The sex surveys of the 1990s cannot be summarized here, but a number of their shared characteristics can be identified. They are based either on interviews or questionnaires (either face-to-face, or self-administered, or by telephone), and have been facilitated by the unquestionably greater willingness in recent decades to talk about sex, as reflected in better participation and response rates and fewer abandons. The theories advanced to interpret the data collected are often, though not always, those which Laumann et al. (1994, pp. 5–24) refer to as 'scripting theory,' 'choice theory' and 'social network theory.' The first postulates that, because of their exposure to an acculturation process, individuals usually follow 'sexual scripts' which prescribe with whom, when, where, how, and why they should have sex. The second places the emphasis on the costs (in time, money, emotional and physical energy, personal reputation, etc.) of sexual behavior. The third seeks to understand why some types of sexual relations occur between people with similar social characteristics whereas others (more unconventional) involve socially more contrasted individuals.

One noteworthy finding from these surveys is that, compared with the developed countries, those of Sub-Saharan Africa are characterized by earlier occurrence of first heterosexual intercourse and a higher level of multiple partnership, but also by a substantially higher

percentage of people who had not had intercourse during the previous month. In other words, in the countries with a 'young' population structure, heterosexual activity tends to begin sooner but occurs less frequently and extends over a shorter period.

5. *Conclusion: Future Directions*

To simplify, it can be said that in the nineteenth century the social sciences (including sexology) focused primarily on the forms of sexuality considered to be 'deviant' or 'perverse.' In addition, they gave priority to an exploration of behavior before beginning to study the psychological aspects (personality, sexual desires and fantasies).

The same process occurred in the twentieth century, but on a broader scale, taking as subject the general population and thus an 'average' sexuality. Initially, between the 1920s and the end of the 1960s, the emphasis was on sexual practices (in particular, 'sexual technique,' and the orgasm). In a second period, however, especially since the start of the 1970s, attention has focused increasingly on sexual desire and fantasies. The fact, for example, that Viagra (the erection-enhancing drug first marketed in 1998) only works for men who feel attracted to their partners, illustrates the need for an understanding of the interior aspects of sexuality, in particular of the psychological blockages, desires and fantasies. This suggests that one trend in the future will be a growth of research on sexual fantasies and the complexities of sexual orientation and identity, and into the effects of pornography, cybersex and sexual addictions.

A second probable trend in future research is the development of the comparative study of 'national' sexualities as revealed in the sex surveys of the 1990s. The data on sexuality that has been assembled needs to be subjected to analysis and interpretation. A comparative analysis of national sex surveys offers an excellent means of identifying the influence of culture on sexual attitudes and behavior as well as on desires and fantasies. It should be possible, for example, to compare the respective influence of cultures that are predominantly hedonistic or ascetic in orientation. Other factors to be assessed include religious beliefs and practices, population aging, democratization, and the relationship between the sexes. This material is potentially the basis for new syntheses in the sociology of sexuality, comparable in scope to the great sociosexological syntheses produced in the first thirty years or so of the twentieth century.

A third trend in future research will be a continuing exploration of the themes developed since the 1970s whose common point is their focus on sexual behavior that is more or less coercive in character: paedophilia, sexual tourism, sexual violence, sexual harassment, and sexual mutilations, notably those inflicted on women.

A fourth line of research for the future follows from the growing numbers of elderly and old people in the population, who increasingly expect to remain sexually active. Their sexuality will surely be the subject of further and more detailed research.

The fifth and final trend for the future concerns a partial renewal of social science research on sexuality from the recent developments in the ethology of sexuality. More generally, indeed, interdisciplinary perspectives can be expected to inform and enrich all areas of social science research in the field of sexual behavior.

Sexual Harassment: Legal Perspectives

After a remarkably swift development in law and popular consciousness, sexual harassment remains the subject of controversy and debate. The concept of sexual harassment is largely an American invention. Like many other concepts that have mobilized social action in the United States, this one emerged in the context of law reform. In the 1970s, US feminists succeeded in establishing sexual harassment as a form of sex discrimination prohibited by Title VII of the Civil Rights Act of 1964 (the major federal statute prohibiting discrimination in employment). Since then, the concept has taken hold in broader arenas such as organizational practice, social science research, media coverage, and everyday thought. Although Title VII remains the primary legal weapon against sexual harassment in the US, traditional anti-discrimination law squares uneasily with the overtly sexual definition of harassment that emanated from 1970s feminist activism and ideas. Just at the time when this narrow sexual definition of harassment has come under criticism in the US, however, that same definition has begun to spread to other nations—inviting inquiry around the globe. Today, sexual harassment's conceptual boundaries are being rethought in the law, in the wider culture, and in feminist thought.

1. *Definitions and Origins*

In the United States, harassment is predominantly defined in terms of unwanted sexual advances. In the eyes of the public and the law, the quintessential case of harassment involves a powerful male supervisor who makes sexual advances toward a female subordinate. Harassment is an abuse of sexuality; it connotes men using their workplace power to satisfy their sexual needs.

This sexual model of harassment was forged in early Title VII law. Some of the earliest cases were brought by women who had been fired for refusing their bosses' sexual advances. Lower courts at first rejected these claims, reasoning that the women had been fired because of their refusal to have affairs with their supervisors and not 'because of [their] sex' within the meaning of the law. The appellate courts reversed; they held employers responsible for the bosses' conducts as a form of sex discrimination now called quid pro quo harassment.

The results were a step forward: It was crucial for the courts to acknowledge that sexual advances can be used as a tool of sex discrimination. But the reasoning spelled trouble, because the courts' logic equated the two. The courts said the harassment was based on sex under Title VII because the advances were driven by a sexual attraction that the male supervisor felt for a woman but would not have felt for a man. By locating the sex bias in the sexual attraction presumed to underline the supervisor's advances, these decisions singled out (hetero) sexual desire as the *sine qua non* of harassment. Had the supervisor demoted the plaintiff or denigrated her intelligence, the court would have had far more difficulty concluding that the conduct was a form of sexism prescribed by law.

Even at the time, there were broader frameworks for understanding women's experiences as sex harassment. Carroll Brodsky's book, *The Harassed Worker* (1976), for example, articulated a comprehensive non-sexual definition of harassment as 'treatment that persistently provokes, pressures, frightens, intimidates, or otherwise discomforts another person.' Rather than a form of sexual exploitation, Brodsky saw harassment as 'a mechanism for achieving exclusion and protection of privilege in situations where there are no formal mechanisms available.' (Brodsky 1976, p. 4). In his usage, 'sexual harassment' referred not simply to sexual advances, but to all uses of sexuality as a way of tormenting those who felt 'discomfort about discussing sex or relating sexually.' (Brodsky 1976, p. 28). A few Title VII decisions had already recognized sexual taunting and ridicule as a mechanism for male supervisors and co-workers to drive women away from higher-paying jobs and fields reserved for men. Indeed, the very concept of harassment as a form of discrimination in the terms and conditions of employment was first invented in race discrimination cases, where judges had discovered that employers could achieve racial segregation not only through formal employment decisions such as hiring and firing, but also through informal, everyday interactions that create an atmosphere of racial inferiority in which it is more difficult for people of color to work.

Analogizing to the race cases, the courts might have likened bosses' demands for sexual favors from women to other discriminatory supervisory demands—such as requiring black women to perform heavy cleaning that is not part of their job description in order to keep them in their place, or requiring women to wear gendered forms of dress or to perform stereotypically feminine duties not considered part of the job when men do it. Or judges might have located the sexism in a male boss's exercise of the paternalist prerogative to punish as an employee someone, who dares to step out of her place, as a woman by refusing the boss sexual favors; sociological analysis reveals that male bosses have penalized female employees for other non-sexual infractions that represent gender insubordination rather than job incompetence (Crull 1987).

But the courts relied instead on a sexualized framework put forward by some feminist lawyers and activists. Toward the mid-1970s, US cultural-radical feminists moved toward a simplistic view of heterosexuality as the lynchpin of women's oppression (Willis 1992, p. 144). Given this ideological commitment, it is not surprising that these early feminists conceived of women's workplace harassment as a

form of unwanted sexual advances analogous to rape. Lin Farley's book, *Sexual Shakedown*, defined harassment as 'staring at, commenting upon, or touching a woman's body; requests for acquiescence in sexual behavior; repeated nonreciprocated propositions for dates; demands for sexual intercourse; and rape.' (Farley 1978, p. 15). A few years later, Catharine MacKinnon argued that harassment is discriminatory precisely because it is sexual in nature—and because heterosexual sexual relations are the primary mechanism through which male dominance and female subordination are maintained (MacKinnon 1979).

In the US, less than a decade later, the consolidation of this narrow view of women's workplace harassment was largely complete. The 1980 Equal Employment Opportunity Commission (EEOC) guidelines defined sex harassment as 'unwelcome sexual advances, requests for sexual favors, and other verbal or physical conduct of a sexual nature'—a definition courts have read to require overtly sexual conduct for purposes of proving both *quid pro quo* harassment (which involves conditioning employment opportunities on submission to sexual advances) and hostile work environment harassment (which involves creating an intimidating or hostile work environment based on sex). Indeed, in hostile environment cases, the lower courts have tended to exonerate even serious sexist misconduct if it does not resemble a sexual advance (Schultz 1998).

Media coverage has infused this view of harassment into popular culture. The 1991 Anita Hill-Clarence Thomas controversy helped solidify the view of harassment as sexual predation. Hill, at the time a novice lawyer in her mid-twenties, claimed that Thomas, her then-supervisor at the Department of Education and later Chair of the EEOC, had pressured her to go out with him and regaled her with lewd accounts of pornographic films and his own sexual prowess (Mayer and Abramson 1994). Soon afterward, the news media broke the story of Tailhook, in which drunken Navy pilots sexually assaulted scores of women at a raucous convention (Lancaster 1991). Later in the 1990s, public attention turned to the harassment lawsuit of a former Arkansas state employee, Paula Jones, who alleged that President Bill Clinton had made crude sexual advances towards her while he was the Governor of Arkansas.

Organizations seeking to avoid legal liability for sexual harassment have also defined it in terms of overtly sexual conduct. Many employers have adopted sexual harassment policies, but Schultz's research reveals that these policies are rarely if ever integrated into broader anti-discrimination programs. Indeed, some employers' efforts to avert sexual harassment may undermine their own efforts to integrate women fully into the workplace, as firms adopt segregationist strategies designed to limit sexual contact between men and women (such as prohibiting men and women from traveling together). Such policies reinforce perceptions of women as sexual objects and deprive them of the equal training and opportunity the law was meant to guarantee.

2. *Current Challenges*

In recent years, the prevailing understanding of sexual harassment has come under challenge in the US. Civil libertarians have voiced concern that imposing vicarious liability on employers for their employees' sexual harassment gives employers a powerful incentive to curb workers' freedom of speech and sexual expression in the workplace. Critics say harassment law incorporates vague standards—including the requirement that the hostile work environment harassment be 'sufficiently severe and pervasive to alter the conditions of the victim's employment and create an abusive working environment'—(*Meritor Savings Bank vs. Vinson*, p. 67)—that permit employers to adopt broad policies that chill sexual speech (Strossen 1995, Volokh 1992). Many employers may not limit their policies to 'unwelcome' conduct, because they will want to avoid costly, contentious inquiries into whether particular sexual interactions were unwelcome. Because few employers have a stake in protecting their employees' freedom of expression (and only government employers have any First Amendment obligation to do so), many firms may simply adopt broad, across-the-board proscriptions on sexual activity and talk on the part of employees (Rosen 1998, Hager 1998). Although there has been no systematic research in this area, some alarming incidents have been reported. (Schuldt 1997), (Grimsley 1996, p. A1).

Such concerns have resonated with a new generation of feminist legal scholars, who have begun to worry about the extent to which equating workplace sexual interaction with sex discrimination replicates neo-Victorian stereotypes of women's sexual sensibilities (Abrams 1998, Franke 1997, Strossen 1995). While civil libertarians have urged repealing or restricting the range of employer liability under Title VII—often, proposing instead to hold individual harassers responsible for their own sexual misconduct under common law (Hager 1998, Rosen 1998), younger feminist scholars have focused on reforming sex harassment law to bring it in line with traditional anti-discrimination goals. Kathryn Abrams defines harassment as sex discrimination not because (hetero) sexual relations inherently subordinate women, but because she believes male workers use sexual advances to preserve masculine control and norms in the workplace; she would limit liability to cases in which the harasser manifestly disregards the victim's objections or ambivalence toward his advances (Abrams 1998). Katherine Franke argues that harassment is a 'technology of sexism' through which men police the boundaries of gender; she would focus on whether men have used sexuality to press women or other men

into conventional 'feminine' or 'masculine' roles (Franke 1997). Both Abrams and Franke attempt to break with the old equation of sexuality and sexism. Yet neither makes a decisive break, for each retains the idea that (hetero) sexual objectification is the key producer of gender (for Abrams, of gender subordination in the workplace, for Franke, of gender performance throughout social life).

Bolder analyses seek to jettison altogether sexual harassment's conceptual underpinnings in sexuality. Janet Halley's queer theory-based critique emphasizes both the cultural/psychic dangers of outlawing the expression of sexuality and the heavier-handed repression such an approach places on sexual minorities. To the extent that harassment law focuses on whether sexual conduct is offensive to a reasonable person, judges and juries will rely on their 'common sense' to evaluate the advances—and other actions—of gays, lesbians, bisexuals, and other sexual dissidents as inherently more offensive than those of heterosexuals (Halley 2000). As Kenji Yoshino has observed, the courts have conditioned liability in same-sex sexual harassment cases on the harasser's sexual orientation. Conduct that courts consider an unwanted sexual advance when the harasser is homosexual is deemed innocuous horseplay when the harasser is heterosexual—an approach that sets up a two-tiered system of justice that has nothing to do with the victim's injury (Yoshino 2000). (See *Sexual Orientation and the Law*.)

For related reasons, Schultz has argued that sex harassment law should abandon its emphasis on sexual misconduct and focus on gender-based exclusion from work's privileges. She argues for reconceptualizing harassment as a means of preserving the masculine composition and character of highly-valued types of work and work competence (Schultz 1998). In Schultz's view, the prevailing sexual understanding of harassment is too narrow, because it neglects more common, non-sexual forms of gender-based mistreatment and discrimination that keep women in their place and prevent them from occupying the same heights of pay, prestige, and authority as men. Indeed, Schultz contends, the centrality of occupational identity to mainstream manhood leads some men to harass other men they regard as unsuitably masculine for the job. At the same time, sexual model risks repression of workers' sexual talk or interaction—even where they do not threaten gender equality on the job. Schultz's call to move away from a sexuality-based harassment jurisprudence builds on the earlier work of Regina Austin, who recognized in 1988 that most workplace harassment was not 'sexual' in nature and proposed a tort of worker abuse to protect employees from class-based mistreatment at the hands of their bosses (Austin 1988). Although Austin was concerned with structures of class and race, recently a more individual dignitary approach has been revived by Anita Bernstein and by Rosa Ehrenreich, who propose protecting employees' rights to equal respect through anti-discrimination and tort law, respectively (Bernstein, 1997, Ehrenreich 1999). Recognizing harassment as just another form of discriminatory treatment restores Title VII's protections to those who allege discriminatory abuse based on characteristics other than gender or even race, such as religion and disability (Goldsmith 1999).

3. *Future Directions*

In the United States, the sexual model of harassment always rested uneasily alongside traditional employment discrimination law—which is concerned with work, not sexuality. Although the future is far from certain, the US Supreme Court's recent sexual harassment decisions seem poised to restore harassment law to its traditional focus.

The Court's 1998 decisions in *Ellerth vs. Burlington Industries* and *Faragher vs. Boca Raton* held that a company's vicarious liability for a supervisor's harassment turns on whether the harassment involves a 'tangible employment action'—such as hiring, firing, or promotion—not on the content of the misconduct or its characterizations as quid pro quo or hostile environment harassment. In the absence of such a tangible action, companies can avoid liability by proving that they adequately corrected harassment a victim reported (or reasonably should have reported) through acceptable in-house channels. By creating a loophole for companies who investigate harassment through their own procedures, the Court sought to counter any current incentives for managers to ban sexual interactions across the board. By adhering to vicarious liability where harassment involves the same tangible employment decisions as more traditional forms of discriminatory treatment, the Court acknowledged that harassment is simply a form of employment discrimination subject to the usual legal rules (White 1999).

The Court's decision in *Oncale vs. Sundowner Offshore Services* further reconciles sexual harassment with the traditional discrimination approach. In *Oncale*, the Court held that male-on-male harassment is actionable under Title VII, taking pains to emphasize that harassment is not to be equated with conduct that is sexual in content or design. 'We have never held that workplace harassment … is … discrimination because of sex merely because the words used have sexual content or connotations,' said the Court (*Oncale vs. Sundowner Offshore Services*, *Inc*., p. 80). By the same token, 'harassing conduct need not be motivated by sexual desire to support an inference of discrimination on the basis of sex.' (*Oncale vs. Sundowner Offshore Services*, *Inc*., p. 80). 'The critical issue,' stressed the Court, 'is whether members of one sex are exposed to disadvantageous terms or conditions of employment to which members of the other

sex are not exposed, (*Oncale vs. Sundowner Offshore Services, Inc.*, p. 80).

The social sciences are also beginning to look beyond the sexual model, providing evidence of the need to conceptualize sex harassment in broader terms. In the early years, most workers attempted to document the prevalence of harassment, albeit with limited results due to their implicit reliance on a conceptually narrow (yet often vague) notion of harassment specified by lists of sexual behaviors derived from the EEOC guidelines (Welsh 1999). Over time, the research has become more multi-faceted, as a burgeoning scholarship has focused greater attention on defining harassment, theorizing its causes, documenting its consequences, and developing predictors. Yet much research remains wedded to the sexual view. Prominent theories of harassment posit that men's tendency to stereotype women as sexual objects is 'primed' by the presence of sexual materials or behavior to induce a 'sex-role spillover' effect that leads men to sexualize women inappropriately in the workplace (Fiske 1993, Gutek 1992). Predictive models search for characteristics that predispose men to harassment, such as a propensity to sexualize women over whom they have some supervisory authority (Pryor et al. 1995). Further examples abound (see Welsh 1999, Borgida and Fiske 1995). Nonetheless, recent research has opened up a broader horizon. A few studies have included measures of gender-based harassment that is not necessarily sexual in content or design: The results suggest that such harassment is more widespread than overtly sexual forms (Frank et al. 1998, Fitzgerald et al. 1988). Social psychologists have begun to look beyond sexual objectification to explore how other gender-based stereotypes and motives can combine with occupational identities and institutional contexts to produce a variety of forms of workplace harassment and discrimination that are not all motivated by sexual attraction (Fiske and Glick 1995). Even some economists have moved away from the conventional view of harassment as sexual coercion that is unrelated to the internal dynamics of labor markets (Posner 1989) to develop innovative theories to explain how incumbent workers can obtain the power to exclude and disadvantage aspiring entrants (Lindbeck and Snower 1988). These developments align social psychological and economic theories more closely with those of sociologists, who have long emphasized harassment's connection to structural features of organizations such as gross numerical imbalance, standardless selection processes, and the absence of managerial accountability (Reskin 2000, Schultz 1991).

In tension with such efforts to transcend a narrow definition of sex harassment in the United States are developments in some other parts of the globe, where the sexual model championed by early US cultural-radical feminists seems to be gaining headway. According to some commentators, the American understanding of sex harassment has been disseminated abroad so successfully that it now forms the foundation for international debates on sex harassment (Cahill 2000). Following closely on the heels of legal developments in the USA, for example, the European Union took steps to condemn and outlaw workplace sex harassment as a violation of women's dignity, and it defined this concept in terms strikingly similar to the definition promulgated by the US EEOC. Encouraged by EU initiatives, feminists in Europe have drawn on particular features of the US model to promote versions of sex harassment law that resonate with their own traditions. In Austria, Cahill shows, feminists capitalized on desires to signal Austria's compliance with the economic First World's laws to press for a harassment law that adopts both the sexualized substantive definition and the privatized enforcement mechanisms of the US approach. The importation of these features allows critics to reject not only the law but also the very existence of harassment as a non-indigenous, imperialist export (Cahill 2000). In France, as Saguy shows, French feminists won a law that criminalizes the use of 'orders, threats, constraint or serious pressure in the goal of obtaining sexual favors, by someone abusing the authority conferred by his position' (Saguy 2000, p. 19 and note 34). This approach incorporates the American cultural-radical feminist view of harassment as a form of sexual abuse yet simultaneously signals distance from what the French perceive to be US sexual prudishness by highlighting that harassment is an abuse of hierarchical authority—an idea that conforms to conventional French views of hierarchical power as inimical to equality. Neither French feminists nor lawmakers connect harassment to a larger system of workplace gender inequality that relegates women to inferior jobs; the gender segregation of work is accepted as a 'neutral' background condition rather than challenged as the structural context of inequality in which sex harassment flourishes and which it fosters. Friedman's work suggests that even in Germany, where there is a tradition of using law to promote workers' empowerment, transplanting the US model of harassment-as-sexual overtures serve to exacerbate what German feminists have decried as a conservative judicial tendency to define sex harassment as a violation of female sexual honor which requires moral purity (Friedman 2000).

It is perhaps ironic that just as German (and other) feminists are trying to highlight the specificity of sexual harassment, a new generation of US feminists are striving to incorporate sexual harassment into broader frameworks for understanding the dynamics of ingroup/outgroup exclusion among different groups of workers—a project that might well be assisted by expanding the German concept of mobbing as a pervasive pattern of workplace harassment that targets an individual for exclusion and abuse at the hands of coworkers and supervisors' (Friedman 2000,

p. 6). What is needed is a structural analysis of how a variety of different forms of harassment—including sexual advances, gender-based and other forms of taunting, physical threats, verbal denigration, work sabotage, heightened surveillance, and social isolation—can be used by socially dominant groups to code and to claim scarce social resources (such as good jobs and a sense of entitlement to them) to the exclusion of others. In this project, Americans have as much to learn from other countries' experiences as vice versa.

It is cause for optimism that so many scholars, activists and policymakers are struggling toward such a broader—and deeper—understanding of harassment. Inspired by new research, new feminisms, and newer social movements (such as queer theory) that are calling into question the old top-down, male-female sexual model, the law of sex harassment awaits being overhauled to fit the world of the twenty-first century.

Sexual Harassment: Social and Psychological Issues

Sexual harassment is generally defined as unwelcome sexual advances, requests for sexual favors, or other verbal or physical conduct of a sexual nature that is either a condition of work or is severe and pervasive enough to interfere with work performance or to create a hostile, intimidating work environment. It may consist of words, gestures, touching, or the presence of sexual material in the work environment. It typically involves a pattern of behavior over a period of time, rather than a single event. We might think about the former as 'an episode of sexual harassment.' In perhaps 90 percent of the episodes, women are the recipients and men are the initiators, but both sexes can harass and both can be harassed by the same sex or the other sex. If sexual harassment meets certain criteria (e.g., unwelcome, severe, and pervasive), it is illegal in many countries, but not all behavior commonly considered sexual harassment violates the law.

1. A Short History of Research on Sexual Harassment

It is no doubt safe to assume that sexual harassment has been around for a long time, but it has been labeled, studied, and legislated for only about 20 years. In 1978, journalist, Lin Farley wrote *Sexual Shakedown* to bring attention to the phenomenon. In 1979, legal scholar, Catharine MacKinnon wrote an influential book that would provide a legal framework for dealing with sexual harassment in the US. MacKinnon argued that sexual harassment was a form of sex discrimination (i.e., denies women equal opportunity in the workplace) and therefore Title VII of the 1964 Civil Rights Act, which forbids discrimination on the basis of sex (among other social categories), should apply. A year after her book was published, the US Equal Employment Opportunity Commission established guidelines on sexual harassment. Early empirical studies of sexual harassment in the workplace and academia started appearing in print about the same time. By 1982, at least one journal (*Journal of Social Issues*) had produced a whole issue devoted to scholarship on the topic. Today sexual harassment is studied by scholars in many countries who work in many fields, including law, psychology (clinical, forensic, organizational, social), sociology, management and human resources, history, anthropology, communication, and the humanities. Within the social sciences, sexual harassment is studied through quantitative techniques that focus on the measurement of constructs and determination of base rate statistics and qualitative case-study techniques focusing on specific occupations such as wait staff and female coal miners.

2. Measurement of Sexual Harassment

In the early 1980s, researchers frequently used the term 'social-sexual behaviors' to distinguish a set of behaviors that might constitute sexual harassment from a legally defined measure of sexual harassment. These sets typically included behaviors unlikely to be considered sexual harassment either under the law or by a majority of the population. By including a broad range of behaviors, researchers could learn whether people's views of specific behaviors differ over time (or across samples). It would also allow researchers to see if legal and illegal social-sexual behaviors have common antecedents and consequences.

More recently, however, sexual harassment is what researchers say they are measuring. This has caused some confusion because many people seem to interpret statistics on sexual harassment to indicate the percentage of the workforce that would have a strong legal claim of sexual harassment. This is not true. Researchers have not attempted to capture the legal definition of harassment because: (a) the legal definition changes as the law develops, so the legal definition is a moving target; (b) laws vary from country to country; (c) targets may experience negative consequences of sexual harassment without having the harassment rise to meet a legal definition; (d) there is no reason to believe that we can learn about sexual harassment only by measuring it to conform to its legal definition. Some scholars now make explicit the point that a lay definition of sexual harassment does not necessarily imply that a law has been broken.

A global item, say, 'Have you ever been sexually harassed,' is rarely used to measure sexual harassment because some researchers contend that it results in an under-reporting of the phenomenon. Workers seem reluctant to acknowledge that they have been sexually

harassed. In addition, asking respondents if they have been sexually harassed places a great cognitive load on them, as they would have to determine first what constitutes sexual harassment and then determine if they had experienced any behavior that met those criteria. In many studies, a single question asking the respondent if she has been sexually harassed is used as an indicator of acknowledging or labeling sexual harassment rather than an indicator of sexual harassment, *per se*.

Most studies measure sexual harassment by asking respondents if they have experienced any of a list of behaviors that might be considered sexual harassment. These measures are generally (but not always) designed to be suitable for both sexes. In some cases, respondents are asked whether they have experienced a list of behaviors that might be considered sexual harassment, and later in the survey asked which of those behaviors they consider sexual harassment, allowing the researcher to determine which of a broad range of behaviors respondents have experienced that they consider sexual harassment.

Multi-item measures of sexual harassment are also based on a list of behaviors that people may have experienced. The best known of these measures is the Sexual Experiences Questionnaire (SEQ) developed by Louise Fitzgerald and her colleagues. The SEQ has experienced many changes; the number of questions asked, the wording of questions, and the wording of responses have all been modified, and its refinement is ongoing. The number of subscales that emerge from it has also changed over time so it is important to keep in mind that all the studies using the SEQ are not necessarily using the same set of questions, scored the same way, and at this point it cannot be used to assess changes over time or differences across studies.

3. *The Prevalence of Sexual Harassment*

A number of studies have relied on random sample surveys including studies of government workers, the military, specific geographical areas, and specific work organizations. Some of these have obtained quite high response rates, some studies have been conducted in Spanish as well as in English, and a few longitudinal analyses have been conducted.

In measuring prevalence, there is some debate about the timeframe that should be considered. Researchers typically inquire about experiences within the past year, the prior two years, or throughout the person's entire work life, depending on the purpose of the study. While critics have cautioned that retrospective measures will introduce inaccuracy or bias, researchers active in the field are less concerned. It is difficult to know if one is currently being sexually harassed and qualitative studies provide convincing examples of events initially not labeled sexual harassment that came to be so labeled at a later date.

3.1 *The Prevalence of Sexual Harassment of Women*

The random-sample studies together suggest that from about 35 percent to 50 percent of women have been sexually harassed at some point in their working lives, where sexual harassment refers to behavior that most people consider sexual harassment. Estimates are higher among certain groups such as women who work in male-dominated occupations. The most commonly reported social-sexual behaviors are the less severe ones, involving sexist or sexual comments, undue attention or body language. Sexual coercion is, fortunately, much rarer, involving 1–3 percent of many samples of women. In contrast, a study of allegations in cases tried in court showed a much higher incidence of severe behaviors, with 22 percent involving physical assault, 58 percent nonviolent physical contact, and 18 percent violent physical contact.

The incidence of sexual harassment of women appears to be rather stable. Three US Merit Systems Protections Board studies spanning 14 years show that 42–44 percent of women in the federal workforce have experienced one or more of a list of potentially sexually-harassing behaviors within the previous 24 months. In addition, the number of charges filed with the US Equal Employment Opportunity Commission may be leveling off in the range of 15,000–16,000 per year (in a labor force of about 120 million people).

3.2 *The Prevalence of Sexual Harassment of Men*

Men have been included in studies of sexual harassment from the very beginning. In her study of a random sample of working men and women in Los Angeles County, Barbara Gutek found that some time during their working lives, from 9 percent to 35 percent of men (depending on definition of harassment) had experienced some behavior initiated by one or more women that they considered sexual harassment. The US Merit Systems Protection Board studies found that from 14 percent to 19 percent of men in the Federal workforce experienced at least one episode of a sexually harassing experience (initiated by either men or women) within the previous two years. These surveys revealed that about one-fifth of the harassed men were harassed by another man. Data from the 1988 US Department of Defense Survey of Sex Roles in the Active Duty Military revealed that about one-third of the men (but about 1 percent of the women) who experienced at least one of nine types of uninvited, unwanted sexual attention during the previous 12 months, reported that the initiator was the same sex. The harassment of men by other men tends to be of two types: lewd comments that were considered offensive and attempts to enforce male gender role behaviors. Harassment by women is somewhat different, consisting of negative remarks and/or unwanted sexual attention.

The available research on sexual harassment of men, admittedly much less than the research on women, suggests that many of the behaviors women might find offensive are not considered offensive to men when the initiators are women and/or they report few negative consequences. In addition, a disproportionate percentage of men's most distressing experiences of sexual harassment come from other men. Presumably these are especially distressing because the recipient's masculinity and/or sexual orientation are being called into question.

3.3 The Prevalence of Sexual Harassment Among Other Groups

Relatively few studies have either focused on or found consistent differences in the experience of sexual harassment beyond the consistent differential rate of sexual harassment of women vs. men. It may be the case that younger and unmarried women are somewhat more likely targets of sexual harassment than older and married women. Lesbian women may be more likely to be sexually harassed than heterosexual women, or they may simply be more likely to label their experiences sexual harassment. Although several authors have suggested that in the US women of color (Asian, African-American, Hispanic, and American Indian) are more likely to be targets of sexual harassment than Caucasian women, the evidence is far from clear. Several random sample surveys found no clear link between ethnicity and the experience of sexual harassment but qualitative studies suggest that women of color experience sexual harassment frequently. Two kinds of arguments have been advanced for reasons why minority women might experience relatively more sexual harassment. A direct argument relies on stereotyping of minorities. Although the stereotypes of African-American women differ from stereotypes of Chicanas or Asian-American women, in each case the stereotype might place these women at greater risk. An indirect argument relies on concepts of power and marginality. As women of color are less powerful and more marginal by virtue of their ethnicity than white women, they may be more prone to sexual harassment.

4. Explanations for Sexual Harassment

Why sexual harassment exists has been of interest to social scientists since the phenomenon acquired a label. The various explanations can be subsumed into four categories: natural/biological perspectives, organizational perspectives, sociocultural explanations, and individual differences perspectives. These explanations tend to be broad in scope, not easily testable in a laboratory.

4.1 Natural/Biological Explanations

There are two natural/biological perspectives: a hormonal model and an adaptive/evolutionary explanation. While intriguing, neither is supported by available data.

4.2 Organizational Explanations

There are two organizational perspectives: sex-role spillover and organizational power. Sex-role spillover, defined as the carry over into the workplace of gender-based expectations that are irrelevant or inappropriate to work, occurs because gender role is more salient than work role and because under many circumstances, men and women fall back on sex role stereotypes to define how to behave and how to treat those of the other sex. Sex-role spillover tends to occur most often when the gender ratio is heavily skewed in either direction, i.e., when the job is held predominantly either by men or by women. In the first situation (predominantly male), nontraditionally employed women are treated differently than their more numerous male co-workers, are aware of that different treatment, report relatively frequent social-sexual behavior at work, and tend to see sexual harassment as a problem. In the second situation (predominantly female), female workers hold jobs that take on aspects of the female sex-role and where one of those aspects is sex object (e.g., cocktail waitress, some receptionists), women may become targets of unwanted sexual attention, but may attribute the way they are treated to their job, not their gender. Several studies find some support for this perspective.

The earliest writings on sexual harassment were about men abusing the power that comes from their positions in organizations to coerce or intimidate subordinate women. Some subsequent statements on the power perspective are gender neutral, suggesting that although men tend to harass women, in principle if women occupied more positions of power, they might harass men in equal measure. This interpretation of sexual harassment as an abuse of organizational power is contraindicated by research showing that about half or more of harassment comes from peers. In addition, both customers and subordinates are also sources of harassment. Sexual harassment by subordinates has been documented primarily in academic settings where, for example, studies find up to half of female faculty at universities had experienced one or more sexually harassing behaviors by male students.

While power cannot explain all sexual harassment, various kinds of power—formal organizational power and informal power stemming from ability to influence—remain potent explanations for at least some sexual harassment. For example, the fact that sexual harassment by customers is fairly common can be

explained, at least in part, by the emphasis employers place on customer satisfaction and the notion that the 'customer is always right.'

Some researchers focus less on broad theoretical perspectives and more on the types of organizational factors that need to be included in models of sexual harassment. Thus far, contact with the other sex and a unprofessional and/or sexualized work environment have been identified as correlates of sexual harassment.

4.3 Sociocultural Explanations

There are at least two ways of thinking of the broader sociocultural context. One is that behavior at work is merely an extension of male dominance that thrives in the larger society. Overall, there is general agreement in the literature about the characteristics of the sex stratification system and the socialization patterns that maintain it. The exaggeration of these roles can lead to sexual harassment. For example, men can sexually harass women when they are overly exuberant in pursuing sexual self-interest at work, or they feel entitled to treat women as sex-objects, or when they feel superior to women and express their superiority by berating and belittling the female sex.

The second way of thinking of the broader sociocultural context is to study the sociocultural system itself and examine how and why status is assigned. According to this view, sexual harassment is an organizing principle of our system of heterosexuality, rather than the consequence of systematic deviance.

4.4 Individual Difference Explanations

Although the data suggest that most sexual harassers are men, most men (and women) are not sexual harassers. This makes the study of personality characteristics particularly relevant. The search for individual-level characteristics of perpetrators does not negate any of the other explanations, but helps to determine, for example, which men in a male-dominated society or which men in powerful positions in organizations harass women when most men do not.

John Pryor developed a measure of the Likelihood to Sexually Harass (LSH) in men, consisting of 10 vignettes that place the respondent in a position to grant someone a job benefit in exchange for sexual favors. Currently the most widely known individual difference measure used in the study of sexual harassment, the LSH, has been validated in a number of studies. For example, undergraduate men who score relatively high on the LSH demonstrate more sexual behavior in a lab experiment and hold more negative attitudes toward women relative to those who report a lower likelihood to sexually harass.

Sexual harassment may be an attempt to immediately gratify the desire for discrimination, intimidation, or sexual pleasure and therefore those people with low self-control may also be more likely to sexually harass. Some research findings support this gender-neutral explanation.

5. Factors Affecting Judgments of Sexual Harassment

The most widely published area of research on sexual harassment measures people's perceptions about sexual harassment. One set of studies attempts to understand which specific behaviors (e.g., repeated requests for a date, sexual touching, stares or glances, a sexually oriented joke) respondents consider to be sexual harassment. The other set of studies attempts to understand factors that affect the way respondents perceive behavior that might be considered sexual harassment. Typically, respondents are asked to read a vignette in which factors are manipulated and then they are asked to make judgments about the behavior in the vignette. The factors that are manipulated include characteristics of the behavior (e.g., touching vs. comments), characteristics of the situation (e.g., the relationship between the initiator and recipient), and characteristics of the initiator and recipient (e.g., sex, age, attractiveness, occupation). In addition, characteristics of the rater (e.g., sex, age) are typically measured.

5.1 The Effects of Rater Sex on Judgments of Sexual Harassment

Sex is the most frequently studied feature in studies about perceptions of sexual harassment. In all, hundreds of studies have been done. These studies have been reviewed using traditional methods and meta-analyses. The conclusions of these reviews are two: (a) women consistently rate vignettes and specific behaviors more sexually harassing than men and (b) the average difference is small, raising questions about the practical significance of these results. Practical significance is important because in the United States it would appear that these studies have had an indirect influence on the Ninth Circuit's 1991 decision, *Ellison vs. Brady*. In that case, the court adopted a new legal standard in hostile environment cases of sexual harassment, the reasonable woman standard, which replaces the traditional reasonable person standard in that Circuit. Juries are asked to evaluate the events from the perspective of a reasonable woman: taking into account all the facts, would a reasonable woman consider the plaintiff to be sexually harassed? The predominant claim is the new standard would force judges and juries to look at the case from the perspective of the complainant, who is typically a woman. This would presumably make it less difficult for a plaintiff to make a convincing claim of hostile work environment harassment. While some recent research suggests that a reasonable woman standard as currently implemented may not result in different

judgments than the traditional reasonable person standard, the magnitude of the gender gap in perceptions about sexual harassment may not justify a change in standards, regardless of the effect of standard itself.

5.2 *The Effects of Other Rater Characteristics on Judgments of Sexual Harassment*

Although gender is far and away the most widely studied factor in the study of sexual harassment perceptions, other factors have been studied. For example, when the initiator is higher status than the recipient, judges generally respond more positively toward the recipient, more negatively toward the initiator, and perceive more harassment than when the initiator is not a supervisor. In addition, several studies that compare students with workers find that students have a broader, more lenient view of social-sexual behavior relative to samples of workers who are typically somewhat older and have more work experience.

6. *Some Remaining Issues*

While much is known, we lack a complete picture of sexual harassment. Must concern about sexual harassment eliminate any kind of dating flirtation at work? How responsible should employers be for the behavior of their employees? How should targets of harassing behavior respond in order to eliminate harassment without damaging their own career possibilities?

Sexual Orientation and the Law

Sexual orientation refers to any classification based on sexual desire or conduct, such as heterosexuality, same-sex sexuality, or bisexuality. It is a classification that includes all sexual orientations, just as race is a classification that includes all races (White, Black, Asian, etc.) However, just as discussions of race tend to focus on marginalized racial groups (such as people of color), discussions of sexual orientation commonly refer to minority sexual orientations, gay, lesbian, or bisexual. As a result, this article will reflect that focus on gay people. It will, however, also note the growing literature on heterosexuality and transgender people.

1. *Homosexuality and Heterosexuality as Historically Contingent*

The study of the law relating to sexually marginalized people, also known as 'queer legal theory,' evolved in the 1980s and 1990s out of feminist legal theory, postmodern theory, and critical race theory. The most influential work informing queer legal theory is Michel Foucault's *History of Sexuality, Vol. 1* (Foucault 1978), which posited that sexual orientation is socially constructed rather than naturally or divinely ordained. This point has been further developed by Judith Butler's performativity theory of sexual orientation and gender, which posits that identities are performed rather than biologically or divinely ordained (Butler 1990).

1.1 *From Conduct to Status and Back to Conduct*

The social construction of sexual orientation is revealed by the different ways in which society and law have viewed same-sex sexuality. Different terms used

to describe same-sex sexuality reflect these changes. Prior to the late nineteenth century, same-sex sexuality was viewed as sinful conduct, redeemable through repentance. The terms 'homosexual' and 'heterosexual' did not appear in English until 1892, along with the idea that sexual orientation was a status. These terms are products of German and English medical research on same-sex sexuality, which saw same-sex sexuality as a status, gave it a name, contrasted it with the previously unmarked status of heterosexuality, and assigned it social meaning as a constellation of characteristics that a person is (rather than particular sexual acts that one does). The terms 'invert' or 'homosexual' refer to this medicalized understanding of same-sex sexuality as a sickness rather than sinful conduct. Oscar Wilde's 1895 trials and imprisonment for gross indecency are credited with introducing into popular culture the status of the male homosexual as effete, artistic, self-centered, and sybaritic.

A third stage, beginning in the 1940s and 1950s, relied on the scientific research of Alfred Kinsey and Evelyn Hooker to contend that same-sex sexuality was a normal variation from opposite-sex sexuality, rather than a disease (Hooker 1957, Kinsey et al. 1948). The nascent homophile movement adopted the term 'gay' to distance itself from the medical judgment associated with 'homosexual.' A fourth stage, emerging through queer theory in the 1990s, rejected the very notion of sexual orientation status (evil or neutral), pointing out the indeterminate and potentially subordinating qualities associated with status-based notions of identity. This stage dubbed minority sexual orientations 'queer' (reclaiming the epithet), treating this anti-status as an epistemological category. To be queer is to believe that racial, sexual, and sexual orientation subordination is wrong. Queer theory arguably uncouples status from conduct, so that one person can be both queer and actively heterosexual.

1.2 Fluidity Between Sexual Orientation and Gender Identity

Sexual orientation and gender issues overlap, but are also distinct in important ways. Both are associated with gender nonconformity. They differ, however, in their fundamental premises. Conventional approaches to sexual orientation presuppose two sexes, and categorize a woman as lesbian if she is with another woman (homosexual literally meaning same-sex), and heterosexual if she is with a man (heterosexual literally meaning different-sex). Transgender theory, in contrast, posits that there are more than two sexes, and that people exist along a continuum of masculinities and femininities. This reasoning renders gay theory's primary assumption absurd; to speak of a person being gay or heterosexual ceases to make sense when there are many more than the two options of being a woman-with-a-woman or woman-with-a-man.

'Transgender' generally refers to gender norm transgression. Some transgender people, known as transsexuals, undergo medical treatment to change from one sex to another. Other categories of transgender people include transvestites (people who cross-dress but do not undergo medical gender reassignment), and transgendered people (those who do not conform to gender norms for the sex they were assigned at birth, but neither do they undergo medical treatment to reassign their sex).

Some cultures do not draw bright lines to distinguish same-sex sexuality from gender identity issues. In Bolivia, for example, men who engage in same-sex sexuality do so within a cultural understanding that one of the participants, in some sense, is female. Men who engage in same-sex sexuality call themselves *gente de ambiente*, or people of the atmosphere (West and Green 1997). Three subcategories of *gente de ambiente* highlight the overlap between sexual orientation and transgender identity in Bolivian culture. *Travestis*, or transvestites, view themselves as women trapped in men's bodies. *Camuflados*, the camouflaged, see themselves as men, but take the receptive role in intercourse, and often pass as heterosexual in public spaces. The third category, *hombres*, or just men, take the penetrating role in intercourse, and are distinguished from heterosexual men in that they respond to sexual overtures from other men. In Bolivia, and elsewhere, these sexual orientation and gender categories are fluid. A man might sleep with men exclusively, only occasionally, or for money. He might desire to sleep with men, but refrain for fear of social or legal condemnation. The very difficulty in deciding the characteristics of identity categories forms the thesis of much postmodern scholarship that identity generally, and sexual identity in particular, is indeterminate because it varies historically, culturally, and within a particular individual's lifetime.

2. Changing Focus of Sexual Orientation Research

Sexual orientation law is a synergy of gay rights advocacy and theoretical academic writings. Advocates bring cases and support legislation countering anti-gay discrimination. Scholars both craft theories that inform these efforts and evaluate the cases and statutes that become law. Two important areas involve anti-sodomy laws and the ban on same-sex marriage.

2.1 Anti-sodomy Laws

Because the criminalization of same-sex sexuality is the most obvious expression of state condemnation, sexual orientation law began by challenging anti-sodomy laws. In the US case *Bowers* vs. *Hardwick*, 478 US 186 (1986), the US Supreme Court upheld Geor-

gia's statute criminalizing sodomy against a constitutional privacy challenge. The Court issued extraordinarily homophobic declarations, such as the concurring opinion's citation of Blackstone (1859) to describe same-sex sodomy as 'an offense of "deeper malignity" than rape, a heinous act "the very mention of which is a disgrace to human nature."' The gratuitous nastiness inspired both numerous critiques of the decision (Goldstein 1988, Thomas 1992) and challenges to other laws disadvantaging gay people.

One strand of this critique challenges the validity of anti-sodomy statutes, arguing that sodomy is an historically contingent category. For example, early Roman–Dutch law (imported to Colonial South Africa) interpreted sodomy as including a wide range of nonconforming sexual acts, such as anal penetration, bestiality, masturbation, oral penetration, penetration with an inanimate object, interfemoral intercourse, and heterosexual intercourse between a Jew and a Christian (West and Green 1997, p. 6). This insight undermines the logic of sodomy law defenders, who, along with the US Supreme Court in *Bowers* vs. *Hardwick*, rest their defense on 'millennia of moral teaching' (Goldstein 1988). If what counts as reprehensible conduct differs markedly among people, places, and times, theorists reason, then one cannot invoke a uniform condemnation of the conduct.

While many governments have decriminalized same-sex sexuality, the criminal ban remains strong in some places. In 2000 in Malaysia, for example, former deputy Prime Minister Anwar Ibrahim was convicted of sodomy and sentenced to nine years in prison after a 14-month trial. At the opposite extreme, the 1996 South African Constitution explicitly forbade sexual orientation discrimination. The ban on gays in the military, like anti-sodomy laws, excludes gay people from full citizenship. While the ban remains in the US, other countries, such as Israel, allow gay people to serve in the military.

2.2 The Ban on Same-sex Marriage

Although anti-sodomy laws are rarely enforced, their existence impedes other anti-discrimination claims, such as gay people's rights to marry or to serve in the military. Since the 1980s, many countries (i.e., South Africa) and US states (i.e., Georgia) have decriminalized same-sex sexuality. Legal advocacy and scholarship has moved on to contest discrimination in other areas. In *Romer* vs. *Evans*, 517, US 620 (1996), the US Supreme Court invalidated a state constitutional amendment that forbade any state entity from protecting gay, lesbian, or bisexual people from discrimination. Advocates and legal scholars, however, have paid far more attention to marriage litigation. In 2001, the Netherlands became the first country to allow same-sex couples to marry. Other countries such as Denmark, France, Greenland, Hungary, Iceland, Norway and Sweden each recognize some type of partnership, which accords same-sex couples (and sometimes opposite-sex unmarried couples) various benefits accorded to married couples.

Parts of Canada and Spain also recognize same-sex partnerships, and domestic partners enjoy some employment benefits in Argentina, Canada, Israel, New Zealand, and South Africa. Other countries, such as Australia, Austria, Belgium, Brazil, the Czech Republic, Germany, Portugal, Spain, and the UK recognize narrower rights, such as succession rights in private housing and some inheritance rights. Australia, New Zealand, Belgium, Denmark, Finland, Germany, Iceland, The Netherlands, Norway, South Africa, Sweden, and the UK recognize same-sex relationships for immigration purposes. Smaller governmental units, such as cities, counties, and provinces around the world, ban discrimination on the basis of sexual orientation.

In the USA, only one state, Vermont, accords same-sex relationships recognition akin to marriage; the federal government and a majority of the states explicitly refuse to recognize same-sex marriage. The Vermont Supreme Court in *Baker* vs. *Vermont*, 744 A.2d 864 [Vt. 1999] found that banning same-sex marriage (or its equivalent under another name) violated the Common Benefits Clause of the Vermont constitution. That clause provides that 'government is, or ought to be, instituted for the common benefit, protection, and security of the people, nation, or community, and not the particular emolument or advantage of any single person, family, or set of persons, who are only a part of that community.' Following the court's instructions, the Vermont legislature created a structure parallel to marriage for same-sex couples, calling it civil union.

3. Theoretical Approaches to Sexual Orientation Law

The emphasis in current theory and research on sexual orientation law is to deconstruct and reconstruct legal regulations that subordinate gay and transgendered people. This rubric includes various ideological and methodological approaches.

3.1 Ideology

Ideological diversity includes both classical liberal and critical approaches. Liberal approaches suggest that gay people are sufficiently similar to heterosexuals to justify equal legal treatment. This approach suggests that altering legal rules to lift the ban on gay participation in marriage or the military will not fundamentally change these institutions. A critical approach, in contrast, contests essentialized notions of identity, seeing it as socially constructed rather than

reflecting essential commonalties among people who engage in same-sex sexuality. This critical approach often seeks a more comprehensive restructuring of legal regulations than simply adding gay people to existing institutions. Instead, critical approaches propose incorporating sexual orientation analysis into other antisubordination discourses, such as feminism, critical race studies, and class analysis. Critical theorists might further propose alternatives to marriage, such as domestic partnership for all people, contending that only new institutions can alleviate the sex/gender hierarchies inherent in marriage.

3.2 Methodology

Postmodern, empirical, and legal economic approaches have contributed to the literature on sexual orientation law. One empirical approach compiles data about rates of arrest and prosecution for sexual offenses, and points out that consensual same-sex sexual activity is unfairly singled out for criminal penalty (Eskridge 1999). The two major premises of this approach, that like parties should be treated alike, and further that the state should generally refrain from interfering in private consensual activities, together lead to the conclusion that the state statutes criminalizing sodomy should be invalidated.

One postmodern approach closely examines the language and reasoning of a judicial opinion to decode the cultural context of the decision, revealing, for example, the Supreme Court's strategic and biased collapse of status and conduct in *Bowers* vs. *Hardwick*. This approach focuses on how the majority decision in *Hardwick* collapsed the distinction between status and conduct, and ignored the many cross-sex couples who commit sodomy by engaging in acts such as fellatio, cunnilingus, and anal intercourse. The majority in *Hardwick* framed the question as 'whether the Federal Constitution confers a fundamental right upon homosexuals to engage in sodomy' focusing the legal inquiry on both a bad act (sodomy) and a bad status (homosexuality). Under this reasoning:

> [I]f sodomy is bad … then homosexuals and heterosexuals who do it are bad. If homosexuals are bad, we are bad whether we've engaged in sodomy or not. To hold both of these positions with consistency, you have to be willing to say that many, many heterosexuals are bad. *This* the majority Justices never acknowledged … They wanted the badness of each to contaminate the other—while heterosexual personhood remained out of the picture, protected from the taint with which it was logically involved. (Halley 1999, pp. 7–8)

By leaving the categories of sexual orientation status and conduct ambiguous, legal doctrine governing consensual sexuality 'remained always ready to focus on "act" or "status" according to the expediencies of the situation' (Halley 1999, p. 8)

An emerging strand of legal scholarship uses legal economic premises to examine heterosexuality as well as same-sex sexuality. US Court of Appeals Judge Richard Posner's book *Sex and Reason* (1992 posited a bioeconomic theory of sexuality that combined sociobiology with legal economics. Posner's often controversial analysis (describing, for example, the economic efficiency in some contexts of female infanticide and baby selling, which he renames 'parental-right selling') provoked a firestorm of response. Yet recent scholarship has built on Posner's economic approach to posit a bargaining theory of sexuality, suggesting that legal regulation should equalize the bargaining positions between men and women (Hirshman and Larson 1998).

4. Future Directions of Theory and Research

The youth of sexual orientation legal research makes it unpredictable. Four likely future trends emerge. First, future research may well include increased use of empirical methods such as compilations data from court records in criminal or family law cases. Second, queer legal theory's emphasis on post-identity analysis and legal doctrine's focus on identity as a foundational category require that future scholarship address the tensions between deconstructing identity and reconstructing a legal regime that does not discriminate on the basis of sexuality or gender performance. Third, scholars are likely to try to resolve the analytical tension between a binary construction of sex that underlies gay theory and a fluid construction of sex that underlies transgender approaches. Fourth and finally, future scholarship and advocacy may focus on the legal regulation of heterosexuality and bisexuality, further developing the literature on how legal regulation misconstrues identity as fixed or natural. On an ideological level, theoretical research is likely to continue to develop in both liberal (assimilationist) and critical (utopian) strands.

Sexual Orientation: Biological Influences

How humans develop sexual orientations is a question that people have pondered for at least a century. In the later part of the twentieth century, scientists began to articulate sophisticated biological theories of how sexual orientations develop. This article critically surveys contemporary biological theories of the development of sexual orientations. In particular, it examines three recent studies of how sexual orientations develop and their theoretical underpinnings. The focus is on these studies, because not only are they positively cited by almost every scientist trying to develop a biological theory of sexual orientation, but also because they are typical in their assumptions and methodology.

1. *What Is a Sexual Orientation?*

A person's sexual orientation concerns his or her sexual desires and fantasies towards others in virtue of their sex (gender). However, a person's sexual orientation is only one part of a person's sexual interest generally. People have a wide range of sexual tastes. Some are attracted to people of certain ages, people of certain body types, of certain races, of certain hair colors, of certain personality types, of certain professions, as well as to people of a certain sex and a certain sexual orientation. Further, people are not only sexually interested in certain sorts of people, some also have quite specific interests in certain sorts of sexual acts, certain venues for sex, or a certain frequency of having sex. We recognize that people can be sorted into all sorts of groups in virtue of their sexual interests, but most contemporary scientific studies focus only on the sex of the people a person is sexually attracted to as an essential feature about him or her. Doing so may be culturally salient but it is not scientifically justified.

2. *What Makes a Theory a Biological One?*

To say that sexual orientation is biologically based is an ambiguous claim; there are various senses in which it is trivially true that sexual orientation is biological. Everything psychological is biologically based. Humans can have sexual orientations while inanimate objects and one-celled organisms cannot because of our biological/psychological make-up. The same sort of claim is true with respect to having a favorite type of music: humans but not single-celled organisms can have a favorite type of music. Even though a preference for classical music seems a paradigmatic example of a learned trait, such a preference is also biological in that a certain cognitive complexity is required in order to have such a preference. Sexual orientation is at least biologically based in the sense that musical preferences are. The central claim of biological research on sexual orientation makes a much bolder claim. It says a person's sexual orientation is inborn or determined at a very early age and, as a result, a person's sexual orientation is 'wired into' his or her brain. To understand the significance of such a claim, it is useful to contrast three models of the role genes and other biological factors might play in sexual orientation (Byne 1996, Stein 1999, pp. 123–7).

According to the *permissive model*, genes or other biological factors influence neuroanatomical structures on which experience inscribes sexual orientation, but biological factors do not directly or indirectly determine sexual orientation. Something like the permissive model correctly describes the development of musical preferences. Various genetic and biological factors make it possible for our experiences with various kinds of music to shape our musical preferences.

Contrast the permissive model with the *direct model*, according to which genes, hormones, or other biological factors directly influence the brain structures that underlie sexual orientation. According to the

direct model, the neurological structures responsible for the direction of a person's sexual attraction toward men or women develop at a very early age as a result of a person's genes or other biological factors. One version of the direct model sees genes in the q28 region of the X chromosome as coding for a set of proteins that causes the INAH-3 region of the hypothalamus to develop so as to determine a person's sexual orientation (LeVay and Hamer 1994).

The direct and the permissive models can be contrasted with the *indirect model*, according to which genes code for (and/or other biological factors influence) temperamental or personality factors that shape how a person interacts with his or her environment and experiences of it, which, in turn, affects the development of his or her sexual orientation. On this view, the same gene (or set of genes) might predispose to homosexuality in some environments, to heterosexuality in others, and have no effect on sexual orientation in others. An example of such a theory is Daryl Bem's theory of sexual orientation according to which biological factors code for childhood personality types and temperaments (for example, aggressiveness, willingness to engage in physical contact, and so on) (Bem 1996, Peplau et al. 1998). In societies like ours where there are significantly different gender roles typically associated with men and women, these different personality and temperament types get molded into gender roles that, in turn, play a crucial role in the development of sexual orientation. The three biological theories of the development of sexual orientation discussed below accept the direct model. However, what evidence there is for these theories is equally consistent with the indirect model.

3. *Is Sexual Orientation Wired into the Brain?*

In 1991, Simon LeVay published a study of the size of INAH-3, a particular cell group in the hypothalamus (LeVay 1991). Starting from the assumption that there are neurological differences between men and women, LeVay decided to look for *sexual-orientation* differences in some of the areas of the hypothalamus that seem to exhibit sex differentiation. He reasoned as follows: given that most people who are primarily attracted to women are men and most people who are primarily attracted to men are women, in order to discover where sexual orientation is reflected in the brain, we should look in parts of the brain that are structured differently for men and women. This picture is based on seeing gay men as having female-typical characteristics and seeing lesbians as having male-typical characteristics. Seeing gay men and lesbians as gender inverts has a certain cultural salience but its scientific merit has been subject to serious criticism (Stein 1999, pp. 202–5, Byne 1994).

To examine the hypothalamus, LeVay had to study portions of human brain tissue that are accessible only after the person has died. Further, LeVay needed to know the sexual orientations of the people associated with the brain tissue he was studying. LeVay's study was made possible as a result of the AIDS epidemic, which had the result of making available brains from people whose self-reported sexual histories are to some extent part of their medical records. LeVay examined 41 brains: 19 of them from men LeVay presumed to be gay because they had died of complications due to AIDS and their medical records suggested that they had been exposed to HIV (the virus that causes AIDS) through sexual activity with other men; six of them from men of undetermined sexual orientation who also died of AIDS and who LeVay presumed were heterosexual; 10 of them from men of undetermined sexual orientation who died of causes other than AIDS and who were also presumed to be heterosexual; and six of them from women all of whom were presumed to be heterosexual, one whom died of AIDS and five who died from other causes. LeVay found that, on average, the INAH-3 of the presumed gay men were significantly smaller than those of the presumed heterosexual men and about the same size as those of the women. From this, he inferred that gay men's INAH-3 are in a sense 'feminized.' Although LeVay rather cautiously concluded that his 'results do not allow one to decide if the size of INAH-3 in an individual is the cause or consequence of that individual's sexual orientation or if the size of INAH-3 and sexual orientation co-vary under the influence of some third unidentified variable,' he also said that his study illustrates that 'sexual orientation in humans is amenable to study at the biological level' (LeVay 1991, p. 1036). In media interviews after the publication of his study he made even stronger claims; he said, for example, that the study 'opens the door to find the answer' to the question of 'what makes people gay or straight' (Gelman 1992).

4. *Is Sexual Orientation Inherited?*

Various studies suggest that sexual orientation runs in families (e.g., Pillard and Weinrich 1986). Such studies show that a same-sex sibling of a homosexual is more likely to be a homosexual than a same-sex sibling of a heterosexual is to be a homosexual; more simply, for example, the brother of a gay man is more likely to be gay than the brother of a straight man. These studies do not establish that sexual orientation is genetic because most siblings, in addition to sharing a significant percentage of their genes, share many environmental variables, that is, they are raised in the same house, are fed the same meals, attend the same schools and have many of the same adult role models. For these reasons, disentangling inherited and environmental influences requires more sophisticated studies.

Heritability studies done by Michael Bailey and Richard Pillard assessed sexual orientation in identical

twins, fraternal twins, nontwin biological siblings, and similarly-aged unrelated adopted siblings (Bailey and Pillard 1991, Bailey et al. 1993). If sexual orientation is genetic, then, first, all identical twins should have the same sexual orientation and, second, the rate of homosexuality among the adopted siblings should be equal to the rate of homosexuality in the general population. If, on the other hand, identical twins are as likely to have the same sexual orientation as adopted siblings, this suggests that genetic factors make very little contribution to sexual orientation.

In both twin studies, subjects were recruited through ads placed in gay publications that asked for homosexual or bisexual volunteers with twin or adoptive siblings. Volunteers were encouraged to reply to the ad 'regardless of the sexual orientation' of their siblings. In both of these studies, the percentage of identical twins who are both homosexual is substantially higher than the percentage with respect to fraternal twins. For example, 48 percent of the identical twins of lesbians were also lesbians, 16 percent of the fraternal twin sisters were lesbians, 14 percent of the nontwin biological sisters were lesbians, as were 6 percent of adoptive sisters. These results show that sexual orientation is at least partly not the result of genetic factors. However, the higher concordance rate is consistent with a genetic effect because identical twins share all of their genes while fraternal twins, on average, share only half of their genes. Also consistent with a genetic effect is the result that the concordance rates for both types of twins are higher than the concordance rates for adopted siblings.

5. *Is Sexual Orientation Genetic?*

Building on heritability studies, Dean Hamer and his collaborators obtained DNA samples from gay brothers in families in which homosexuality seemed surprisingly common. These samples were analyzed using *linkage analysis*, a technique for narrowing the location of a gene for some trait, to see if there was any particular portion of the X chromosome that was identical in the pairs of brothers at an unexpectedly high frequency (Hamer et al. 1993). Hamer found that a higher than expected percentage of the pairs of gay brothers had the same genetic sequences in a particular portion of the q28 region of the X chromosome (82 percent rather than the expected 50 percent). In other words, he found that gay brothers are much more likely to share the same genetic sequence in this particular region than they are to share the same genetic sequence in any other region of the X chromosome. Hamer's study suggests that the q28 region is the particular place where sexual orientation differences are inscribed. This study does *not*, contrary to popular belief, claim to identify any *particular* genetic sequence associated with homosexuality. At best, it has found that many of the pairs of homosexual brothers had the same genetic sequences in this portion of the X chromosome. When Hamer is at his most precise, he says that his study shows that 'at least one subtype of male sexual orientation is genetically influenced' (Hamer et al. 1993, p. 321). In other contexts, Hamer is less careful. For example, in his book, *Science of Desire*, he talks of 'gay genes,' going so far as to use this term in the book's subtitle (Hamer and Copeland 1994).

6. *Problems with These (and Other) Studies*

6.1 *Lack of Confirmation*

Independent confirmation is the earmark of the scientific method. LeVay's results have not been independently confirmed (Byne 1996) and Hamer's study has been recently disconfirmed (Rice et al. 1999). Although various research teams have confirmed the twin study results, a recent and more sophisticated study by Bailey undermines the methodology of early twin studies (Bailey et al. in press). Bailey systematically recruited subjects from a registry of identical and fraternal twins in Australia. In women, the percentage of identical twins of bisexuals and homosexuals who are also either bisexual or homosexual was between 24 and 30 percent (depending on how the boundaries of these groups are drawn), while the percentage of same-sex fraternal twins of bisexual and homosexual women was between 10 and 30 percent. Not only is the difference between identical and fraternal twins significantly smaller than in previous studies but the percentages for identical twins with the same sexual orientations are dramatically lower. Although these results can be read as consistent with the direct model, the evidence is much weaker than earlier heritability studies suggested.

6.2 *Problems with the Subject Pool*

This Australian study shows that the results of earlier twin and family studies (Bailey and Pillard 1991, Bailey et al. 1993, Hamer et al. 1993), which recruited subjects through HIV clinics, lesbian and/or gay organizations, newspapers, and other nonsystematic methods, must have been inflated by sampling bias. In particular, it suggests that gay men and lesbians with identical twins of the same sexual orientation are more likely to participate in such studies. If an experiment makes use of a subject pool that is in some way biased, then this gives rise to doubts about the conclusions based on it. LeVay's subject pool is also biased. In particular, the homosexual population in his study is made up exclusively of men who died from complications due to AIDS and who told hospital staff that they had engaged in same-sex sexual activities.

6.3 Methods of Classification

A related problem with such studies concerns the determination of subjects' sexual orientations. Conclusions based on studies that inaccurately assign sexual orientations to subjects are weak. LeVay assumed, on the basis of no particular evidence, that all the women in his study were heterosexual and that all the men in his studies whose hospital records did not indicate same-sex sexual activity were heterosexual. Other studies that rely on a family member to report a person's sexual orientation may be similarly problematic. Further, by assuming that there are two sexual orientations—gay and straight—and that people can be easily and reliably classified as one or the other on the basis of their behavior or their self-report, scientific research accepts, without strong justification, that our cultural presumptions about human sexual desires are scientifically valid (Stein 1999, pp. 201–13).

6.4 Undefended Assumptions

Generally, most biological research on sexual orientation accepts without argument a quite particular picture of sexual orientation. For example, many studies in the emerging research program unquestioningly accept the inversion assumption, according to which lesbians and gay men are seen as gender inverts and many studies assume the direct relevance of animal models of sexual behavior to human sexual orientation (Stein 1999, pp. 164–79). More crucially, such studies typically accept that a person's sexual orientation is a deep scientific property about her and that sexual orientation is a 'window into a person's soul.' This view of the centrality of sexual orientation to human nature is neither culturally universal nor scientifically established (Stein 1990, Stein 1999, pp. 93–116).

7. Conclusion

Although there is some evidence that is consistent with biological factors playing an indirect role in the development of sexual orientations, there is no convincing evidence that biological factors are a direct cause of sexual orientation. How human sexual desires develop is an interesting research question, but we are probably rather far from answering it.

Sexual Orientation: Historical and Social Construction

Sexual orientation is a much used but fundamentally ambiguous concept. It came into use in discussions of sexuality in the 1970s largely as a synonym for homosexual desire and object choice, less frequently for heterosexual patterns. 'Sexual orientation' suggests an essential sexual nature. The task of historical or social constructionist approaches is to suggest that this belief is what itself needs investigation. Constructionist approaches seek to do two broad things: to understand the emergence of sexual categorizations (such as 'the homosexual' or 'the heterosexual' in western cultures since the nineteenth century) within their specific historical and cultural contexts; and to interpret the sexual meanings, both subjective and social, which allow people to identify with, or reject,

these categorizations. It is, thus, largely preoccupied, not with what causes individual desires or orientations, but with how specific definitions develop within their historic contexts, and the effects these definitions have on individual self-identifications and collective meanings.

1. *The Rise of Constructionist Approaches to Sexuality*

The classical starting point for social constructionist approaches is widely seen as an essay on *The Homosexual Role* by the British sociologist, Mary McIntosh (1968). Its influence can be traced in a range of historical studies from the mid-1970s (Weeks 1977, Greenberg 1988), and it has been anthologized frequently (e.g., Stein 1992). What is important about the work is that it asks what was at the time a new question: not, as had been traditional in the sexological tradition from the late nineteenth century, what are the causes of homosexuality, but rather, why are we so concerned with seeing homosexuality as a condition that has causes? And in tackling that new question, McIntosh proposed an approach that opened up a new research agenda through seeing homosexuals 'as a social category, rather than a medical or psychiatric one.' Only in this way, she suggests, can the right questions be asked, and new answers proposed. Using Kinsey (Kinsey et al. 1948), McIntosh makes a critical distinction between homosexual behavior and 'the homosexual role.' Homosexual behavior is widespread; but distinctive roles have developed only in some cultures, and do not necessarily encompass all forms of homosexual activity. The creation of a specialized, despised, and punished role or category of homosexual, such as that which developed in Britain from the early eighteenth century, was designed to keep the bulk of society pure in rather the same way that the similar treatment of some kinds of criminal keeps the rest of society law-abiding. McIntosh drew on a variety of intellectual sources, from structural functionalism to dramaturgical approaches, but clearly central to her argument was a form of labeling theory. The creation of the homosexual role was a form of social control designed to minoritize the experience, and protect and sustain social order and traditional sexual patterns.

If McIntosh put on the agenda the process of social categorization, another related but distinctive approach that shaped social constructionism came from the work of Gagnon and Simon, summarized in their book *Sexual Conduct: The Social Sources of Human Sexuality* (1974). Drawing again on the work of Kinsey and symbolic interactionist traditions, they argued that, contrary to the teachings of sexology, sexuality, far from being the essence of 'the natural,' was subject to sociocultural shaping to an extraordinary degree. The importance culture attributes to sexuality may, therefore, they speculated, not be a result of its intrinsic significance: society may have had a need to invent its importance and power at some point in history. Sexual activities of all kinds, they suggested, were not the results of an inherent drive but of complex psychosocial processes of development, and it is only because they are embedded in social scripts that the physical acts themselves become important. These insights suggested the possibility of exploring the complex processes by which individuals acquired subjective meanings in interaction with significant others, and the effects of 'sexual stigma' on these developmental processes (Plummer 1975).

By the mid-1970s, it is possible to detect the clear emergence of a distinctive sociological account, with two related concerns. One focused on the social categorization of sexuality, asking questions about what historical factors shaped sexual differences which appeared as natural but were in fact cultural. The other was concerned primarily with methods of understanding the shaping of subjective meanings through sexual scripting, which allowed a better understanding of the balance between individual and collective sexual meanings.

A third theoretical element now came into play: that represented by the work of Foucault (1976/1979). Foucault's essay is often seen, misleadingly, as the starting point of constructionist approaches, but there can be no doubt of the subsequent impact of what was planned as a brief prolegomena to a multivolumed study. Like Gagnon and Simon, Foucault appeared to be arguing that 'sexuality' was a 'historical invention.' Like McIntosh, and others who had been influenced by her, he saw the emergence of the concept of a distinctive homosexual personage as a historical process, with the late nineteenth century as the key moment. The process of medicalization, in particular, was seen as a vital explanatory factor. Like McIntosh, he suggested that psychologists and psychiatrists have not been objective scientists of desire, as the sexological tradition proclaimed, but on the contrary 'diagnostic agents in the process of social labeling' (McIntosh 1968). But at the same time, his suggestion that people do not react passively to social categorization—'where there is power, there is resistance'—left open the question of how individuals react to social definitions, how, in a word that now became central to the debate, *identities* are formed in the intersection of social and subjective meanings.

2. *Sexual Behavior, Sexual Categories, and Sexual Identities*

The most crucial distinction for social constructionism is between sexual behavior, categories, and identities. Kinsey et al (1948) had shown that there was no

necessary connection at all between what people did sexually and how they identified themselves. If, in a much disputed figure, 37 per cent of the male population had had some sort of sexual contact with other men to the point of orgasm, yet a much smaller percentage claimed to be exclusively homosexual, identity had to be explained by something other than sexual proclivity or practice. Yet at the same time, by the 1970s, many self-proclaimed homosexuals were 'coming out,' in the wake of the new lesbian and gay movement. Many saw in the historicization of the homosexual category a way of explaining the stigma that homosexuality carried. What was made in history could be changed in history. Others, however, believed clearly that homosexuality was intrinsic to their sense of self and social identity, essential to their nature. This was at the heart of the so-called social constructionist–essentialist controversy in the 1970s and 1980s (Stein 1992). For many, a critique of essentialism could also be conceived of as an attack on the very idea of a homosexual identity, a fundamental challenge to the hard won gains of the lesbian and gay movement, and the claim to recognition of homosexuals as a legitimate minority group. This was the source of the appeal of subsequent theories of a 'gay gene' or 'gay brain,' which suggested that sexual orientation was wired into the human individual.

It is important to make several clear points in response to these debates, where social scientific debates became a marker of social movement differences. First, the distinction between behavior, categories, and identities need not necessarily require the ignoring of questions of causation, it merely suspends them as irrelevant to the question of the social organization of sexuality. Foucault himself stated that: 'On this question I have absolutely nothing to say' (cited in Halperin 1995). The really important issue is not whether there is a biological or psychological propensity that distinguishes those who are sexually attracted to people of the same gender from those who are not. More fundamental are the meanings these propensities acquire, however, or why ever they occur, the social categorizations that attempt to demarcate the boundaries of meanings, and their effect on collective attitudes and individual sense of self. Social categorizations have effects in the real world, whether or not they are direct reflections of inherent qualities and drives.

The second point to be made is that the value of the argument about the relevance of theories of a 'homosexual role' does not depend ultimately on the validity of the variants of role theory (cf. Whitam and Mathy 1986; Stein 1992). The use of the word 'role' was seen by McIntosh (1968) as a form of shorthand, referring not only to a cultural conception or a set of ideas but also to a complex of institutional arrangements which depended on and reinforced these ideas. Its real importance as a concept is that it defined an issue that required exploration. Terms such as constructionism and roles are in the end no more than heuristic devices to identify and understand a problem in studying sexuality in general and homosexuality in particular. It is transparently obvious that the forms of behavior, identity, institutional arrangements, regulation, beliefs, ideologies, even the various definitions of the 'sexual,' vary enormously through time and across cultures and subcultures. A major objective of historical and social constructionist studies of the erotic has been to problematize the taken for granted, to denaturalize sexuality in order to understand its human dimensions and the coils of power in which it is entwined, how it is shaped in and by historical forces and events. The historicization of the idea of the homosexual condition is an excellent pioneering example of this.

The third point that requires underlining is that, regardless of evidence for the contingency of sexual identities, this should not imply that personal sexual identities, once acquired, can readily be sloughed off. The fact that categories and social identities are shaped in history does not in any way undermine the fact that they are fully lived as real. The complex relationship between societal categorization and the formation of subjectivities and sexual identities has in fact been the key focus of writing about homosexuality since the mid-1970s. On the one hand, there is a need to understand the classifying and categorizing processes which have shaped our concepts of homosexuality—the law, medicine, religion, patterns of stigmatization, formal and informal patterns of social regulation. On the other, it is necessary to understand the level of individual and collective reception of, and battle with, these classifications and categorizations. The best historical work has attempted to hold these two levels together, avoiding both sociological determinism (you are what society dictates) or extreme voluntarism (you can be anything you want): neither is true (see discussion in Vance 1989).

Some of the most interesting work has attempted to explore the subcultures, networks, urban spaces, or even rural idylls that provided the space, the conditions of possibility, for the emergence of distinctive homosexual identities. McIntosh's suggestion that the late seventeenth century saw the emergence of a subcultural context for a distinctive homosexual role in England has been enormously influential. Her rediscovery of the London mollies' clubs has been the starting point of numerous historical excavations (e.g., Trumbach 1977; Bray 1982). There is now plentiful work which attempts to show that subcultures and identities existed before the late seventeenth century, for example, in the early Christian world (Boswell 1980), or in other parts of Europe (see essays in Herdt 1994), just as there have been scholars who have argued that we cannot really talk about homosexual identities until the late nineteenth, or even mid-twentieth centuries (see essays in Plummer 1981). There is a real historical debate. As a result, it would

now seem remarkable to discuss sexual identities (and their complex relationship to social categorizations) without a sense of their historical and social context. Sexual identities are made in history, not in nature.

3. Heterosexuality and Homosexuality

Identities are not, however, created in isolation from other social phenomena. In particular, a history of homosexual identities cannot possibly be a history of a single homogeneous entity, because the very notion of homosexuality is dependent, at the very least, on the existence of a concept of heterosexuality, which in turn presupposes a binary notion of gender. Only if there is a sharply demarcated difference between men and women does it become meaningful to distinguish same sex from other sex relationships. Social constructionism, Vance (1989) noted, had paid little attention to the construction of heterosexuality. But without a wider sense that 'the heterosexual' was also a social construction, attempts to explain the invention of 'the homosexual' made little sense. One of the early attractions of the first volume of Foucault's *The History of Sexuality* was precisely that it both offered an account of the birth of the modern homosexual, and put that into a broader historical framework: by postulating the invention of sexuality as a category in western thought, and in delineating the shifting relationships between men and women, adults and children, the normal and the perverse, as constituent elements in this process. Foucault himself was criticized for putting insufficient emphasis on the gendered nature of this process, but this was more than compensated for by the developing feminist critique of 'the heterosexual institution,' with its own complex history (MacKinnon 1987; Richardson 1996).

Central to these debates was the perception that sexuality in general is not a domain of easy pluralism, where homosexuality and heterosexuality sit easily side by side. It is structured in dominance, with heterosexuality privileged, and that privilege is essentially male oriented. Homosexuality is constructed as a subordinate formation within the 'heterosexual continuum,' with male and female homosexuality having a different relationship to the dominant forms. In turn, once this is recognized, it becomes both possible and necessary to explore the socially constructed patterns of femininity and masculinity (Connell 1995).

Although the constructionist debates began within the disciplines of sociology and history, later developments, taking forward both theoretical and political (especially feminist) interventions, owed a great deal to postructuralist and deconstructionist literary studies, and to the emergence of 'queer studies.' Whereas history and sociology characteristically have attempted to produce order and pattern out of the chaos of events, the main feature of these approaches is to show the binary conflicts reflected in literary texts. The texts are read as sites of gender and sexual contestation and, therefore, of power and resistance (Sedgwick 1990). Sedgwick's work, and that of the American philosopher, Butler (1990) were in part attempts to move away from the essentialist/constructionist binaries by emphasizing the 'performative' nature of sex and gender. This in turn opened up what might be called the 'queer moment' that radically challenged the relevance of fixed sexual categorizations. For queer theorists, the perverse is the worm at the center of the normal, giving rise to sexual and cultural dissidence and a transgressive ethic, which constantly works to unsettle binarism and to suggest alternatives.

4. Comparative Perspectives

Much of the debate about the homosexual/heterosexual binary divide was based on the perceived Western experience, and was located in some sense of a historical development. Yet from the beginning, comparisons with non-Western sexual patterns were central to constructionist perspectives. Foucault (1976/1979) compared the Western 'science of sex' with the non-Western 'erotic arts.' It was the very fact of different patterns of 'institutionalised homosexuality,' that formed the starting point of McIntosh's essay, where she had identified two key regulating elements: between adults and nonadults (as in the intergenerational sex which denoted the passage from childhood to adulthood in some tribal and premodern societies), and between the genders (as in the case of the native American 'berdache'). For some writers, these patterns are the keys to understanding homosexuality in premodern times. Historians have traced the evolution over time of patterns of homosexual life which have shifted from intergenerational ordering, through categorization around gender and class, to recognizably modern forms of egalitarian relationships (for a historical perspective see Trumbach 1998). So it is not surprising that constructionist approaches have led to an efflorescence of studies of sexuality in general, and homosexuality in particular, in other cultures, tribal, Islamic, southern (Herdt 1994). This comparative framework increasingly has been deployed within contemporary western societies to highlight the difficulty of subsuming behavior within a confining definition of condition or fixed orientation.

5. Beyond Constructionism

Historical and social constructionism has advanced and changed rapidly since the 1970s. The 'category' that early scholars were anxious to deconstruct has become 'categories' which proliferate in contemporary societies. 'Roles,' neat slots into which people could be expected to fit as a response to the bidding of the agents of social control, have become 'performances'

(Butler 1990) or 'necessary fictions' (Weeks 1995), whose contingencies demand exploration. 'Identities,' which once seemed categoric, are now seen as fluid, relational, hybrid: people are not quite today what they were yesterday, or will be tomorrow. Identities have come to be seen as built around personal 'narratives,' stories people tell each other in the various interpretive communities to which they belong (Plummer 1995). Individual identities, it is increasingly recognized, are negotiated in the ever-changing relationship between self and other, within rapidly changing social structures and meanings. Sexual orientation may, or may not, be a product of genetics, psychosocial structuring, or environmental pressures. That issue, which has tortured sexology for over a century, may or may not be resolved at some stage in the future. For the constructionist, however, other questions are central: not what causes the variety of sexual desires, 'preferences' or orientations that have existed in various societies at different times, but how societies shape meanings around sexual diversity, and the effects these have on individual lives.

Sexual Perversions (Paraphilias)

1. Definition

Modern usage tends to favor the word 'paraphilia' rather than 'deviance' or 'perversion.' In this article these latter terms will be used only in their historical context. The word 'paraphilia' means a love of (*philia*) the beyond or irregular (*para*), and is used instead of those words which today have pejorative implications that are not always relevant. The term itself is used to describe people, usually men, with intense sexual urges that are directed towards nonhuman objects, or the suffering or humiliation of oneself or one's partner, or more unacceptably, towards others who are incapable of giving informed consent, such as children, animals, or unwilling adults. People who are paraphiliacs often exhibit three or four different aspects, and clinical psychiatric conditions (personality disorders or depression) may sometimes be present.

Paraphilias include: exhibitionism (the exposure of ones genitals to a stranger, sometimes culminating in masturbation); voyeurism or peeping (the observance of strangers undressing or having sexual intercourse,

without their being aware of the voyeur, who usually masturbates); fetishism (the use of inanimate objects for arousal, usually articles of women's underwear, although if these are used to cross-dress, transvestic fetishism is the diagnosis); frotteurism (the rubbing of the genitals against the buttocks, or the fondling of an unsuspecting woman, usually in a crowded situation, so that detection of the perpetrator is unlikely). Pedophilia refers to men sexually attracted to children, some to girls, some to boys and some to either sex. Some pedophiles are attracted sexually only to children, the exclusive types, but some are attracted to adults as well, the nonexclusive type.

Sexual sadism and sexual masochism (S&M) involve the infliction or reception of pain respectively to necessitate arousal and orgasm. Sadistic fantasies that involve obtaining complete control of the victim are particularly dangerous and may result in death. Some masochistic behaviors that involve self-asphyxiation as part of a masturbatory ritual can result in accidental death. Other paraphilias include the use for sexual purposes of corpses (necrophilia), animals (zoophilia), feces (coprophilia), enemas (klismaphilia) and urine (urophilia).

It is of particular interest that just as masturbation is nowadays excluded from being considered a deviant act, so homosexuality, which figured so largely in this area in earlier times, was removed as a paraphilia in the 1974 edition of the *Diagnostic and Statistical Manual of Mental Disorders*.

2. Greek Mythology

The ancient Greeks often ascribed to their gods extreme forms of sexual behavior. Whether this reflected fears or wishful thinking or actual practices is obviously very difficult to evaluate. Zeus's myriad affairs were often conducted in the form of animals or even inanimate objects, such as a cloud or a shower of gold, and his objects of desire were male or female, as indeed were those of the other gods and heroes. Artemis and Athena both eschewed sex altogether and remained adamantly virginal. The mighty Hercules cross-dressed to be humiliated by Queen Omphale, while Theseus and Achilles both donned women's clothes without apparent later loss of esteem (Licht 1969, Bullough 1976).

3. History

3.1 The Hunter-gatherer Past

In most species sexuality and reproduction are of necessity tied together and overlap, but in modern humans it is the relatively recent separation of sexuality from reproduction that represents a crucial evolutionary phase. Despite huge sociological changes we are genetically still at the stage of hunter-gatherers, who had a shorter life, no menopause and long periods between childbirth due to prolonged breast feeding. Perhaps because of better nutrition, and possibly exposure to electric light (which affects the hypothalamus), girls in the developed countries in the 1990s have their first period at around 13 years of age, and ovulation starts soon afterwards, with pregnancy being a distinct possibility. Usually most women have conceived and had their children by 30–40 years of age, which, assuming many will reach 80 years of age, leaves some 40–50 years of life to enjoy non-reproductive sex. Sex therefore takes on new meanings and fulfils other roles, perhaps as a recreational activity, which allows time for sexual variant behavior (Short 1976).

3.2 Sexuality

Numerous so-called Venus figurines and cave paintings have been found from between 25,000 and 10,000 years ago that depict almost all of the sexual acts with which we are familiar today. What the meanings and significance of these depictions were to the people who created them we can only speculate. Early studies showed that paraphilias were present universally in every culture and throughout every historical period. Often tied up with religious rites, sacred prostitution, and/or phallic cults, public shows of self-immolation, sadism, fetishism, and homosexuality flourished. Iwan Bloch believed that every sensory organ could function as an erotogenous zone, and so form the basis for a so-called perversion. Freud pointed out that the ancients laid stress on the instinct itself, whereas we today are preoccupied with its object. Thus it was considered wrong to be passive, that is, to be penetrated anally by one's slave, but acceptable to penetrate him or her. Today the object, that is, whom a man penetrates, is important.

3.3 Classifications

The enormous variations found in human sexual behavior have always been part of the heritage of humankind, but it was not until the eighteenth century in the West that such activities were labeled and put into categories, so that attempts at a scientific classification could be made. These categories varied from culture to culture and showed a great deal of fluidity, as each culture constructed the behavior in different ways. The essential behaviors remained constant, however, and it was rather how each society considered them, whether they approved or disapproved, that created the particular sexual climate. Classifications thus offer an insight into the current thinking of each particular time.

The Marquis de Sade (1740–1814), while imprisoned in the Bastille, wrote a full description of most perversions and suggested a classification about

100 years before his successors, Krafft-Ebing, Havelock Ellis, and Freud. He wrote many short stories on sexual themes including incest and homosexuality. He also foresaw the women's rights issue, which he treated in a compassionate and modern way, yet this did not preclude his use of women as victims in his writings. His *120 Days of Sodom* is perhaps his main work on perversion, although all his works contain little homilies about sex and morals. As de Sade lived in an age that was both turbulent and brutal, it says something for the humanity of the man that he implored us not to laugh at or sneer at those with deviant impulses, but rather to look upon them as one might a cripple, with pity and understanding. De Sade offers the following classification for sexuality (Gorer 1962):

(a) People with weak or repressed sexual desires—the nondescript majority, he saw as cannon fodder for the next two groups;

(b) Natural perverts (born so);

(c) Libertines—people who imitate group (b), but wilfully rather than innately.

De Sade's admiration was for group (b). The *120 Days of Sodom*, written while Sade was in the Bastille, contains examples of all these, and the range extends from foot fetishism, various types of voyeurism, obsessional rituals and bestiality, to frank sadism and murder. Sade described many sexual acts involved with body fluids, sperm, blood, urine, saliva, and feces.

Jeremy Bentham (1748–1832), the utilitarian philosopher who believed that nature has placed humankind under the governance of two sovereign masters, *pain* and *pleasure*, published his essay on pederasty in 1785 in which he argued cogently for the decriminalization of sodomy (then punishable by hanging), and other sexual acts. He challenged the notion current at the time that such behaviors weaken men, threaten marriage, and diminish the population. He went on to discuss these punishments as an irrational antipathy to pleasure, and he highlighted the dangers that prohibitions incur, i.e., possible blackmail and false accusations (Crompton 1978).

In the nineteenth century, Darwin in his theory of evolution was able to explain the presence of gill slits and the tail present in the early human embryo as well as the appendix, as evidence of our evolutionary past. Ernst Haeckel, Darwin's forceful adherent, developed the concept that ontogeny recapitulated phylogeny (see *Evolution, Natural and Social: Philosophical Aspects*). It was argued from this that if elements from our past physical evolution were so preserved, why should this not apply to our psychological history? Thus sexual perversions were deemed to reflect a return to an earlier developmental stage in phylogeny that had somehow become fixated, so that perverts, like other races and women, were at a lower point on the evolutionary ladder. Following on from Darwin's observations of hermaphroditism in nature, Karl A. Ulrichs (whose pseudonym was Numa Numantius) believed male homosexuals to be female souls in men's bodies.

Succeeding generations of doctors and sexologists argued these points and many offered alternative classifications of the perversions to reflect their views. These are mainly of historical value now, but perhaps we could look at Krafft-Ebing's classification as an example. He believed that life was a struggle between instinct and civilization, and that mental illness created no new instincts, but only altered those that already existed. He believed that hereditary taint and excessive masturbation were among the causes of sexual perversion. His classification, which is self-explanatory, was as follows:

Group 1: deviation of the sex impulse. Too little sexual feeling (impotence, frigidity); too much (satyriasis and nymphomania), and sexual feeling appearing at the wrong time (in childhood or old age) or being directed wrongly (at children, the elderly or animals).

Group 2: Sexual release through other forms of activity (inflicting or receiving pain or sexual bondage).

Group 3: Inverted sexuality (homosexuality, bisexuality, and transvestism).

Krafft Ebing's *Psychopathia Sexualis* ran into 12 editions in his lifetime, with many revisions, and although he did write some of the more explicit details in Latin, the *British Medical Journal* in 1893 lamented that the entire book had not been written in Latin, 'in the decent obscurity of a dead language.' Like Sade before him, Krafft Ebing spoke of 'perverts' as 'stepchildren of nature,' and asked for a more medical and sympathetic approach rather that mere legal strictures.

His belief that most perversions were mainly congenital was challenged by Alfred Binet who argued that with fetishism (a term he coined), for example, the fetish may take many different forms, for example, an obsession with the color of the eyes, bodily odors, various types of dress, or different inanimate objects. Heredity could not dictate this choice, rather a chance phenomena that occurred in childhood was more likely as a cause. Furthermore, on this argument, the fetishist could just as well become a sadist, masochist, or homosexual if early childhood events had been so conducive. As many individuals were exposed to such childhood events and did not develop a perversion, however, Binet had to conclude that there could well be a congenital morbid state in those who did so. Albert Moll argued further that as all biological organs and functions were subject to variations and anomalies, why should the sexual behaviors be any different?

Moll further believed that the sense of smell was always an important factor in mammalian sexuality, and the advent of clothing in human culture diminished this. Wilhelm Fliess, an ENT surgeon and colleague of Freud, drew attention to the erectile

tissues of the nose and its similarity to that of the penis and clitoris. The upright posture adopted by humans had distanced them from the ground, away from feces and smell, so diminishing the importance of olfaction in human arousal, and forming what Freud described as an abandoned erotogenous zone (Sulloway 1992).

Today these mechanisms have been somewhat elaborated. A region in the nasal septum (Jacobson's organ), is linked by nerves to the hypothalamus, a region of the brain that controls sex-hormone secretion. Small volatile chemicals known as pheromones, found in sweat around the genital and axillary regions, are known to stimulate this nasal pathway. Subtle differences in the pheromone balance depend on the individual's genetic make-up, and it is possible that these differences give a biological basis for avoidance of attraction to one's near relatives who exhibit similar profiles. The importance of smell in animal sexuality is well known, and it is of interest that to many fetishists it is soiled rather than clean female underwear that arouses them (Goodman 1998).

Freud believed that each individual from infancy to adulthood repeated the moral development of the race, from sexual promiscuity, to perversion, and then on to heterosexual monogamy. There was a correct developmental path, during which the infant, from the stage of polymorphous perversity, went through various phases of development, and negotiated the Oedipal situation and castration complex. Freud believed that perversions arose because of arrested development leading to fixations on this pathway due to sexual trauma. Those who did not deviate when so exposed in childhood, Freud believed to have been protected by constitutional factors, namely an innate sense of propriety that had been acquired through moral evolution. He classified as deviants those who have different sexual aims (from normal vaginal intercourse), for example, sadists, fetishishists, and those who have a different love object (from the normal heterosexual partner), such as pedophiles or homosexuals (Weeks 1985) (see *Psychoanalysis: Current Status*).

4. *Modern Times*

At the beginning of the twenty-first century, technology-led cultures have had a profound effect on sexual behavior, which has expanded to fill the different niches in the manner of Darwin's 'tangled bank.' We may see even greater fluidity of such behaviors in the future. Just two areas will be briefly considered.

4.1 *Fetishism and Fashion*

Today the fashion industry makes much use of fetishism in its designs. Magazines cater for a whole range of people, both gay and straight, with fetishistic and S&M interests. Relatively new phenomena have appeared in recent times, such as 'vogueing' where the devotee dresses up as a facsimile body of an admired personality either of the same sex (homovestism), or of the opposite sex (the well-known transvestism). Common examples are Elvis Presley and Madonna lookalikes. Voguers compete with each other for realness. Fans who obtain objects, such as articles of clothing or signed photographs from their idols, or who in the USA search the dustbins of stars for trinkets (so-called 'trashcanners') and later use these in their sexual fantasies, resemble classical fetishists in their behavior (Gammon and Makinen 1994, Goodman 1998).

4.2 *Technology and Sexuality*

Every technological invention has altered society in some way and this applies equally to the field of sexual behavior. Newspapers allow wide advertisement of sexual services, the telephone made possible obscene telephone calls, while commercial sex lines have utilized this phenomenon so that men (it is mainly men who use them) can dial and indulge in sexual talk for the price of the call. The automobile is often used as a place of sexual assignation, the home video for viewing obscene material, and the camcorder for making erotic home movies.

The term 'cybersex' is used for people who wish to indulge in erotic fantasies through the Internet. The Internet provides a means of getting in touch with other like-minded individuals worldwide, so that fantasies, which may previously have existed only in the mind of one individual, can be exchanged, enhanced, and embellished. Arrangements have been made for such people to meet in order to carry out acts, which have included pedophilia, rape, and even murder. The perpetrator(s) may take on a different age or gender persona ('gender bending'), to entrap the unwary, especially children. As a result of this, groups have been set up to combat these problems, for example, the Cyberangels in the UK, who monitor the net and inform the police where necessary.

Psychologically some individuals in tedious relationships may find that occasional looks at erotica enlivens their sex lives, but others have become obsessed and addicted to on-line sex ('hot chatting'), and indeed have needed therapy to help them cope (Durkin and Bryant 1995). Virtual reality, which offers the possibility of taking part in a virtual sexual scenario, will further increase the scope of sexual variant behavior.

5. *Recent Scientific Advances in the Understanding of the Paraphilias*

5.1 *The Brain*

The human brain reached its present size and proportions about 50,000–100,000 years ago. The brain

consists of regions which formed at different epochs in vertebrate evolution. It is the hypothalamus that is largely concerned with the hormonal control of reproduction. Certain nuclei found here in homosexual men have been claimed to be more female than male-like, and similar findings have been made in male to female transsexuals (Swaab et al. 1997). Sexual fantasy depends on the cerebral cortex, which is of such complexity that an almost infinite variety of mental responses are possible which ensures a unique plasticity to the range of sexual behaviors.

Furthermore, following head injury or the use of certain drugs, paraphilic behavior may become evident in individuals who did not show such tendencies before. Medical conditions such as temporal lobe epilepsy have been associated with fetishism in some patients. New noninvasive techniques for studying the brain, such as functional magnetic resonance imaging and positron emission tomography are helping to elucidate its functions.

5.2 Genes and the Developing Fetus

The contributions of genes and development to adult sexual behavior have been a topic of intense debate for many years. Recently, new discoveries have added fuel to this argument, and new concepts have been considered.

In humans the Y-chromosome slows down the growth rate in the male fetus, which is consequently born relatively more immature compared with the female and is therefore more vulnerable. Thus males have a higher perinatal mortality and a higher incidence of accidental death, and later in life they show an increased vulnerability to cardiac disease and certain forms of cancer. Mental handicap, which includes autism and epilepsy, is more common in men than women and perhaps the preponderance of the paraphilias in males is also a reflection of this vulnerability (Ounsted and Taylor 1972).

Do genes play some part in determining human sexual behaviors and orientation? Certainly in *Drosophila*, the fruit fly, where male and female behavior were once considered separate and exclusive, recent experimental manipulations of various genes have produced bisexual and homosexual behaviors in males. Even courtship chains, both heterosexual and homosexual (like something out of the Marquis de Sade), have been seen, behaviors that never occur in the wild (Yamamoto et al. 1996). In humans, some paraphiliac behavior does seem to run in families (Gorman 1964, Cryan et al. 1992), and suggestions of a gene occurring on the X-chromosome that predisposes to male homosexuality have been made (Hamer and Copeland 1994).

Developmental factors are also of seeming importance in future behaviors and it is the presence of the two hormones, testosterone, and estrogen, that are thought to influence the developing fetus. This has been shown in mice and other species. When a male fetus is placed in between two female fetuses leakage of female hormones may feminize the male. Testosterone can masculinize the female if a female is between two males (Vom Saal and Bronson 1980).

Stress applied to pregnant rats just one week before delivery resulted in homosexual and bisexual behaviors in males (Ward and Weisz 1980) and Dorner et al. (1983) thought that the stress of war in pregnant women resulted in a higher incidence of male homosexuality in the German population.

Sex hormones, particularly testosterone, are known to interact with the immune system. It has been suggested that the mother's immune system triggered by a male fetus can affect male psychosexual development, especially if she has had many pregnancies. This would further inhibit her immune system and may explain the preponderance of elder brothers in the families of homosexuals and certain pedophiles (Blanchard and Bogaert 1996) (see *Homosexuality and Psychiatry*).

6. The Future

Freud and the sexologists considered the libido in terms of the combustion engine and electricity, as well as using biological ideas that were extant at the time. Today as knowledge in all fields converges, concepts from one area are fertilized as never before by ideas from others. Cybernetics, the study of control and communication in artificial neural networks, has been applied to biological systems such as the brain. Chaos theory, a concept derived from nonlinear dynamics and used initially to predict the weather, has been applied to numerous other areas of research which include fetal development and sexual behavior, as well as various branches of psychology (Goodman 1997).

Waddington (1975) portrayed fetal development as a mountainous terrain, in which the fetus is the ball that rolls down the valleys, which depict the possible developmental pathways. These pathways represent the culmination of millions of years of evolution and are relatively resistant to change. Both genetic factors and early environmental stresses may divert the fetus onto another pathway however, although the system does have a degree of stability. It may well be that certain paraphiliacs and individuals with homosexual or transsexual identities have been diverted from the more common (but not necessarily more normal) path of heterosexual identity. If sexual orientation and behavior are linked to cognition, as seems to be true, then variations could have evolutionary possibilities by throwing up individuals who have the ability to think differently from their peers, offering no little advantage in the struggle for survival. The epistemological solipsism of the developing brain needs sex for its development in the world and not just for pro-

creation (Freeman 1995). Sexual behavior and its variants therefore may merely be a reflection of this process. We should contemplate it with a sense of awe.

Sexual Preference: Genetic Aspects

In many animals, females preferentially mate with males that are adorned with extravagant traits like bright feathers or complicated courtship behavior. As a result such sexual preference has led to the evolution of many elaborate male signals as for example nightingale song or peacock feathers. Many male extravagant traits are thus clearly caused by female sexual preferences, but why did female preference evolve in the first place. Several different hypotheses have been proposed to explain the evolution of female choice. Here, these hypotheses and the available empirical evidence that might help to distinguish between them are discussed.

1. Sexual Selection and the Sex Roles

Males and females in most animal species differ to a large extent in their morphology and their behavior. Female birds are, for example, often drab and coy compared to their colorful and sexually active mates. In many species, males compete with other males for access to females and often use specialized horns, teeth or other weapons, whereas their mates often do not fight with other females. The basic reason behind these sex differences is gamete size that often differs by several orders of magnitude between the sexes. Females produce relatively large gametes, the eggs, and accordingly can only produce relatively few of them. Males, on the other hand, produce large numbers of tiny sperm cells. Due to this difference in the number of gametes available, female reproductive success usually is limited by the number of eggs produced, and multiple matings by females have at most only a small effect on female reproductive success. Male reproductive success, however, is mainly limited by the number of eggs fertilized and thus by the number of mates obtained and not so much by sperm

number (Clutton-Brock and Vincent 1991). Males therefore can benefit from attractiveness and from competition for mating partners whereas females probably benefit more by choosing the best ones among the many available mates. In accordance with this expectation, females often seem to carefully examine the available males and reject mating attempts by nonpreferred males (Andersson 1994). In peacocks, for example, hens prefer males with large colorful feathers that are distributed symmetrically, and in some other birds, females prefer males with large song repertoires. The few species where males heavily invest in offspring, e.g., some katydids with large parental investment, as well as seahorses and wading birds with exclusive paternal care, confirm the rule. In these species females usually compete for mates and males choose among females because males are limited by the number of offspring they can care for and females are limited by the number of males they can obtain to care for their offspring. These studies on sex role reversed species show that the sex difference in the benefit of additional matings after the first one is the driving force behind sexual selection. With standard sex roles, male traits that impair survival but render males especially attractive to females can evolve since male traits that are preferred by females will cause an increased mating frequency. Due to the effect of mating frequency on male reproductive success, these traits can lead to an increased lifetime mating success even when male survival decreases. The splendid feathers of male peacocks for example probably decrease male survival because this shiny ornament will also attract predators and make escape less efficient. Less adorned males may live longer. However, when they leave, on average, fewer offspring than attractive males, genes for being less adorned will go extinct. Compared to the evolution of male traits under the influence of female choice, the evolution of female preference is less easy to explain. In the next section the possible routes for the evolution of female preference are described.

2. *Theoretical Models for the Evolution of Preferences*

Several hypothesis have been presented to explain the evolution of female preference that causes females to choose their mating partners among the available males (see Kirkpatrick and Ryan 1991, Maynard Smith 1991, for reviews). The simplest possibility would be that males differ in the amount of resources provided or in their fertilization rate. According to this hypothesis, choosy females increase the number of offspring produced and they thus benefit directly from their choice. In some birds, for example, those males are preferred as mates that provide superior territories and outstanding paternal care. Another possible explanation for the evolution of female preferences is that choice has an influence on the genetic quality of the offspring. According to this hypothesis females benefit indirectly when offspring of preferred males have superior viability or increased mating success compared to the offspring of nonpreferred males. And finally, female preference might have evolved in another context than sexual selection, that is, female birds might prefer males with blue feathers because it is adaptive to react positively to blue when blue berries constitute a valuable resource so that female sensory physiology became tuned to this color. This model has accordingly been termed sensory exploitation hypothesis, meaning that males exploit female sensory physiology to attain attractiveness (Ryan and Keddy-Hector 1992).

For all of these models, genetic variation in preference is essential since evolution of all traits rests on the existence of genetic variance. Despite the importance of such data, not very many species have been examined for genetic variance in female preference. In most of the examined species, ranging from insects to mice, within population variation in female preference seems generally to be influenced by additive genetic variance (Bakker and Pomiankowski 1995). Such genetic variance in preference means that this trait can easily evolve whenever there is a selective advantage to a specific preference. In the following paragraph the different hypotheses for the evolution of female preferences will be discussed in more detail and the genetic aspects of these models will be concentrated on.

When females benefit directly from their choice by increased lifetime fecundity, it is easy to see that any new choice will evolve as long as the extra benefit gained is larger than the extra cost paid for female choice. For example, females might prefer healthy mates because this might reduce the risk of infection during mating. Choosing males with intact and shiny feathers might thus reduce the risk of ectoparasite transfer during copulation. For models that rest on indirect benefits of female preference, females only gain from choice regarding the genetic quality of their offspring. For these indirect benefit models of female preference, the male trait also needs to have genetic variance. One of these hypotheses, Fisher's arbitrary sexual selection model, predicts that female choice should evolve in response to the evolution of male traits. If females prefer males with a specific trait size, a linkage disequilibrium (a nonrandom association of genes) will build up, since the genes for the preference and the genes for the male trait will co-occur together more frequently than by chance. The existence of choosy females will, in addition, cause increased reproductive success of these preferred males. Since these males also carry a disproportional share of the preference allele, due to the linkage disequilibrium that is caused by the preference, the preference evolves in response to the evolution of the male trait (Kirkpatrick and Ryan 1991). If sexual selection is strong and if preference and male trait are heritable, both the

male trait and the female preference are predicted to evolve by a positive feedback that eventually might lead to runaway selection. The distinctive and sufficient genetic condition for Fisher's arbitrary sexual selection model thus is a genetic correlation between female preference and male traits. According to the good genes hypothesis, another hypothesis that suggests indirect benefits of female preferences, choosy females benefit not only by producing preferred sons but also by producing offspring with superior viability. For such a process to work, male attractiveness needs to indicate male viability. Speaking in genetic terminology, there has to be a genetic correlation between male signaling traits and viability. Since a genetic correlation between female preference and male signaling traits will also build up as a result under the good genes model, such a correlation thus cannot be taken as evidence for the arbitrary sexual selection model but it means that one of the indirect benefit models helps to maintain the preference. To provide evidence that the sensory exploitation model helps to explain the evolution of female preference, one has to show that female preference evolved before the male trait and thus independent of mate choice. The usual way is to show that female preference is more ancestral in phylogeny than the male trait. One of the best studied examples of this hypothesis is the tungara frog, *Physalaemus pustulosus*, where females have a preference for a male acoustic signal that is not produced by the males, but males of a closely related species do produce it. The suggested explanation for this pattern is that female choice evolved first in the ancestor of both species and the male trait evolved later in only one of those species. However, the loss of the attractive male signal during phylogeny cannot be excluded as an alternative explanation.

3. *Testing Genetic Aspects of Sexual Selection Models*

The good genes hypothesis predicts that females benefit from choosing attractive males because these males will produce offspring with superior viability. The critical problem for this hypothesis is that attractive males need to have higher viability. Why should such a correlation between attractiveness and viability exist? The most prominent explanation is the following: Attractive signals are costly and only males with superior viability are able to afford these costs so that only those males can attain high attractiveness. This view of condition-dependent signaling is supported by empirical data showing that in various insects, spiders, and frogs the production of attractive courtship signals consumes more energy than the production of less attractive signals. Also, males that suffer from disease or are starving are usually not as attractive as healthy competitors. Such a process of condition-dependent signaling leads to a genetic correlation between male signaling traits and male viability when there is genetic variation for both traits. If females prefer males with signaling traits that are correlated with viability, female choice can evolve since it will become associated with high viability and a rare female choice allele can thus be expected to increase in frequency when the costs of female choice are low. If females choose among males on the basis of a male trait, a genetic correlation will build up between male trait and female preference at the same time. Since this prediction is identical to the critical and sufficient condition for the arbitrary sexual selection model, experimental separation of these two non-exclusive hypotheses is difficult.

The most frequent method to examine whether the good genes hypothesis contributes to maintain female preference is to compare the viability of the offspring of preferred males with the viability of average or nonpreferred males. In some studies using this method, female choice seems to have an astonishingly large effect on offspring viability, in other studies, no significant effect was observed (see Møller and Alatalo 1999 for a review).

Theoretical models show that these indirect sexual selection benefits are unlikely to increase offspring fitness by more than a few percent (Kirkpatrick 1996). Since direct benefits are suggested to incur larger benefits, evolution of female preferences is predicted to be dominated by direct benefits if these can be obtained by female choice. However, even a small indirect benefit to sexual preferences may be large enough for quick evolution when choice is not very costly. With an exhaustive literature review Møller and Alatalo (1999) showed that a significant positive correlation coefficient between male viability and attractiveness exists on average and they therefore proposed that females can gain a few percent regarding the viability of their offspring when they carefully choose among the potential mates.

In general, the evolution and maintenance of sexual preference seems to be due to various factors. Empirical evidence exists in favor of each of the most prominent hypotheses—direct benefits, sensory exploitation, Fisher's arbitrary sexual selection and good gene models. These hypotheses are not mutually exclusive and some of them might work synergistically. In the future, more studies examining the quantitative genetics of sexually selected traits are necessary to evaluate the importance of the different hypotheses (Bakker 1999).

4. *The Maintenance of Genetic Variation in Male Traits*

4.1 *Theoretical Expectation*

Both indirect sexual selection models depend on the existence of genetic variance in male traits and will in

turn also cause strong selection on these traits. For theoretical reasons it has often been argued that genetic variance of traits under strong selection will usually be smaller than the genetic variance of traits that are less strongly selected (Fisher 1930). This difference occurs because under strong selection, all but the most beneficial alleles will disappear quickly from a population. In line with these arguments, life history traits that are closely connected to fitness have a lower additive genetic variance than morphological traits that are believed to be under weaker selection. If strong selection would deplete genetic variance in male attractiveness or viability, the benefit of female preference would decrease and if there are costs to female choice, females would accordingly benefit from refraining from choice and saving these costs. However, females seem to choose strongly among males in most animal species (Andersson 1994). Furthermore, female choice and the effects of sexual selection on male traits are most obvious in lekking species, where males court females at courtship territories and do not provide any resources for the females. In these cases, direct benefits are unlikely and it is not easy to see why sensory exploitation should be more frequent in these species. The indirect benefit models are thus the only ones that are likely to explain why females strongly select among the available males in lekking species and elsewhere when males do not provide resources. However, when females exert sexual selection on male viability or attractiveness, the genetic variance in male quality should decrease and the benefit of the preference will also decrease in response. The important question thus is whether male genetic variance is large enough to counterbalance the costs of being choosy.

4.2 Empirical Evidence for Genetic Variance among Males

There is ample evidence for genetic variance in male signaling traits and in attractiveness: crosses between populations that differ in the male signaling trait show that the difference is inherited; heritability estimates from father-son comparisons show that genetic variation exists even within populations and artificial selection experiments have proven that sexually selected male traits can evolve quickly. Despite strong sexual selection on male signaling traits, sexually selected traits generally seem to have heritabilities that are as large as the values for traits that are assumed to be only under weak selection (Pomiankowski and Møller 1995). The deviation from the theoretical expectation is even more impressive when one compares the additive genetic variance (another measure for genetic variance that does not depend on the extent of environmental influence on the trait under consideration) between sexually selected traits and traits that are assumed to be not under sexual selection. Sexually selected traits have significantly larger additive genetic variance than other traits, showing that the existing genetic variation is sufficient for both indirect sexual selection models.

4.3 Possible Reasons for the Maintenance of Genetic Variance

The extent of genetic variation present in natural populations thus seems to contradict the theoretical expectations. It is, therefore, important to understand how extensive genetic variance can be maintained in the face of strong sexual selection. Among the hypotheses put forward to explain these data that seem to contradict the theory, the following three causes for the maintenance of genetic variance shall be discussed in some detail because they have received considerable credit: capture of genetic variance in condition, host-parasite coevolution, and meiotic drive.

Male signals are only likely to honestly indicate male viability, when attractive signals are costly because otherwise males with low viability will also be able to produce these attractive signals. When signals are costly, only males in good condition will be able to produce attractive signals (Zahavi 1975). Due to this process, male signal quality will indicate a male's condition. Since male condition is assumed to possess large genetic variance because many traits will influence condition, male signals will capture genetic variance in condition and can in this way maintain the genetic variance in male viability necessary for the good genes model (Rowe and Houle 1996).

Another hypothesis suggests that host-parasite coevolution is important in maintaining genetic variance in male signaling traits (Hamilton and Zuk 1982, Westneat and Birkhead 1998). Let us assume there are male traits that indicate that a male is free of parasites or resistant to parasites. If such resistance is heritable, females would clearly benefit from choosing those males and female preference could accordingly evolve. With increasing resistance, selection on the parasite would lead to new types of parasites that in turn will cause the selection of new resistance. This arms race can in principle lead to a persistent and large advantage to female preference for resistant males because genetic variance in males is maintained since superior male genotypes change with time. There is some indication that such a process also works in humans, where scents from potential partners with dissimilar MHC-genes (an immunologically important group of genes) are preferred (Wedekind and Furi 1997).

Preference of females for males resistant to the action of meiotic drive has also recently been proposed as a scenario that allows persistent benefits of female choice. In stalk-eyed flies, females prefer males with longer eyestalks, and lines selected for longer eyestalks show increased resistance to meiotic drive (Wilkinson et al. 1998). It was, therefore, suggested that females

benefit from choosing males with large eyestalks because resistance to meiotic drive is more frequent in these males. Theoretical simulations, however, revealed that the predicted process cannot occur, but they showed that the avoidance of males possessing meiotic drive does allow persistent benefits for female preference (Reinhold et al. 1999).

5. *Genetics of Sexually Selected Traits: X-chromosomal Bias*

Based on reciprocal crosses between two *Drosophila* species, Ewing (1969) long ago proposed that a disproportional part of the genes that influence traits important for mate recognition reside on the X-chromosome. Recently, two reviews revealed that X-chromosomal genes actually have a disproportionate effect on sex and reproduction related traits in humans and on sexually selected traits in animals. Using large molecular databases, Saifi and Chandra (1999) compared the linkage of mutations influencing traits related to sex and reproduction with all other traits. Their analysis shows that genes influencing traits related to sex and reproduction are several times more likely to be linked to the X-chromosome than other traits. With a different method using literature data on reciprocal crosses, Reinhold (1998) found that the influence of X-chromosomal genes is much stronger for traits that are likely to be under sexual selection than for other genes. On average, about one third of the difference between the two parental lines used for the reciprocal crosses was caused by X-chromosomal genes when sexually selected traits were considered. For those traits that were classified to be not under sexual selection, this value was much smaller—on average two percent of the difference was due to X-linked genes—and was not significantly different from zero.

Such a bias towards the X-chromosome can be expected for traits that are influenced by sexually antagonistic selection (Rice 1984) and for sex-limited traits that are under fluctuating selection (Reinhold 1999). Antagonistic selection occurs if the optimal phenotype differs for males and females and if a genetic correlation between the sexes prevents the phenotypes to reach their evolutionary stable optimum. Under sexually antagonistic selection, sex-linked traits can be expected to evolve faster than other traits because sex-linked traits almost always differ in their expression in the two sexes. Rare recessive X-chromosomal genes, for example, will always be expressed when they occur in the heterogametic sex (the sex that has two different sex chromosomes; in humans the males, they posses an X as well as a Y-chromosome) and will be expressed almost not at all in the homogametic sex. This difference in expression then provides the raw material selection can work on, so that preferential X-linkage can be expected for traits under sexually antagonistic selection. Under fluctuating selection the fate of an allele is influenced by its geometric mean fitness a fitness measure that is equivalent to the case of effective interest rates when the interest rate on a financial investment fluctuates in time. This fitness measure is influenced by the extent of expression of a trait. Between autosomal and X-chromosomal genes there is such a difference in the extent of expression: (a) X-chromosomal genes coding for sex limited male traits in heterogametic males are only expressed to one third because the other two thirds of all X-chromosomes are present in females that do not express the genes under consideration; (b) Autosomal sex-limited genes, i.e. genes that are expressed in only one sex and do not reside on the sex chromosomes but lie on any of the other chromosomes, are, in contrast, expressed to one half provided they are not totally recessive. Due to this difference in expression, autosomal genes coding for the same phenotype as X-chromosomal genes have a disadvantage compared to X-linked genes. As a consequence, X-chromosomal genes coding for sex limited traits are expected to evolve more easily than autosomal genes (Reinhold 1999). The observed X-bias for sexually selected traits can accordingly be explained by the effect of fluctuating selection on these sex-limited traits.

Sexual Risk Behaviors

By the mid-1980s, the menace of AIDS had made indiscriminate sexual behavior a serious risk to health. Under certain conditions sexual behavior can threaten health and psychosocial well-being. Unwanted pregnancies and sexually transmitted diseases (STDs) such as gonorrhea and syphilis have long been potential negative consequences of sexual contact. Yet today HIV infection receives most attention. Because of this, the article will focus on the risk of HIV infection through sexual contact, while HIV infection through needle sharing, maternal-child transmission, and transfusion of blood and blood products will not be addressed. This article is divided into five sections. Section 1 defines sexual risk behavior and delimits the scope. Section 2 discusses the research methodology in this field. Section 3 presents epidemiological data on sexual behavior patterns and HIV infection status among relevant population groups. Section 4 examines the determinants of risk behavior. Section 5 concludes with a discussion of strategies for reducing risk exposure.

1. *Definitions*

Sexuality is an innate aspect of humanity and is oriented toward sensory pleasure and instinctual satisfaction. It goes beyond pure reproduction and constitutes an important part of sensual interaction. Sexual behavior embodies the tension between biological determination, societal and cultural norms, and an individual's personal life choices. Sexuality and sexual behavior are subject to constant change. Sexual mores and practices differ widely both within and between cultures, and also from epoch to epoch. One defining feature of sexuality is, therefore, the diversity of sexual conduct and the attitudes surrounding it.

Sexual risk behavior can be described as sexual behavior or actions which jeopardize the individual's physical or social health. High-risk sexual practices, such as unprotected intercourse with infected individuals, constitute unsafe sexual conduct, and therefore deserve to be classified as a health risk behavior or behavioral pathogen (Matarazzo et al. 1984) on a par with smoking, lack of exercise, unhealthy diet, and excessive consumption of alcohol. Among the STDs, which include gonorrhea, syphilis, genital herpes, condylomata, and hepatitis B among others, HIV infection and AIDS are by far the most dangerous. It has linked love and sexuality with disease and death. If an HIV-infected person fails to inform a partner of his or her serostatus (positive HIV antibody test), unprotected sexual intercourse resulting in the partner's infection has also legal consequences.

In general, unprotected sexual intercourse (i.e., without condoms) with an HIV-infected partner is of risk. HIV may be acquired asymptomatically and transmitted unknowingly. There is a 'hierarchy' in the level of risk involved in sexual practices. High-risk sexual practices include unprotected anal intercourse (especially for the receptive partner) and unprotected vaginal intercourse (again, more for the receptive partner) with infected individuals, as well as any other practices resulting in the entry or exchange of sexual fluids or blood among the partners. Oral sex, on the other hand, carries only a low risk (see *Sexually Transmitted Diseases: Psychosocial Aspects*). Petting is not considered sexual risk behavior. The risk of sexual behavior is a function of the partner's infection status, the sexual practices employed, and the protective measures used. Sex with a large number of sexual partners is also risky because of the higher probability of coming into contact with an infected partner. The risk can be minimized or ruled out entirely by appropriate protective measures: low-risk sexual practices, use of condoms, and avoidance of sexual contact with HIV positive partners.

Sexual risk behavior also applies to the area of family planning. Unwanted pregnancies may occur if the sexual partners do not use safe methods of contraception. If the partners do not wish to have children, sexual contact risks an undesired outcome. Unwanted pregnancy can have consequences ranging from changes in life plans, in the partnership, and in decisions to abort with the ensuing emotional stress and medical risks. Deviant sexual behavior such as exhibitionism or pedophilia cannot be defined as risk behavior.

The analysis of sexual risk behavior falls in the domains of psychology, sociology, medicine, and the public health sciences (Bancroft 1997, McConaghy 1993). Research is available in the areas of health psychology, health sociology and social science AIDS research (von Campenhourdt et al. 1997; see the journal *AIDS Care*; see *HIV Risk Interventions*). The terms used in studies more frequently than 'sexual risk behavior' are 'HIV risk behavior,' 'HIV protective behavior,' 'AIDS-preventive behavior,' 'HIV-related preventive behavior,' 'safer sexual behavior,' 'safe sex,' or 'safer sex' (DiClemente and Peterson 1994, Oskamp and Thompson 1996). These descriptions ought to be given preference over the term 'sexual risk behavior' in order to prevent pathologizing certain sexual practices; it is not the sexual practice as such which presents the risk, but the partner's infection status. Although this term will be used further here, this issue ought to be kept in mind.

2. *Research on Sexual Risk Behavior*

Assessment of sexual risk behavior is complicated by problems in research methodology. Fundamentally, research in sexology faces the same methodological problems as other social sciences. Studies of sexual behavior require special survey instruments and must take into account factors influencing data acquisition and results (see Bancroft 1997). The most important methods of data collection include questionnaires, personal interviews, telephone surveys, and self-monitoring. None of these methods is clearly superior to the others. The quality of retrospective data depends on the selected period, the memory capacity of study participants, the frequency of the behavior, and whether the behavior is typical. In general, in research on sexuality no adequate external criteria are available to validate reporting. Psychophysiological data exist only to a limited extent, and field experiments and participatory observations are usually not applicable. Since the different survey methods and instruments involve differential advantages and disadvantages, a combination of methods would be appropriate. However, this is often not feasible due to practical constraints including limited resources and constrained access to target groups.

When conducting scientific surveys on sexual behavior, it is important to inform and instruct study participants about the purpose of the investigation. Questions must be phrased in a neutral and unprejudiced manner. For sensitive issues, such as taboo topics and unusual sexual practices, the phrasing of questions and their position in the questionnaire are critical. When surveying populations with group-specific language codes (e.g., minorities that have a linguistic subculture), it is necessary to discuss sexual terms with the interviewees beforehand. The willingness to participate in the study and to answer survey questions can be influenced by the fear of reprisals if the answers become public. Depending on the objectives of the study and the study sample, relative anonymity (via telephone interview) can play an important role in the willingness to participate and the openness of responses.

Independent of the selected survey instrument, exaggerations, understatements, and socially desirable answers are to be expected, particularly to questions about sexual risk behavior. Study participants report their own behavior based on role expectations and their self-image. Thus, it is important to assess and control for appropriate motivational and dispositional variables, such as social desirability and the tendency for self-disclosure and attitudes toward sexuality. The person of the researcher, in particular his or her sex, age, and sexual orientation, has an important influence on response behavior. For example, for a heterosexual study sample it may be advisable that male participants be questioned by a male interviewer and female participants by a female interviewer. A heterosexual interviewer must be prepared not to be accepted by homosexual participants. This applies in particular when questions address highly intimate sexual experiences and sexual risk behavior.

Generalizability is one of the most serious problems when reporting data from scientific surveys on sexuality. Access to the study sample and the willingness to participate are more closely linked to relevant personal characteristics of the participants (sexual experiences, attitude toward sexuality) compared to other research. Participants tend to show, for example, greater self-disclosure, a broader repertoire of sexual activities, less guilt, and less anxiety than nonparticipants. Since randomized or quota selection are rarely possible, an exact description of the sampling frame is essential to permit an estimate of the representativity of the sample and the generalizability of the results. Generally, study findings are often based on reports by individuals who are, to a substantial degree, self-selected. This must be taken into consideration when evaluating the findings of studies on sexual behavior.

3. *Epidemiology*

Data on the epidemiology of sexual risk behavior can be acquired from different sources. Numbers can be obtained through studies on sexual risk behavior, focusing on the behavior itself. As mentioned above,

methodological problems often plague such studies. Even if rates of condom use and numbers of sexual partners are assessed correctly, they may not provide the specific information needed to present the epidemiology of sexual risk behavior. The finding that about 50 percent of heterosexual men do not regularly use condoms is only relevant if they do not use condoms in sexual encounters with potentially infected partners. This information, however, is rarely available from existing studies. Numbers can also be extrapolated from incidence and prevalence rates on sexually transmitted disease or unwanted pregnancies.

These data focus on consequences rather than the risk behavior itself, and extrapolation to the prevalence of risk behaviors is complicated by the fact that it is sometimes difficult to distinguish how an infection was transmitted (sexual contact, transfusions, or needle sharing). In addition, reporting may be incomplete or inaccurate for the following reasons: (a) not all countries require compulsory registration of HIV infections, (b) cases are often recorded anonymously which may result in multiple registrations of the same case, and (c) there may be a high number of unreported cases that do not find their way into the statistics.

Despite these methodological problems, epidemiological data are necessary and useful for behavioral research. The available epidemiological data on sexual risk behavior from European and US American sources are presented below for five different subgroups: adolescents, ethnic groups, homosexuals, heterosexuals, and prostitutes. These subgroups are not exhaustive, but they elucidate the differences and specificity of epidemiological data on sexual risk behavior (see *Sexually Transmitted Diseases: Psychosocial Aspects*).

3.1 Adolescents

Adolescents comprise a special group concerning sexual risk behavior. Their initiation into sexuality may shape their sexual behavior for many years to come. They have as yet no rigid sexual behavior patterns and are subject to influences from their peers, parents, the media, and other sources. Compared to the 1970s, teenagers are sexually active at a younger age. Many teenagers (about 25 percent of males and 40 percent of females) have had sexual intercourse by the time they reach 15 years of age, and the mean age of first sexual intercourse is between 16 and 17 years. Because adolescents are sexually active earlier in their lives, they also engage in sexual risk behavior at an earlier age. The majority have several short-term sexual relationships, and by the end of their teens about half report having had more than four partners. The majority of adolescents report being exclusively heterosexual, but an increasing number of teenage males report being bisexual or homosexual.

Data on infection rates show that sexually transmitted diseases are widespread among adolescents. The human papilloma virus (HPV) is likely to be the most common STD among adolescents, with a prevalence of 28–46 percent among women under the age of 25 in the US (Centers for Disease Control and Prevention 2000). The prevalence of HIV infection is increasing slightly among adolescents, but accurate data are difficult to obtain. Due to its long incubation period, those with AIDS in their twenties probably contracted the virus as adolescents, and such cases are on the rise. Teenage pregnancy is still an issue, although numbers generally have decreased. The numbers are still high, especially in the US, where 11 percent of all females between ages 15 and 19 become pregnant (Adler and Rosengard 1996). Data on behavior indicate that about 75 percent of adolescents use contraception. Adolescents in steady relationships predominantly use the pill, while adolescents with casual sexual encounters mainly use condoms. Most adolescents are aware of the risk of pregnancy when sexually active, and they use condoms for the purpose of contraception rather than for protection against STDs. Most of them have sufficient knowledge about HIV infection and AIDS, although erroneous assumptions still prevail. Personal vulnerability to AIDS is perceived to be fairly low, and awareness of other sexually transmitted diseases is practically nonexistent. Alcohol and drug use, common among adolescents, further influence sexual behavior among adolescents including reduced frequency of condom use.

3.2 Ethnic Groups

There are distinct differences in HIV infection among different ethnic groups. Data on infection rates are available mainly from studies conducted in the US. These show that African–Americans face the highest risk of contracting HIV. Despite making up about 12 percent of the US population, the prevalence among African–Americans is 57 percent of HIV diagnoses and 45 percent of AIDS cases. Almost two-thirds of all reported AIDS cases in women are among African–Americans. The incidence rate of reported AIDS cases is eight times the rate of whites (Centers for Disease Control and Prevention 1999). The Hispanic population has the next highest prevalence rates. Hispanics accounted for about 20 percent of the total number of new AIDS cases in 1998, while their population representation was about 13 percent. Their rate is about four times that of whites. It is likely that differences in sexual behavior underlie these statistics, but most studies of behavior have focused on one specific group rather than comparing them with each other.

Possible reasons for differences in infection rates could be that (a) members of ethnic groups often have a lower socioeconomic status and have less access to health care, (b) they are less educated and score lower on HIV risk behavior knowledge, (c) they com-

municate less with partners about sexual topics, and men often have a dominant role in relationships, such that women have difficulty discussing promiscuity and condom use, and (d) men often are less open about their sexual orientation and their HIV status compared to white men.

3.3 Homosexuals

Homosexual men (men who have sex with men) are a high-risk group for contracting HIV infection. Estimates suggest that 5 percent to 8 percent of all homosexual men are HIV positive. Unprotected sexual contact among homosexual men accounts for about 50 percent of all HIV infections (Robert Koch-Institut 1999). Compared to other groups, homosexual men are more likely to engage in sexual risk behavior, including receptive or insertive anal sex and higher numbers of sexual partners. However, prevention campaigns seem to have influenced the sexual behavior of this group. An estimated three-quarters of homosexual men now report using condoms, especially with anonymous partners. There also seems to be a decline in the overall number of sexual partners. However, some homosexual men continue to expose themselves to considerable risk of HIV infection. Although more homosexual men are using condoms, they often do not use them consistently in all potentially risky sexual encounters. Also, especially those who still engage in unprotected sex are usually sexually very active and/or have multiple partners. Studies on sexual behavior often overlook this fact when reporting rates of condom use. Homosexual women are at practically no risk of HIV infection through sexual behavior.

3.4 Heterosexuals

Heterosexuals in monogamous relationships are at low risk for contracting HIV. However, often both partners have had previous sexual contacts, and there is no guarantee that all of those past partners were not infected. Most cases of HIV transmission in this setting are male to female and result from the man's past high-risk sexual contacts, including homosexual relations and encounters with prostitutes. Sex tourism to countries with high rates of HIV adds particular risk. Differences in sexual behavior between men and women, combined with the relatively higher efficiency of HIV transmission from male to female, have the consequence that in developed countries only 5 percent of all HIV infections in men are due to unprotected heterosexual intercourse, whereas for women the figure is 33 percent.

Rates of condom use among heterosexual couples vary from study to study, but about 40–60 percent of sexually active individuals report not using condoms. No conclusive data are available in which settings condoms are used. Up to 23 percent of heterosexual men and 35 percent of heterosexual women report having had two or more sexual partners in the past five years, and up to 6 percent of men and 3 percent of women admit to extramarital sex in the past 12 months. Thus, condom use in these settings is of greatest relevance (Johnson et al. 1994, Laumann et al. 1994). Most individuals in monogamous relationships use condoms as a method of contraception rather than as a means of protection against infection.

3.5 Prostitutes

There seems to be a distinction between 'drug-related' and 'professional' prostitutes. HIV infections are fairly uncommon among professional prostitutes in developed countries; studies report rates of 0.5 percent to 4 percent. Rates of infection among drug-related prostitutes are much higher, with about 30 percent being HIV infected. Behavioral patterns differ between the two groups. Drug-related prostitutes may be forced by either financial need or dependence on a drug supplier to conform to the wishes of their clients, often including sexual intercourse without condoms. This is less the case for professional prostitutes who have more of a choice in their clients and who can insist on using condoms. Rates for unprotected sex among drug-related prostitutes range from 41 percent to 74 percent. In contrast, rates for professional prostitutes range from 20 percent to 50 percent. Rates may be even higher for male prostitutes (Kleiber and Velten 1994).

4. Determinants of Risk Behavior

Models that attempt to describe and explain HIV risk and protective behavior include the following factors: cultural factors (e.g., ethnic group, social norms), social and environmental factors (e.g., membership in subgroups, knowing HIV-infected individuals), demographic factors (socioeconomic status, marital status), biographic factors (e.g., sexual orientation, attitude toward health), and psychosocial factors (e.g., level of knowledge about STD risk, self-efficacy, attitude toward condoms). Sociological models emphasize the way risk behavior is influenced by social class, educational level and the overall social context.

Social disadvantage often goes hand in hand with lack of opportunities for health maintenance and medical care, and with a higher level of risk-taking behavior. Sexual behavior is imbedded in the mode of living of the individual and is closely tied in with the social environment. Some sociological theories focus on the aspect of communication in intimate relationships and economic factors (e.g., financial dependence). Especially among subgroups such as substance abusers, prostitutes and the socioecono-

mically disadvantaged, social and economic conditions can be the central factor that controls behavior.

Psychological models focus on determinants of risk behavior that entail processes taking place within the individual. Although a large number of studies have been published since the mid-1980s, and despite a long tradition of research into risk-taking behavior even before the era of AIDS (Yates 1992), there is no comprehensive and sufficiently well-founded theory to explain sexual risk behavior (Bengel 1996). Most significant in the field of sexual risk behavior are the social-psychological models (e.g., Theory of Reasoned Action and Planned Behavior, Theory of Protection Motivation, and the AIDS Risk Reduction Model; see *Health Behavior: Psychosocial Theories*). For the purpose of this article the AIDS Risk Reduction Model is presented because it entails the most direct links to preventive strategies.

It distinguishes between (a) demographic and personality variables, (b) labeling stage variables, (c) commitment stages variables, and (d) enactment stage variables (Catania et al. 1990). Demographic factors such as gender, age, and education, as well as personality factors such as impulsivity or the readiness to take risks contribute little in explaining sexual risk behavior (Sheeran et al. 1999). Also of limited predictive value are labeling stage variables such as knowledge of AIDS, sexual experience, and threat appraisal or risk perception. The assumption is that each individual makes a personal assessment of the risk of infection or disease (perceived vulnerability and perceived severity). A heterosexual, monogamous male, for instance, may perceive the menace of AIDS as a severe health issue, but may feel personally invulnerable or nonsusceptible. However, some individuals who conduct manifest sexual risk behaviors may underestimate their personal risk as compared to others and thereby perform an 'optimistic bias' (see *Health Risk Appraisal and Optimistic Bias*). Many studies have shown significant but tenuous correlations between threat appraisal variables and risk behavior.

Commitment stage variables influence behavior more substantially and include: (a) social influence: perception of social pressure from significant others to use or not use a condom and of a sexual partner's attitude toward condoms; (b) beliefs about condoms: attitudes toward condoms, intentions, and perceived barriers to condom use; (c) self-efficacy: confidence in the ability to protect oneself against HIV; and (d) pregnancy prevention: condom use for contraceptive purposes. Social pressure, self-efficacy, attitudes toward condoms, as well as previous use of condoms correlate closely and significantly with HIV protective behavior.

The extent to which protective or risky behavior is displayed also depends on situative and interactive factors, the enacting stage variables. Particularly among casual sexual encounters, lack of immediate condom availability can be the decisive determinant of risk behavior. The nature of the relationship and, in particular, the level of communication about safe sex play a central role in risk behavior. Can the partners communicate about HIV and protective behavior, or are they afraid of offending the partner and jeopardizing what could otherwise be a valued romance?

The significance of the influencing factors above varies, depending on the target behavior (e.g., condom use, sexual practices) and on target group (e.g., homosexuals, adolescents, prostitutes; see, e.g., Flowers et al. 1997). All available theoretical approaches and models assume that HIV-protective behavior is governed by a rational decision process. Emotional and motivational factors, as well as planned behavior and action control, largely have been disregarded in these models and have also been insufficiently researched. After experiencing a risk situation, individuals change both their risk perception and their appraisal of the options available for risk management. Especially when uncertainty or fear about HIV infection is high, cognitive coping (e.g., 'I know my partner's friends, so he is not HIV infected') and behavioral coping (e.g., seeking HIV antibody testing) are deployed.

5. *Strategies for Behavioral Change*

Reducing the rates of infections with HIV and other sexually transmitted diseases and preventing unwanted pregnancies constitute major tasks for health science and policy. Although sexual risk behavior in most important target groups is difficult to assess, and explanatory models lack empirical validation and are incomplete, preventive programs must be developed and implemented (Kelly 1995). A societal agreement on target groups and on methods used in such prevention programs is essential. The need to prevent the spread of AIDS has triggered lively and controversial discussions in many countries: should the emphasis be on information and personal responsibility, or should regulatory measures be employed to stem the tide of the disease? Controversy has raged among scientists about the ability to influence sexual behavior and the right of the state to intervene in such intimate affairs. There is agreement, however, that sexual risk behavior cannot be regarded as an isolated mode of personal conduct, but must be seen in the context of an individual's lifestyle and social environment.

Prevention programs promote the use of condoms as the basic method of protection. They promulgate a message of personal responsibility to prevent risk: 'protect yourself and others.' AIDS prevention programs in Western European and North American countries have pursued two objectives: (a) to convey basic information on modes of transmission and methods of protection and (b) to motivate the popu-

lation to assess individual risk and undertake behavioral change if needed. These recommendations start by urging 'safe sex,' that is, use of condoms and avoidance of sexual practices in which body fluids are exchanged, in any situation where infection is a potential risk. Individuals are also advised to reduce the number of sexual partners, to avoid anonymous sexual partners and to reduce the use of substances that may result in loss of control.

Prevention programs use mass communicative, personal, and structural measures. Mass communication involves dissemination of information via media such as radio, TV, newspaper, and posters, as well as distribution of brochures and informational leaflets. These media may be intended for all audiences or may be aimed at a specific group. The information is conveyed in simple, concrete, everyday language, describing the modes of transmission and the options available for protection. Personal measures include telephone hotlines, events, and seminars for special target groups, street-working, individual counseling, and information for sex tourists. These person-to-person prevention programs aim at fostering recognition of the problem, improving the level of knowledge, and changing attitudes, intentions, and behaviors of members of particular target groups. Structural measures include the provision of sterile syringes for intravenous drug users, easy access to condoms, and the improvement of the social situation of prostitutes. Preventive measures must be tailored to the lifestyle, environment, and language of each target group given its specific risk behavior pattern and risk of HIV infection. Programs that rely entirely on the generation of fear enhance risk perception but offer no coping alternatives. Specific messages alone, for instance an appeal for condom use, are also often inadequate to bring about (permanent) behavior changes. Communication among sexual partners should be encouraged as one of the crucial target parameters of prevention.

Evaluation of prevention programs has suggested that they have been successful at conveying the most important information about AIDS. In certain sections of the population there are nevertheless uncertainties, irrational assumptions, and false convictions about risk of infection through such activities as kissing or work contacts. The acceptance level of this information varies widely depending on the target group and is lowest among intravenous drug users. As expected, outside of those groups at especially high risk, the greatest fear of infection prevails among persons below the age of 35 and among singles. Only moderate behavioral change has been found among intravenous drug users. Rapid and significant changes in behavior have been found among homosexual males, especially in cities (fewer sexual partners, fewer high-risk sexual practices, increased use of condoms). Yet only a minority practices safe sex all the time, and some of the behavioral changes are relatively unstable. Some experts fear that the messages of preventive campaigns are wearing off and that some individuals are now less concerned about becoming infected than in the past. This may be due to impact of the new antiviral drugs, which have changed the perception of HIV from that of a death sentence to that of a chronic, manageable disease.

Sexuality and Gender

The meaning of the terms sexuality and gender, and the ways that writers have theorized the relationship between the two, have changed considerably over the last 40 years. The term sexuality has various connotations. It can refer to forms of behavior, it may include ideas about pleasure and desire, and it is also a term that is used to refer to a person's sense of sexual being, a central aspect of one's identity, as well as certain kinds of relationships. The concept of gender has also been understood in relation to varying criterion. Prior to the 1960s, it was a term that referred primarily to what is coded in language as masculine or feminine. The meaning of the term gender has subsequently been extended to refer to personality traits and behaviors that are specifically associated either with women or men; to any social construction having to do with the male/female distinction, including those which demarcate female bodies from male bodies; to gender being thought of as the existence of materially existing social groups 'men' and 'women' that are the product of unequal relationships. In this latter sense, gender as a socially meaningful category is dependant on a hierarchy already existing in any given society, where one class of people (men) have systematic and institutionalized power and privilege over another class of people (women) (Delphy 1993). The term *patriarchy* or, more recently, the phrase 'patriarchal gender regimes,' is used as a way of conceptualizing the oppression of women which results.

More recently, the notion of gender as social practice has emerged and is associated with the work of Judith Butler (1990), who argues that gender is performatively enacted through a continual citation and reiteration of social norms. Butler offers a similar analysis of sexuality, claiming that far from being fixed and naturally occurring, (hetero) sexuality is 'unstable,' dependant on ongoing, continuous, and repeated performances by individuals 'doing heterosexuality,' which produce the illusion of stability. There is no 'real' or 'natural' sexuality to be copied or imitated: heterosexuality is itself continually in the process of being reproduced.

Such ideas are part of the establishment of a new canon of work on sexuality and gender that has emerged since the 1960s. This newer approach differs radically from the older tradition put forward by biologists, medical researchers, and sexologists, which developed through the late nineteenth century and was profoundly influential during the first half of the twentieth century. The traditional approach to understanding sexuality and gender has been primarily concerned with establishing 'natural' or 'biological' explanations for human behavior. Such analyses are generally referred to as *essentialist*. More recent approaches, although not necessarily denying the role of biological factors, have emphasized the importance of social and cultural factors; what is now commonly known as the *social constructionist* approach.

The sociological study of sexuality emerged in the 1960s and 1970s and was informed by a number of theoretical approaches that were significant at the time; notably symbolic interactionism, labeling theory and deviancy theory, and feminism. The work of writers such as John Gagnon and William Simon (1967, 1973) in the US, and Mary McIntosh (1968) and Kenneth Plummer (1975) in the UK, was particularly important in establishing a different focus for thinking about sexuality. A primary concern of such works was to highlight how sexuality is social rather than natural behavior and, as a consequence, a legitimate subject for sociological enquiry.

Gagnon and Simon developed the notion of *sexual scripts* which, they argued, we make use of to help define who, what, where, when, how, and—most anti-essentialist of all—why we have sex. A script refers to a set of symbolic constructs which invest actors and actions, contexts and situations, with 'sexual' meaning—or not as the case may be. People behave in certain ways according to the meanings that are imputed to things; meanings which are specific to particular historical and cultural contexts; meanings that are derived from scripts learnt through socialization and which are modified through ongoing social interactions with others. Most radical of all, Gagnon and Simon claimed that not only is sexual conduct socially learnt behavior, but the reason for wanting to engage in sexual activity, what in esssentialist terms is referred to as sexual 'drive' or 'instinct,' is in fact a socially learnt goal. Unlike Freud, who claimed the opposite to be true, Gagnon and Simon suggested that social motives underlie sexual actions. They saw gender as central to this and detailed how in con-

temporary Western societies sexual scripts are different for girls and boys, women and men. Here gender is seen as a central organizing principle in the interactional process of constructing sexual scripts. In this sense gender can be seen as constitutive of sexuality, at the same time as sexuality can be seen as expressive of gender. Thus, for example, Gagnon and Simon argue that men frequently express and gratify their desire to appear 'masculine' through specific forms of sexual conduct. For example, for young men in most Western cultures first sexual intercourse is a key moment in becoming a 'real man,' whereas this is not the same for young women. It is first menstruation rather than first heterosex that marks being constituted as 'women.'

Another important contribution to the contemporary study of sexuality, which has posed similar challenges to essentialist theories, is the *discourse analysis* approach. One example is the work of Michel Foucault (1979) and his followers, who claim that sexuality is a modern 'invention' and that by taking 'sexuality' as their object of study, various discourses, in particular medicine and psychiatry, have produced an artificial unity of the body and its pleasures: a compilation of bodily sensations, pleasures, feelings, experiences, and actions which we call 'the sexual.' Foucault understands sex not as some essential aspect of personality governed by natural laws that scientists may discover, but as an *idea* specific to certain cultures and historical periods. Foucault draws attention to the fact that the history of sexuality is a history of changing forms of regulation and control over sexuality. What 'sexuality' is defined as, its importance for society, and to us as individuals may vary from one historical period to the next. Furthermore, Foucault argues, as do interactionists, that sexuality is regulated not only through prohibition, but is produced through definition and categorization, in particular through the creation of sexual categories such as, for example, 'heterosexual' and 'homosexual.' Foucault argues that, while both heterosexual and homosexual behavior has existed in all societies, there was no concept of a person whose sexual identity is 'homosexual' until relatively recently. Although there is some disagreement among writers as to precisely when the idea of the homosexual person emerged, it has its origins in the seventeenth to nineteenth centuries, with the category lesbian emerging somewhat later than that of male homosexuality. Such analyses have also highlighted how medical and psychiatric knowledge during the late nineteenth and early twentieth centuries was a key factor in the use of the term 'homosexual' to designate a certain type of person rather than a form of sexual conduct.

A major criticism of Foucault's work is that insufficient attention is given to examining the relationship between sexuality and gender. Feminist writers in particular have pointed out how in Foucault's account of sexuality there is little analysis of how women and men often have different discourses of sexuality. Sexuality is employed as a unitary concept and, such critic's claim, that sexuality is male. Despite such criticisms, many feminists have utilized Foucauldian perspectives.

A further challenge to essentialist ideas about sexuality and gender is associated with psychoanalysis, in particular the reinterpretation of Freud by Jacques Lacan. For Lacan and his followers sexuality is not a natural energy that is repressed; it is language rather than biology that is central to the construction of 'desire.' Lacanian psychoanalysis has had a significant influence on the development of feminist theories of sexuality and gender, although some writers have been critical of Lacan's work (Butler 1990).

At the same time as social scientists and historians were beginning to challenge the assumption that sexual desires and practices were rooted in 'nature,' more and more people were beginning to question dominant ideas about gender roles and sexuality. The late 1960s/early 1970s saw the emergence of both women's and gay and lesbian liberation movements in the US and Europe. An important contribution to analyses of sexuality and gender at that time was the distinction feminists, along with some sociologists and psychologists, sought to make between the terms sex and gender. Sex referred to the biological distinction between females and males, whereas gender was developed and used as a contrasting term to sex. Gender refers to the social meanings and value attached to being female or male in any given society, expressed in terms of the concepts femininity and masculinity, as distinct from that which is thought to be biologically given (sex). Feminists have used the sex/gender distinction to argue that although there may exist certain biological differences between females and males, societies superimpose different norms of personality and behavior that produce 'women' and 'men' as social categories. It is this reasoning that led Simone de Beauvoir (1964) to famously remark 'One is not Born a Woman.'

More recently, a new understanding of gender has emerged. Rather than viewing sex and gender as distinct entities, sex being the foundation upon which gender is superimposed, gender has increasingly been used to refer to any social construction to do with the female/male binary, including male and female bodies. The body, it is argued, is not free from social interpretation, but is itself a socially constructed phenomenon. It is through understandings of gender that we interpret and establish meanings for bodily differences that are termed sexual difference (Nicholson 1994). Sex, in this model, is subsumed under gender. Without gender we could not read bodies as differently sexed; gender provides the categories of meaning for us to interpret how the body appears to us as 'sexed.'

Feminists have critiqued essentialist understandings of both sexuality and gender and have played an

important role in establishing a body of research and theory that supports the social constructionist view. However, feminist theories of sexuality are not only concerned with detailing the ways in which our sexual desires and practices are socially shaped; they are also concerned to ask how sexuality relates to gender and, more specifically, what the relationship is between sexuality and gender inequality? It is this question which perhaps more than any other provoked discussion and controversy between feminists during the 1970s and 1980s.

Most feminists would agree that historically women have had less control in sexual encounters than their male partners and are still subjected to a double standard of sexual conduct that favors men. It is, for example, seen as 'natural' for boys to want to have sex and with different partners, whereas exactly the same behavior that would be seen as understandable and extolled in a boy is censured in a girl. Sexually active women are subject to criticism and are in danger of being regarded as a 'slut' or a 'slag.' Where feminists tend to differ is over the importance of sexuality in understanding gendered power differences. For many radical feminists sexuality is understood to be one of the key mechanisms through which men have regulated women's lives. Sexuality, as it is currently constructed, is not merely a reflection of the power that men have over women in other spheres, but is also productive of those unequal power relationships. Sexuality both reflects and serves to maintain gender divisions. From this perspective the concern is not so much how sexual desires and practices are affected by gender inequalities, but, more generally, how constructions of sexuality constrain women in many aspects of their daily lives from restricting their access to public space to shaping health, education, work, and leisure opportunities (Richardson 1997). Fears of sexual violence, for instance, may result in many women being afraid to go out in public on their own, especially at night. It is also becoming clearer how sexuality affects women's position in the labor market in numerous ways; from being judged by their looks as right or wrong for the job, to sexual harassment in the workplace as a common reason given by women for leaving paid employment.

Other feminists have been reluctant to attribute this significance to sexuality in determining gender relations. They prefer to regard the social control of women through sexuality as the outcome of gendered power inequalities, rather than its purpose. There is then a fundamental theoretical disagreement within feminist theories of sexuality, over the extent to which sexuality can be seen as a site of male power and privilege, as distinct from something that gendered power inequalities act upon and influence.

In the 1990s a new perspective on sexuality and sexual politics emerged fueled by the impact of HIV and AIDS on gay communities and the anti-homosexual feelings and responses that HIV/AIDS revitalized, especially among the 'moral right.' One response by scholars was queer theory; a diverse body of work that aims to question the assumption in past theory and research that heterosexuality is 'natural' and normal. Queer theory is often identified, especially in its early stages of development, with writers associated with literary criticism and cultural studies, and generally denotes a postmodernist approach to understanding categories of gender and sexuality. The work of Eve Sedgwick (1990), Judith Butler (1990), and Teresa de Lauretis (1991), for instance, might be taken as key to the development of queer theory.

A principal characteristic of queer theory is that it problematizes sexual and gender categories in seeking the deconstruction of binary divides underpinning and reinforcing them such as, for instance, woman/man; feminine/masculine; heterosexual/homosexual; essentialist/constructionist. While queer theory aims to develop existing notions of gender and sexuality, there are broader implications of such interventions. As Sedgwick (1990) and others have argued, the main point is the critique of existing theory for its heterosexist bias rather than simply the production of theory about those whose sexualities are marginalized such as, for example, lesbians and gay men.

Sexuality is the primary focus for analysis within queer theory and, while acknowledging the importance of gender, the suggestion is that sexuality and gender can be separated analytically. In particular, queer theorists are centrally concerned with the homo/heterosexual binary and the ways in which this operates as a fundamental organizing principle in modern societies. The emphasis is on the centrality of homosexuality to heterosexual culture and the ways in which the hetero/homo binary serves to define heterosexuality at the center, with homosexuality positioned as the marginalized 'other.' Feminist perspectives, on the other hand, have tended to privilege gender in their analyses—the woman/man binary—and, as I have already outlined above, are principally concerned with sexuality insofar as it is seen as constitutive, as well as determined by, gendered power relations.

Of particular significance for the development of our understanding of the relationship between queer and feminism is a rethinking of the distinction between sexuality and gender.

The relationship between sexuality and gender has, then, been theorized in different ways by different writers. These can be grouped into five broad categories. First, some theories place greater emphasis on gender insofar as concepts of sexuality are understood to be largely founded upon notions of gender (Gagnon and Simon 1973, Jackson 1996). For example, it is impossible to talk meaningfully about heterosexuality or homosexuality without first having a notion of one's sexual desires and relationships as being directed to a particular category of gendered persons. Others propose a different relationship, where sexu-

ality is understood to be constitutive of gender. The radical feminist Catherine MacKinnon (1982), for example, suggests that it is through the experience of 'sexuality,' as it is currently constructed, that women learn about gender, learn what 'being a woman' means. 'Specifically, "woman" is defined by what male desire requires for arousal and satisfaction and is socially tautologous with "female sexuality" and the "female sex"' (MacKinnon 1982). A third way of understanding the relationship between sexuality and gender, which moves away from causal relationships where one is seen as more or less determining of the other, is one which allows for the possibility that the two categories can be considered as analytically separate, if related, domains. Gayle Rubin (1984) in her account of what she terms a 'sex/gender system,' and others who have been influenced by her work, such as Eve Sedgwick (1990), make this distinction between sexuality and gender, which means that it is possible for sexuality to be theorized apart from the framework of gender difference. This is a model favored by many queer theorists. Alternatively, we may reject all of these approaches in favor of developing a fourth model which relies on the notion that sexuality and gender are inherently co-dependent and may not usefully be distinguished one from the other (Wilton 1996).

The stage in our contemporary understandings of sexuality and gender are such that there can be no simple, causal model that will suffice to explain the interconnections between them. However, rather than wanting to privilege one over the other, or seeking to analytically distinguish sexuality and gender or, alternatively, to collapse the two, we might propose a fifth approach which investigates 'their complex interimplication' (Butler 1997). It is this articulation of new ways of thinking about sexuality and gender in a dynamic, historically, and socially specific relationship that is one of the main tasks facing both feminist and queer theory (Richardson 2000).

Sexuality and Geography

Geographical questions concerning sexuality are ideally investigated by combining empirical work with theories of how and why particular sexualities garner spatial force and cultural meaning. In practice, most

theoretical treatments of sexuality in geography have dealt with normative forms of heterosexuality in industrial contexts. Queries about heterosexuality have centered partially on theorizing why and how procreation is given symbolic, spatial, and practical centrality in different cultural and historical contexts. Other theoretical queries have involved analyzing how heterosexual metaphors and expectations inform the structure and meaning of language, discourse, and place. For instance, what is the historical and spatial significance of saying master bedroom, cockpit, capitalist penetration, motherland, virgin territory, mother-earth, or father-sky? In contrast, empirical work has centered on documenting where nonheterosexualities take place, how states and societies regulate nonheterosexual places, bodies, and practices, and the sociospatial difficulties and resistances faced by those who desire nonheterosexual places and identities. Some empirical work also addresses the marginalized places of sex workers in heterosexual sex-work trades.

The disparity between theoretical vs. empirical work reflects how knowledge and power intersect spatially. Most persons today are compelled to assume, and are hence familiar with, the bodily and spatial arrangements of heterosexual gestures and public displays of affection, procreational practices (marriages, buying a 'family' home, having children) and forms of entertainment. Consequently, little explanatory or descriptive analytical space is needed. In contrast, the bodily and spatial arrangements of those assuming non-normative sexualities are commonly hidden from view and relatively unknown. They therefore require documentation before theorization can proceed.

Intersections between geography and sexuality cannot be understood singularly by listing research accomplished to date. Rather, discussion about how geographers have formally and informally navigated sexuality debates is needed to contextualize how external politics have informed internal concerns and research agendas.

1. The Sociology of Sexuality Research in Geography

Few geographers have, until recently, explored how sexuality shapes and is shaped by the social and spatial organization (what geographers call the sociospatiality) of everyday life. Fewer still have explored how geography as a discipline is shaped by heterosexual norms and expectations, or what is called heteronormativity. The ways that modern heterosexuality informs everyday life are not seen or studied because it is taken as natural. Hence, most people unconsciously use it to structure the sociospatiality and meaning of their lives, living out and within what Butler (1990) calls a 'heterosexual matrix.' Many cultural settings in which heterosexuality predominates place great practical and ideological value on procreation. Here, couplings of persons with genitalia qualified as oppositely sexed are presumed to be biologically natural, feeding into culturally constructed ideals of gender identities and relations (WGSG 1997). In modern industrial contexts, boys and girls are expected to grow up to be fathers and mothers who settle into a nuclear household to procreate. Given modern heterosexuality's centrality in determining what is natural, it commonly grounds notions of ontology (being), epistemology (ways of knowing), and truth.

The socially constructed 'naturalness' of heterosexuality in modern contexts is produced and reproduced at a variety of geographical scales. Many nation-states, for example, define and regulate heterosexuality as the moral basis of state law and moral order (e.g., The Family), forbidding sexual alliances not ostensibly geared towards procreation (Nast 1998).

Such laws and related political, cultural, and epistemological strictures have historically limited the kinds of spatial questions geographers have thought, imagined, or asked. Today, precisely when the existence and sovereignty of nation-states is being challenged by transnational actors so, too, is the relevance of the nuclear family being questioned, suggesting partial societal and political symbiosis between family and state types. Nevertheless, for the time being, heterosexual strictures predominate across sociospatial domains, helping to account for geography's generalized disciplinary anxiety towards: (a) those who conduct research on, or question, how heterosexuality is sociospatially made the norm, (b) geographers who hold queer identities, and (c) those engaged in queer identity research. The word queer, here, refers to persons practicing non-normative kinds of sexuality. The word is not meant to efface sexuality differences, but to stress the oppositional contexts through which those who are non-normative are made marginal (see Elder et al. in press). By the late 1980s geographers in significant numbers had brought analytical attention to the violence involved in sustaining what Rich (1980) has named, 'compulsory heterosexuality' (e.g., Foord and Gregson 1986, Bell 1991, Valentine 1993a, 1993b, WGSG 1997, Nast 1998). Part of this violence has to do with the fact that most geographic research fails to question how heterosexuality is spatially channeled to shape the discipline and everyday life.

Heterosexuality's incorporation into the micropractices and spaces of the discipline means that heteronormativity dominates the ways geographers investigate space. Witness the sustained heterosexist practices and spaces of geography departments and conferences (e.g., Chouinard and Grant 1995, Valentine 1998), heterosexist geographical framings or epistemologies of space, nature, and landscape, and the discipline's heterosexist empirical interests, divisions, and focii (e.g., Rose 1993, Binnie 1997a). Even

feminist geographical analyses rarely show how constructions of gender relate to the heterosexual practices to which they are attached Foord and Gregson 1986, Townsend in WGSG 1997, p. 54). In these ways, heterosexuality underpins geographical notions of self, place, sex, and gender (Knopp 1994). Consequently, geographers reproduce hegemonic versions of hetero sex and oedipal (or, nuclear) family life, helping to make these appear legitimate, natural, morally right, and innocent.

2. *Theoretical Research on Heterosexuality and Geography*

Perhaps the first geographers to *theorize* heterosexuality's impact were Foord and Gregson (1986). Using a realist theoretical framework, they argued that gender divisions of male and female derive from procreation and, hence, heterosexuality. Later, Rose (1993) demonstrated how the language, interests, methods, theories, and practices of certain subfields in geography (particularly time geography and humanistic geography) bely a masculinity that, respectively, ignores women's lives or renders them nostaglic objects of desire, not unlike how landscapes and nature have been romanticized and feminized in the discipline. Yet the masculinity Rose describes in heterosexual; it is heteromasculinity. Heteromasculinity can additionally be argued to reside in epistemologies and empirical focii of geographic research generally (Knopp 1994), especially physical geography and some Marxian analyses of space.

Nast (1998) theorizes that modern heteromasculinity is not a singular entity set in structural opposition to femininity asin traditional binary theories of gendered binaries. Rather, the heteromasculine is structured along two imagined, symbolized, and enaced avenues: (a) the filial (son-like) and (b) the paternal. The filial is constructed as hyperembodied and hence celebrates-as-it-constructs men's superior physical strength and courage. The paternal is different in that it celebrates men's superior intellectual strength, objectivity, and cunning and is written about as though disembodied. These *two* masculinities are antagonistically inter-related in an imaginary and symbolic framework supportive of the prototypical industrial, oedipal family.

In the context of globalization and nationalisms, Gibson-Graham (1999) and Nast (1998), respectively, theorize how heterosexualities and geographies discursively and practically make one another. Gibson-Graham analyzes the striking rhetorical parallels between some Marxian theoretical constructions of capital and some social constructions of rape that cast women as victims. Thus, many Marxian theories script capitalism as violently irrepressible, a force that destroys noncapitalist social relations with which it comes into contact. Such theorization gathers force from heterosexualized language and imagery, such that capitalism and its effects are rendered *naturally* and forever singular, hard, rapacious, and spatially penetrative. Analogously, raped women have commonly been scripted as victims of men's *naturally* and singularly superior strength and virility. Rape, once initiated, is judged as unstoppable or inevitable. Women are therefore encouraged to submit (like noncapitalist groups) to heteromasculinity's logic-violence. For Gibson-Graham, what needs to be resisted is not the 'reality' that women and markets are naturally rapable or that men and capitalism are monolithically superior and rapacious. Rather, imaginaries and discursive formations need to be deployed that allow for difference and agency and that support, facilitate, and valorize resistance and change.

Nast (1998) drawing upon Foucaultian notions of discourse as *useful*, similarly shows how heteronormativity is dispersed across sociospatial circuits of everyday life, including discourses and practices of the body, nation, transnation, and world. Focusing on modern nationalist language and imagery, she shows that many representations of nation-states depend upon images of a pure *maternal* and pure nuclear family. In these instances, heteromasculine control over women's bodies and procreation is commonly linked to eugenics or racialized notions of national purity. Obversely, some nation-states, particularly fascist ones, are represented using phallic language and imagery that glorify the oedipal (nuclear) family *father*. Cast as superior protector of family and nation, he and his sons defend against that deemed weak and polluting, including other 'races' and the maternal. Nuclear familial imagery and practices have also been used in the context of industrial interests providing, for example, practical and aesthetic means for systematically alienating and reproducing labor. Here, the nuclear family is a core setting for producing and socializing industrial workers, with the family and family home fetishized as natural protected places of privacy and peace.

3. *Empirical Research on Sexuality and Geography in Sociospatial Context*

Most sexuality research in geography consists of empirical studies of sexuality. In many cases the research is undertheorized, partially reflecting the nascent state of sexuality research wherein specificities of sexualities are mapped out before they are theorized across contexts. Many of those documenting the spatial contours of sexualized bodies and practices have focused on: (a) marginalized heterosexuals, such as sex workers, and (b) queer bodies and places. The former is heteronormative to the degree that the researchers do not specify that it is heterosexuality

with which they work; they also do not theorize heterosexuality's specific sociospatial force in the contexts they study. Consequently their work reinforces popular senses that when one speaks of sex, it is naturally and singularly heterosex. In contrast, working against the grain of heterosexual norms and [expectations] because they are researchers who study the spatiality of queer bodies and places call attention to the specific sexuality(ies) through and against which they work.

Perhaps because in some postindustrial contexts the nuclear family and procreational economies went into decline in the 1970s (alongside the Fordist family), social movements involving queer sexualities obtained greater popular recognition and political and material might, especially where related to gay men. It was at this time that a first wave of queer geographical work broke surface, dealing primarily with white gay male investors in urban contexts and drawing largely upon Marxian theories of rent. Many of these works were unpublished and bore descriptive titles (but see Weightman 1980; for unpublished works, see Elder et al. in press).

In tandem with increased scholarly production was an increase in the scholarly *visibility* of queer geographers (see Elder et al. in press). Evidence of increased networking among sexuality researchers is *Mapping Desire*, the first edited collection on sexuality and geography (Bell and Valentine 1995). The collection, like other works produced towards the late 1980s and 1990s, reflects broad geographical interests, ranging from heterosexual prostitution in Spain, to state surveillance and disciplinary actions towards Black men and women in apartheid South Africa, to the 'unsafeness' of the traditional nuclear family home for many lesbians. The works consists mostly of case studies detailing how marginalized identities are lived out, negotiated, and contested. Ironically, given the collection's title, no spatial theories of desire are presented.

Institutional recognition of queer geographers or sexuality research was not sought in English-speaking contexts until the 1990s and only then, in the United States and Britain. In the 1980s, members of the Association of American Geographers (AAG) formed the Lesbigay Caucus, subsequently holding organizational meetings at annual AAG meetings and co-sponsoring sessions. In 1992 a small group of British geographers created The Sexuality and Space Network, a research and social network affilated loosely with the Institute of British Geographers. That same year, members of the Lesbigay Caucus decided to work for creation of a Sexuality and Space Specialty Group within the AAG which, unlike the caucus, would sponsor sessions and research committed to exploring inter-relations between sexuality and space. The Specialty Group was granted official status in 1996, becoming the first group of its kind in the discipline.

Empirical work on sexuality and geography is gendered, especially in the context of queer research. Most scholars writing about lesbian spaces are women documenting geographies of women's fear and discrimination and how these are resisted at different scales and in different contexts. In contrast, most researchers addressing gay male spaces are men. In contrast to lesbian-related research, that related to gay men speaks mostly to proactive market measures successfully taken in securing urban-based private property and terrorities, particularly queer cultural districts produced through large investments in real estate and small business. In either case, western contexts prevail.

Thus, Patricia Meono-Picado (Jones et al. 1997) documents how Latina lesbians in New York used spatial tactics to oppose the homophobic programming of a Spanish-language radio station, Valentine (1993b) and McDowell (in Bell and Valentine 1995) chart how some lesbians tenuously negotiate their identities in the workplace, Rothenberg (in Bell and Valentine 1995) discusses the informal networks lesbians use to create community and safety, and Johnston (1998) speaks of the importance of gyms as safe public spaces for alternative female embodiments. Valentine also discusses discriminations faced by lesbians everyday (1993a) and the considerable diversity within and among lesbian communities. (in Jones et al. 1997). Finally, Chouinard and Grant (1995) argue against marginalization of disabled and lesbian women in the academy, comparing their exclusions as disabled and lesbian women, respectively.

In contrast, the urban market emphasis present in much gay male research is partly evident in titles such as, '*The Broadway Corridor: Gay Businesses as Agents of Revitalization in Long Beach, California*' (Ketteringham 1983 cited in Elder et al. in press). The title secondarily speaks to a phenomenon present in much research, particularly about gay male spaces, namely, the exclusionary use of the word '*gay*'. While a study may pertain to gay men only, the word 'gay,' like heteropatriachal designations of 'man,' is commonly deployed as though it speaks for all queer communities. It thereby obliterates the specificities and identities of those not gay-male-identified (Chouinard and Grant (1995). Perhaps the most prominent and prolific scholar pioneering research into urban markets and queer life is Larry Knopp. Though his work centers on gay male gentrification, he has consistently attempted to theorize gendered spatial differences in queer opportunity structures and life (e.g., Knopp 1990, Lauria and Knopp 1985).

Gay men's desires and differential abilities to procure spatial security at scales and densities greater than that obtained by lesbians (for example, Boystown in Chicago, the Castro district in San Francisco, the West End in Vancouver, Mykonos and Korfu in Greece, and cruising areas for western gay men in Bangkok) have been a source of scholarly debate.

Castells (1983) argued early on, for example, that urban-based gay men form distinct neighborhoods because, as men, they are inherently more territorial. Adler and Brennan (1992) disagree, contending that lesbians, as women, are relatively disadvantaged economically and more prone to violence and attack. Consequently, they are less able to secure territory, legitimacy, visibility (see also Knopp 1990).

More recent analyses have taken a comparative or cross-cultural look at queer life, entertaining both greater analytical specificity and diversity along lines of gender, 'race,' disability, and/or national or rural–urban location (e.g., Brown 2000, Bell and Valentine 1995, Chouinard and Grant 1995). There is also nascent research on state regulation of sexuality, national identity, and citizenship (e.g., Binnie 1997b, Nast 1998) and on intersections of sexuality and the academy (JGHE 1999).

Despite the increased presence of queer research and researchers in the discipline, sexuality research, especially that which deconstructs heterosexuality or which makes queer sexuality visible, is still considered radical (Chouinard and Grant 1995, Valentine 1998, JGHE 1999). Negative reactions point to anxieties over research that expose heterosexuality's artifice, research that implicitly argues against the privileges and privileging power relations upon which heterosexual ontologies of truth and gender are grounded. The depth of fear is made poignantly clear in a recent article by Valentine (1998) about the ongoing homophobic harassment levied at her by someone in the discipline who collapses her sexuality (she is a lesbian) with her sexuality research on lesbians, explicitly naming both a moral abomination.

4. *Future Research*

A number of areas for future research suggest themselves. First, theorization is needed in addressing sexuality–geography links. What kinds of spatial and symbolic work do normative and queer sexualities practically accomplish across historical and cultural place? More work is needed that explores how normative heterosexualities vary across time and place, in keeping with diverse sociocultural expressions, uses and values of kinship and family structures. Moreover, the nuclear family is apparently in decline unevenly across place and time, in keeping with shifts in places of industrialization, begging the question as to whether some sexualities and affective familial patterns are better suited to certain political economies than to others (see also Knopp 1994). If this is the case, what kinds of sexual identities and desires work well in postindustrial places, and how are industrial restructuring processes affecting oedipal family life and the commoditization of normative and oppositionally sexed identities? What sorts of alternative sociospatial alliances are needed to allow diverse sexualities to coexist? Are gay white men between the ages of 25 and 40 ideally situated economically and culturally to take advantage of the decline of the nuclear family in postindustrial contexts, which do not depend as much upon, or value, procreation?

Second, sexuality–geography research needs to be more theoretically and empirically attuned to differences produced through normative and oppositional constructions of race, gender, class, disability, age, religious beliefs, and nation. Little gender research has been done in the context of queer communities, for example. Are sociospatial interactions between gay male and lesbian communities devoid of gendered tensions? Does patriarchy disappear in spaces of gay male communities (Chouinard and Grant 1995, Knopp 1990)? Are lesbians or gay men situated outside the signifying strictures of heteronormative codes of femininity and masculinity? And how are constructions of race expressed sexually and geographically? Much work needs to be done on how persons of color have been put into infantilized, subordinate positions and places associated with the white-led Family. African-American men after emancipation, for example, were consistently constructed as rapist-sons sexually desirous of the white mother. What kind of work do these and other similarly sexed constructions accomplish in colonial and neocolonial contexts (Nast 2000)? Similarly, why does sex with young boys and men of color, particularly in Southeast Asia, have such wide market appeal among privileged gay white men, resulting in considerable sexualized tourism investment? And what kind of cultural, political, and economic work is achieved through sado-masochistic constructions threaded across sexed and raced communities? What precisely is being constructed and why? Finally, how do sociospatial debates about, and constructions of sexuality, continue to shape the theories, practices, and empirical concerns of geography?

Sexually Transmitted Diseases: Psychosocial Aspects

Sexually transmitted diseases (STDs) including HIV place an enormous burden on the public's health. In 1995, the World Health Organization (WHO) estimated that, worldwide, there were 333 million new cases of chlamydia, gonorrhea, syphilis, and trichomoniasis in 15- to 49-year-olds. In 1999, WHO estimated that there were 5.6 million new HIV infections worldwide, and that 33.6 million people were living with AIDS. Although it is not who you are, but what you do that determines whether you will expose yourself or others to STDs including HIV, STDs disproportionately affect various demographic groupings. For example, STDs are more prevalent in urban settings, in unmarried individuals, and in young adults. They are also more prevalent among the socioeconomically disadvantaged and various ethnic groups. For example, in 1996 in the United States, the incidence of reported gonorrhea per 100,000 was 826 among black non-Hispanics, 106 among Native Americans, 69 among Hispanics, 26 among white non-Hispanics, and 18.6 among Asian/Pacific Islanders (Aral and Holmes 1999).

Demographic differences in STD rates are most likely explained by differences in sexual behaviors or disease prevalence. Thus, demographic variables are often referred to as risk markers or risk indicators. In contrast, sexual and healthcare behaviors that directly influence the probability of acquiring or transmitting STDs represent true risk factors. From a psychosocial perspective, it is these behavioral risk factors (and not risk markers) that are critical for an understanding of disease transmission (see *Sexual Risk Behaviors*).

1. Transmission Dynamics

To understand how behavior contributes to the spread of an STD, consider May and Anderson's (1987) model of transmission dynamics: $Ro = \beta cD$, where, Ro = Reproductive Rate of Infection. When Ro is greater than 1, the epidemic is growing; when Ro is less than 1, the epidemic is dying out; and when $Ro = 1$, the epidemic is in a state of equilibrium, β = measure of infectivity or tranmissability, c = measure of interaction rates between susceptibles and infected individuals, and D = measure of duration of infectiousness

Each of the parameters on the right hand side of the equation can be influenced by behavior. For example, the transmission rate (β) can be lowered by increasing consistent and correct condom use or by delaying the onset of sexual activity. Transmissibility can also be reduced by vaccines, but people must utilize these vaccines and before that, it is necessary for people to have participated in vaccine trials. Decreasing the rate of new partner acquisition will reduce the sexual interaction rate c and, at least for bacterial STDs, duration of infectiousness D can be reduced through the detection of asymptomatic or through early treatment of symptomatic STDs. Thus, increasing care seeking behavior and/or increasing the likelihood that one will participate in screening programs can affect the reproductive rate. Given that STDs are

important cofactors in the transmission of HIV, early detection and treatment of STDs will also influence HIV transmissibility (β). Finally, D can also be influenced by patient compliance with medical treatment, as well as compliance with partner notification.

Clearly, there are a number of different behaviors that, if changed or reinforced, could have an impact on the reproductive rate R_o of HIV and other STDs. A critical question is whether it is necessary to consider each of these behaviors as a unique entity, or whether there are some more general principals that can guide our understanding of any behavior. Fortunately, even though every behavior is unique, there are only a limited number of variables that need to be considered in attempting to predict, understand, or change any given behavior.

2. *Psychosocial Determinants of Intention and Behavior*

Figure 1 provides an integration of several different leading theories of behavioral prediction and behavior change (cf. Fishbein et al. 1992). Before describing this model, however, it is worth noting that theoretical models such as the one presented in Fig. 1 have often been criticized as 'Western' or 'US' models that don't apply to other cultures or countries. When properly applied, however, these models are culturally specific, and they require one to understand the behavior from the perspective of the population being considered. Each of the variables in the model can be found in almost any culture or population. In fact, the theoretical variables contained in the model have been assessed in over 50 countries in both the developed and the developing world. Moreover, the relative importance of each of the variables in the model is expected to vary as a function of both the behavior and the population under consideration (see *Health Behavior: Psychosocial Theories*).

2.1 *Determinants of Behavior*

Looking at Fig. 1, it can be seen that any given behavior is most likely to occur if one has a strong intention to perform the behavior, if one has the necessary skills and abilities required to perform the behavior, and if there are no environmental constraints preventing behavioral performance. Indeed, if one has made a strong commitment (or formed a strong intention), has the necessary skills and abilities, and if there are no environmental constraints to prevent behavioral performance, the probability is close to one that the behavior will be performed (Fishbein et al. 1992).

Clearly, very different types of interventions will be necessary if one has formed an intention but is unable to act upon it, than if one has little or no intention to perform the behavior in question. Thus, in some populations or cultures, the behavior may not be performed because people have not yet formed intentions to perform the behavior, while in others, the problem may be a lack of skills and/or the presence of

Figure 1
An integrative model

environmental constraints. In still other cultures, more than one of these factors may be relevant. For example, among female commercial sex workers (CSWs) in Seattle, Washington, only 30 percent intend to use condoms for vaginal sex with their main partners, and of those, only 40 percent have acted on their intentions (von Haeften et al. 2000). Clearly if people have formed the desired intention but are not acting on it, a successful intervention will be directed either at skills building or will involve social engineering to remove (or to help people overcome) environmental constraints.

2.2 Determinants of Intentions

On the other hand, if strong intentions to perform the behavior in question have not been formed, the model suggests that there are three primary determinants of intention: the attitude toward performing the behavior (i.e., the person's overall feelings of favorableness or unfavorableness toward performing the behavior), perceived norms concerning performance of the behavior (including both perceptions of what others think one should do as well as perceptions of what others are doing), and one's self-efficacy with respect to performing the behavior (i.e., one's belief that one can perform the behavior even under a number of difficult circumstances) (see *Self-efficacy and Health*). As indicated above, the relative importance of these three psychosocial variables as determinants of intention will depend upon both the behavior and the population being considered. Thus, for example, one behavior may be determined primarily by attitudinal considerations while another may be influenced primarily by feelings of self-efficacy. Similarly, a behavior that is driven attitudinally in one population or culture may be driven normatively in another. Thus, before developing interventions to change intentions, it is important first to determine the degree to which that intention is under attitudinal, normative, or self-efficacy control in the population in question. Once again, it should be clear that very different interventions are needed for attitudinally controlled behaviors than for behaviors that are under normative influence or are related strongly to feelings of self-efficacy. Clearly, one size does not fit all, and interventions that are successful in one culture or population may be a complete failure in another.

2.3 Determinants of Attitudes, Norms, and Self-efficacy

The model in Fig. 1 also recognizes that attitudes, perceived norms, and self-efficacy are all, themselves, functions of underlying beliefs—about the outcomes of performing the behavior in question, about the normative proscriptions and/or behaviors of specific referents, and about specific barriers to behavioral performance. Thus, for example, the more one believes that performing the behavior in question will lead to 'good' outcomes and prevent 'bad' outcomes, the more favorable one's attitude toward performing the behavior. Similarly, the more one believes that specific others think one should (or should not) perform the behavior in question, and the more one is motivated to comply with those specific others, the more social pressure one will feel (or the stronger the norm) with respect to performing (or not performing) the behavior. Finally, the more one perceives that one can (i.e., has the necessary skills and abilities to) perform the behavior, even in the face of specific barriers or obstacles, the stronger will be one's self-efficacy with respect to performing the behavior.

It is at this level that the substantive uniqueness of each behavior comes into play. For example, the barriers to using and/or the outcomes (or consequences) of using a condom for vaginal sex with one's spouse or main partner may be very different from those associated with using a condom for vaginal sex with a commercial sex worker or an occasional partner. Yet it is these specific beliefs that must be addressed in an intervention if one wishes to change intentions and behavior. Although an investigator can sit in their office and develop measures of attitudes, perceived norms, and self-efficacy, they cannot tell you what a given population (or a given person) believes about performing a given behavior. Thus, one must go to members of that population to identify salient behavioral, normative, and efficacy beliefs. One must understand the behavior from the perspective of the population one is considering.

2.4 The Role of 'External' Variables

Finally, Fig. 1 also shows the role played by more traditional demographic, personality, attitudinal, and other individual difference variables (such as perceived risk). According to the model, these types of variables primarily play an indirect role in influencing behavior. For example, while men and women may hold different beliefs about performing some behaviors, they may hold very similar beliefs with respect to others. Similarly rich and poor, old and young, those from developing and developed countries, those who do and do not perceive they are at risk for a given illness, those with favorable and unfavorable attitudes toward family planning, etc., may hold different attitudinal, normative or self-efficacy beliefs with respect to one behavior but may hold similar beliefs with respect to another. Thus, there is no necessary relation between these 'external' or 'background' variables and any given behavior. Nevertheless, external variables such as cultural and personality differences should be reflected in the underlying belief structure.

3. The Role of Theory in HIV/STD Prevention

Models, like the one represented by Fig. 1, have served as the theoretical underpinning for a number of successful behavioral interventions in the HIV/STD arena (cf. Kalichman et al. 1996). For example, the US Centers for Disease Control and Prevention (CDC) have supported two large multisite studies based on the model in Fig. 1. The first, the AIDS Community Demonstration Projects (Fishbein et al 1999), attempted to reach members of populations at risk for HIV/STD that were unlikely to come into contact with the health department. The second, Project RESPECT, was a multisite randomized controlled trial designed to evaluate the effectiveness of HIV/STD counseling and testing (Kamb et al. 1998). Project RESPECT asked whether prevention counseling or enhanced prevention counseling were more effective in increasing condom use and reducing incident STDs than standard education.

Although based on the same theoretical model, these two interventions were logistically very different. In one, the intervention was delivered 'in the street' by volunteer networks recruited from the community. In the other, the intervention was delivered one-on-one by trained counselors in an STD clinic. Thus, one involved community participation and mobilization while the other involved working within established public health settings. In addition, one was evaluated using the community as the unit of analysis while the other looked for behavior change at the individual level.

Despite these logistic differences, both interventions produced highly significant behavioral change. In addition, in the clinic setting (where it was feasible to obtain biologic outcome measures), the intervention also produced a significant reduction in incident STDs. The success of these two interventions is due largely to their reliance on established behavioral principles. More important, it appears that theory-based approaches that are tailored to specific populations and behaviors can be effective in changing STD/HIV related behaviors in different cultures and communities (cf. NIH 1997).

4. The Relation between Behavioral and Biological Outcome Measures

Unfortunately, behavior change (and in particular, self-reported behavior change), is often viewed as insufficient evidence for disease prevention, and several investigators have questioned the validity of self-reports of behavior and their utility as outcome measures in HIV/STD Prevention research. For example, Zenilman et al. (1995) investigated the relationship between STD clinic patients self-reported condom use and STD incidence. Patients coming to an STD clinic in Baltimore, Maryland, who agreed to participate in the study were examined for STDs upon entry and approximately 3 months later. At the time of the follow-up exam, participants were asked to report the number of times they had sex in the past month and the number of times they had used a condom while having sex. Those who reported 100 percent condom use were compared with those who reported sometime use or no use of condoms with respect to incident (or new) STDs.

Zenilman et al. (1995) found no significant relationship between self-reported condom use and incident STDs. Based on this finding, they questioned the veracity of the self-reports and suggested that intervention studies using self-reported condom use as the primary outcome measure were at best suspect and at worst, invalid. Such a view fails to recognize the complex relationship between behavioral and biological measures.

4.1 Transmission Dynamic Revisited

Consider again the May and Anderson (1987) model of transmission dynamics: $Ro = \beta cD$. It is important to recognize that the impact on the reproductive rate, of a change in any one parameter, will depend upon the values of the other two parameters. Thus, for example, if one attempted to lower the reproductive rate of HIV by reducing transmission efficiency (either by reducing STDs or by increasing condom use), the impact of such a reduction would depend upon both the prevalence of the disease in the population and the sexual mixing patterns in that population. Clearly, if there is no disease in the population, decreases (or increases) in transmission efficiency can have very little to do with the spread of the disease. Similarly, a reduction in STD rates or an increase in condom use in those who are at low risk of exposure to partners with HIV will have little or no impact on the epidemic. In contrast, a reduction in STDs or an increase in condom use in those members of the population who are most likely to transmit and/or acquire HIV (that is, in the so-called core group), can, depending upon prevalence of the disease in the population, have a big impact on the epidemic (cf. Pequegnat et al. 2000).

To complicate matters further, it must also be recognized that changes in one parameter may directly or indirectly influence one of the other parameters. For example, at least some people have argued that an intervention program that increased condom use successfully, could also lead to an increase in number of partners (perhaps because now one felt somewhat safer). If this were in fact the case, an increase in condom use would not lead necessarily to a decrease in the reproductive rate. In other words, the impact of a given increase (or decrease) in condom use on STD/HIV incidence will differ, depending upon the values of the other parameters in the model. In addition, it's important to recognize that condom use behaviors are very different with 'safe' than with 'risky' partners. For example, condoms are used much more frequently

with 'occasional' or 'new' partners than with 'main' or 'regular' partners (see e.g., Fishbein et al 1999).

Thus, one should not expect to find a simple linear relation (i.e., a correlation) between decreases in transmission efficiency and reductions in HIV seroconversions. Moreover, it should be recognized that many other factors may influence transmission efficiency. For example, the degree of infectivity of the donor; characteristics of the host; and the type and frequency of sexual practices all influence transmission efficiency; and variations in these factors will also influence the nature of a relationship between increased condom use and the incidence of STDs (including HIV).

In addition, although correct and consistent condom use can prevent HIV, gonorrhea, syphilis, and probably chlamydia, condoms are less effective in interrupting transmission of herpes and genital warts. Although one is always better off using a condom than not using a condom, the impact of condom use is expected to vary by disease. Moreover, for many STDs, transmission from men to women is much more efficient than from women to men. For example, with one unprotected coital episode with a person with gonorrhea, there is about a 50 to 90 percent chance of transmission from male to female, but only about a 20 percent chance of transmission from female to male.

It should also be noted that one can acquire an STD even if one always uses a condom. Consistent condom use is not necessarily correct condom use, and incorrect condom use and condom use errors occur with surprisingly high frequencies (Fishbein and Pequegnat 2000, Warner et al. 1998). In addition, at least some 'new' or incident infections may be 'old' STDs that initially went undetected or that did not respond to treatment. Despite these complexities, it is important to understand when, and under what circumstances, behavior change will be related to a reduction in STD incidence. Unfortunately, it is unlikely that this will occur until behaviors are assessed more precisely and new (or incident) STDs can be more accurately identified. From a behavioral science or psychosocial perspective, the two most pressing problems and the greatest challenges are to assess correct, as well as consistent, condom use, and to identify those at high or low risk for transmitting or acquiring STDs (see *HIV Risk Interventions*).

4.2 Assessing Correct and Consistent Condom Use

Condom use is most often assessed by asking respondents how many times they have engaged in sex and then asking them to indicate how many of these times they used a condom. One will get very different answers to these questions depending upon the time frame used (lifetime, past year, past 3 months, past month, past week, last time), and the extent to which one distinguishes between the type of sex (vaginal, anal, or oral) and type of partner (steady, occasional, paying client). Irrespective of the time frame, type of partner or type of sex, these two numbers (i.e., number of sex acts and number of times condoms were used) can be used in at least two very different ways. In most of the literature (particularly the social psychological literature), the most common outcome measure is the percent of times the respondent reports condom use (i.e., for each subject, one divides the number of times condoms were used by the number of sex acts).

Perhaps a more appropriate measure would be to subtract the number of time condoms were used from the number of sex acts. This would yield a measure of the number of unprotected sex acts.

Clearly, if one is truly interested in preventing disease or pregnancy, it is the number of unprotected sex acts and not the percent of times condoms are used that should be the critical variable. Obviously, there is a difference in one's risk of acquiring an STD if one has sex 1,000 times and uses a condom 900 times than if one has sex 10 times and uses a condom 9 times. Both of these people will have used a condom 90 percent of the time, but the former will have engaged in 100 unprotected sex acts while the latter will have engaged in only 1.

By considering the number of unprotected sex acts rather than the percent of times condoms are used, it becomes clear how someone who reports always using a condom can get an STD or become pregnant. To put it simply, consistent condom use is not necessarily correct condom use, and incorrect condom use almost always equates to unprotected sex.

4.3 How Often Does Incorrect Condom Use Occur?

There is a great deal of incorrect condom use. For example, Warner et al. (1998) asked 47 sexually active male college students (between 18 and 29 years of age) to report the number of times they had vaginal intercourse and the number of times they used condoms in the last month. In addition the subjects were asked to quantify the number of times they experienced several problems (e.g., breakage, slippage) while using condoms. Altogether, the 47 men used a total of 270 condoms in the month preceding the study. Seventeen percent of the men reported that intercourse was started without a condom, but they then stopped to put one on; 12.8 percent reported breaking a condom during intercourse or withdrawal; 8.5 percent started intercourse with a condom, but then removed it and continued intercourse; and 6.4 percent reported that the condom fell off during intercourse or withdrawal. Note that all of these people could have honestly reported always using a condom, and all could have transmitted and/or acquired an STD!

Similar findings were obtained from both men and women attending STD clinics in the US (Fishbein and Pequegnat 2000). For example, fully 34 percent of

women and 36 percent of men reported condom breakage during the past 12 months, with 11 percent of women and 15 percent of men reporting condom breakage in the past 3 months. Similarly, 31 percent of the women and 28 percent of the men reported that a condom fell off in the past 12 months while 8 percent of both men and women report slippage in the past 3 months. Perhaps not surprisingly women are significantly more likely than men to report condom leakage (17 percent vs. 9 percent). But again, the remarkable findings are the high proportion of both men and women reporting different types of condom mistakes. For example, 31 percent of the men and 36 percent of the women report starting sex without a condom and then putting one on, while 26 percent of the men and 23 percent of the women report starting sex with a condom and then taking it off and continuing intercourse. This probably reflects the difference between using a condom for family planning purposes and using one for the prevention of STDs including HIV.

The practice of having some sex without a condom probably reflects incorrect beliefs about how one prevents pregnancy. Irrespective of the reason for these behaviors, the fact remains that all of these 'errors' could have led to the transmission and/or acquisition of an STD despite the fact that condoms had, in fact, been used.

In general, and within the constraints of one's ability to accurately recall past events, people do appear to be honest in reporting their sexual behaviors including their condom use. Behavioral scientists must obtain better measures, not of condom use per se, but of correct and consistent condom use, or perhaps even more important, of the number of unprotected sex acts in which a person engages.

4.4 Sex With 'Safe' and 'Risky' Partners

Whether one uses a condom correctly or not is essentially irrelevant as long as one is having sex with a safe (i.e., uninfected) partner. However, to prevent the acquisition (or transmission) of disease, correct and consistent condom use is essential when one has sex with a risky (i.e., infected) partner. Although it is not possible to always know whether another person is safe or risky, it seems reasonable to assume that those who have sex with either a new partner, an occasional partner, or a main partner who is having sex outside of the relationship are at higher risk than those who have sex only with a main partner who is believed to be monogamous. Consistent with this, STD clinic patients with potential high risk partners (i.e., new, occasional, or nonmonogamous main partners) were significantly more likely to acquire an STD than those with potential low risk partners (18.5 percent vs. 10.4 percent; Fishbein and Jarvis 2000).

One can also assess people's perceptions that their partners put them at risk for acquiring HIV. For example, the STD clinic patients were also asked to indicate, on seven-place likely (7)/unlikely (1) scales, whether having unprotected sex with their main and/or occasional partners would increase their chances of acquiring HIV. Not surprisingly those who felt it was likely that unprotected sex would increase their chances of acquiring HIV (i.e., those with scores of 5, 6, or 7) were, in fact, significantly more likely to acquire a new STD (19.4 percent) than those who perceived that their partner(s) did not put them at risk (i.e., those with scores of 1, 2, 3, or 4—STD incidence = 12.6 percent).

Somewhat surprising, clients' perceptions of the risk status of their partners were not highly correlated with whether they were actually with a potentially safe or dangerous partner ($r = .11$, $p < .001$). Nevertheless, both risk scores independently relate to STD acquisition. More specifically, those who were 'hi' on both actual and perceived risk were almost four times as likely to acquire a new STD than were those who are 'lo' on both actual and perceived risk. Those with mixed patterns (i.e., hi/lo or lo/hi) are intermediate in STD acquisition (Fishbein and Jarvis 2000). So, it does appear possible to not only find behavioral measures that distinguish between those who are more or less likely to acquire a new STD, but equally important, it appears possible to identify measures that distinguish between those who are, or are not, having sex with partners who are potentially placing them at high risk for acquiring an STD.

4.5 STD Incidence as a Function of Risk and Correct and Consistent Condom Use

If this combined measure of actual and perceived risk is 'accurate' in identifying whether or not a person is having sex with a risky (i.e., an infected) or a safe (i.e., a noninfected) partner, condom use should make no difference with low-risk partners, but correct and consistent condom use should make a major difference with high-risk partners. More specifically, correct and consistent condom use should significantly reduce STD incidence among those having sex with potential high-risk partners. Consistent with this, while condom use was unrelated to STD incidence among those with low-risk partners, correct and consistent condom use did significantly reduce STD incidence among those at high risk. Not only are these findings important for understanding the relationship between condom use and STD incidence but they provide evidence for both the validity and utility of self-reported behaviors. In addition, these data provide clear evidence that if behavioral interventions significantly increase correct and consistent condom use among people who perceive they are at risk and/or who have a new, an occasional, or a nonmonogamous main partner, there will be a significant reduction in STD incidence. On

the other hand, if, among this high-risk group, we only increase consistency of use without increasing correct use and/or if we only increase condom use among those at low risk, then we will see little or no reduction in STD (or HIV) incidence.

5. *Future Directions*

Clearly it is time to stop using STD incidence as a 'gold standard' to validate behavioral self-reports and to start paying more attention to understanding the relationships between behavioral and biological outcome measures. It is also important to continue to develop theory-based, culturally sensitive interventions to change a number of STD/HIV related behaviors. While much of the focus to date has been on increasing consistent condom use, interventions are needed to increase correct condom use and to increase the likelihood that people will come in for screening and early treatment, and, for those already infected, to adhere to their medical regimens. Indeed, it does appear that we now know how to change behavior, and that under appropriate conditions, behavior change will lead to a reduction in STD incidence. While many investigators have called for 'new' theories of behavior change, 'new' theories are probably unnecessary. What is needed, however, is for investigators and interventionists to better understand and correctly utilize existing, empirically supported theories in developing and evaluating behavior change interventions.

Shamanism

Shamanism is a tradition of part-time religious specialists who establish and maintain personalistic relations with specific spirit beings through the use of controlled and culturally scripted altered states of consciousness (ASC). Shamans employ powers derived from spirits to heal sickness, to guide the dead to their final destinations, to influence animals and forces of nature in a way that benefits their communities, to initiate assaults on enemies, and to protect their own communities from external aggression.

Shamans exercise mastery over ASC and use them as a means to the culturally approved end of mediating between human, animal, and supernatural worlds. Shamans draw upon background knowledge, conveyed through myth and ritual, which renders intelligible the potentially chaotic experience of ASC. The criterion of control helps to distinguish shamanism from the use of ASC in other traditions.

Shamanism has long been a subject of inquiry and controversy in diverse academic disciplines, with many hundreds of accounts of shamanic practices published

by the early 1900s. It has also been a topic of spiritual interest to the wider public in Europe and North America for the past several decades. Depending on the perspective taken, shamanism is either the most archaic and universal form of human spirituality or a culturally distinct religious complex with historical roots in Siberia and a path of diffusion into North and South America. The latter view is adopted in the following.

1. *Siberian Origin and Common Features*

The term 'shaman' is drawn from seventeenth century Russian sources reporting on an eastern Siberian people, the Evenk (Tungus). In the classic work on the subject by the historian of religion Mircea Eliade, 'shamanism' is used to refer to a complex of beliefs and practices diffused from northern Asia to societies in central and eastern Asia, as well as through all of North and South America. Eliade's comparative work specifies a core constellation of ideas common to shamanic traditions. The classic shamanic initiation involves the novice's selection—frequently unwanted and resisted—by a spirit(s), a traumatic and dangerous series of ordeals, followed by a death and rebirth that sometimes involves violent dismembering and subsequent reconstitution of the fledgling shaman's body. The archetypal shamanic cosmology is vertically tiered, with earth occupying the middle level and a cosmic tree or world mountain serving as a connecting path for shamans to travel to other cosmic planes (up or down) in pursuit of their 'helping spirits.'

Shamans use a variety of techniques to enter the ASC in which they communicate with their spirit helpers: sensory deprivation (e.g., fasting, meditation), repetitive drumming and/or dancing, and ingestion of substances with psychoactive properties (e.g., plant hallucinogens). The last of these means is particularly important in the shamanism of Central and South America, where an impressive array of plants and animal-derived chemicals have been used for their hallucinogenic properties (e.g., peyote, datura, virola, and poison from the *Bufo marinus* toad).

Among the most commonly reported characteristics of the shaman's ASC are transformations into animals, and flights to distant places. Shamanic animals include the jaguar (lowland South America), the wolf (North American Chukchee), and bears, reindeer and fish (Lapp). Shamanic flights are undertaken to recapture the wandering souls of the sick, to intercede on behalf of hunters with spirits that control animal species, and to guide the dead to their final destination.

The fact that shamans are often called upon to heal the sick should not lead to the conclusion that they are always concerned with the well being of their fellows. While the Hippocratic Oath of Western medicine prohibits physicians from doing harm, shamans frequently engage in actions meant to sicken, if not kill, their adversaries. This is an important corrective to romanticized images of the shamanic vocation.

2. *Popular and Professional 'Shamanism'*

Beginning in the 1960s there developed a convergence in the professional and popular interests in shamanism. Inspired by the experimentation with hallucinogenic drugs on the part of American and European youth, attention was drawn to the physiology and psychology of altered states of consciousness. In academic circles, this led to speculations about the neurochemical foundations of hallucinatory experiences and their potential therapeutic benefits. Investigations were undertaken into the imagery of shamanic states of consciousness to determine how much could be attributed to universal, physiologically related sensory experiences. One often cited collection of essays, published in the journal *Ethos* (Prince 1982), sought to link the shaman's ASC to the production of the naturally occurring opiates known as endorphins. Scholars argued that this might account for the healing effect of shamanic therapies.

In the popular cultures of North America and Europe, stress came to be placed on shamanism as an avenue to self-exploration, a means by which persons from any culture could advance their quest for spiritual understandings. The legacy of this development is to be found in the forms of 'neoshamanism' among New Age religions, which draw eclectically from more traditional shamanic practices. Native North and South American societies have been special sources of inspiration for practitioners of neoshamanism, but not always with the willing support of the indigenous people.

At the same time, and in response to the evolution of research in symbolic anthropology, anthropologists have contributed increasingly sophisticated ethnographic analyzes of the metaphysical underpinnings of shamanism in specific societies. These anthropologists concentrate their attention on the complexities of shamanic cosmologies and the relationships between shamanic symbolism and crucial features of the natural world (e.g., important animal and plant species, meteorological phenomena, and geographic landmarks).

An especially detailed analysis of a shamanic tradition comes from the Warao of the Orinoco Delta in Venezuela. The German-born and American-trained anthropologist Johannes Wilbert documents the mythic cosmology that supports the work of three distinct kinds of shamans, each of which are responsible for the care and feeding of specific gods. The highest ranking shaman, the Wishiratu ('Master of Pains' or Priest Shaman), responds when the Kanobos (Supreme Beings) send sickness to a Warao village. The Bahanarotu is also a curer, but has a special

responsibility for a fertility cult centered on an astonishingly complex supernatural location, the House of Tobacco Smoke, where four insect couples and a blind snake play a game of chance under the watchful eye of a swallow-tailed kite. The Hoarotu (Dark Shaman) has the unpleasant but essential task of feeding human flesh to the Scarlet Macaw, the God of the West. The preferred food of the other gods is tobacco smoke, which is also the vehicle by which Warao shamans enter ASC—by hyperventilating on long cigars made of a strong black leaf tobacco.

3. Research Directions

3.1 Dead Ends and Detours

There have been a number of dead ends and detours in shamanism studies. An unfortunate amount of energy was spent in fruitless discussions of the mental health of shamans—whether or not their abnormal behavior justified the application of psychiatric diagnoses (e.g., schizophrenia). Most scholars now recognize that the culturally patterned nature of shamans' behavior and the positive value placed on their social role make the application of mental illness labels inappropriate.

Another distraction came when cultural evolutionists hypothesized that shamanism was an intermediary stage in the developmental sequence of religious forms, in-between magic and institutionalized religion. Attempts to treat shamanism exclusively as an archaic expression of human religiosity flounder on the perseverance and even revitalization of shamanic traditions in cultures around the world. For example, the remarkable resiliency of shamanic practices is evident in the continuity between contemporary *curanderismo* (curing) on Peru's north coast and shamanic iconography dating to the pre-Hispanic Chavin culture (approx. 900–200 BC).

3.2 Positive Directions

A still limited amount of research has been directed toward the important question of how effective are shamanic treatments. This work has been troubled by serious theoretical issues (e.g., what constitutes 'efficacy') and thorny methodological questions (e.g., is the double blind, randomized trial possible under the unusual circumstances of shamanic rituals?). The previously cited endorphin theory has not been confirmed ethnographically. Another approach has adapted psychiatric questionnaires to before and after treatment interviews with shamanic patients.

A fruitful line of investigation has focused on the relationship between shamanism and culturally constructed notions of gender. Shamans sometimes 'bend' gender roles (e.g., transvestitism) and the sicknesses they treat can be entangled in gender-based conflicts. Some scholars suggest that where women dominate in the shaman role there is a less adversarial model of supernatural mediation than with male shamans. The best examples of gender-focused research come from East Asia (especially Korea), where the majority of shamans are women, and from the Chilean Mapuche, among whom female and cross-dressing male shamans have predominated since at least the sixteenth century.

A final body of research worth noting focuses on the capacity of shamanic traditions to survive and thrive even under the most disruptive social and political conditions. Agents of culture change, whether they are Soviet-era ideologues in Siberia or Christian missionaries in the Amazon, have been repeatedly frustrated in their attempts to obliterate shamanic practices. In recent decades, shamans have even become central figures in the politics of ethnicity and in antidevelopment protests. Scholars have shown that shamans accomplish this survival feat not by replicating ancient traditions, but by continuously reinventing them in the light of new realities and competing symbolic structures. While this strategy may occasion debates about what constitutes an 'authentic' shaman, it is nevertheless the key to shamanism's continuing success.

4. A Plea for Terminological Precision

The most serious threat to the academic study of shamanism lies in the broad application of the term to any religiously inspired trance form. To so dilute the concept as to make it applicable to Kung trance dancers, New Age spiritualists, and Mexican Huichol peyote pilgrims is to render it meaningless. The value of a scientific term is that it groups together phenomena that are alike in significant regards, while distinguishing those that are different. The promiscuous use of the term shaman will ultimately leave it as generic as 'spiritual healer,' and just as devoid of analytic value.

Shame and the Social Bond

Many theorists have at least implied that emotions are a powerful force in social process. Although Weber didn't refer to emotions directly, his emphasis on values implies it, since values are emotionally charged beliefs. Especially in his later works, Durkheim proposed that collective sentiments created social solidarity through moral community. G. H. Mead proposed emotion as an important ingredient in his social psychology. For Parsons it is a component of social action in his AGIL scheme (Parsons and Shils 1955).

Marx implicated emotions in class tensions in the solidarity of rebelling classes. Durkheim proposed that '… what holds a society together—the 'glue' of solidarity—and [Marx implied that] what mobilizes conflict—the energy of mobilized groups—are emotions' (Collins 1990).

But even the theorists who dealt with emotions explicitly, Durkheim, Mead, and Parsons, did not develop concepts of emotion, investigate their occurrence, nor collect emotion data. Their discussions of emotion, therefore, have not borne fruit. The researchers whose work is reviewed here took the step of investigating a specific emotion.

1. *Seven Pioneers in the Study of Social Shame*

Five of the six sociologists reviewed acted independently of each other. In the case of Elias and Sennett, their discovery of shame seems forced upon them by their data. Neither Simmel nor Cooley define what they mean by shame. Goffman only partially defined embarrassment. The exception is Helen Lynd, who was self-conscious about shame as a concept. Lynd's book on shame was contemporaneous with Goffman's first writings on embarrassment and realized their main point: face-work meant avoiding embarrassment and shame.

Helen Lewis's empirical work on shame (1971) was strongly influenced by Lynd's book. She also was sophisticated in formulating a concept of shame, and in using systematic methods to study it. Sennett's work involved slight outside influence. He approvingly cited the Lynd book on shame in *The Hidden Injuries of Class* (1972), and his (1980) has a chapter on shame.

1.1 *Simmel: Shame and Fashion*

Shame plays a significant part in only one of Simmel's essays, on fashion (1904). People want variation and change, he argued, but they also anticipate shame if they stray from the behavior and appearance of others. Fashion is the solution to this problem, since one can change along with others, avoiding being isolated, and therefore shame (p. 553). Simmel's idea about fashion implies conformity in thought and behavior among one group in a society, the fashionable ones, and distance from another, those who do not follow fashion, relating shame to social bonds.

There is a quality to Simmel's treatment of shame that is somewhat difficult to describe, but needs description, since it characterizes most of the other sociological treatments reviewed here. Simmel's use of shame is casual and unselfconscious. His analysis of the shame component in fashion occurs in a single long paragraph. Shame is not mentioned before or after. He doesn't conceptualize shame or define it, seeming to assume that the reader will know the meaning of the term. Similar problems are prominent in Cooley, Elias, Sennett, and Goffman. Lynd and Lewis are exceptions, since they both attempted to define shame and locate it with respect to other emotions.

1.2 *Cooley: Shame and the Looking Glass Self*

Cooley (1922), like Simmel, was direct in naming shame. For Cooley, shame and pride both arose from self-monitoring, the process that was at the center of his social psychology. His concept of 'the looking glass self,' which implies the social nature of the self, refers directly and exclusively to pride and shame. But he made no attempt to define either emotion. Instead he used the vernacular words as if they were self-explanatory.

To give just one example of the ensuing confusion: in English and other European languages, the word pride used without qualification usually has an inflection of arrogance or hubris (pride goeth before the fall). In current usage, in order to refer to the kind

of pride implied in Cooley's analysis, the opposite of shame, one must add a qualifier like justified or genuine. Using undefined emotion words is confusing.

However, Cooley's analysis of self-monitoring suggests that pride and shame are the basic social emotions. His formulation of the social basis of shame in self-monitoring can be used to amend Mead's social psychology. Perhaps the combined Mead–Cooley formulation can solve the inside–outside problem that plagues psychoanalytic and other psychological approaches to shame, as I suggest below.

1.3 Elias: Shame in the Civilizing Process

Elias undertook an ambitious historical analysis of what he calls the 'civilizing process' (1994). He traced changes in the development of personality and social norms from the fifteenth century to the present. Like Weber, he gave prominence to the development of rationality. Unlike Weber, however, he gave equal prominence to emotional change, particularly to changes in the threshold of shame: 'No less characteristic of a civilizing process than "rationalization" is the peculiar molding of the drive economy that we call "shame" and "repugnance" or "embarrassment".'

Using excerpts from advice manuals, Elias outlined a theory of modernity. By examining advice concerning etiquette, especially table manners, body functions, sexuality, and anger, he suggests that a key aspect of modernity involved a veritable explosion of shame.

Elias showed that there was much less shame about manners and emotions in the early part of the period he studied than there was in the nineteenth century. In the eighteenth century, a change began occurring in advice on manners. What was said openly and directly earlier begins only to be hinted at, or left unsaid entirely. Moreover, justifications are offered less. One is mannerly because it is the right thing to do. Any decent person will be courteous; the intimation is that bad manners are not only wrong but also unspeakable, the beginning of repression.

The change that Elias documents is gradual but relentless; by a continuing succession of small decrements, etiquette books fall silent about the reliance of manners, style, and identity on respect, honor, and pride, and avoidance of shame and embarrassment. By the end of the eighteenth century, the social basis of decorum and decency had become virtually unspeakable. Unlike Freud or anyone else, Elias documents, step by step, the sequence of events that led to the repression of emotions in modern civilization.

By the nineteenth century, Elias proposed, manners are inculcated no longer by way of adult to adult verbal discourse, in which justifications are offered. Socialization shifts from slow and conscious changes by adults over centuries to swift and silent indoctrination of children in their earliest years. No justification is offered to most children; courtesy has become absolute. Moreover, any really decent person would not have to be told. In modern societies, socialization automatically inculcates and represses shame.

1.4 Richard Sennett: Is Shame the Hidden Injury of Class?

Although *The Hidden Injuries of Class* (1972) carries a powerful message, it is not easy to summarize. The narrative concerns quotes from interviews and the authors' brief interpretations. They do not devise a conceptual scheme and a systematic method. For this reason, readers are required to devise their own conceptual scheme, as I do here.

The book is based on participant observation in communities, schools, clubs, and bars, and 150 interviews with white working class males, mostly of Italian or Jewish background, in Boston for one year beginning in July of 1969 (p. 40–1).

The hidden injuries that Sennett and Cobb discovered might be paraphrased: their working class men felt that first, because of their class position, they were not accorded the respect that they should have received from others, particularly from their teachers, bosses and even from their own children. That is, these men have many complaints about their status. Secondly, these men also felt that their class position was at least partly their own fault. Sennett and Cobb imply that social class is responsible for both injuries. They believe that their working men did not get the respect they deserved because of their social class, and that the second injury, lack of self-respect, is also the fault of class, rather than the men's own fault, as most of them thought.

Sennett and Cobb argue that in US society, respect is largely based on individual achievement, the extent that one's accomplishments provide a unique identity that stands out from the mass of others. The role of public schools in the development of abilities forms a central part of Sennett and Cobb's argument. Their informants lacked self-respect, the authors thought, because the schooling of working class boys did not develop their individual talents in a way that would allow them to stand out from the mass as adults. In the language of emotions, they carry a burden of feelings of rejection and inadequacy, which is to say chronic low self-esteem (shame).

From their observations of schools, Sennett and Cobb argue that teachers single out for attention and praise only a small percentage of the students, usually those who are talented or closest to middle-class. This praise and attention allows the singled-out students to develop their potential for achievement. The large majority of the boys, however, are ignored and, in subtle ways, rejected.

There are a few working class boys who achieve their potential through academic or athletic talent. But the large mass does not. For them, rather than

opening up the world, public schools close it off. Education, rather than becoming a source of growth, provides only shame and rejection. For the majority of students, surviving school means running a gauntlet of shame. These students learn by the second or third grade that is better to be silent in class rather than risk humiliation of a wrong answer. Even students with the right answers must deal with having the wrong accent, clothing, or physical appearance. For most students, schooling is a vale of shame.

1.5 Helen Lynd: Shame and Identity

During her lifetime, Helen Lynd was a well-known sociologist. With her husband, Robert, she published the first US community studies, *Middletown* and *Middletown in Transition*. But Lynd was also profoundly interested in developing an interdisciplinary approach to social science. In her study *On Shame and the Search for Identity* (1961), she dealt with both the social and psychological sides of shame. She also clearly named the emotion of shame and its cognates, and located her study within previous scholarship, especially psychoanalytic studies. But Lynd also modified and extended the study of shame by developing a concept, and by integrating its social and psychological components.

In the first two chapters, Lynd introduced the concept of shame, using examples from literature to clarify each point. In the next section, she critiques mainstream approaches in psychology and the social sciences. She then introduces ideas from lesser known approaches, showing how they might resolve some of the difficulties. Finally, she has an extended discussion of the concept of identity, suggesting that it might serve to unify the study of persons by integrating the concepts of self, ego, and social role under the larger idea of identity.

Lynd's approach to shame is much more analytical and self-conscious than the other sociologists reviewed here. They treated shame as a vernacular word. For them, shame sprung out of their data, unavoidable. But Lynd encounters shame deliberately, as part of her exploration of identity.

Lynd explains that shame and its cognates get left out because they are deeply hidden, but at the same time pervasive. She makes this point in many ways, particularly in the way she carefully distinguishes shame from guilt.

One idea that Lynd develops is profoundly important for a social theory of shame and the bond, that sharing one's shame with another can strengthen the relationship: 'The very fact that shame is an isolating experience also means that … sharing and communicating it … can bring about particular closeness with other persons' (Lynd 1961, p. 66). In another place, Lynd went on to connect the process of risking the communication of shame with the kind of role-taking that Cooley and Mead had described: 'communicating shame can be an experience of … entering into the mind and feelings of another person' (p. 249).

Lynd's idea about the effects of communicating and not communicating shame was pivotal for Lewis's (1971) concepts of acknowledged and unacknowledged shame, and their relationship to the state of the social bond, as outlined below.

1.6 Goffman: Embarrassment and Shame in Everyday Life

Although shame goes largely unnamed in Goffman's early work, embarrassment and avoidance of embarrassment is the central thread. Goffman's *Everyperson* is always desperately worried about his image in the eyes of the other, trying to present herself with her best foot forward to avoid shame. This work elaborates, and indeed, fleshes out, Cooley's abstract idea of the way in which the looking glass self leads directly to pride or shame.

Interaction Ritual (1967) made two specific contributions to shame studies. In his study of face work, Goffman states what may be seen as a model of 'face' as the avoidance of embarrassment, and losing face as suffering embarrassment. This is an advance, because it offers readily observable markers for empirical studies of face. The importance of this idea is recognized, all too briefly, at the beginning of Brown and Levinson's (1987) study of politeness behavior.

Goffman's second contribution to the study of shame was made in a concise essay on the role of embarrassment in social interaction (1967). Unlike any of the other shame pioneers in sociology, he begins the essay with an attempt at definition. His definition is a definite advance, but it also foretells a limitation of the whole essay, since it is behavioral and physiological, ignoring inner experience. Framing his analysis in what he thought of as purely sociological mode, Goffman omitted feelings and thoughts. His solution to the inside–outside problem was to ignore most of inner experience, just as Freud ignored most of outside events.

However, Goffman affirms Cooley's point on the centrality of the emotions of shame and pride in normal, everyday social relationships, 'One assumes that embarrassment is a normal part of normal social life, the individual becoming uneasy not because he is personally maladjusted but rather because he is not … embarrassment is not an irrational impulse breaking through social prescribed behavior, but part of this orderly behavior itself' (1967, pp. 109, 111).

Even Goffman's partial definition of the state of embarrassment represents an advance. One of the most serious limitations of current contributions to the sociology of emotions is the lack of definitions of the emotions under discussion. Much like Cooley, Elias and Sennett, Kemper (1978) offers no definitions of emotions, assuming that they go without saying. Hochshild (1983) attempts to conceptualize various

emotions in an appendix, but doesn't go as far as to give concrete definitions of emotional states. Only in Retzinger (1991, 1995) can conceptual and operational definitions of the emotions of shame and anger be found.

2. Lewis's Discovery of Unacknowledged Shame

Helen Lewis's book on shame (1971) involved an analysis of verbatim transcripts of hundreds of psychotherapy sessions. She encountered shame because she used a systematic method for identifying emotions, the Gottschalk–Gleser method (Gottschalk et al. 1969, Gottschalk 1995), which involves use of long lists of keywords that are correlated with specific emotions.

Lewis found that anger, fear, grief, and anxiety cues showed up from time to time in some of the transcripts. She was surprised by the massive frequency of shame cues. Her most relevant findings:

(a) Prevalence: Lewis found a high frequency of shame markers in all the sessions, far outranking markers of all other emotions combined.

(b) Lack of awareness: Lewis noted that patient or therapist almost never referred to shame or its near cognates. Even the word embarrassment was seldom used. In analyzing the context in which shame markers occurred, Lewis identified a specific context: situations in which the patient seemed to feel distant from, rejected, criticized, or exposed by the therapist.

However, the patient's showed two different, seemingly opposite responses in the shame context. In one, the patient seemed to be suffering psychological pain, but failed to identify it as shame. Lewis called this form overt, undifferentiated shame. In a second kind of response, the patient seemed not to be in pain, revealing an emotional response only by rapid, obsessional speech on topics that seemed somewhat removed from the dialogue. Lewis called this second response bypassed shame.

3. Shame, Anger, and Conflict

In her transcripts, Lewis found many episodes of shame that extended over long periods of time. Since emotions are commonly understood to be brief signals (a few seconds) that alert us for action, the existence of long-lasting emotions is something of a puzzle. Lewis's solution to this puzzle may be of great interest in the social sciences, since it provides an emotional basis for longstanding hostility, withdrawal, or alienation.

She argued that her subjects often seemed to have emotional reactions to their emotions, and that this loop may extend indefinitely. She called these reactions 'feeling traps.' The trap that arose most frequently in her data involved shame and anger. A patient interprets an expression by the therapist as hostile, rejecting or critical, and responds with shame or embarrassment. However, the patient instantaneously masks the shame with anger, then is ashamed of being angry. Apparently, each emotion in the sequence is brief, but the loop can go on forever. This proposal suggests a new source of protracted conflict and alienation, one hinted at in Simmel's treatment of conflict.

Although Lewis didn't discuss other kinds of spirals, there is one that may be as important as the shame–anger loop. If one is ashamed of being ashamed, it is possible to enter into a shame–shame loop that leads to silence and withdrawal. Elias's work on modesty implies this kind of loop.

4. Shame and the Social Bond

Finally, Lewis interpreted her findings in explicitly social terms. She proposed that shame arises when there is a threat to the social bond, as was the case in all of the shame episodes she discovered in the transcripts. Every person, she argued, fears social disconnection from others.

Lewis's solution to the outside–inside problem parallels and advances the Darwin–Mead–Cooley definition of the social context of shame. She proposed that shame is a bodily and/or mental response to the threat of disconnection from the other. Shame, she argued, can occur in response to threats to the bond from the other, but in can also occur in response to actions in the 'inner theatre,' in the interior monologue in which we see ourselves from the point of view of others. Her reasoning fits Cooley's formulation of shame dynamics, and also Mead's (1934) more general framework: the self is a social construction, a process constructed from both external and internal social interaction, in role-playing and role-taking.

5. Shame as the Social Emotion

Drawing upon the work of these pioneers, it is possible to take further steps toward defining shame. By shame, I mean a large family of emotions that includes many cognates and variants, most notably embarrassment, humiliation and related feelings such as shyness, that involve reactions to rejection or feelings of failure or inadequacy. What unites all these cognates is that they involve the feeling of a threat to the social bond. That is, I use a sociological definition of shame, rather than the more common psychological one (perception of a discrepancy between ideal and actual self). If one postulates that shame is generated by a threat to the bond, no matter how slight, then a wide range of cognates and variants follow: not only embarrassment, shyness, and modesty, but also feelings of rejection or failure, and heightened self-consciousness of any kind. Note that this definition usually subsumes the psychological one, since most ideals are social, rather than individual.

If, as proposed here, shame is a result of threat to the bond, shame would be the most social of the basic emotions. Fear is a signal of danger to the body, anger a signal of frustration, and so on. The sources of fear

and anger, unlike shame, are not uniquely social. Grief also has a social origin, since it signals the loss of a bond. But bond loss is not a frequent event. Shame on the other hand, following Goffman, since it involves even a slight threat to the bond, is pervasive in virtually all social interaction. As Goffman's work suggests, all human beings are extremely sensitive to the exact amount of deference they are accorded. Even slight discrepancies generate shame or embarrassment. As Darwin (1872) noted, the discrepancy can even be in the positive direction; too much deference can generate the embarrassment of heightened self-consciousness.

Especially important for social control is a positive variant, a sense of shame. That is, shame figures in most social interaction because members may only occasionally feel shame, but they are constantly anticipating it, as Goffman implied. Goffman's treatment points to the slightness of threats to the bond that lead to anticipation of shame. For that reason, my use of the term shame is much broader than its vernacular use. In common parlance, shame is an intensely negative, crisis emotion closely connected with disgrace. But this is much too narrow if we expect shame to be generated by even the slightest threat to the bond.

6. *Conclusion*

The classic sociologists believed that emotions are crucially involved in the structure and change of whole societies. The authors reviewed here suggest that shame is the premier social emotion. Lynd's work, particularly, suggests how acknowledgement of shame can strengthen bonds, and by implication, lack of acknowledgment can create alienation. Lewis's work further suggests how shame–anger loops can create perpetual hostility and alienation. Acknowledged shame could be the glue that holds relationships and societies together, and unacknowledged shame the force that divides them.

T. J. Scheff

Shared Belief

1. *Introducing the Concept of Shared Belief*

The importance of the notion of shared belief has been emphasized by philosophers, economists, sociologists, and psychologists at least since the 1960s (the earlier contributors include Schelling 1960, Scheff 1967, Lewis 1969, and Schiffer 1972). This article deals with the strongest kind of shared belief, to be called 'mutual belief.' While a belief can be shared in the trivial sense of two or more people having the same belief, mutual belief requires the kind of strong sharing which requires at least the participants' awareness (belief) of their similar belief. Mutual belief is one central kind of collective attitude, examples of others being collective intentions, wants, hopes, and fears. Understandably, collective attitudes are central explanatory notions in the social sciences, as one of the tasks of these sciences is to study collective phenomena, including various forms of collective thinking and acting (see below for illustrations).

There is some special, additional interest in the notion of shared belief as mutual belief. First, mutual beliefs serve to characterize social or intersubjective existence in a sense that does not rely on the participants' making agreements or contracts. Thus, many social relations, properties, and events arguably involve mutual beliefs (cf. Lewis 1969, Ruben 1985, Lagerspetz 1995, Tuomela 1995). As a simple example, think of the practice of two persons, *A* and *B*, shaking

hands. It presupposes that *A* believes that *B* and *A* are shaking hands, and that *A* also believes that *B* believes similarly; and *B* must believe analogously. Similarly, communication has been argued by many philosophers, especially Grice, to involve mutual belief (cf. Schiffer 1972, Grice 1989). Second, characterizations of many other collective attitudes in fact depend on the notion of mutual belief (cf. Balzer and Tuomela 1997).

In social psychology and sociology theoreticians often speak about *consensus* instead of mutual belief. The notion of consensus—with the core meaning 'mutual belief'—has been regarded as relevant to such topics as public opinion, values, mass action, norms, roles, communication, socialization, and group cohesion. It can also be mentioned that fads, fashions, crazes, religious movements, and many other related phenomena have been analyzed partly in terms of shared beliefs, consensus, shared consensus, mutual belief, or some similar notions. As pointed out by the sociologist Scheff (1967), such analyses have often gone wrong because they have treated consensus merely as shared first-order belief. Thus, as Scheff argues, consensus as mere first-order agreement does not properly account for 'pluralistic ignorance' (where people agree but do not realize it) and 'false consensus' (where people mistakenly think that they agree). Scheff proposes an analysis in terms of levels of agreement corresponding to a hierarchy of so-called loop beliefs (e.g., in the case of two persons *A* and *B*, *A* believes that *B* believes that *A* believes that something *p*). As is easily seen, pluralistic ignorance and false consensus are second-level phenomena. The third level will have to be brought in when speaking about people's awareness of these phenomena. Other well-known social psychological notions requiring more than shared belief are Mead's concept of 'taking the role of the generalized other,' Dewey's 'interpenetration of perspectives,' and Laing's metaperspectives (see, for example, Scheff 1967).

There are two different conceptual–logical approaches to understanding the notion of mutual (or, to use an equivalent term, common) belief: (a) the *iterative* account, and (b) the *reflexive* or *fixed-point* account. According to the iterative account, mutual belief is assumed to mean iteratable beliefs or dispositions to believe (cf. Lewis 1969, Chap. 2, and, for the weaker account in terms of dispositions to come to believe, Tuomela 1995, Chap. 1). In the two-person case, mutual belief amounts to this according to the iterative account: *A* and *B* believe that *p*, *A* believes that *B* believes that *p* (and similarly for *B*), *A* believes that *B* believes that *A* believes that *p* (and similarly for *B*); and the iteration can continue as far as the situation demands. In the case of loop beliefs there is accordingly mutual awareness only in a somewhat rudimentary sense. As will be seen, in many cases one needs only two iterations for functionally adequate mutual belief: *A* and *B* believe that *p* and they also believe that they believe that *p*. However, there are other cases in which it may be needed to go higher up in the hierarchy.

The fixed-point notion of mutual belief can be stated as follows: *A* and *B* mutually believe that *p* if and only if they believe that *p* and also believe that it is mutually believed by them that *p*. No iteration of beliefs is at least explicitly involved here. Correspondingly, a clear distinction can be made between the iterative or the level-account and the fixed-point account (to be briefly commented on in Sect. 4).

One can speak of the individual (or personal) mode and the group mode of having an attitude such as belief or intention. This article deals with the general notion of mutual belief, be it in the individual mode or in the group mode. Some remarks on the present distinction are anyhow appropriate here. The group-mode sense, expressible by 'We, as a group, believe that *p*,' requires that the group in question is collectively committed to upholding its mutual belief or at least to keeping the members informed about whether it is or can be upheld. This contrasts with mutual belief in an aggregative individual mode involving only personal commitments to the belief in question. When believing in the group-mode sense, group members are accordingly committed to a certain shared view of a topic and to group-mode thoughts such as 'We, as a group, believe that *p*.' Group-mode beliefs are central in the analysis of the kinds of beliefs that structured social groups such as organizations and states have. According to the 'positional' account defended by Tuomela (1995), the group members authorized for belief or view formation collectively accept the views which will qualify as the beliefs the group has. These views are group-mode views accepted for the group and are strictly speaking acceptances of something as the group's views rather than beliefs in the strict sense.

2. *Mutual Beliefs More Precisely Characterized*

This section will be concerned with what mutual beliefs involve over and above plain shared beliefs, and the Sect. 3 takes up the problem of how many layers of hierarchical beliefs are conceptually or psychologically needed. (The discussion below draws on the treatment in Tuomela 1984 and 1995.)

Consider now the iterative account starting with the case of two persons, *A* and *B*. Recall from Sect 1 that according to the standard iterative account *A* and *B* mutually believe that *p* if and only if *A* believes that *p*, *B* believes that *p*, *A* believes that *B* believes that *p* (and similarly for *B*), *A* believes that *B* believes that *A* believes that *p* (and similarly for *B*), and so on, in principle ad infinitum. In the general case, the account defines that it is mutually believed in a group, say *G*, that *p* if and only if *a*) everyone in *G* believes that *p*, *b*) everyone believes that everyone believes that *p*, *c*) everyone believes that everyone believes that everyone

believes that p, and so on *ad infinitum*. The word 'everyone' can of course be qualified if needed and made dependent on some special characteristics; for example, it can be restricted to concern only every fully fledged, adequately informed, and suitably rational member of the group.

A major problem with the iterative account is that it seems in some cases it is psychologically realistic. It loads the people's minds with iterated beliefs which people, after all, do not experientially have and possibly, because of lack of rationality and memory, cannot have. Thus, the account must be improved to make it better correspond to psychological reality. One way to go is to operate partly in terms of lack of disbelief. A person's lack of disbelief that p is defined as that it is not the case the person believes the negation of p. One can try to define mutual belief schematically by saying that it is mutually believed in G that p if and only if everyone believes that p, iterated n times, and from level $n+1$ on everyone lacks the disbelief that p. With $n = 2$, viz. two levels actually present, this definition says that mutual belief amounts to everyone's believing that p and everyone's believing that everyone believes that p and that everyone lacks the disbelief that p from the second level on.

The basic reason for using this amended iterative approach is that no more levels of positive belief than people actually have should be required. Provided that the value of n can be established, the present account satisfies this. It must be assumed here that the agents in question are to some degree intelligent and rational as well as free from emotional and other disturbances so that they, for instance, do not lack a higher-order belief when they really ought to have one in order to function optimally.

While the iterative account amended with the use of the notion of lack of disbelief seems viable for some purposes, an alternative analysis is worth mentioning. This analysis amends the original iterative account in that it requires iterative beliefs up to some level n and from that level on requires only the disposition to acquire higher-order beliefs in appropriate conditions. These appropriate conditions, serving to determine the value of n, include both background conditions and more specific conditions needed for acquiring the belief in question. First, the agents in G must be assumed to be adequately informed and share both general cultural and group-specific information; especially, they must have the same standards of reasoning so that they are able to 'work out the same conclusions' (see Lewis 1969, Chap. 2, and Heal 1978). Second, they must be sufficiently intelligent and rational, and they must be free from cognitive and emotional disturbances to a sufficient degree (so that there are no psychological obstacles for adding the $n+1$st order belief when a genuine mutual belief is involved and for not adding it, or indeed for adding its negation, when a genuine mutual belief is not involved). A typical releasing condition for the disposition to acquire a higher-order belief would be simply that the agents are asked about higher-order beliefs (or are presented with other analogous problems concerning them).

There is not much to choose between the two amended accounts, and the matter will not be discussed further here. With the conceptual machinery at hand, one can deal with, for instance, the mentioned phenomena of pluralistic ignorance and false consensus. An account of pluralistic ignorance, concerning something p, must obviously include the idea that everyone believes that p. Second, it must say that the agents do not have the belief that they agree. Compatibly with this, it can still be required that that they do not disbelieve that they believe that p. As to false consensus, it must be required that not everyone believes that p and that, nevertheless, it is believed by everyone that everyone believes that p.

3. *Mutual Beliefs and the Level Problem*

Let us next discuss the level problem. Given the iterative account, the problem is how many iterative levels of belief are conceptually, epistemically, or psychologically needed for success in various cases. The criteria here are functionality and success. For instance, how many levels of belief does successful joint action require? The level question is difficult to answer in general terms. However, it can be conjectured that in certain cases at least two levels (viz. $n = 2$), relative to the base level, are needed for mutual belief, but no more. In some other cases this is not enough. Generally speaking, there are very seldom epistemic or psychological reasons for going beyond the fourth level. For many agents level $n = 4$ probably is psychologically impossible or at least very difficult to handle in one's reasoning.

The base level is the level zero at which the sentence or proposition p is located, and p will concern or be about an agent's or agents' actions, dispositions to act, intentions, beliefs (or something related); or, alternatively, p can be (or concern) a belief content. In the analysis below it is accepted that the beliefs—at least those going beyond the level $n = 2$—need not be proper occurrent or standing beliefs or even subconscious ones but only dispositions to form the belief in question. (See Audi 1994, for the relevant notion of a disposition to form a belief.)

The claim that $n = 2$ is not only necessary but also sufficient in many typical cases is allowed to involve social loop beliefs where the content of mutual belief could be, for instance, that A believes that B believes that A will act in a certain way, or believes that such and such is the case. What the base level will be is relative to the topic at hand. That at least two levels are needed can be regarded as a conceptual truth (related to the notion 'social existence'); that in many typical cases no more is needed or that in some other

cases four layers are needed can be regarded as general psychological theses concerning the actual contents of people's minds in those situations.

The present view allows that a need may arise to add layers indefinitely. There follows a recursive argument to show that such a situation is possible in principle. Given an analysis of mutual belief in terms of iteration of beliefs such as ours, then at each level under consideration one may start asking questions about people's realizing (or believing) such and such, where 'such and such' refers to the level at hand. This game obviously can go on indefinitely as far as the involved agents' reasoning capacities (or whatever relevant capacities) permit. This is an inductive argument (in the mathematical sense—the first step is obvious) for the open and infinite character of the hierarchy of nested beliefs.

To discuss the level problem in more concrete terms, let us consider mutual belief in the case of two agents, A and B. First we let our base-level sentences be related to the agents' performances of their parts as follows:

(a) A will do his part of X (in symbols, $p(A)$);

(b) B will do his part of X ($p(B)$).

Next, let us assume:

(i) A believes that (a) and (b);

(ii) B believes that (a) and (b).

This is a social or mutual recognition of the agents' part-performances in the context of joint action.

The sentence p in (a) and (b) may alternatively concern other things than action. Thus it may represent a belief content, for example $p =$ The earth if flat, and we will consider this case below.

Considering joint action, it can be argued that $n = 2$ is both necessary and sufficient for successful performance. In this example, A will obviously have to believe that B will do her part. This gives her some social motivation to perform her own part. Concentrating on our reference point individual A and genuine joint action X (in which the agents' performances of their parts are interdependent), A must also believe (or be disposed to believe, at any rate, viz. come to form the belief if asked about the matter) that B believes that A will do her part. For otherwise A could not believe with good reason that B will do her part, for B would—if she does not so believe—lack the social motivation springing from her belief that A will do her part. However, if she did lack that motivation, A could not on this kind of ground defensibly form the belief that B will perform her part. This argument shows that it must be required that the agents have a loop belief or at least a disposition to have a loop belief:

(iii) A believes that (i) and (ii);

(iv) B believes that (i) and (ii).

For instance, (iii) gives the loop 'A believes that B believes that $p(A)$,' and this means that in the present kind of case $n = 2$ is necessary and normally also sufficient (relative to the chosen base level).

An analogous claim can be defended in the case of belief. Here the defense can be given in terms of the recognition by the agents that they share a belief. Suppose that each member of the Flat Earth Society not only believes that the Earth is flat, but—because of being organized into a belief group—the members all share this information. This second-order belief indicates the first level at which social and mutual belief can be spoken of in an interesting sense, for at this level people recognize that the others in the group believe similarly, and this establishes a doxastic social connection; at level one that recognition is, however, missing. This is a typical case of a social property, and again $n = 2$ is both necessary and normally sufficient for acting in matters related to the shape of the Earth *qua* a member of the society.

Suppose next the members of the Flat Earth Society now begin to reflect upon this second-order belief of theirs and come to form the belief that indeed it does exist. (Perhaps a sociologist has just discovered that they share the second-order belief and told them about it.) They might wonder how strong this second-order awareness is, and so on. All this entails that on some occasions third-order beliefs may be needed, although the standard case clearly would be second-order beliefs accompanied by a disposition to go higher up, if the need arises. Analogously, in the case of joint action in some very special cases, for example, double loop beliefs may be needed for rational action.

The reader should be reminded that not all social notions depend on mutual belief. For instance, latent social influence and power do not require it, nor does a unilateral love relation between two persons.

4. *Mutual Belief as Shared We-belief*

What has been called 'we-attitudes' are central for an account of social life (see Tuomela, 1995, Chap. 1, Tuomela and Balzer 1999). A we-attitude is a person's attitude (say belief, want, fear, etc.) concerning something p (a proposition, or sentence) such that (1) this person has the attitude in question and believes that (2) everyone in the group has the attitude and also believes that there is a mutual belief to the effect that (2) in the group. Of these, clause (1) is required because there cannot of course be a truly shared attitude without all the members participating in that attitude. Clause (2) gives a social reason for adopting and having the attitude A, and (3) strengthens the reason by making it intersubjective. (A shared we-attitude can be either in the group mode or in the individual mode; cf. Sect. 1.)

A shared we-belief is a we-belief (be it in the individual or in the group mode) which (ideally) all the group members have. To take an example, a shared we-belief that the Earth is flat entails that the group members believe that the Earth is flat, that the group members believe that the Earth is flat, and also that it

is a mutual belief in the group that the group members believe that the Earth is flat.

Shared we-beliefs can be related to the reflexive or fixed-point account of mutual belief. According to the simplest fixed-point account, mutual belief is defined as follows: it is a mutual belief in a group that p if and only if everyone in the group believes that p and also that it is mutually believed in the group that p. It can thus be seen that the account of mutual belief given by the fixed-point theory is equivalent to the definiens in the definition of a shared we-belief. In the fixed-point approach the syntactical infinity involved in the iterative approach is cut short by a finite fixed-point formula, that is an impredicative construct in which the joint notion to be 'defined' already occurs in the definiens. Under certain rationality assumptions about the notion of belief it can be proved that the iterative approach, which continues iterations ad infinitum, gives the fixed-point property as a theorem (see Halpern and Moses 1992 and, for a more general account, Balzer and Tuomela 1997).

The fixed-point account is in some contexts psychologically more realistic, as people are not required to keep iterative hierarchies in their minds. Note, however, that it depends on context whether the iterative approach or the fixed-point approach is more appropriate. Thus, in the case of successful joint action, at least loop beliefs must be required.

Sherrington, Sir Charles Scott (1857–1952)

> Like this old Earth that lolls through sun and shade,
> Our part is less to make than to be made.
> (Sherrington 1940, p. 259)

To characterize the broad span of Sherrington's engagement he should be described as 'Pathologist, Physiologist, Philosopher and Poet.' It is somewhat arbitrary to pick out only two of them because it is the combination of all these elements that made him both great and unique. However, hardly any other physiologist since 1800 made such a fundamentally important contribution to the knowledge and to the development of concepts in modern neurophysiology. Moreover, when advanced in years, he was the first to attempt a contribution to the solution of the age-old problem of brain/body and mind on a well-founded neuroscientific basis.

1. The Life

Born in London on November 27, 1857, Sherrington was brought up in Ipswich and Norwich. From his earliest years he felt a strong attraction to poetry, a love which never left him throughout his life. Some of his poems were published in various magazines and later were partly collected in a small volume (Sherrington 1925).

In 1876 Sherrington first enrolled at St. Thomas' Hospital Medical School in London and in 1881 matriculated at Cambridge University, where he received his B.A. in 1884 and his M.D. in 1885. During his undergraduate years he started his research in neuroanatomy and neuropathology, publishing his first papers on these studies in 1884 together with John Newport Langley (Langley and Sherrington 1884). This was the beginning of a very productive publishing activity with almost 320 scientific publications (for Sherrington's complete bibliography see Fulton 1952). During his initial postgraduate period at Cambridge

Sherrington's scientific interests concentrated on neurohistology and pathology. This period was interrupted by expeditions to epidemics of Asian Cholera in Spain and Italy. The autopsied material taken during these expeditions he analyzed together with J. Graham Brown and Charles S. Roy in England (1885) and with Rudolf Virchow and Robert Koch in Germany (1886). In 1890 Sherrington was appointed lecturer in physiology at St. Thomas' Hospital in London where he mainly performed clinical work. A year later he received the position of the Professor-Superintendent at the Brown Institute at the University of London, where he became remarkably productive with a variety of publications which reflected his pathological, but also his increasing neurophysiological interest. In 1895 Sherrington received his first appointment to a full professorship of physiology at the University College in Liverpool, where he investigated intensely the organization of the spinal cord.

At age 56 (in 1913) Sherrington entered probably the busiest period of his scientific career when he was appointed to the chair of physiology at Oxford University, from which he did not retire until 1935, when he was 78. It was during his Oxford time that he, together with Edgar Adrian, received the Nobel Prize for Medicine in 1932 (the greatest tribute among numerous honours and rewards, like, for example the Presidency of the Royal Society 1920–25, some 21 international honorary doctorates, and many medals and honorary memberships of British and international societies and academies, among these the corresponding membership of *l'Institut de France*). Three of his students at Oxford were later Nobel Prize winners: Howard Walter Florey, John Carew Eccles and Ragnar Granit.

In the early 1930s Sherrington performed his last physiological experiments and he felt free to turn to his other great love, the philosophy of the nervous system. Having retired to his old hometown of Ipswich in 1935, his scientific interest was increasingly enriched by philosophical considerations that became evident in the Gifford Lectures, held between 1937 and 1938. Obviously, it was also Sherrington's interest in Natural Philosophy that caused him to work on Goethe (Sherrington 1942) and Jean Fernel, a French physician and philosopher of the sixteenth century (Sherrington 1946).

Though his body was crippled by arthritis, his intellectual capacities remained undimmed until his death in Eastbourne on March 4 1952.

2. *The Physiologist*

Regarding the nervous system as a functional unity resulting from its well-organised parts, Sherrington investigated a variety of motor and sensory systems: the topographical organisation of the motor cortex, the binocular integration in vision, as well as the different receptor systems. However, his main efforts concentrated on the spinal cord and its reflex function in motor control. He explicitly admitted that spinal reflex behaviour is not 'the most important and far-reaching of all types of nerve behavior' but represents the advantage that 'it can be studied free from complication with the psyche' (Sherrington 1906/1947, Foreword, p. xiii).

In the spinal cord, isolated from the brain, he carefully analyzed almost all spinal reflex-types from the 'simple' two-neurone reflex arc of the stretch reflex (first described by him), via the complex partly nociceptive flexion and crossed extension reflex and co-ordinated rhythmic scratching and stepping reflexes, up to goal-directed reflex movements of the limbs towards irritating stimuli. Right from the beginning he demonstrated that spinal reflexes are not following a stereotyped all-or-nothing behavior, but that the adaptability of reflexes, based on graduated amplitude, irradiation, and mutual interference between different reflex types, is of great importance for motor control. Sherrington was the first to suggest that inhibition had at least the same functional importance for motor coordination—and other nervous functions—as excitation, not only at the spinal level but also at the brain level and for descending motor commands. This view also opened up new insights into the background of motor disorders observed in various neurological syndromes.

Though some of the reflexes and other motor and sensory phenomena described by Sherrington had been noted earlier, his experimental observations and their analyses were altogether more exact and careful than those of former investigations. Thus, he disproved e.g., several of Pflügers's reflex laws and the assumption of Descartes (1677) and John and Charles Bell (1826) that reciprocal inhibition is localized peripherally in the muscle. However, the higher experimental sophistication alone would not for sure have received that particularly high enduring recognition. Indeed, Sherrington's most important contribution to neuroscience resulted from his unique capability to condense his immense knowledge on sensory and motor functions and on the structure of the nervous system (partly derived from an intense contact with the famous Spanish neurohistologist Santiago Ramón y Cajal) in an almost visionary synopsis of the integrative action of the nervous system, which laid the foundation for the great progress of neuroscience in the twentieth century and which has lost none of its basic validity. This synopsis made his book *The Integrative Action of the Nervous System* (1906) a milestone in neurophysiology, which has been compared 'in importance with Harvey's' 300 years older '*De motu cordis* in marking a turning point in the history of physiological thought' (Fulton 1952, p. 174). For Sherrington, spinal reflexes did not have a 'purpose' but a 'meaning.' He replaced the formerly presumed 'soul' of the spinal cord (e.g., Legallois 1812, Pflüger

1853) as the driving force for reflexes and even voluntary movements by an astonishing exactly considered function of spinal interneuronal activity. He replaced the Cartesian reflex behaviorist view by the still-relevant view that the performance of coordinated movements as a basis for animal and 'conscious' human behavior requires an integration of 'intrinsically' generated brain functions with 'extrinsically' induced reflex functions. In this context he suggested that the pure 'apsychical' reflex behavior without a contribution of 'mind' loses in importance with phylogenetic ascendance, playing the smallest role in man: 'The spinal man is more crippled than is the spinal frog' (Sherrington 1906/1947, Foreword, p. xiv).

As a true scientist Sherrington never felt that he had arrived at any incontrovertible truth and in a typically unpretentious understatement he concluded: 'I have dealt very imperfectly with a small bit of a large problem…. The smallness of the fragment is disappointing' (1931 p. 27); this a statement from a man about whom Frederick George Donnan wrote in 1921 to the Nobel Committee: 'In the field of physiology and medicine, Professor Sherrington's works remind one of that of Kepler, Copernicus and Newton in the field of mechanics and gravitation' (in H. Schück et al., 1962, p. 310).

3. *The Philosopher*

Like for example, Descartes before and Eccles after him, Sherrington realised that mere experimental investigation of the nervous system was not sufficient to solve the fundamental problem of the body/brain–mind relation, particularly the difficulty of explaining how it actually works. In the Rede Lecture on *The Brain and its Mechanism* (Sherrington 1933) in which he considered the complexity of the brain functions in motor control and behavior and in which he tentatively approached this problem, Sherrington took a fully dualistic view. He even negated any scientific right to 'conjoin mental experience with the physiological…. The two … seem to remain disparate and disconnected' (1933, pp. 22–3).

But later in the Gifford Lectures, which he held in Edinburgh in 1937–1938 (published as *Man on his Nature* in Sherrington 1940 and as an extensively revised new edition in 1951) he took up the great enigma of the brain–mind relation in the light of his new neuroscientific knowledge. Rejecting the assumption of a mysterious mind of a 'heavenly' origin he stated, 'Ours is an earthly mind which fits our earthly body' (Sherrington 1940, p. 164). 'Mind' for Sherrington was coupled to motor acts, 'mind' only being recognizable via motor acts. He suggested that 'mind' is graduable, that a recognizable 'mind' is developing in the developing brain in humans and to varying degrees in animals. Regarding the relation between the two concepts of 'energy' (assuming 'matter' also as 'energy' in the physical sense) and 'mind', he concluded that 'mind' as a function of the living brain is mortal, while the 'energy' the matter—is immortal, just changing its state when the brain is dying. In his discussions he entirely avoided the complicating problem of an 'immortal soul', which he, as being himself oriented towards Natural Religion, left to the Revealed Religions: 'When on the other hand the mind-concept is so applied as to insert into the human individual an immortal soul, again a trespass is committed' (Sherrington 1940, p. 355).

When Sherrington with something like resignation stated, 'But the problem of how that [body-mind] liaison is effected remains unsolved; it remains where Aristotle left it more than 2000 years ago' (Sherrington 1906/1947, Foreword, p. xxiii) he probably underestimated the contribution of his step towards the direction of a solution by defining 'mind' as a function of the brain requiring a complex integrative action of the nervous system; a view which was taken up and further developed by one of his students, Sir John C. Eccles (1970, Eccles and Gibson 1979).

4. *And Now?*

As stated in Sect. 3 the experimentally well-based theories and concepts, which Sherrington had creatively developed with great visionary imagination, formed a well-recognised secure foundation for future developments in the neurosciences.

The half-century after Sherrington's death has brought an immense increase in neuroscientific knowledge. First, particularly, the technique of microrecordings from nerve cells and the analysis of ionic membrane mechanisms confirmed and extended the knowledge and hypotheses based on Sherrington's activities on brain and spinal functions in sensory perception, motor control, and behavior. Then new techniques allowed for analytic investigation of more and more detailed neuronal structures, functions, and interactions down to the molecular level. New gentechnical approaches enabled the 'production' of innumerable variants of mice with defined genetic defects at the molecular level.

However, the bewildering mass of results originating from these experiments opened up a host of new questions. What is required now is a new 'Sherringtonian' approach which comprises a complex critical analysis of today's entire neuroscientific knowledge (from molecular mechanisms up to the level to complex behaviour) in an integrative synopsis and which develops new concepts to explain the sophisticated brain functions and their relation to mind as expressed by behavior. Despite the exponential increase in detailed neuroscientific knowledge, we have not really come closer to a solution of that problem since Sherrington.

Short-term Memory, Cognitive Psychology of

The concept of short-term memory has been of theoretical significance to cognitive psychology since the late 1950s. Some investigators have even argued that 'all the work of memory is in the short-term system' (Shiffrin 1999, p. 21). However, others have claimed that short-term memory is an archaic concept and there is no need to distinguish the processes involved in short-term memory from other memory processes (Crowder 1993).

1. *Definitions and Terminology*

'Short-term memory' refers to memory over a short time interval, usually 30 s or less. Another term for the same concept is 'immediate memory.' Both these terms have been distinguished from the related terms 'short-term store' and 'primary memory,' each of which refers to a hypothetical temporary memory system. However, the term 'short-term memory' has also been used by many authors to refer to the temporary memory system. Thus, here the term 'short-term memory' is used in both senses.

It is important to distinguish 'short-term memory' from the related concepts 'working memory' (see *Working Memory, Psychology of*) and 'sensory memory'. Some authors have used the terms 'short-term memory' and 'working memory' as synonymous, and indeed the term 'working memory' has been gradually replacing the term 'short-term memory' in the literature (and some authors now refer to 'short-term working memory'; see Estes 1999). However, 'working memory' was originally adopted to convey the idea that active processing as well as passive storage is involved in temporary memory. 'Sensory memory' refers to memory that is even shorter in duration than short-term memory. Further, sensory memory reflects the original sensation or perception of a stimulus and is specific to the modality in which the stimulus was presented, whereas information in short-term memory has been coded so that it is in a format different from that originally perceived.

2. *Historical Development and Empirical Observations*

An initial description of short-term memory was given by James (1890), who used the term 'primary memory' and described it as that which is held momentarily in consciousness. The intense study of short-term memory began almost 70 years later with the development of the distractor paradigm (Brown 1958, Peterson and Peterson 1959).

2.1 *The Distractor Paradigm*

In this paradigm, a short list of items (usually five or fewer) is presented to subjects for study. If the subjects recall the list immediately, perfect performance results because the list falls within their memory span. However, before the subjects recall the items, they engage in an interpolated activity, the distractor task,

which usually involves counting or responding to irrelevant material. The purpose of the distractor task is to prevent the subjects from rehearsing the list items. The length of the distractor task varies, and its duration is called the 'retention interval.' By comparing performance after various retention intervals, it was found that the rate of forgetting information from short-term memory is very rapid, so that after less than 30 s little information remains about the list of items.

Another central finding from the distractor paradigm involves the serial position curve, which reveals accuracy for each item in the list as a function of its position. The curve is typically bowed and symmetrical with higher accuracy for the initial and final positions than for the middle positions. The distractor task typically requires serial recall (i.e., recall in the order in which the items were presented; see *Representation of Serial Order, Cognitive Psychology of*). Two types of errors occur with this procedure. Transposition errors are order errors in which subjects recall an item in the wrong position. Nontransposition errors are substitution errors in which subjects replace an item with one not included in the list. For example, if subjects receive the list BKFH and recall VKBH, they make a nontransposition error in the first position and a transposition error in the third. The bowed serial position curve reflects the pattern of transposition errors. The pattern of nontransposition errors shows instead a relatively flat function with errors increasing slightly across the list positions.

Errors in the distractor paradigm can also be classified by examining the relation between the correct item and the item that replaces it. In the example, the subjects replace B with V. Because those two letters have similar-sounding names, the error is called an 'acoustic confusion error', and such errors occur often in the distractor paradigm. Even visually presented items are typically coded in short-term memory in an acoustic or speech representation. This fact was first illustrated in an experiment in which subjects were shown a list of six consonants for immediate serial recall. The errors were classified by a confusion matrix, in which the columns indicate the letter presented and the rows indicate the letter actually recalled. A high correlation was found between the confusion matrix resulting from this memory task when subjects recalled a list of visually presented letters, and the confusion matrix resulting from a listening task when subjects heard one letter at a time and simply named it with no memory requirement (Conrad 1964).

2.2 *The Free Recall Task*

Another paradigm commonly used in the early investigation of short-term memory was the free recall task, in which subjects are given a relatively long list of items and then recall them in any order they choose. When the list is recalled immediately, the subjects show greater memory for the most recent items. This 'recency effect' was attributed to the fact that the final items in the list, but not the earlier ones, are still in short-term memory at the termination of the list presentation. Support for this conclusion came from the observation that if presentation of the list is followed by a distractor task, then there is no recency effect, although as in the case of immediate recall there is a 'primacy effect,' or advantage for the initial items in the list. The explanation offered for the elimination of the recency effect with the distractor task is that the final list items are no longer in short-term memory after the distractor activity. Further support for this explanation came from finding that other variables like list length and presentation rate had differential effects on the recency and earlier sections of the serial position curve. Specifically, subjects are less likely to recall an item when it occurs in a longer list for all except the most recent list positions. Likewise, subjects are less likely to recall an item in a list presented at a faster rate for all but the recency part of the serial position curve.

3. *Theoretical Accounts*

The most widely accepted account of short-term memory was presented in the 1960s in what was subsequently termed the 'modal model' because of its popularity. The core assumption of that model is the distinction between short-term memory, which is transient, and long-term memory, which is relatively permanent. The fullest description of the modal model was provided by Atkinson and Shiffrin (1968), who also distinguished between short-term memory and sensory memory.

3.1 *The Buffer Model*

Atkinson and Shiffrin's 'buffer model,' as it has been called, is characterized along two dimensions (Atkinson and Shiffrin 1968). Following a computer analogy, the first dimension involves the structural features of the system, analogous to computer hardware, and the second dimension involves the 'control processes,' or operations under the control of the subjects, analogous to computer software. The structural features of the buffer model include the sensory registers (with different registers for each sense), short-term store, and long-term store. The control process emphasized is rote rehearsal, which takes place in part of short-term store called the 'buffer.' The rehearsal buffer has a small capacity with a fixed number of slots (about four).

To account for performance in the free recall task, it is assumed that each item enters the buffer and when the buffer is full the newest item displaces a randomly selected older item. While an item is in the buffer,

information about it is transferred to long-term store, with the amount of information transferred a linear function of the time spent in the buffer. Although information about an item thereby gets transferred to long-term store, the item remains in the buffer until it is displaced by an incoming item. At test, subjects first respond with any items in the buffer and then try to retrieve other items from long-term store, with the number of retrieval attempts fixed (see *Memory Retrieval*). These assumptions allow the model to account for the various empirical observations found with the free recall task. The model accounts for the recency effect and its elimination with a distractor task because the final items are still in the buffer immediately after list presentation but get displaced from the buffer by the interpolated material of the distractor task. The model accounts for the primacy effect by assuming that the buffer starts out empty so the initial items reside in the buffer longer than subsequent items because they are not subject to displacement until the buffer is full. The effect of list length is due to the fixed number of attempts to retrieve information from long-term store. The longer the list, the smaller is the likelihood of finding a particular item. The effect of presentation rate is due to the linear function for transferring information from short-term to long-term store. More information is transferred when the rate is slower so that retrieving an item from long-term store is more likely at a slower rate.

There have been numerous refinements and expansions of the buffer model since it was first proposed. These updated versions have been termed 'SAM' (search of associative memory) and 'REM' (retrieving effectively from memory). However, these refinements have been focused on the search processes in long-term memory, and the short-term memory component of the model remains largely intact (Shiffrin 1999).

3.2 The Perturbation Model

Whereas the buffer model explains the results of the free recall task, a popular model proposed by Estes (1972) explains the results of the distractor paradigm. According to this 'perturbation model', the representation in memory of each item in a list is associated with a representation of the experimental context. This contextual representation is known as a 'control element.' It is assumed that if the control element is activated, then the representations of the items associated with it are activated in turn, allowing for their recall. Forgetting is attributed in part to the fact that the context shifts with time so that subjects may be unable to activate the appropriate control element after a delay. Reactivation of the item representations by the control element does not only occur at the time of test. In addition, there is a reverberatory loop providing a periodic recurrent reactivation of each item's representation, with the difference in reactivation times for the various items reflecting the difference in their initial presentation times. This reverberatory activity provides the basis for the short-term memory of the order of the items in a list. Because of random error in the reactivation process, timing perturbations result, and these perturbations may be large enough to span the interval separating item representations, thereby leading to interchanges in the order of item reactivations and, hence, transposition errors during recall. Because such interchanges can occur in either the forward or backward direction for middle items in the list but in only one direction for the first and last items, the bowed serial position function for transposition errors is predicted. The symmetry in the serial position function is predicted with the assumption that timing perturbations do not start until all the list items have been presented. Because interchanges can also occur between the list items and the interpolated distractor items, the gradually increasing proportion of nontransposition errors is also predicted.

The original version of the perturbation model included only the perturbation process responsible for short-term memory, but subsequent research documented the need to include a long-term memory process in addition to the short-term perturbation process (Healy and Cunningham 1999). Other extensions allowed the perturbation model to account for a wide range of findings in the distractor paradigm and also to provide insights into other memory processes such as those responsible for memory distortions in eyewitness situations (Estes 1999; see also *Eyewitness Memory: Psychological Aspects*).

3.3 Theoretical Controversies and Complications

Although models of memory typically include the distinction between short- and long-term memory, some investigators have pointed to problems with some of the evidence establishing the need to postulate a distinct short-term memory. For example, Craik and Lockhart (1972) argued that short-term memory cannot be distinguished by the exclusive use of speech coding, as suggested by Conrad (1964). Craik and Lockhart proposed an alternative framework called 'levels of processing,' according to which information is encoded at different levels and the level of processing determines the subsequent rate of forgetting (see *Memory: Levels of Processing*).

More recent arguments against the need for a separate short-term memory were made by Crowder (1993), who pointed out that the rapid forgetting across retention intervals in the distractor paradigm is not found on the first trial of an experiment. He also pointed out that a recency effect like that in immediate free recall is found in a number of tasks relying exclusively on long-term memory. Healy and McNamara (1996) dismissed some of these arguments with two general considerations. First, information

can be rapidly encoded in long-term memory, so that, for example, recall can derive from long-term memory rather than short-term memory on the first trial of an experiment before interference from previous trials has degraded the long-term memory representation. Second, although recency effects occur in many memory paradigms, the specific properties and causes of the serial position functions differ across paradigms.

Memory models also typically make the distinction between sensory and short-term memory. However, an important exception is Nairne's 'feature model' (Nairne 1990). Instead of distinguishing between these two types of memory stores or processes, the feature model distinguishes between two types of memory trace features—modality independent (which involve speech coding) and modality dependent (which are perceptual but not sensory). According to this model, during recall subjects compare the features of the memory trace to the features of various item candidates. Forgetting occurs as the result of feature overwriting, by which a new feature can overwrite an old feature but only if the two features are of the same type (modality dependent or modality independent).

Although short-term memory is distinguished from both sensory and long-term memory by most contemporary models of memory, including a recent 'composite model' proposed by Estes (1999) to describe the current state of theorizing, many current models have broken down short-term memory into different subcomponent processes. The most popular of these models is Baddeley's 'working memory model' (Baddeley 1992), which includes an attentional control system called the 'central executive' (see *Attention: Models*) and two 'slave systems,' the phonological loop (responsible for speech coding) and the visuospatial sketchpad (responsible for the coding of both spatial and visual information). Recent neuropsychological evidence (Martin and Romani 1994) has led to a further breakdown into semantic and syntactic components in addition to the components of Baddeley's system.

Despite these controversies and complications, it seems clear that the concept of 'short-term memory' will continue in the future to play an important role in our theoretical understanding of cognitive processes.

Short-term Memory: Psychological and Neural Aspects

1. Short-term Memory

'Short-term memory' refers to a number of systems with limited capacity (in the verbal domain, roughly the 'magical' number 7 ± 2 items: Miller 1956) concerned with the temporary retention (in the range of seconds) of a variety of materials. Knowledge of the functional and anatomical organization of short-term memory in humans, and its role in cognition as at the turn of the twenty-first century, is herewith presented, drawing data from three main sources of evidence: (a)

behavioral studies in normal individuals and in brain-injured patients with selective neuropsychological short-term memory deficits; (b) correlations between the anatomical localization of the cerebral lesion and the short-term memory disorder of brain-damaged patients; (c) correlations between the activation of specific cerebral areas and the execution of tasks assessing short-term retention in normal subjects. The two more extensively investigated aspects of short-term memory are considered: verbal and visual/spatial. 'Short-term memory' is closely related to the concept of 'working memory' (see *Working Memory, Psychology of Working Memory, Neural Basis of*). The present article focuses on the 'storage' and 'rehearsal' components of the system, rather than on the cognitive operations and executive functions currently associated with 'working memory.' However, the section devoted to the uses of short-term memory illustrates some of the working aspects of short-term retention.

2. *Historical Origin of the Construct 'Short-term Memory'*

Suggestions of a distinction between two types of memory, one concerned with temporary retention, and the other having the function of a storehouse for materials which have been laid out of sight, date back at least to John Locke's '*Essay Concerning Human Understanding*' (1700). William James (1895) revived the distinction, suggesting the existence of a limited-capacity 'primary memory,' embracing the present and the immediate past, and subserving consciousness (see *Consciousness, Neural Basis of*). Psychological research in the nineteenth century and in the first half of the twentieth century was, however, mainly concerned with the diverse factors affecting learning and retention, in the context of a basically unitary view of human memory. It was only in the 1950s that short-term memory became the object of systematic behavioral studies in normal subjects (Baddeley 1976). In the late 1960s the division of human memory into a short- and a long-term system became a current view (Atkinson and Shiffrin 1968).

3. *Functional Architecture of Short-term Memory*

3.1 *Evidence from Normal Subjects*

Three main behavioral phenomena suggest the existence of a discrete limited-capacity system, concerned with short-term retention (Baddeley 1976, Baddeley 1986, Glanzer 1972). (a) Accuracy in recalling a short list of stimuli (e.g., trigrams of consonants or of words) decreases dramatically in a few seconds if the subjects' repetition of the memory material (rehearsal) is prevented by a distracting activity such as counting backwards by threes. (b) In the immediate free recall of a sequence of events, such as words, the final five to six stimuli on the list are recalled better that the preceding ones. This 'recency effect' vanishes after a few seconds of distracting activity, and is minimally affected by factors such as age, rate of presentation of the stimuli, and word frequency. (c) In the immediate serial recall of verbal material (memory span), the subject's performance is affected by factors such as phonological similarity and word length, with the effects of semantic factors being comparatively minor. Each of these phenomena subsequently proved to be considerably more complex than initially thought. They were also interpreted as compatible with a unitary, single-system, view of human memory. This account proved untenable, however, mainly on the basis of neuropsychological evidence.

These empirical observations illustrate the main characteristics of 'short-term memory': a retention system with limited capacity, where the memory trace, in the time range of seconds, shows a decay, which may be prevented through rehearsal. Material stored in short-term memory has a specific representational format, which, in the case of the extensively-investigated verbal domain, involves phonological codes, separately from lexical-semantic representations stored in long-term memory. The latter contribute, however, to immediate retention, e.g., in verbal span tasks.

The functional architecture of phonological short-term memory has been investigated in detail using effects which break down storage and rehearsal subcomponents. The effect of phonological similarity, whereby the immediate serial recall of auditory and visual verbal material is poorer for sequences of phonologically similar stimuli than for dissimilar ones, reflects the coding which takes place in the phonological short-term store. The effect of word length, whereby the immediate serial recall of auditory and visual verbal material is poorer for sequences of long words than for short ones, is held to reflect the activity of the process of rehearsal, abolished by 'articulatory suppression,' i.e., a continuous uttering of an irrelevant speech sound. Suppression, while disrupting rehearsal, also reduces immediate memory performance in span tasks. The interaction between phonological similarity, input modality and articulatory suppression, with suppression abolishing phonological similarity only when the stimuli are presented visually, suggests that rehearsal participates in the process of conveying visual verbal material to the phonological short-term store. Finally, some phonological judgments (such as rhyme and stress assignment) are held to involve the articulatory components of rehearsal, because the performance of normal subjects is selectively impaired by suppression (Burani et al. 1991).

In the nonverbal domain a similar distinction is drawn between visual and spatial short- and long-term memory systems, with the relevant representational

Figure 1
Short-term forgetting of a single letter by patient PV after 3 to 15 seconds of delay filled by arithmetic distracting activity. With an auditory input, dramatic forgetting occurred within a few seconds. In the visual modality, the patient's performance was at ceiling. Immediate recall was fully accurate in both input modalities, ruling out perceptual and response-related deficits, differently from the short-term memory disorder (Source: data from Basso A, Spinnler H, Vallar G, Zanobio M E 1982 Left hemisphere damage and selective impairment of auditory-verbal short-term memory. *Neuropsychologia* **20**: 263–274)

format being in terms of the shape or spatial location of the stimulus (Baddeley 1986, Della Sala and Logie 1993). Also in the visuo-spatial domain, similarity, recency and interference effects have been observed. Visuo-spatial short-term memory is likely to comprise storage and rehearsal (pictorial and spatial) components. In the case of spatial locations, rehearsal may be conceived in terms of planned movements (e.g., ocular, manual reaching, locomotion) towards a target coded in a spatial reference frame, (e.g., egocentric).

3.2 Evidence from Brain-injured Patients

Studies in patients with localized brain damage provide unequivocal evidence that supports the independence of short- and long-term memory systems, conjuring up a double dissociation of deficits. In patients with 'global amnesia,' which may be characterized as a selective impairment of the declarative or explicit component of long-term memory (see *Declarative Memory, Neural Basis of*; *Episodic and Autobiographical Memory: Psychological and Neural Aspects*) verbal and visuo-spatial short-term memory are unimpaired, with immediate serial span, the recency effect in immediate free recall, short-term forgetting being within normal limits. This functional dissociation suggests a serial organization of the two systems, with temporary retention being a necessary condition for long-term storage (Atkinson and Shiffrin 1968).

Since the late 1960s selective impairments of short-term memory have been reported (Vallar and Papagno 1995, Vallar and Shallice 1990). The more extensively investigated area concerns auditory-verbal (phonological) short-term memory. Patients show a disproportionate reduction of the auditory-verbal span to an average of less than three items (digits, letters, or words); the recency effect in immediate free recall of auditory-verbal lists of words is abolished; short-term forgetting is abnormally rapid. The disorder is modality-specific, with the level of performance being better when the material is presented visually (Fig. 1). This input-related dissociation has two main implications: (a) discrete phonological and visual short-term memory components exist; (b) in the input–output processing chain, the phonological short-term store should be envisaged as an input system, rather than an output buffer store. This division argues against a monolithic view of the system as a single store, which is amodal, i.e., not specific for the different sensory modalities (see Atkinson and Shiffrin 1968). Additional support to this input locus of the system comes from the observation that in some of these patients speech production is entirely preserved.

Patients with defective phonological short-term memory may show unimpaired long-term verbal and visuo-spatial learning (Fig. 2). This observation further corroborates the complete independence of short- and long-term memory systems, but is incompatible with a serial organization, in which defective short-term memory entails a long-term memory impairment (see Atkinson and Shiffrin 1968), suggesting a parallel architecture instead. After early perceptual analysis, information may enter short- or long-term memory, either of which may be selectively disrupted by brain damage. The learning abilities of these patients are, however, dramatically impaired when the phonological material to be learned does not possess pre-existing lexical-semantic representations in long-term memory. This is the case of pronounceable meaningless sequences of letters, such as non-words, or words of a language unknown to the subject (Fig. 2).This phonological learning deficit indicates that, within a specific representational domain, temporary retention in short-term memory is necessary for stable long-term learning and retention, as predicted by serial models.

Other brain-injured patients show deficits of short-term retention in the visual and spatial domain, even though these patterns of impairment have been explored less extensively than the phonological disorder. Immediate retention of short sequences of spatial

Figure 2
Word (A) and nonword (B) paired-associate learning by patient PV and matched control subjects (C), with auditory presentation. The patient's performance was within the normal range with native language (Italian) words, dramatically defective with unfamiliar nonwords (Russian words transliterated into Italian) (Source: Baddeley A D, Papagno C, Vallar G 1988 When long-term learning depends on short-term storage. *Journal of Memory and Language* **27**: 586–595)

locations, as assessed by a block tapping task (a spatial analogue of digit span), may be selectively defective, with verbal memory being unaffected, in both its short- and long-term components. In other patients, the deficit may involve the visual (shape) component of short-term memory, while impairments in the short-term visual recognition of unfamiliar faces, objects, voices, colours have been also described. The disorder of patients with defective visual imagery (as assessed, for instance, by tasks requiring colour or size comparisons) may be interpreted in terms of an impaired visual short-term memory store (see *Visual Imagery, Neural Basis of*). A deficit of visuo-spatial short-term memory may also disrupt long-term learning of unfamiliar non-verbal material, as assessed by recognition memory for unfamiliar faces and objects. This extends to the visuo-spatial domain the conclusion that long-term acquisition requires short-term storage.

The process of rehearsal has been traditionally described as an activity which, through rote repetition, refreshes the short-term memory trace, preventing its decay. The precise characteristics of rehearsal have been elucidated in more detail in recent years, particularly in the domain of phonological memory. Rehearsal may be conceived in terms of the recoding of the memory trace from input (auditory-verbal) to output-related (articulatory) representations and vice-versa. More specifically, rehearsal of verbal material has long been regarded as 'articulatory' in nature, involving output-related verbal processes—such as the motor programming of speech production in a phonological assembly system or output buffer—the actual articulation of the material to be rehearsed (subvocal rehearsal), or both.

Anarthric subjects, who are unable to utter any articulated speech sound due to congenital disorders or brain damage acquired in adult age, may, nonetheless, show a preserved immediate memory, including verbal rehearsal. This suggests that the process is 'central' and does not require the activity of the peripheral musculature. Brain-damaged patients with a selective impairment of rehearsal (Vallar et al. 1997) show a defective immediate verbal span, as do patients with damage to the phonological short-term store. Both components of phonological memory contribute to immediate retention, though the phonological store provides a major retention capacity. The ability to perform phonological judgments is disrupted, however, by damage to the rehearsal process, but not to the phonological store. By contrast, a defective rehearsal leaves the recency effect in immediate free recall of auditory lists of words largely unimpaired. This recency effect is largely reduced or absent in patients with damage to the phonological short-term store.

4. The Uses of Short-term Memory

Is there a use for a system providing the temporary retention of a limited amount of stimuli, besides infrequent situations such as the following? A friend tells us an unfamiliar eight-digit number, which we have to dial on a telephone placed on the other side of a large street and we have no paper and pencil to write it down. The answer is positive. Short-term retention contributes to the stable acquisition of new information in long-term memory. More specifically, phonological short-term memory plays an important role in learning new vocabulary and participates in the processes of speech comprehension and production (see *Speech Perception*; *Speech Production, Psychology of*).

4.1 Long-term Learning

The observation that patients with defective auditory-verbal span are also impaired in learning unfamiliar pronounceable letter sequences gives rise to the possibility that phonological memory may contribute to a relevant aspect of language development, the acquisition of vocabulary (Fig. 2). Similarly, subjects with a developmental deficit of phonological memory are impaired in vocabulary acquisition and in non-word learning. An opposite pattern is provided by subjects with a congenital cognitive impairment which selectively spares phonological short-term memory. Acquisition of vocabulary, foreign languages and non-word learning are also preserved. Converging evidence from different subject populations supports this view. Correlational studies in children have shown that the capacity of phonological memory is a main predictor of the subsequent acquisition of vocabulary, both in the native and in a second language. In normal adult subjects, the variables which disrupt immediate memory span (phonological similarity, item length, articulatory suppression) also impair the acquisition of non-words.

Polyglots have a greater capacity of phonological memory, compared to nonpolyglots, and a better ability to learn novel words. Phonological short-term memory may be considered as a learning device for the acquisition of novel phonological representations, and the building up of the phonological lexicon (Baddeley et al. 1998). A few observations in brain-damaged patients suggest a similar role for visuo-spatial short-term memory in the acquisition of new visual information, such as unfamiliar faces and objects.

4.2 Language Processing

The idea that short-term retention contributes to speech comprehension dates back to the 1960s. Phonological memory may withhold incoming auditory-verbal strings, while syntactic and lexical-semantic analyses are performed. Patients with defective phonological memory show a preserved comprehension of individual words, as well as many sentential materials, and a normal ability to decide whether or not sentences are grammatically correct. This may reflect, on the one hand, the operation of on-line lexical-semantic processes, heuristics and pragmatics, and, on the other, the complete independence of syntactic and lexical-semantic processes from phonological memory. Patients are however impaired by 'complex' sentences, where 'complexity' refers to a number of non-mutually-exclusive factors, such as: (a) a high speed of material presentation, which prevents the immediate build-up of an unambiguous cognitive representation; (b) word order conveying meaning-crucial information (e.g., in sentences in which a semantic anomaly is introduced by a change in the linear arrangement of words: 'The world divides the equator into two hemispheres, the southern and the northern'); (c) extralinguistic presuppositions biasing the interpretation of the spoken message.

Under such conditions, adequate interpretation may require backtracking to the verbatim (phonological) representation of the sentence, temporarily held in phonological memory. This provides a 'back-up' or 'mnemonic window' resource for performing supplementary cognitive operations necessary for comprehension (Vallar and Shallice 1990).

5. Neural Architecture of Short-term Memory

5.1 Phonological Short-term Memory

Anatomoclinical correlation studies in brain-damaged patients with a selective impairment of the auditory-verbal span indicate that the inferior parietal lobule (supramarginal gyrus) of the left hemisphere, at the temporoparietal junction, represents the main neural correlate of the 'store' component of phonological short-term memory (Vallar and Papagno 1995). The frontal premotor regions in the left hemisphere and other structures such as the insula are the major neural correlates of the 'rehearsal' component, even though the available anatomoclinical data are more limited (Vallar et al. 1997).

Functional neuroimaging studies in normal subjects concur with this pathological evidence, to suggest a left-hemisphere-based network. Activation in the left supramarginal gyrus [Brodmann's area (BA) 40] is associated with the 'store' component of short-term phonological memory, activation in the left frontal premotor BA 44 (Broca's area) and BA 6, and in the left insula, with the 'rehearsal' component (Paulesu et al. 1996). In these studies, in line with the behavioral evidence from normal subjects and patients, an immediate verbal span task activates both the inferior

parietal region (phonological short-term store) and the premotor cortex (rehearsal process) in the left hemisphere. Conversely, rhyme judgements selectively activate the left premotor regions, whose damage, in turn, disrupts the patients' ability to perform this task. These activation and lesion-based data support, from an anatomofunctional perspective, the behavioral distinction between a 'storage' component and a 'rehearsal process' in phonological short-term memory. Furthermore, they qualify 'rehearsal' as a process which makes use of components also concerned with the planning (i.e., programming in the left premotor cortex) of articulated speech. Seen in this perspective, phonological memory may be regarded as a component of the language system. Finally, connectionist modelling of this architecture is currently being developed (Burgess and Hitch 1999).

5.2 *Visual and Spatial Short-term Memory*

Studies in brain-damaged patients suggest an association between damage to the posterior regions of the right hemisphere and defective spatial short-term memory, as assessed by tasks requiring the reproduction of sequences of spatial locations. There is also evidence suggesting that damage to the posterior regions of the left hemisphere brings about disorders of visual short-term memory, such as defective immediate retention of sequences of visual stimuli, (e.g. lines), and impaired recognition of more than one visual stimulus at a time (defective simultaneous form perception) (Vallar and Papagno 1995).

Neuroimaging activation studies in humans support the distinction between primarily spatial (a location, a 'where' component) and visual short-term memory systems (Smith et al. 1995). The main neural correlates of spatial memory for locations include the occipital extra-striate, posterior–inferior parietal, dorsolateral premotor and prefrontal cortices. Short-term visual recognition memory is associated with activations in a network including the posterior–inferior parietal, temporal and ventral premotor and prefrontal cortices. Right hemisphere regions may play a more relevant role in spatial memory for locations, while left hemisphere regions are more involved in visual memory for objects. These patterns of activation indicate an association of the 'dorsal visual stream' with spatial short-term memory for locations and of the 'ventral visual stream' with short-term visual recognition memory.

6. *Conclusion*

Behavioural observations and neuroanatomical evidence from normal subjects and brain-injured patients concur in suggesting that 'short-term memory' should be conceived as a multiple-component system with specific functional properties and discrete neural correlates. These systems secure the retention of a limited amount of material in the time range of seconds and contribute to relevant aspects of cognition, such as long-term learning.

Shyness and Behavioral Inhibition

Since the 1980s, the study of shyness, behavioral inhibition, and social withdrawal in childhood has taken on a research trajectory that can best be described as voluminous. Yet, these related phenomena remain something of a mystery, carrying with them a variety of definitions and a number of very different perspectives concerning psychological significance. Because there appear to be several different characterizations of forms of shy, inhibited, or nonsocial behavior, the first goal of this article is to provide a definitional framework.

1. *Shyness, Behavioral Inhibition, and Social Withdrawal: Definitions*

In their efforts to identify the etiology of children's personalities and social behaviors, developmental scientists have attempted to determine the relevant dispositional dimensions of temperament that may underlie children's actions that are displayed consistently across situations, and continuously over time. One such dispositional construct is *behavioral inhibition* (Kagan 1997). Behavioral inhibition has been defined variously as (a) an inborn bias to respond to unfamiliar events by showing anxiety; (b) a specific vulnerability to the uncertainty all children feel when encountering unfamiliar events that cannot be assimilated easily; and (c) one end of a continuum of possible initial behavioral reactions to unfamiliar objects or challenging social situations. These definitions highlight some common elements: behavioral inhibition is (a) a pattern of responding or behaving, (b) possibly biologically determined, such that (c) when unfamiliar and/or challenging situations are encountered, (d) the child shows signs of anxiety, distress, or disorganization.

The term *shyness* has been used to refer to inhibition in response to novel *social* situations. In infancy and early childhood, shyness is elicited by feelings of anxiety and distress when confronted by unfamiliar people. To some, such behavior serves an adaptive purpose in that it removes children from situations they perceive as discomforting and dangerous (Buss 1986). But variability of the infantile shyness response is great; some children clearly demonstrate the behavior excessively.

In middle childhood, children have the cognitive skill to compare themselves with others and to understand that others can, and do, pass judgment on them. It is this understanding of social comparison and evaluation that can elicit shy behavior among older children, adolescents and adults (Buss 1986). That is, children may remove themselves from situations they believe will be discomforting because others will pass judgment on their skills, personae, and so on. Again, variability is great; some children display shyness that is clearly out-of-the ordinary.

A related construct is *social withdrawal*, a phenomenon that refers to the consistent (across situations and over time) display of solitary behavior when encountering *both* familiar and/or unfamiliar peers (Rubin and Stewart 1996). Thus, shyness is embedded within the construct of social withdrawal. The common denominator for inhibition, shyness, and social withdrawal is that the representative behavior is one that moves children *away* from their social worlds, that is, *solitude*.

2. *Different Forms of Inhibition, Shyness, and Solitude*

Inhibited behavior in the face of the unfamiliar typically has been assessed by observing very young children as they are confronted by unfamiliar adults, objects, or peers. Insofar as shyness is concerned, it is best exemplified behaviorally by the display of socially *reticent* behavior during the preschool and early childhood periods. Among unfamiliar others, reticent preschoolers hang back, watching peers from afar; they make few social initiations and back away from initiations made by others. When asked to speak up in groups of unfamiliar peers, reticent children choose not to do so at all, and if they do speak, it is uncomfortably and for a very short period of time. Further, when asked to collaborate with peers to solve problems, they spend their time watching others rather than providing the requested help.

Reticence is one of several forms of solitude demonstrated by children (Rubin and Asendorpf 1993). Some preschoolers appear to be satisfied playing with objects rather than people. These children play alone, constructing and exploring objects. The term used to describe such behavior is *solitary-passivity* (Coplan et al. 1994). When others initiate interaction with solitary-passive children, they do not back away; further, they participate fully and actively in-group problem-solving behavior. Thus unlike shy children who have a high social avoidance motivation, those whose solitary behavior is mainly of the solitary-passive ilk may be described as having a low social approach motivation.

Still yet other children demonstrate solitude that appears to reflect immaturity. These young children engage in solitary-sensorimotor activity (*solitary-active play*), repeating motor movements with or without objects (Coplan et al. 1994).

2.1 Developmental Differences and Change

Typically all forms of solitude decrease from early through middle and late childhood. As noted above, causes of shy behavior change from early wariness to the anxiety associated with being socially evaluated. While reticent behavior tends to decrease with age, it is also the case that the 'meanings' of different forms of solitude change as well. For example, as children come to cope with their social anxieties among unfamiliar peers, they become increasingly likely to display that form of solitude that had been viewed earlier as normal and adaptive—*solitary-exploration* and *construction*. Thus, with increasing age, such constructive solitude becomes increasingly associated with measures of social wariness, and physiological markers of anxiety and emotion dysregulation (see below).

3. Putative Causes of Inhibition, Shyness, and Social Withdrawal

3.1 Physiology

Behavioral inhibition has been thought to emanate from a physiological 'hard wiring' that evokes caution, wariness, and timidity in unfamiliar social and nonsocial situations. Inhibited infants and toddlers differ from their uninhibited counterparts in ways that imply variability in the threshold of excitability of the amygdala and its projections to the cortex, hypothalamus, sympathetic nervous system, corpus striatum, and central gray. That there is a physiological basis underpinning behavioral inhibition is drawn from numerous psychophysiological studies. For example, stable patterns of right frontal EEG asymmetries in infancy predict temperamental fearfulness and behavioral inhibition in early childhood (Calkins et al. 1996). The functional role of hemispheric asymmetries in the regulation of emotion may be understood in terms of an underlying motivational basis for emotional behavior, specifically along the *approach–withdrawal continuum*. Infants exhibiting greater relative right frontal asymmetry are more likely to withdraw from mild stress, whereas infants exhibiting the opposite pattern of activation are more likely to approach.

Another physiological entity that distinguishes wary from nonwary infants and toddlers is vagal tone, an index of the functional status or efficiency of the nervous system, marking both general reactivity and the ability to regulate one's level of arousal. Reliable associations have been found between vagal tone and inhibition in infants and toddlers: children with *lower vagal tone* (consistently high heart rate due to less parasympathetic influence) tend to be more behaviorally inhibited (Kagan et al. 1987).

In early childhood, *reticent* behavior is associated with the same physiological markers as is the case for behavioral inhibition in infancy and toddlerhood. Thus, in early childhood, reticent, fearful, solitary behavior is associated with greater relative right frontal EEG activation; but constructive solitude is not (Fox et al. 1996). Further, parents view children who have such EEG asymmetries as anxious. Among older, elementary school-age children, shy, reticent behavior among *familiar* peers (i.e., *social withdrawal*) has been associated positively with internalized negative emotions such as nervousness, distress, and upset; and negatively related to positive emotions such as enthusiasm and excitement.

3.2 Parent–Child Relationships

Attachment theorists maintain that the primary relationship develops during the first year of life, usually between the mother and the infant (Bowlby 1973). Maternal sensitivity and responsiveness influence whether the relationship will be secure or insecure. Researchers have shown that securely attached infants are likely to be well adjusted, socially competent, and successful at forming peer relationships in early and middle childhood whereas insecurely attached children may be less successful at social developmental tasks.

Researchers have proposed that those infants who are temperamentally reactive and who receive insensitive, unresponsive parenting come to develop an insecure-ambivalent ('C'-type) attachment relationship with their primary caregivers (e.g., Calkins and Fox 1992). In novel settings these 'C' babies maintain close proximity to the attachment figure (usually the mother). When the mother leaves the room briefly, these infants become quite unsettled. Upon reunion with the mother, these infants show angry, resistant behaviors interspersed with proximity—or contact-seeking behaviors. It is argued further that this constellation of infant emotional hyperarousability and insecure attachment may lead the child to display inhibited/wary behaviors as a toddler, and there are data supportive of this conjecture.

Given that the social behaviors of preschoolers and toddlers who have an insecure 'C'-type attachment history are thought to be guided largely by fear of rejection, it is unsurprising to find that when these children are observed in peer group settings, they appear to avoid rejection by demonstrating passive, adult-dependent behavior and withdrawal from social interaction. Lastly, 'C' babies lack confidence and assertiveness at age 4 years; then, at age 7 years they are seen as passively withdrawn (Renken et al. 1989).

3.3 Parenting

Recently, researchers have shown that parental influence and control maintain and exacerbate child

inhibition and social withdrawal. For example, mothers of extremely *inhibited* toddlers have been observed to display overly solicitous behaviors (i.e., intrusively controlling, unresponsive, physically affectionate). Mothers of *shy* preschoolers do not encourage independence and exploration. And mothers of *socially withdrawn* children tend to be highly controlling, overprotective, and poor reciprocators of their child's displays of positive behavior and positive affect. Lastly, researchers have shown that mothers of socially withdrawn children are more likely than those of normal children to use such forms of psychological control statements, as devaluation, criticism, and disapproval. Taken together, these parenting practices may attack the child's sense of self-worth (for a review, see Rubin et al. 1995).

4. *Correlates and Consequences of Inhibition, Shyness, and Social Withdrawal*

Researchers who have followed, longitudinally, the course of development for inhibited infants have found strong consistency of behavior over time. As a group, children identified as extremely inhibited are more likely to be socially wary with unfamiliar peers in both the laboratory and at school, and to exhibit signs of physiological stress during social interactions (Kagan et al. 1987). In a longitudinal study extending into adulthood, Caspi and Silva (1995) found that individuals identified as shy, fearful, and withdrawn at 3 years reported that they preferred to stick with safe activities, be cautious, submissive, and had little desire to influence others at 18 years. A subsequent follow-up at age 21 on interpersonal functioning showed that these same children were normally adjusted in both their work settings and their romantic relationships.

Social withdrawal appears to carry with it the risk of a child's developing negative thoughts and feelings about the *self*. Highlighting the potential long-term outcomes of social withdrawal is a recent report which showed that social withdrawal among familiar peers in school at age 7 years predicted negative self-perceived social competence, low self-worth, loneliness, and felt peer-group insecurity among adolescents aged 14 years (Rubin et al. 1995). These latter findings are augmented by related research findings. For example, Renshaw and Brown (1993) found that passive withdrawal at age 9 to12 years predicted loneliness assessed one year later. Ollendick et al. (1990) reported that 10-year-old socially withdrawn children were more likely to be perceived by peers as withdrawn and anxious, more disliked by peers, and more likely to have dropped out of school than their well-adjusted counterparts five years later. Finally, Morison and Masten (1991) indicated that children perceived by peers as withdrawn and isolated in middle childhood were more likely to think negatively of their social competencies and relationships in adolescence. In sum, it would appear as if early social withdrawal, or its relation to anxiety, represents a behavioral marker for psychological and interpersonal maladaptation in childhood and adolescence.

5. *Summary and Future Directions*

The study of inhibition and shyness garnered an enormous amount of attention in the 1990s. Most empirical research has focused on the contemporaneous and predictive correlates of social reticence, shyness, and withdrawal at different points in childhood and adolescence. These correlated variables include those of the biological, intrapersonal, interpersonal, and psychopathology ilk that have been chosen from conceptual frameworks pertaining to the etiology, stability, and outcomes of socially wary and withdrawn behaviors. Thus far, it appears that socially inhibited children have a biological disposition that fosters emotional dysregulation in the company of others. These children, if overly directed and protected by their primary caregiver, become reticent and withdrawn in the peer group. In turn, such behavior precludes the development of social skills and the initiation and maintenance of positive peer relationships. Yet again, this transactional experience seems to lead children to develop anxiety, loneliness, and negative self-perceptions of their relationships and social skills.

Despite these strong conclusions, however, it is important to recognize that the data bases upon which these conclusions rest are relatively few. Clearly, replication work is necessary. The extent to which dispositional factors interact with parenting styles and parent–child relationships to predict the consistent display of socially withdrawn behavior in familiar peer contexts still needs to be established. Further, the sex differences discussed above require additional attention.

Lastly, our knowledge of the developmental course of inhibition, shyness, and social withdrawal is constrained by the almost sole reliance on data gathered in Western cultures. Little is known about the developmental course of these phenomena in Eastern cultures such as those in China, Japan, or India; and even less is known in Southern cultures such as those found in South America, Africa, and southern Europe. It may well be that depending on the culture within which these phenomena are studied, the biological, interpersonal, and intrapersonal causes, concomitants, and consequences of inhibition, shyness, and social withdrawal may vary. In short, cross-cultural research is necessary, not only for the study of these phenomena, but also for most behaviors that are viewed as deviant or reflective of intrapsychic abnormalities in the West.

Sibling-order Effects

Historically, sibling order has influenced important aspects of social, economic, and political life, and it continues to do so today in many traditional societies. Discriminatory inheritance laws and customs about royal succession that favor firstborns and eldest sons are just two examples. Sibling-order effects have also been documented for a wide variety of behavioral tendencies, although the magnitude and causal interpretation of these effects have been subject to debate. In the Darwinian process of competing for parental favor, siblings often employ strategies that are shaped by their order of birth within the family, and these strategies exert a lasting impact on personality. Radical revolutions are particularly likely to elicit differences in support by birth order. These behavioral patterns appear to be mediated by differences in personality as well as by differing degrees of identification with the family.

1. Social, Economic, and Political Consequences

Many societies—especially in past centuries and in non-Western parts of the world—have engaged in practices that favor one sibling position over another. For example, most traditional societies permit infanticide, especially when a child has a birth defect or when an immediately older infant is still breastfeeding. However, no society condones the killing of the elder of two siblings (Daly and Wilson 1988). An extensive survey of birth order and its relationship to social behavior in 39 non-Western societies found that the birth of a first child typically increases the status of parents and stabilizes the marriage. In addition, firstborns were generally found to receive more elaborate birth ceremonies, were given special privileges, and tended to exert authority over their younger siblings. In most of these 39 societies, firstborns maintained supremacy over their younger siblings even in adulthood. They also gained control of a greater share of parental property than laterborns, were more likely to become head of their local kin group, and tended to exert greater power in relationships with nonfamily members (Rosenblatt and Skoogberg 1974).

Previously, many Western societies employed sibling order as a means of deciding who inherits parental property or assumes political power. Primogeniture (the policy by which the eldest child or son automatically inherits property or political authority) was the most commonly employed mechanism, but other discriminatory inheritance practices have also been employed. For example, secondogeniture involves leaving the bulk of parental property to the second child or second son, and ultimogeniture involves leaving such property to the lastborn or youngest son.

Most variations in inheritance practices by sibling order can be understood by considering the advantages that accrue from such policies, given local economic circumstances (Hrdy and Judge 1993). For example, primogeniture has generally been practiced in societies where wealth is stable and based on limited land, and where talent does not matter much. Leaving the bulk of parental property to a single offspring avoids subdividing estates and hence reducing the social status of the family patronymic—something that was particularly important in past centuries among the landed aristocracy. However, in Renaissance Venice economic fortunes were generally based on speculative commerce rather than ownership of property, and parents typically subdivided their estates equally so as to maximize the chances of having one or more commercially successful offspring (Herlihy 1977). Ultimogeniture is a policy often found in societies that impose high death taxes on property. This inheritance practice has the consequence of maximizing the interval between episodes of taxation, thus reducing the overall tax burden.

Even in societies employing inheritance systems that favor one sibling over others, parents have commonly provided more or less equally for their offspring by requiring the child who inherits the family estate to pay a compensatory amount to each sibling. Primogeniture and related practices did not always mean disinheritance—a common misassumption. In medieval and early modern times, however, primogeniture among the landed aristocracy did mean that some younger sons and daughters faced difficult economic and social prospects. Among the medieval Portuguese nobility, for example, landless younger sons and daughters were significantly less likely to marry and leave surviving offspring (Boone 1986). Younger sons, for example, left 1.6 fewer children than did eldest sons. Younger sons were also nine times more likely than eldest sons to father a child out of wedlock. Because they posed a serious threat to political stability in their own country, younger sons were channeled by the state into expansionist military campaigns in faraway places such as India, where they often died in battle or from disease. Similarly, the Crusades can be seen, in part, as a church-state response to this domestic danger (Duby 1977). The surplus of landless younger daughters in the titled nobility was dealt with by sending them to nunneries.

2. *Personality*

Birth-order differences have long been claimed in the domain of personality, although these claims have remained controversial despite considerable research on this topic. Psychologists have investigated the consequences of birth order ever since Charles Darwin's cousin Francis Galton (1874) reported that eldest sons were overrepresented as members of the Royal Society. After breaking away from Sigmund Freud in 1910 to found a variant school of psychoanalysis, Alfred Adler (1927) focused on birth order in his own attempt to emphasize the importance of social factors in personality development. A secondborn, Adler considered firstborns to be 'power-hungry conservatives.' He characterized middleborns as competitive and lastborns as spoiled and lazy.

Since Adler speculated about birth order and its consequences for personality in 1927, psychologists have conducted more than 2000 studies on the subject. Critics of this extensive literature have argued that most of these studies are inadequately controlled for key covariates, such as social class and sibship size; that studies often conflict; and that birth-order differences in personality and IQ seem to have been overrated (Ernst and Angst 1983). Meta-analysis—a technique for aggregating findings in order to increase statistical power and reliability—suggests a different conclusion. If we consider only those well-designed studies controlling for important background variables that covary with birth order and can introduce spurious cross-correlations, a meta-analytic review reveals consistent birth-order differences for a wide range of personality traits (Sulloway 1995). For instance, firstborns are generally found to be more conscientious than laterborns, a difference that is exemplified by their being more responsible, ambitious, and self-disciplined. In addition, firstborns tend to be more conforming to authority and respectful of parents. Firstborns also tend to have higher IQs than their younger siblings—a reduction of about one IQ point is observed, on average, with each increment in birth rank (Zajonc and Mullally 1997).

These and other birth-order differences in personality can be usefully understood from a Darwinian perspective on family life (Sulloway 1996). Because they share, on average, only half of their genes, siblings will tend to compete unless the benefits of cooperating are greater than twice the costs (Hamilton 1964). In this Darwinian story about sibling competition, birth order does not exert a direct biological influence on personality. For example, there are no genes for being a firstborn or a laterborn. Instead, birth order is best seen as a proxy for various environmental influences, particularly disparities in age, physical size, power, and status within the family. These physical and mental differences lead siblings to pursue alternative strategies in their efforts to maximize parental investment (which includes emotional as well as physical

resources). This perspective on how sibling order shapes personality accords with research in behavioral genetics, which finds that most environmental influences on personality are not shared by siblings and hence belong to the 'nonshared environment' (Plomin and Daniels 1987).

Prior to the twentieth century, half of all children did not survive childhood. Even minor differences in parental favor would have increased an offspring's chances of getting out of childhood alive. Because eldest children have already survived the perilous early years of childhood, they are more likely than younger siblings to reach the age of reproduction and to pass on their parents' genes. Quite simply, a surviving eldest child was generally a better Darwinian bet than a younger child, which is why parents in most traditional societies tend to bias investment, consciously or unconsciously, toward older offspring. An exception to this generalization involves youngest children born toward the end of a woman's reproductive career. These children also tend to be favored, since they cannot be replaced (Salmon and Daly 1998).

Even when parents do not favor one offspring over another, siblings compete to prevent favoritism. Siblings do so, in part, by cultivating family niches that correspond closely with differences in birth order. Firstborns, for example, tend to act as surrogate parents toward their younger siblings, which is a good way of currying parental favor. As a consequence, firstborns tend to be more conservative and parent-identified than their younger siblings, which is one of the most robustly documented findings in the literature. Laterborns cannot compete as effectively as firstborns for this surrogate parent niche, since they cannot baby-sit themselves. As a consequence, laterborns seek alternative family niches that will help them to cultivate parental favor in different ways. To do so, they must often look within themselves for latent talents that can only be discovered through systematic experimentation. Toward this end, laterborns tend to be more open to experience—that is, more imaginative, prone to fantasies, and unconventional—propensities that offer an increased prospect of finding a valued and unoccupied family niche.

In addition to their efforts to cultivate alternative family niches, siblings diverge in personality and interests because they employ differing strategies in dealing with one another. These strategies are similar to those observed in mammalian dominance hierarchies. Because firstborns are physically bigger than their younger siblings, they are more likely to employ physical aggression and intimidation in dealing with rivals. Firstborns are the 'alpha males' of their sibling group, and they generally boss and dominate their younger brothers and sisters. For their own part, laterborns tend to employ low-power strategies to obtain what they want, including pleading, whining, cajoling, humor, social intelligence, and, whenever expedient, appealing to parents for assistance. Laterborns also tend to form coalitions with one another in an effort to circumvent the physical advantages enjoyed by the firstborn. Middle children are the most inclined to employ diplomatic and cooperative strategies. Some middle children are particularly adept at nonviolent methods of protest. Martin Luther King, Jr., the middle of three children, began his career as a champion of nonviolent reform by interceding in the episodes of merciless teasing that his younger brother inflicted upon their elder sister.

Only children represent a controlled experiment in birth-order research. They have no siblings and therefore experience no sibling rivalry. As a consequence, they are not driven to occupy a particular family niche. Although only children, like other firstborns, are generally ambitious and conform to parental authority, they are intermediate between firstborns and laterborns on most other personality traits. Because age spacing can affect functional sibling order, a firstborn whose next younger sibling is six or more years younger is effectively like an only child. Similarly, large age gaps can make some laterborns into functional firstborns or only children.

That brothers and sisters differ from one another for strategic reasons, rather than randomly, has been shown by studies involving more than one sibling from the same family (Schachter 1982). In one study, firstborns were found to be significantly different in personality and interests from secondborns, who were significantly different from thirdborns. By contrast, the first and third siblings were not as different as adjacent pairs, presumably because of less competition. This process of sibling differentiation has been termed 'deidentification' and extends to relationships with parents. For example, a firstborn child sometimes identifies more strongly with one parent than another. In such cases, the secondborn tends to identify more strongly with the parent that is not already preferred by the firstborn.

The most compelling evidence for birth-order effects in personality comes from studies in which siblings assess each other's personalities (Paulhus et al. 1999, Sulloway 1999). Such within-family designs control for the kinds of spurious correlations that can result from comparing individuals from different family backgrounds. Studies based on such direct sibling comparisons exhibit consistent birth-order effects in the expected direction. When the results are organized according to the Five-Factor Model of personality (Costa and McCrae 1992), firstborns tend to be more conscientious and slightly more neurotic than laterborns, whereas laterborns tend to be more agreeable, extraverted, and open to experience than firstborns.

Although reasonably consistent patterns for birth order and personality are observed according to the Five-Factor Model of personality, findings are significantly heterogeneous for three of the five personality dimensions. For example, firstborns tend to be more assertive than laterborns, which is an in-

dicator of extraversion, but laterborns tend to score higher on most other facets of extraversion, which include being more fun-loving, sociable, and excitement seeking. Similarly, laterborns tend to be more open to experience in the sense of being unconventional, whereas firstborns tend to be more open to experience in the sense of being intellectually oriented. Lastly, firstborns are more neurotic in the sense of being anxious about status, but laterborns are more neurotic in the sense of being more self-conscious.

As measured by direct sibling comparisons within the family, birth-order differences explain about four percent of the variance in personality, less than does gender and substantially more than do age, family size, or social class. In studies controlled for differences in age, sex, social class, and sibship size, siblings are about twice as likely to exhibit traits that are consistent with their sibling positions as to exhibit inconsistent traits. In short, not every laterborn has a laterborn personality (just as some firstborns deviate from the expected trend), but a reasonably consonant pattern is nevertheless present.

One still-unresolved question about birth order and personality is the extent to which within-family patterns of behavior transfer to behavior outside the family of origin. Recent studies suggest that birth-order effects observed in extrafamilial contexts are about one-third to one-half the magnitude of those manifested within the family (Sulloway 1999). Relative to firstborn spouses and roommates, for example, laterborn spouses and roommates are generally perceived to be more agreeable and extraverted, but less conscientious and neurotic. Outside the family of origin, birth-order effects seem to manifest themselves most strongly in intimate living relationships and in dominance hierarchies. These findings are not surprising, since they involve the kind of behavioral contexts in which sibling strategies were originally learned.

3. *Behavior During Radical Revolutions*

Some of the best evidence for sibling differences in behavior outside the family of origin comes from social and intellectual history. During socially radical revolutions, laterborns have generally been more likely than firstborns to question the status quo and to adopt a revolutionary alternative. This difference is observed even after controlling for the fact that laterborns, in past centuries at least, appear to have been more socially liberal than firstborns. As a rule, these effects are very context sensitive. During the Protestant Reformation, for example, laterborns were nine times more likely than firstborns to suffer martyrdom in support of the Reformed faith. (This statistic is corrected for the greater number of laterborns in the general population.) In countries that turned Protestant, such as England, firstborns were five times more likely than laterborns to suffer martyrdom for their refusal to abandon their allegiance to the Catholic faith. Thus laterborns gave their lives in the service of radical rebellion, whereas firstborns did so in an effort to preserve the waning orthodoxy. There was no generalized tendency, however, for laterborns to become 'martyrs' (Sulloway 1996).

Similarly, during the French Revolution firstborn deputies to the National Convention generally voted according to the expectations of their social class, whereas laterborn deputies were more likely to vote in the opposite manner. For this reason, there was only a modest tendency for firstborns and laterborns to vote in a particular manner, since voting was generally influenced by other important considerations that determined what it meant to conform or rebel in a rapidly changing political environment.

In response to radical conceptual changes in science one finds similar differences by birth order. Firstborns tend to be the guardians of what Thomas Kuhn (1970) has called 'normal' science, during which research is guided by the prevailing paradigms of the day. By contrast, laterborns tend to be the outlaws of science, sometimes flaunting its accepted methods and assumptions in the process of attempting radical conceptual change. During the early years of the Copernican revolution, which challenged church doctrine by claiming that the earth rotates around the sun, laterborns were five times more likely than firstborns to endorse this heretical theory. Copernicus himself was the youngest of four children. When Charles Darwin, the fifth of six children, became an evolutionist in the 1830s, he was 10 times more likely to do so than a firstborn. During other notable revolutions in science—including those led by laterborns such as Bacon, Descartes, Hutton, Semmelweis, and Heisenberg, and by occasional firstborns such as Newton and Einstein—younger siblings have typically been twice as likely as firstborns to endorse the new and radical viewpoint. Conversely, when new scientific doctrines, such as vitalism and eugenics, have appealed strongly to social conservatives, firstborns have been more likely than laterborns to pioneer and endorse such novel but ideologically conservative ideas. These birth-order effects typically fade over the course of scientific progress, as conceptual innovations accumulate supporting evidence and eventually convince the scientific majority.

In spite of their predilection for supporting radical innovations, laterborns have no monopoly on scientific truth. They were nine times more likely than firstborns to support Franz Joseph Gall's bogus theory of phrenology, which held that character and personality could be read by means of bumps on the head. In their willingness to question the status quo, laterborns run the risk of error through over-eager rebellion, just as firstborns sometimes err by resisting valid conceptual changes until the mounting evidence can no longer be denied.

During 'normal' science, firstborns possess a slight advantage over laterborns. Being more academically successful, firstborns are more likely than laterborns to become scientists. They also tend to win more Nobel prizes. This finding might seem surprising, but, according to the terms of Nobel's will, Nobel prizes have generally been given for 'discoveries' or creative puzzle solving in science, not for radical conceptual revolutions. Firstborn scientists who have innovated within the system include James Watson and Francis Crick, who together unraveled the structure of DNA, and Jonas Salk, who developed the polio vaccine. Such historical facts highlight another important point, namely, that firstborns and laterborns do not differ in overall levels of 'creativity.' Rather, firstborns and laterborns are preadapted to solving dissimilar kinds of problems by employing disparate kinds of creative strategies.

4. Family Sentiments

The kinds of birth-order effects that are observed during radical historical revolutions may depend as much on differences in 'family sentiments' as they do on personality. As Salmon and Daly (1998) have shown, firstborns (and to a lesser extent lastborns) are more strongly attached to the family system than are middle children. Historically, radical revolutions have tapped differences in family sentiments in two important ways. First, being considerably older than their offspring, parents were more likely to endorse the status quo, given that age is one of the best predictors of the acceptance of new and radical ideas (Hull et al. 1978). For this reason, endorsing a radical revolution has usually meant opposing parental values and authority, something that firstborns (and to a lesser extent lastborns) are less likely to do than are middleborns. Second, most radical revolutions, even in fields such as science, have tended to raise issues that are directly relevant to issues of parental investment and discrimination among offspring, filial loyalty, and overall identification with the family system. During the Reformation, for example, Protestant leaders such as Martin Luther strongly advocated the right to marriage by previously celibate clergymen and nuns, who tended to be younger sons and daughters. These Protestant leaders also advocated the egalitarian principles of partible inheritance, by which property—and even political rule—were subdivided equally among offspring (Fichtner 1989). During the height of the controversies raging over Darwin's theory of evolution, Darwin noted that discriminatory inheritance practices posed a serious impediment to human evolution, remarking to Alfred Russel Wallace: 'But oh, what a scheme is primogeniture for destroying natural selection!' (Sulloway 1996, p. 54).

Even when radical ideology does not play a central role in conceptual change, and when discriminatory inheritance systems are also not a factor, differences in identification with the family can impact on social and political attitudes. As Salmon (1998) has shown experimentally, political speeches appeal differentially to individuals by birth order depending on whether kinship terms are included in the speech. Firstborns and lastborns are more likely to react positively to speeches that employ kinship terms such as 'brother' and 'sister,' whereas middle children prefer speeches that employ references to 'friends.' To the extent that radical social movements make use of kinship terms, which they often do, birth-order differences in family sentiments will tend to influence how siblings react to radical change.

5. Conclusion

In past centuries birth order and functional sibling order have influenced such diverse social and political phenomena as royal succession, expansionist military campaigns, religious wars and crusades, geographic exploration, and inheritance laws. Even today, birth order and family niches more generally are among the environmental sources of personality because they cause siblings to experience the family environment in dissimilar ways. In particular, birth order introduces the need for differing strategies in dealing with sibling rivals as part of the universal quest for parental favor. This is a Darwinian story, albeit one with a marked environmental twist. Although siblings appear to be hard-wired to compete for parental favor, the specific niche in which they have grown up determines the particular strategies they adopt within their own family. Finally, because birth order and family niches underlie differences in family sentiments, including filial loyalty and self-conceptions about family identity, the family has historically supplied a powerful engine for revolutionary change.

Sibling Relationships, Psychology of

Siblings—brothers and sisters—have a key place in legends, history and literature throughout the world, from the era of the Egyptians and Greeks onward. The great majority of children (around 80 percent in Europe and the USA) grow up with siblings, and for most individuals their relationships with their siblings are the longest-lasting in their lives. Scientific study of the psychology of siblings is relatively recent, but is fast-growing, centering chiefly on studies of childhood and adolescence. The scientific interest of siblings lies, in particular, in the following domains: the nature and the potential influence of siblings on each other's development and adjustment, the illuminating perspective the study of siblings provides on developmental issues, and the challenge that siblings present to our understanding of how families influence development—why siblings differ notably in personality and adjustment even though they grow up within the same family, the significance of their shared and separate family experiences, and their genetic relatedness.

1. The Term 'Siblings'

This term is usually applied to 'full' siblings, brothers and sisters who are the offspring of the same mother and father, and share 50 percent of their genes; however, with the changes in family structure during the later decades of the twentieth century, increasing numbers of children have relationships with 'half siblings,' children with whom they share one biological parent, and 'step-siblings,' children who are unrelated biologically.

2. The Nature of Sibling Relationships

2.1 Characteristics of the Relationship

The relationship between siblings is one that is characterized by distinctive emotional power and intimacy from infancy onward. It is a relationship that offers children unique opportunities for learning about self and other, with considerable potential for affecting children's well-being, intimately linked as it is with each child's relationship with the parents. Clinicians and family systems theorists have, from early in the twentieth century, expressed interest in the part siblings play in family relationships, and in the adjustment of individuals. However, until the 1980s there was relatively little systematic research on siblings (with the notable exception of the classic studies of birth order by Koch 1954). In the 1980s and 1990s, research interest broadened greatly to include the investigation of sibling developmental influences, sources of individual differences between siblings, and links between family relationships (Boer and Dunn 1990, Brody 1996).

Individual differences in how siblings get along with each other are very marked from early infancy; siblings' feelings range from extreme hostility and rivalry to affection and support, are often ambivalent, and are expressed uninhibitedly. The relationship is also notable for its intimacy: siblings know each other very well, and this can be a source of both support and conflict. These characteristics increase the potential of the relationship for developmental influence. Because of the emotional intensity and familiarity of their relationships, the study of siblings provides an illuminating window on what children understand about each other, which has challenged and informed

conceptions of the development of early social understanding (Dunn 1992).

2.2 Developmental Changes in Sibling Relationships

As children's powers of understanding and communication develop, their sibling relationships change. Younger siblings play an increasingly active role in the relationship during the preschool years, and their older siblings take increasing interest in them. During middle childhood their relationships become more egalitarian; there is disagreement about how far this reflects an increase in the power of younger siblings over older siblings, or a decrease in the dominance both older and younger try to exert. A decrease in warmth between siblings during adolescence parallels the patterns of change found in the parent–child relationship as adolescents become increasingly involved with peers outside the family (Boer and Dunn 1990). There is a paucity of studies of siblings in adulthood; however, what information we have indicates that in the USA, most siblings maintain contact, communicate and share experiences until very late in life (Cicirelli 1996). During middle age, most adults describe feelings of closeness, rather than rivalry with their siblings, even when they have reduced contact, though family crises can evoke sibling conflict. Closeness and companionship become increasingly evident among older adults. Step- and half-siblings also continue to keep contact with each other, though they see each other less often than full siblings. Relationships with sisters appear to be particularly important in old age; this is generally attributed to women's emotional expressiveness and their traditional roles as nurturers. Little systematic research has focused on ethnic differences; however, in a national sample in the USA, sibling relationships in African-American, Hispanic, non-Hispanic whites, and Asian-American adult respondents were compared; the conclusion was that the similarities across groups in contact and social support far outweighed the differences (Riedmann and White 1966).

Siblings play a central role in adults' lives in many other cultures; the psychology of these relationships remains to be studied systematically.

2.3 Continuities in Individual Differences in Relationships

Do the marked individual differences in the affection or hostility that siblings show toward each other in early childhood show stability through middle childhood and adolescence? Research described in Brody (1996) indicates there is some continuity over time for both the positive and negative aspects of sibling relations, but there is also evidence for change. Contributors to change included new friendships children formed during the school years, which led to loss of warmth in the sibling relationship, or increased jealousy; developmental changes in the individuals; and life events (the majority of which contributed to increased intimacy and warmth, an exception being divorce or separation of parents). Research on adult siblings shows the relationship is not a static one during adulthood: life events, employment changes, etc. affect adult siblings' relations—some increasing intimacy and contact, others with negative effects (Cicirelli 1996).

2.4 Influences on Individual Differences

The temperament of both individuals in a sibling dyad is important in relation to conflict between them, and the match in their temperaments, too (Brody 1996). The effects of gender and age gap are less clear: Findings are inconsistent for young siblings, while research on children in middle childhood indicates that these 'family constellation' effects influence the relationship in complex ways; gender and socioeconomic status apparently increase in importance as influences on the sibling relationship during adolescence.

Most striking are the links between the quality of sibling relationships and other relationships within the family—the parents' relationships with each child, and the mother–partner or marital relationship. These connections are considered next.

3. Siblings, Parents, and Peers: Connections Between Relationships

To what extent and in what ways do parent–child relationships influence sibling relationships? Currently there is much debate and some inconsistency in the research findings. First, there is some evidence that the security of children's attachment to their parents is correlated with later sibling relationship quality, and that positive parent–child relations are correlated with positive sibling relations. Note that conclusions cannot be drawn about the direction of causal influence from these correlational data. There are also data that fit with a 'compensatory' model, in which intense supportive sibling relationships develop in families in which parents are uninvolved. This pattern may be characteristic of families at the extremes of stress and relationship difficulties.

More consistent is the evidence that differential parent–child relationships (in which more attention and affection, and less punishment is shown by a parent toward one sibling than another) are associated with more conflicted, hostile sibling relationships (Hetherington et al. 1994). These links are especially clear for families under stress, such as those who have experienced divorce, and in those with disabled or sick siblings. Again, note that the evidence is correlational.

Indirect links between parent–child and sibling relationships have been documented in studies of the arrival of a sibling; a number of different processes are implicated ranging from general emotional disturbance, through processes of increasing cognitive complexity—such as increased positivity between siblings in families in which mothers talked to the firstborn about the feelings and needs of the baby in early months. This evidence indicates that even with young siblings, processes of attribution and reflection may be implicated in the quality of their developing relationship.

The quality of the marital relationship is also linked to sibling relationships: mother–partner hostility is associated with increased negativity between siblings, while affection between adult partners is associated with positivity between siblings. Both direct pathways between marital and sibling relationships, and indirect pathways (via parent–child relationships) are implicated (Dunn et al. 1999).

4. *Developmental Influence*

4.1 *Influence on Adjustment*

Three adjustment outcome areas in which siblings are likely to exert influence are aggressive and externalizing behavior, internalizing problems, and self esteem. For example, hostile aggressive sibling behavior is correlated with increasing aggressive behavior by the other sibling. Patterson and his group have shown the shaping role that siblings play in this pattern (Patterson 1986), for both clinic and community samples. The arrival of a sibling is consistently found to be linked to increased problems: disturbance in bodily functions, withdrawal, aggressiveness, dependency, and anxiety. It is thought these changes are linked to parallel changes in interaction between the 'displaced' older siblings and the parents.

A growing literature links sibling influence to deviant behavior in adolescence. For example, frequent and problematic drinking by siblings increases adolescents' tendency to drink: siblings appear to have both a direct effect and an indirect later effect on other sibs' risks of becoming a drinker—through adolescents' selection of peers who drink. Siblings can also be an important source of support in times of stress, and act as therapists for siblings with some problems, such as eating disorders (Boer and Dunn 1990).

4.2 *Influence on Social Understanding*

The kinds of experience children have with their siblings are related to key aspects of their socio-cognitive development. For instance, positive cooperative experiences with older siblings are correlated with the development of greater powers of understanding emotion and others' mental states, both in early and middle childhood. Direction of effects in these associations is not clear: children who are good at understanding feelings and others' minds are more effective cooperative play companions, thus their early sophistication in social understanding may contribute to the development of cooperative play, which itself fosters further social understanding (Dunn 1992). Other aspects of prosocial, cooperative behavior, pretend play, and conflict management have all been reported to be associated with the experience of friendly sibling interactions.

While it appears plausible that experiences with siblings should 'generalize' to children's relationships with peers, the story appears more complex, and there is not consistent evidence for simple positive links. The emotional dynamics and demands of sibling and friend relationships are very different.

5. *Why Are Siblings So Different From One Another?*

Striking differences between siblings in personality, adjustment, and psychopathology have been documented in a wide range of studies. These present a challenge to conventional views of family influence, as the children are growing up within the same family. Extensive studies by behavior geneticists have now shown that the sources of environmental influence that make individuals different from one another work *within* rather than *between* families. The contribution of sibling studies to our understanding of the relative roles of genetics and environment in studies of socialization and development has been notable: the message here is not that family influence is unimportant, but that we need to document those experiences that are specific to each child in the family, and need to study more than one child in the family if we are to clarify what are the salient environmental influences on development (Dunn and Plomin 1990, Hetherington et al. 1994). The developmental research that documents the extreme sensitivity with which children monitor the interaction between other family members, and the significance of differential parent–child relationships combine here to clarify the social processes that are implicated in the development of differences between children growing up in the 'same' family.

6. *Methodological Issues*

For the study of siblings in childhood, a combination of naturalistic and structured observations, interviews with parents and siblings have proved most useful. Children are articulate and forthcoming about their relations with their siblings, and cope with interviews and questionnaires from an early age. As in the study of any relationship, it is important to get both participants' views on their relationship as these may

differ, and both are valid. Cicirelli (1996) points out some particular methodological problems with studying siblings in adults: incomplete data sets formed when one sibling is unwilling or unable to participate, choices over which dyad is picked, and limitations in sample representativeness.

7. Future Directions

Exciting future directions in sibling research include: clarification of the links between family relationships (including those involving step-relations); identification of the processes of family influence—for which we need studies with more than one child per family; further investigation of the role of genetics in individual development; and further exploration of significant sibling experiences for social understanding in middle childhood and adolescence.

Sign Language

Until recently, most of the scientific understanding of the human capacity for language has come from the study of spoken languages. It has been assumed that the organizational properties of language are connected inseparably with the sounds of speech, and the fact that language is normally spoken and heard determines the basic principles of grammar, as well as the organization of the brain for language. There is good evidence that structures involved in breathing and chewing have evolved into a versatile and efficient system for the production of sounds in humans. Studies of brain organization indicate that the left cerebral hemisphere is specialized for processing linguistic information in the auditory–vocal mode and that the major language-mediating areas of the brain are connected intimately with the auditory–vocal channel. It has even been argued that hearing and the development of speech are necessary precursors to this cerebral specialization for language. Thus, the link between biology and linguistic behavior has been identified with the particular sensory modality in which language has developed.

Although the path of human evolution has been in conjunction with the thousands of spoken languages the world over, recent research into signed languages has revealed the existence of primary linguistic systems that have developed naturally independent of spoken languages in a visual–manual mode. American Sign Language (ASL), for example, a sign language passed down from one generation to the next of deaf people, has all the complexity of spoken languages, and is as capable of expressing science, poetry, wit, historical change, and infinite nuances of meaning as are spoken languages. Importantly, ASL and other signed languages are not derived from the spoken language of the surrounding community: rather, they are autonomous languages with their own grammatical form and meaning. Although it was thought originally that signed languages were universal pantomime, or broken forms of spoken language on the hands, or loose collections of vague gestures, now scientists around the world have found that there are signed languages that spring up wherever there are communities and generations of deaf people (Klima and Bellugi 1988).

One can now specify the ways in which the formal properties of languages are shaped by their modalities of expression, sifting properties peculiar to a particular language mode from more general properties common to all languages. ASL, for example, exhibits formal structuring at the same levels as spoken languages (the internal structure of lexical units and the grammatical scaffolding underlying sentences) as well as the same kinds of organizational principles as spoken languages. Yet the form this grammatical structuring assumes in a visual–manual language is apparently

deeply influenced by the modality in which the language is cast (Bellugi 1980).

The existence of signed languages allows us to enquire about the determinants of language organization from a different perspective. What would language be like if its transmission were not based on the vocal tract and the ear? How is language organized when it is based instead on the hands moving in space and the eyes? Do these transmission channel differences result in any deeper differences? It is now clear that there are many different signed languages arising independently of one another and of spoken languages. At the core, spoken and signed languages are essentially the same in terms of organizational principles and rule systems. Nevertheless, on the surface, signed and spoken languages differ markedly. ASL and other signed languages display complex linguistic structure, but unlike spoken languages, convey much of their structure by manipulating spatial relations, making use of spatial contrasts at all linguistic levels (Bellugi et al. 1989).

1. *The Structure of Sign Language*

As already noted, the most striking surface difference between signed and spoken languages is the reliance on spatial contrasts, most evident in the grammar of the language. At the lexical level, signs can be separated from one another minimally by manual parameters (handshape, movement, location). The signs for *summer*, *ugly*, and *dry* are just the same in terms of handshape and movement, and differ only in the spatial location of the signs (forehead, nose, or chin). Instead of relying on linear order for grammatical morphology, as in English (*act*, *acting*, *acted*, *acts*), ASL grammatical processes nest sign stems in spatial patterns of considerable complexity (see Fig. 1), marking grammatical functions such as number, aspect, and person spatially. Grammatically complex forms can be nested spatially, one inside the other, with different orderings producing different hierarchically organized meanings.

Similarly, the syntactic structure specifying relations of signs to one another in sentences of ASL is also essentially organized spatially. Nominal signs may be associated with abstract points in a plane of signing space, and it is the direction of movement of verb signs between such endpoints that marks grammatical relations. Whereas in English, the sentences 'the cat bites the dog' and 'the dog bites the cat' are differentiated by the order of the words, in ASL these differences are signaled by the movement of the verb between points associated with the signs for *cat* and *dog* in a plane of signing space. Pronominal signs directed toward such previously established points or loci clearly function to refer back to nominals, even with many signs intervening (see Fig. 2). This spatial organization underlying syntax is a unique property of visual-gestural systems (Bellugi et al. 1989).

2. *The Acquisition of Sign Language by Deaf Children of Deaf Parents*

Findings revealing the special grammatical structuring of a language in a visual mode lead to questions about the acquisition of sign language, its effect on non-language visuospatial cognition, and its representation in the brain. Despite the dramatic surface differences between spoken and signed languages—simultaneity and nesting sign stems in complex co-occurring spatial patterns—the acquisition of sign language by deaf children of deaf parents shows a remarkable similarity to that of hearing children learning a spoken language. Grammatical processes in ASL are acquired at the same rate and by the same processing by deaf children as are grammatical processes by hearing children learning English, as if there were a biological timetable underlying language acquisition.

Figure 1
Spatially organized (three-dimensional) morphology in ASL

Figure 2
Spatialized syntax

Figure 3
Deaf children's grammatical overregularizations

First words and first signs appear at around 12 months; combining two words or two signs in children, whether deaf or hearing, occurs by about 18–20 months, and the rapid expansion signaling the development of grammar (morphology and syntax) develops in both spoken and signed languages by about 3–3$\frac{1}{2}$ years. Just as hearing children show their mastery and discovery of grammatical regularities by producing overregularizations ('I goed there,' 'we helded the rabbit'), deaf children learning sign language show evidence of learning the spatial morphology signaling plural forms and aspectual forms by producing overregularizations in spatial patterns (see Fig. 3).

3. *Neural Systems Subserving Visuospatial Languages*

The differences between signed and spoken languages provide an especially powerful tool for understanding the neural systems subserving language. Consider the following: In hearing/speaking individuals, language processing is mediated generally by the left cerebral hemisphere, whereas visuospatial processing is mediated by the right cerebral hemisphere. But what about a language that is communicated using spatial contrasts rather than temporal contrasts? On the one hand, the fact that sign language has the same kind of complex linguistic structure as spoken languages and the same expressivity might lead one to expect left hemisphere mediation. On the other hand, the spatial medium so central to the linguistic structure of sign language clearly suggests right hemisphere or bilateral mediation. In fact, the answer to this question is dependent on the answer to another, deeper, question concerning the *basis* of the left hemisphere specialization for language.

Specifically, is the left hemisphere specialized for language processing *per se* (i.e., is there a brain basis for language as an independent entity)? Or is the left hemisphere's dominance generalized to process any type of information that is presented in terms of temporal contrasts? If the left hemisphere is indeed specialized for processing language itself, sign language processing should be mediated by the left

hemisphere, as is spoken language. If, however, the left hemisphere is specialized for processing fast temporal contrasts in general, one would expect sign language processing to be mediated by the right hemisphere. The study of sign languages in deaf signers permits us to pit the nature of the signal (auditory-temporal vs. visual-spatial) against the type of information (linguistic vs. nonlinguistic) that is encoded in that signal as a means of examining the neurobiological basis of language (Poizner et al. 1990).

One program of studies examines deaf lifelong signers with focal lesions to the left or the right cerebral hemisphere. Major areas, each focusing on a special property of the visual-gestural modality as it bears on the investigation of brain organization for language, are investigated. There are intensive studies of large groups of deaf signers with left or right hemisphere focal lesions in one program (Salk); all are highly skilled ASL signers, and all used sign as a primary form of communication throughout their lives. Individuals were examined with an extensive battery of experimental probes, including formal testing of ASL at all structural levels; spatial cognitive probes sensitive to right-hemisphere damage in hearing people; and new methods of brain imaging, including structural and functional magnetic resonance imaging (MRI, fMRI), event-related potentials (ERP), and positron emission tomography (PET). This large pool of well-studied and thoroughly characterized subjects, together with new methods of brain imaging and sensitive tests of signed as well as spoken language allows for a new perspective on the determinants of brain organization for language (Hickok and Bellugi 2000, Hickok et al. 1996).

3.1 Left Hemisphere Lesions and Sign language Grammar

The first major finding is that so far only deaf signers with damage to the left hemisphere show sign language aphasias. Marked impairment in sign language after left hemisphere lesions was found in the majority of the left hemisphere damaged (LHD) signers, but not in any of the right hemisphere damaged (RHD) signers, whose language profiles were much like matched controls. Figure 4 presents a comparison of LHD, RHD, and normal control profiles of sign characteristics from The Salk Sign Diagnostic Aphasia Examination—a measure of sign aphasia. The RHD signers showed no impairment at all in any aspect of ASL grammar; their signing was rich, complex, and without deficit, even in the spatial organization underlying sentences of ASL. By contrast, signers with LHD showed markedly contrasting profiles: one was agrammatic after her stroke, producing only nouns and a few verbs with none of the grammatical apparatus of ASL, another made frequent paraphasias at the sign internal level, and several showed many grammatical paraphasias, including neologisms, particularly in morphology.

Another deaf signer showed deficits in the spatially encoded grammatical operations which link signs in sentences, a remarkable failure in the spatially organized syntax of the language. Still another deaf signer with focal lesions to the left hemisphere reveal dissociations not found in spoken language: a dissociation between sign and gesture, with a cleavage between capacities for sign language (severely impaired) and manual pantomime (spared). In contrast, none of the RHD signers showed any within-sentence deficits; they were completely unimpaired in sign sentences and not one showed aphasia for sign language (in contrast to their marked nonlanguage spatial deficits, described below) (Hickok and Bellugi 2000, Hickok et al. 1998).

Moreover, there are dramatic differences in performance between left- and right-hemisphere damaged signers in formal experimental probes of sign competence. For example, a test of the equivalent of rhyming in ASL provides a probe of phonological processing. Two signs 'rhyme' if they are similar in all but one phonological parametric value such as handshape, location, or movement. To tap this aspect of phonological processing, subjects are presented with an array of pictured objects and asked to pick out the two objects whose signs rhyme (Fig. 5). The ASL signs for *key* and *apple* share the same handshape and movement, and differ only in location, and thus are like rhymed pairs. LHD signers are significantly impaired relative to RHD signers and controls on this test, another sign of the marked difference in effects of right- and left-hemisphere lesions on signing. On other tests of ASL processing at different structural levels, there are similar distinctions between left- and right-lesioned signers, with the right-lesioned signers much like the controls, but the signers with left hemisphere lesions significantly impaired in language processing. Moreover, studies have found that there can be differential breakdown of linguistic components of sign language (lexicon and grammar) with different left hemisphere lesions.

3.2 Right Hemisphere Lesions and Nonlanguage Spatial Processing

These results from language testing contrast sharply with results on tests of nonlanguage spatial cognition. RHD signers are significantly more impaired on a wide range of spatial cognitive tasks than LHD signers, who show little impairment. Drawings of many of the RHD signers (but not those with LHD) show severe spatial distortions, neglect of the left side of space, and lack of perspective. RHD deaf signers show lack of perspective, left neglect, and spatial disorganization on an array of spatial cognitive nonlanguage tests (block design, drawing, hierarchical

Figure 4
Left hemisphere lesions lead to sign language aphasias

Figure 5
Rhyming task with LHD and RHD signers

processing), compared with LHD deaf signers. Yet, astonishingly, these severe spatial deficits among RHD signers do not affect their competence in a spatially nested language, ASL. The case of a signer with a right parietal lesion leading to severe left neglect is of special interest: Whereas his drawings show characteristic omissions on the left side of space, his signing (including the spatially organized syntax) is impeccable, with signs and spatially organized syntax perfectly maintained.

The finding that sign aphasia follows left hemisphere lesions but not right hemisphere lesions provides a strong case for a modality-independent *linguistic* basis for the left hemisphere specialization for language. These data suggest that the left hemisphere is predisposed biologically for language, independent of language modality. Thus, hearing and speech are not necessary for the development of hemisphere specialization—sound is not crucial. Furthermore, the finding of a dissociation between competence in a spatial language and competence in nonlinguistic spatial cognition demonstrates that it is the type of information that is encoded in a signal (i.e., linguistic vs. spatial information) rather than the nature of the signal itself (i.e., spatial vs. temporal) that determines the organization of the brain for higher cognitive functions.

4. *Language, Modality, and the Brain*

Analysis of patterns of breakdown in deaf signers provides new perspectives on the determinants of hemispheric specialization for language. First, the data show that hearing and speech are not necessary for the development of hemispheric specialization: sound is *not* crucial. Second, it is the left hemisphere that is dominant for sign language. Deaf signers with damage to the left hemisphere show marked sign language deficits but relatively intact capacity for processing nonlanguage visuospatial relations. Signers with damage to the right hemisphere show the reverse pattern. Thus, not only is there left hemisphere specialization for language functioning, there is also complementary specialization for nonlanguage spatial functioning. The fact that grammatical information in sign language is conveyed via spatial manipulation does not alter this complementary specialization.

Furthermore, components of sign language (lexicon and grammar) can be selectively impaired, reflecting

differential breakdown of sign language along linguistically relevant lines. These data suggest that the left hemisphere in humans may have an innate predisposition for language, regardless of the modality. Since sign language involves an interplay between visuospatial and linguistic relations, studies of sign language breakdown in deaf signers may, in the long run, bring us closer to the fundamental principles underlying hemispheric specialization.

Sign Language: Psychological and Neural Aspects

Signed languages of the deaf are naturally occurring human languages. The existence of languages expressed in different modalities (i.e., oral–aural, manual–visual) provides a unique opportunity to explore and distinguish those properties shared by all human languages from those that arise in response to the modality in which the language is expressed. Despite the differences in language form, signed languages possess formal linguistic properties found in spoken languages. Sign language acquisition follows a developmental trajectory similar to spoken languages. Memory for signs exhibits patterns of interference and forgetting that are similar to those found for speech. Early use of sign language may enhance certain aspects of nonlanguage visual perception. Neuropsychological studies show that left hemisphere regions are important in both spoken and sign language processing.

1. Linguistic Principles of American Sign Language

1.1 Language and Deaf Culture

Sign languages are naturally-occurring manual languages that arise in communities of deaf individuals. These manual communication systems are fully expressive, systematic human languages and are not merely conventionalized systems of pantomime nor manual codifications of a spoken language. Many types of deafness are inheritable and it is not unusual to find isolated communities of deaf individuals who have developed complex manual languages (Groce 1985). The term Deaf Community has been used to describe a sociolinguistic entity that plays a crucial role in a deaf person's exposure to and acceptance of sign language (Padden and Humphries 1988). American Sign Language (ASL), used by members of the Deaf community in the USA and Canada, is only one of many sign languages of the world, but it is the one that has been studied most extensively .

1.2 Structure of American Sign Language

A sign consists of a hand configuration that travels about a movement path and is directed to or about a specific body location. Sign languages differ from one another in the inventories and compositions of hand-shapes, movements, and locations used to signal linguistic contrasts just as spoken language differ from one another in the selection of sounds used, and how those sounds are organized into words. Many sign languages incorporate a subsystem in which orthographic symbols used in the surrounding spoken language communities are represented manually on the hands. One example is the American English manual alphabet, which is produced on one hand and allows users of ASL to represent English lexical items.

All human languages, whether spoken or signed, exhibit levels of structure which govern the composition and formation of word forms and specify how words combine into sentences. In formal linguistic analyses, these structural levels are referred to as phonology, morphology and the syntax of the language. In this context, phonological organization refers to the patterning of the abstract formational

units of a natural language (Coulter and Anderson 1993). Compared to spoken languages in which contrastive units (for example, phonemes) are largely arranged in a linear fashion, signed languages exhibit simultaneous layering of information. For example, in a sign, a handshape will co-occur with, rather than follow sequentially, a distinct movement pattern.

ASL exhibits complex morphology. Morphological markings in ASL are expressed as dynamic movement patterns overlaid on a more basic sign form. These nested morphological forms stand in contrast to the linear suffixation common in spoken languages (Klima and Bellugi 1979). The prevalence of simultaneous layering of phonological content and the nested morphological devices observed across many different sign languages likely reflect an influence of modality on the realization of linguistic structure. Thus the shape of human languages reflects the constraints and affordances imposed by the articulator systems involved in transmission of the signal (i.e., oral versus manual) and the receptive mechanisms for decoding the signal (i.e., auditory versus visual).

A unique property of ASL linguistic structure is the reliance upon visuospatial mechanisms to signal linguistic contrasts and relations. One example concerns the use of facial expressions in ASL. In ASL, certain syntactic and adverbial constructions are marked by specific and obligatory facial expressions (Liddell 1980). These linguistic facial expressions differ significantly in appearance and execution of affective facial expressions. A second example concerns the use of inflectional morphology to express subject and object relationships. At the syntactic level, nominals introduced into the discourse are assigned arbitrary reference points along a horizontal plane in the signing space. Signs with pronominal function are directed toward these points, and the class of verbs which require subject/object agreement obligatorily move between these points (Lillo-Martin and Klima 1990). Thus, whereas many spoken languages represent grammatical functions through case marking or linear ordering, in ASL grammatical function is expressed through spatial mechanisms. This same system of spatial reference, when used across sentences, serves as a means of discourse cohesion (Winston 1995).

1.3 Sign Language Acquisition

Children exposed to signed languages from birth acquire these languages on a similar maturational timetable as children exposed to spoken languages (Meier 1991). Prelinguistic infants, whether normally hearing or deaf, engage in vocal play commonly known as babbling. Recent research has shown that prelinguistic gestural play referred to as manual babbling will accompany vocal babbling. There appear to be significant continuities between prelinguistic gesture and early signs in deaf children exposed to American Sign Language, though questions remain as to whether manual babbling is constrained by predominantly motoric or linguistic factors (Cheek et al. 2001, Petitto and Marantette 1991).

Between 10 and 12 months of age, children reared in signing homes begin to produce their first signs, with two-sign combinations appearing at approximately 18 months. Some research has suggested a precocious early vocabulary development in signing children. However, these reports are likely to be a reflection of parents' and experimenters' earlier recognition of signs compared to words rather than underlying differences in development of symbolic capacities of signing and speaking children.

Signing infants produce the same range of grammatical errors in signing that have been documented for spoken language, including phonological substitutions, morphological overregularizations, and anaphoric referencing confusions (Petitto 2000). For example, in the phonological domain a deaf child will often use only a subset of the handshapes found in the adult inventory, opting for a simpler set of 'unmarked' handshapes. This is similar to the restricted range of consonant usage common in children acquiring a spoken language.

2. Psycholinguistic Aspects of Sign Language

Psycholinguistic studies of American Sign Language have examined how the different signaling characteristics of the language impact transmission and recognition. Signs take longer to produce than comparable word forms. The average number of words per second in running speech is about 4 to 5, compared with 2 to 3 signs per second in fluent signing. However, despite differences in word transmission rate, the proposition rate for speech and sign is the same, roughly one proposition every 1 to 2 seconds. Compare, for example the English phrase 'I have already been to California' with the ASL equivalent, which can be succinctly signed using three monosyllabic signs, glossed as FINISH TOUCH CALIFORNIA.

2.1 Sign Recognition

Studies of sign recognition have examined how signs are recognized in time. Recognition appears to follow a systematic pattern in which information about the location of the sign is reliably identified first, followed by handshape information and finally the movement. Identification of the movement reliably leads to the identification of the sign. Interestingly, despite the slower articulation of a sign compared to a word, sign recognition appears to be faster than word recognition. Specifically, it has been observed that proportionally less of the signal needs to be processed in order to uniquely identify a sign compared to a spoken

word. For example, one study reports that only 240 msec. or 35 percent of a sign has to be seen before a sign is identified (Emmory and Corina 1990). In comparable studies of spoken English, Grosjean (1980) reports that 330 msec. or 83 percent of a word has to be heard before a word can be identified. This finding is due, in part, to the simultaneous patterning of phonological information in signs compared to the more linear patterning of phonological information characteristic of spoken languages. These structural differences in turn have implications for the organization of lexical neighborhoods. Spoken languages, such as English, may have many words that share in their initial phonological structures (tram, tramp, trampoline, etc.) leading to greater coactivation (and thus longer processing time) during word recognition. In contrast, ASL sign forms are often formationally quite distinct from one another, permitting quicker selection of a lexical unique entry.

2.2 Memory for Signs

Efforts to explore how the demands of sign language processing influence memory and attention have led to several significant findings. Early studies of memory for lists of signs report classic patterns of forgetting and interference, including serial position effects of primacy and recency (i.e., signs at the beginning and the end of a list are better remembered than items in the middle). Likewise, when sign lists are composed of phonologically similar sign forms, signers exhibit poorer recall (Klima and Bellugi 1979). This result is similar to what has been reported for users of spoken language, where subjects exhibit poorer memory for lists of similarly sounding words (Conrad and Hull 1964). These findings indicate that signs, like words, are encoded into short-term memory in a phonological or articulatory code rather than in a semantic code.

More recent work has assessed whether Baddeley's (1986) working memory model pertains to sign language processing. This model includes components that encode linguistic and visuospatial information as well as a central executive which mediates between immediate and long-term memory. Given the spatial nature of the sign signal, the question of which working memory component(s) is engaged during sign language processing is particularly interesting. Wilson and Emmorey (2000) have shown word-length effects in signs; it is easier to maintain a cohort of short signs (monosyllabic signs) than long signs (polysyllabic signs) in working memory. They also report effects of 'articulatory suppression.' In these studies, requiring a signer to produce repetitive, sign-like hand movements while encoding and maintaining signs in memory has a detrimental effect on aspects of recall. Once again, analogous effects are known to exist for spoken languages and these phenomena provide support for a multicomponent model of linguistic working memory that includes both an articulatory loop and a phonological store. Finally, under some circumstances deaf signers are able to utilize linguistically relevant spatial information to encode signs, suggesting the engagement of a visuospatial component of working memory.

2.3 Perception and Attention

Recent experiments with native users of signed languages have shown that experience with a visual sign language may improve or alter visual perception of nonlanguage stimuli. For example, compared to hearing nonsigners, deaf signers have been shown to possess enhanced or altered perception along several visual dimensions such as motion processing (Bosworth and Dobkins 1999), mental rotation, and processing of facial features (Emmorey 2001). For example, the ability to detect and attend selectively to peripheral, but not central, targets in vision is enhanced in signers (Neville 1991). Consistent with this finding is evidence for increased functional connectivity in neural areas mediating peripheral visual motion in the deaf (Bavelier et al. 2000).

As motion processing, mental rotation, and facial processing underlie aspects of sign language comprehension, these perceptual changes have been attributed to experience with sign language. Moreover, several of these studies have reported such enhancements in hearing signers raised in deaf signing households. These findings provide further evidence that these visual perception enhancements are related to the acquisition of a visual manual language, and are not due to compensatory mechanisms developed as a result of auditory deprivation.

3. Neural Organization of Signed Language

3.1 Hemispheric Specialization

One of the most significant findings in neuropsychology is that the two cerebral hemispheres show complementary functional specialization, whereby the left hemisphere mediates language behaviors while the right hemisphere mediates visuospatial abilities. As noted, signed languages make significant use of visuospatial mechanisms to convey linguistic information. Thus sign languages exhibit properties for which each of the cerebral hemispheres shows specialization. Neuropsychological studies of brain injured deaf signers and functional imaging studies of brain intact signers have provided insights into the neural systems underlying sign language processing.

3.2 Aphasia in Signed Language

Aphasia refers to acquired impairments in the use of language following damage to the perisylvian region

of the left hemisphere. Neuropsychological case studies of deaf signers convincingly demonstrate that aphasia in signed language is also found after left hemisphere perisylvian damage (Poizner et al. 1987). Moreover, within the left hemisphere, production and comprehension impairments follow the well-established anterior versus posterior dichotomy. Studies have documented that frontal anterior damage leads to Broca-like sign aphasia. In these cases, normal fluent signing is reduced to effortful, single-sign, 'telegraphic' output with little morphological complexity (such as verb agreement). Comprehension, however, is left largely intact. Wernicke-like sign aphasia following damage to the posterior third of the perisylvian region presents with fluent but often semantically opaque output, and comprehension also suffers. In cases of left hemisphere damage, the occurrence of sign language paraphasias may be observed. Paraphasia may be formationally disordered (for example, substituting an incorrect hand shape) or semantically disordered (producing a word that is semantically related to the intended form). These investigations serve to underscore the importance of left hemisphere structures for the mediation of signed languages and illustrate that sign language breakdown is not haphazard, but rather honors linguist boundaries (Corina 2000).

The effects of cortical damage to primary language areas that result in aphasic disturbance can be differentiated from more general impairments of movement. For example Parkinson's disease leads to errors involving timing, scope, and precision of general movements including, but not limited to, those involved in speech and signing. These errors produce phonetic disruptions in signing, rather than higher-level phonemic disruptions that are apparent in aphasic signing (Corina 1999).

Apraxia is defined as an impairment of the execution of a learned movement (e.g., saluting, knowing how to work a knife and fork). Lesions associated with the left inferior parietal lobe result in an inability to perform and comprehend gestures (Gonzalez Rothi and Heilman 1997). Convincing dissociations of sign language impairment with well-preserved praxic abilities have been reported. In one case, a subject with marked sign language aphasia affecting both production and comprehension produced unencumbered pantomime. Moreover, both comprehension and production of pantomime were found to be better preserved than was sign language. These data indicate that language impairments following left hemisphere damage are not attributable to undifferentiated symbolic impairments and demonstrate that ASL is not simply an elaborate pantomimic system.

3.3 Role of the Right Hemisphere in ASL

Studies of signers with right hemisphere damage (RHD) have reported significant visuospatial disruption in nonlinguistic domains (e.g., face processing, drawing, block construction, route finding, etc.) but have reported only minimal language disruption. Problems in the organization of discourse have been observed in RHD signers, as have also been reported in users of spoken languages. More controversial are the influences of visuospatial impairment in the use of highly spatialized components of the language such as complex verb agreement and the classifier system. Further work is needed to understand whether these infrequently reported impairments (both in comprehension and production) reflect core linguistic deficits or rather reflect secondary effects of impaired visuospatial processing.

3.4 Functional Imaging

Recent studies using functional brain imaging have explored the neural organization of language in users of signed languages. These studies have consistently found participation of classic left hemisphere perisylvian language areas in the mediation of sign language in profoundly deaf, lifelong signers. For example Positron Emission Tomography studies of production in British Sign Language (McGuire et al. 1997) and Langue des Signes Quebecoise (Petitto et al. 2000) reported deaf subjects activated left inferior frontal regions, regions similar to those that mediate speech in hearing subjects. Researchers using Functional Magnetic Resonance imaging techniques in investigating comprehension of ASL in deaf and hearing native users of signed language have shown significant activations in frontal opercular areas (including Broca's area and dorsolateral prefrontal cortex) as well as in posterior temporal areas (such as Wernicke's area and the angular gyrus) (Neville et al. 1998). Also reported was extensive activation in right hemisphere regions. Subsequent studies have conferred that aspects of the right posterior hemisphere activation appear to be unique to sign language processing and present only in signers who acquired sign language from birth (Newman et al. in press).

Investigations of psychological and neural aspects of signing reveal strong commonalities in the development and cognitive processing of signed and spoken languages despite major differences in the surface form of these languages. Early exposure to a sign language may lead to the enhancements in the specific neural systems underlying visual processing. There appears to be a strong biological predisposition for left hemisphere structures in the mediation of language, regardless of the modality of expression.

Signal Detection Theory

Signal detection theory (SDT) is a framework for interpreting data from experiments in which accuracy is measured. It was developed in a military context (see *Signal Detection Theory, History of*), then applied to sensory studies of auditory and visual detection, and is now widely used in cognitive science, diagnostic medicine, and many other fields. The key tenets of SDT are that the internal representations of stimulus events include variability, and that perception (in an experiment, or in everyday life) incorporates a decision process. The theory characterizes both the representation and the decision rule.

1. Detection and Discrimination Experiments

Consider an auditory experiment to determine the ability of a listener to detect a weak sound. On some trials, the sound is presented, and the listener is instructed to say 'yes' (I heard it) or 'no' (I did not hear it). On other trials, there is no sound, discouraging the observer from responding 'yes' indiscriminately. The presence of variability in sensory systems leads us to call these latter presentations *noise* (N) trials, and the former *signal plus noise* ($S+N$) trials. Possible data based on 50 trials of each type are given in Table 1. Responses of 'yes' on signal trials are called *hits*, and

Table 1
Response frequencies in an auditory detection experiment

	'Yes'	'No'	Total
Signal + noise	42	8	50
Noise	15	35	50

Figure 1
Distributions assumed by SDT to result from N and $S+N$. The horizontal axis is scaled in standard deviation units, and the difference between the means is d'. The observer responds 'yes' for values to the right of the criterion (vertical line), 'no' for those to the left

on no-signal trials are called *false alarms*. The observer's performance can be summarized by a *hit rate* (here 0.84) and a *false-alarm rate* (here 0.30).

The variability principle implies that repeated presentation of the signal leads to a distribution of internal effect, as does repeated presentation of no signal. In the most common SDT model, these distributions are assumed to be normal, and to differ only in mean, as shown in Fig. 1.

How does the observer reach a decision in this experiment, when any observation on the 'internal effect' axis is ambiguous with regard to source? The best decision rule is to establish a *criterion* value c on the axis, and respond 'yes' for values to the right of c, 'no' for values to the left. The location of the criterion can be determined from the data, for the area above it under the $S+N$ distribution must equal the hit rate. Consulting a table of the normal distribution reveals that in the example above the criterion must therefore be about one standard deviation below the mean of that distribution. Similarly, the area above the criterion under the N distribution must equal the false-alarm rate, so the criterion is about 0.5 standard deviations above the mean of that distribution.

2. *Sensitivity and Response Bias*

Figure 1 offers natural interpretations of the *sensitivity* of the observer in the task and of the *decision rule*. Sensitivity, usually denoted d', is reflected by the difference between the two distribution means; this characteristic of the representation is unaffected by the location of the criterion, and is thus free of response bias. The magnitude of d' is found easily by computing the distances between each mean and the criterion, found in the last section:

$$d' = z(\textit{hit rate}) - z(\textit{false-alarm rate}) \qquad (1)$$

where $z(p)$ is the point on a unit-normal distribution above which the area p can be found. The function z is negative for arguments less than 0.5 and positive for arguments above that value. In the example,

$$d' = z(0.84) - z(0.30) = 0.994 - (-0.524) = 1.518$$

Criterion location is one natural measure of response bias. If evaluated relative to the point at which the two distributions cross, it can be calculated by a formula analogous to Eqn. 1:

$$c = -\tfrac{1}{2}[z(\textit{hit rate}) + z(\textit{false-alarm rate})] \qquad (2)$$

In the example above

$$c = -\tfrac{1}{2}[z(0.84) + z(0.30)] = -0.235,$$

that is, the criterion is slightly to the left of the crossover point, as in fact is shown in Fig. 1.

3. *Receiver Operating Characteristic (ROC) Curves*

If sensitivity truly is unaffected by the location of the response criterion, then a shift in that criterion should leave d' unchanged. An observer's decision rule can be manipulated between experimental runs through instructions or payoffs. In the more efficient rating method, a rating response is required; the analysis assumes that each distinct rating corresponds to a different region along the axis of Fig. 1, and that each region is defined by a different criterion. The data are analyzed by calculating a hit and false-alarm rate for each criterion separately. A plot of hit rate vs. false alarm rate is called a *receiver-operating characteristic*, or *ROC*; the ROC that would be produced from the

Figure 2
An ROC curve, the relation between hit and false-alarm rates, both of which increase as the criterion location moves (from right to left, in Fig. 1)

representation in Fig. 1 is shown in Fig. 2. Points at the lower end of the curve correspond to high criteria, and the curve is traced out from left to right as the criterion moves from right to left in Fig. 1.

The shape of the ROC is determined by the form of the distributions in the representation, and data largely support the normality assumption. However, the assumption that the $S+N$ and N distributions have the same variance is often incorrect (Swets 1986). In such cases, the area under the ROC is a good measure of accuracy (Swets and Pickett 1982); this index ranges from 0.5 for chance performance to 1.0 for perfect discrimination. An entire ROC (from a rating experiment, for example) is needed to estimate this area.

4. *Alternative Assumptions About Representation*

The essence of signal detection theory is the distinction between the representation and the decision rule, not the shape of the underlying distributions, and two types of nonnormal distributions have been important. One such distribution is the *logistic*, which has a shape very similar to the normal but is computationally more tractable. Logistic models have been used for complex experimental designs, and for statistical analysis. Another family of distributions, whose shape is *rectangular*, leads to rectilinear ROCs and can be interpreted as support for 'thresholds' that divide discrete perceptual states. Such curves are unusual, experimentally, but have been found in studies of recognition memory (Yonelinas and Jacoby 1994). Models using threshold assumptions have been developed for complex experimental situations, such as source monitoring in memory; in this context, they are called multinomial models (see *Discrete State Models of Information Processing*).

5. *Identification and Classification Along a Single Dimension*

Detection theory is extended easily to experiments with multiple stimuli differing on a single dimension. For example, a set of tones differing only in intensity may be presented one at a time for *identification* (the observer must identify the exact stimulus presented) or *classification* (the observer must sort the set into two or more categories). The representation is assumed to be a set of distributions along a decision axis, with $m-1$ criteria used to assign responses to m categories.

SDT analysis allows the calculation of d' (or a related measure, if equal variances are not assumed) for any stimulus pair, and an interesting question concerns the relation between this value and that found in a discrimination task using just those two stimuli. According to a theory of Braida and Durlach (1988), identification d' will be lower than discrimination d' by an amount that reflects memory constraints in the former task. The predicted relation is qualitatively correct for many stimulus dimensions, and can be quantitatively predicted for tones differing in intensity.

6. *Complex Discrimination Designs and Multidimensional Detection Theory*

The one-interval design for measuring discrimination is appropriate for some applications (it seems quite natural in recognition memory, for example, where the $S+N$ trials are studied items and the N trials are foils), but other methods are often preferred. One popular technique is *two-alternative forced-choice* (2AFC), in which *both* stimuli are presented on every trial and the observer must say whether N or $S+N$ occurred first. Another method is *same-different*, in which there are again two intervals, but each interval can contain either of the two stimuli and the observer must say whether the two stimuli are the same or different.

These and many other designs can be analyzed by assuming that each interval is represented by a value on a separate, independent perceptual dimension. Although d' is a characteristic of the stimuli and the observer, and therefore constant across paradigms, performance as measured by percent correct [$p(c)$] varies widely (Macmillan and Creelman 1991). For example, Sect. 2 showed that if $d' = 1.5$, $p(c) = 0.77$ in the one-interval task; but in 2AFC the same observer would be expected to score $p(c) = 0.86$, and in the same-different task as low as $p(c) = 0.61$. The relation between one-interval and 2AFC was one of the first

predictions of SDT to be tested (Green and Swets 1966), whereas that between same-different and other paradigms is a more recent topic of investigation. An interesting aspect of same-different performance is that two distinct decision strategies are available, and their use depends on aspects of the experimental design and stimulus set (Irwin and Francis 1995)

Many identification and classification experiments use stimulus sets that themselves vary in multiple dimensions perceptually, and SDT analysis can be extended to this more general case. Multidimensional detection theory has been particularly helpful in clarifying questions about independence (see Ashby 1992) (see *Signal Detection Theory: Multidimensional*).

7. *Comparing Observed with Ideal or Theoretically-derived Performance*

Detection theory has provided a forum for asking a slate of questions about the optimality of performance. One set of issues concerns the degree to which human behavior falls below the ideal level set by stimulus variability. Early auditory experiments using external noise revealed that human 'efficiency' was often quite high, though never perfect. A different type of application concerns the theoretical prediction of the ratio between the $S+N$ and N standard deviations, which can be derived from the shape of the ROC shape. For example, this ratio should be less than unity for detection experiments in which signal parameters are not known by the observer (Graham 1989). Ratcliff et al. (1994) showed that for an important class of recognition memory models, the ratio should be approximately 0.8, as it is empirically.

Some strong assumptions about the decision process that is at the heart of SDT have been tested. In general, these are well supported for one-dimensional representations, but complications sometimes arise for higher dimensionality. Do observers establish fixed criteria? Experiments requiring discrimination between *distributions* of stimuli have shown that they do when the variability is in one dimension and with adequate experience in two dimensions as well. Do observers set 'optimal' criteria? Actual criterion settings are often conservative compared to ideal ones predicted by Bayes's Theorem. In a multidimensional task, observers appear to adopt appropriate decision boundaries when those are simple in form (e.g., linear), but fall short of optimality when more complex rules are required. Does the representation remain fixed in the face of task variation? In one dimension, this amounts to the original, often-replicated datum that d' (or some sensitivity measure) is unchanged when criterion changes. In more than one dimension, attentional effects can alter the representation (Nosofsky 1986), and the question of what *is* invariant in these cases is still unresolved.

Signal Detection Theory, History of

1. *Introduction and Scope*

Signal detection theory (SDT) sprouted from World War II research on radar into a probability-based theory in the early 1950s. It specifies the optimal observation and decision processes for detecting electronic signals against a background of random interference or noise. The engineering theory, culminating in the work of Wesley W. Peterson and Theodore G. Birdsall (Peterson et al. 1954), had foundations in mathematical developments for theories of statistical inference, beginning with those advanced by Jerzy

Neyman and E. S. Pearson (1933). SDT was taken into psychophysics, then a century-old branch of psychology, when the human observer's detection of weak signals, or discrimination between similar signals, was seen by psychologists as a problem of inference. In psychology, SDT is a model for a theory of how organisms make fine discriminations and it specifies model-based methods of data collection and analysis. Notably, through its analytical technique called the receiver operating characteristic (ROC), it separates sensory and decision factors and provides independent measures of them. SDT's approach is now used in many areas in which discrimination is studied in psychology, including cognitive as well as sensory processes. From psychology, SDT and the ROC came to be applied in a wide range of practical diagnostic tasks, in which a decision is made between two confusable alternatives (Swets 1996) (see also *Signal Detection Theory*).

2. *Electronic Detection and Statistical Inference*

Central to both electronics and statistics is a conception of a pair of overlapping, bell-shaped, probability (density) functions arrayed along a unidimensional variable, which is the weight of evidence derived from observation. In statistical theory, the probabilities are conditional on the null hypothesis or the alternative hypothesis, while in electronic detection theory they are observational probabilities conditional on noise-alone or signal-plus-noise. The greater the positive weight of evidence, the more likely a signal, or significant experimental effect, is present. A cutpoint must be set along the variable to identify those observed values above the cutpoint that would lead to rejection of the null hypothesis or acceptance of the presence of the designated signal. Errors are of commission or omission: type I and type II errors in statistics, and false alarms and misses in detection. Correct outcomes in detection are hits and correct rejections. Various decision rules specify optimal cutpoints for different decision goals. The weight of evidence is unidimensional because just two decision alternatives are considered. Optimal weights of evidence are monotone increasing with the *likelihood ratio*, the ratio of the two overlapping bell-shaped probability functions. It is this ratio, and not the shapes of the functions, that is important.

3. *Modern Signal Detection Theory*

In the early 1950s, Peterson and Birdsall, then graduate students in electrical engineering and mathematics, respectively, at the University of Michigan, developed the general mathematical theory of signal detection that is still current. In the process they devised the ROC—a graphical technique permitting measurement of two independent aspects of detection performance: (a) the location of the observer's cutpoint or decision criterion and (b) the observer's sensitivity, or ability to discriminate between signal-plus-noise and noise-alone, irrespective of any chosen cutpoint. The two measures characterize performance better than the single one often used, namely, the signal-to-noise ratio (SNR) expressed in energy terms that is necessary to provide a 50 percent hit (correct signal acceptance) probability at a fixed decision cutpoint, say, one yielding a conditional false-alarm probability of 0.05. A curve showing conditional hit probability versus SNR is familiar in detection theory and is equivalent to the power function of statistical theory. These curves can be derived as a special case of the ROCs for the SNR values of interest.

4. *The ROC*

The ROC is a plot of the conditional hit (true–positive) proportion against the conditional false-alarm (false–positive) proportion for all possible locations of the decision cutpoint. Peterson's and Birdsall's SDT specifies a form of ROC that begins at the lower left corner (where both proportions are zero) and rises with smoothly decreasing slope to the upper right corner (where both proportions are 1.0)—as the decision cutpoint varies from very strict (at the right end of the decision variable) to very lenient (at the left end). This is a 'proper' ROC, and specifically not a 'singular' ROC, or one intersecting axes at points between 0 and 1.0. The locus of the curve, or just the proportion of area beneath it, gives a measure of discrimination capacity. An index of a point along the curve, for example, the slope of the curve at the point, gives a measure of the decision cutpoint that yielded that point (the particular slope equals the criterial value of likelihood ratio). SDT specifies the discrimination capacity attainable by an 'ideal observer' for any SNR for various practical combinations of signal and noise parameters (e.g., signal specified exactly and signal specified statistically) and hence the human observer's efficiency can be calculated under various signal conditions. SDT also specifies the optimal cutoff as a function of the signal's prior probability and the benefits and costs of the decision outcomes.

5. *Psychology's Need for SDT and The ROC*

Wilson P. Tanner, Jr., and John A. Swets, graduate students in psychology at Michigan in the early 1950s, became aware of Peterson's and Birdsall's work on the same campus as it began. Tanner became acquainted through his interest in mathematical and electronic concepts as models for psychological and neural processes and Swets was attracted because of his interest in quantifying the 'instruction stimulus' in

psychophysical tasks, in order to control the observer's response criterion. As they pursued studies in sensory psychology, these psychologists had become dissatisfied with psychophysical and psychological theories based on overlapping bell-shaped functions that assumed fixed decision cutpoints and incorporated measures only of discrimination capacity, which were possibly confounded by attitudinal or decision processes. Prominent among such theories were those of Gustav Theodor Fechner (1860), Louis Leon Thurstone (1927), and H. Richard Blackwell (1963); see Swets (1996, Chap. 1).

Fechner and Thurstone conceived of a symmetrical cutpoint, where the two distributions cross, because they presented two stimuli on each trial with no particular valence; that is, both stimuli were 'signals' (lifted weights, samples of handwriting). Fechner also studied detection of single signals, but did not compare them to a noise-alone alternative and his theory was essentially one of variable representations of a signal compared to an invariant cutpoint. This cutpoint was viewed as a physiologically determined sensory threshold (akin to all-or-nothing nerve firing) and hence the values of the sensory variable beneath it were thought to be indistinguishable from one another.

Blackwell's task and model were explicitly of signals in noise, but the observer was thought to have a fixed cutpoint near the top of the noise function, for which the false-alarm probability was negligible, and, again, the values below that cutpoint were deemed indistinguishable. For both threshold theorists, the single measure of performance was the signal strength required to yield 50 percent correct positive responses, like the effective SNR of electronic detection theory, and it was taken as a statistical estimate of a sensory threshold. In psychology, the curve relating percentage of signals detected to signal strength is called the psychometric function. There had been some earlier concern in psychology for the effect of the observer's attitude on the measured threshold, e.g., Graham's (1951) call for quantification of instruction stimuli in the psychophysical equation, but no good way to deal with non-sensory factors had emerged.

In 1952, Tanner and Swets joined Peterson and Birdsall as staff in a laboratory of the electrical engineering department called the Electronic Defense Group. They were aware of then-new conceptions of neural functioning in which stimulus inputs found an already active nervous system and neurons were not lying quiescent till fired at full force. In short, neural noise as well as environmental noise was likely to be a factor in detection and then the observer's task is readily conceived as a choice between statistical hypotheses. Though a minority idea in the history of psychophysics (see Corso 1963), the possibility that the observer deliberately sets a cutpoint on a continuous variable (weight of evidence) seemed likely to Tanner and Swets. A budding cognitive psychology (e.g., 'new look' in perception) supported the notion of extrasensory determinants of perceptual phenomena, as represented in SDT by expectancies (prior probabilities) and motivation (benefits and costs).

6. *Psychophysical Experiments*

The new SDT was first tested in Swets's doctoral thesis in Blackwell's vision laboratory (Tanner and Swets 1954; Swets et al. 1961–see Swets 1964, Chap. 1). It was then tested with greater control of the physical signal and noise parameters in new facilities for auditory research in the electrical engineering laboratory. Sufficiently neat empirical ROCs were obtained in the form of the curved arc specified by SDT. ROCs found to be predicted by Blackwell's 'high-threshold' theory—straight lines extending from some point along the left axis, that depended on signal strength, to the upper right hand corner—clearly did not fit the data. Other threshold theories, e.g., 'low-threshold' theories, did not fare much better in experimental tests (Swets 1961–see Swets 1964, Chap. 4). It was recognized later that linear ROCs of slope = 1, intersecting left and upper edges of the graph symmetrically, were predicted by several other measures and their implicit models (Swets 1996, Chap. 3) and also gave very poor fits to sensory data (and other ROC data to be described; Swets 1996, Chap. 2). After a stint as observer in Swets's thesis studies, David M. Green joined the engineering laboratory as an undergraduate research assistant. He soon became a full partner in research, and co-authored a laboratory technical report with Tanner and Swets in 1956 that included the first auditory studies testing SDT. Birdsall has collaborated in research with the psychologists over the following decades and commented on a draft of this article.

The measure of discrimination performance used first was denoted d' ('d prime') and defined as the difference between the means of two implicit, overlapping, normal (Gaussian) functions for signal-plus-noise and noise-alone, of equal variance, divided by their common standard deviation. A value of d' can be calculated for each ROC point, using the so-called single-stimulus *yes–no* method of data collection. Similarly, a value of d' can be calculated for an observer's performance under two other methods of data collection: the multiple-stimulus *forced-choice* method (one stimulus being signal-plus noise and the rest noise-alone) and the single-stimulus *confidence-rating* method. Experimental tests showed that when the same signal and nonsignal stimuli were used with the three methods, essentially the same values of d' were obtained. The measures specified by threshold theories had not achieved that degree of consistency or internal validity.

For many, the most conclusive evidence favoring SDT's continuous decision variable and rejecting the high-threshold theory came from an experiment sug-

gested by Robert Z. Norman, a Michigan mathematics student. Carried out with visual stimuli, the critical finding was that a second choice made in a four-alternative forced-choice test, when the first choice was incorrect, was correct with probability greater than 1/3 and that the probability of it being correct increased with signal strength (Swets et al. 1961, Swets 1964, Chap. 1).

Validating the rating method, as mentioned above, had the important effect of providing an efficient method for obtaining empirical ROCs. Whereas under the yes–no method the observer is induced to set a different cutpoint in each of several observing sessions (each providing an ROC point), under the rating method the observer effectively maintains several decision cutpoints simultaneously (the boundaries of the rating categories) so that several empirical ROC points (enough to define a curve) can be obtained in one observing session.

7. *Dissemination of SDT in Psychology*

Despite the growing evidence for it, acceptance of SDT was not rapid or broad in psychophysical circles. This was partly due to threshold theory having been ingrained in the field for a century (as a concept and a collection of methods and measures), and probably because SDT arose in an engineering context (and retained the engineers' terminology), the early visual data were noisy, and the first article (Tanner and Swets 1954) was cryptic. Dissemination was assisted when J. C. R. Licklider brought Swets and Green to the Massachusetts Institute of Technology where they participated in Cambridge's hotbed of psychophysics and mathematical psychology, and where offering a special summer course for postgraduates led to a published collection of approximately 35 of the articles on SDT in psychology that had appeared by then, along with tables of d' (Swets 1964). Licklider also hired both of them part-time at the research firm of Bolt Beranek and Newman Inc., where they obtained contract support from the National Aeronautics and Space Administration to write a systematic textbook (Green and Swets 1966). Meanwhile, Tanner mentored a series of exceptional graduate students at Michigan. All were introduced by Licklider to the Acoustical Society of America where they enjoyed a feverishly intense venue for discussion of their ideas at biannual meetings and in the Society's journal. Another factor was the active collaboration with Tanner of James P. Egan and his students at Indiana University.

8. *Extensions of SDT in Psychology*

Egan recognized the potential for applying SDT in psychology beyond the traditional psychophysical tasks. He extended it to the less tightly defined vigilance task, that is, the practical military and industrial observing task of 'low-probability watch' (Egan et al. 1961–see Swets 1964, Chap. 15), and also to speech communication (Egan and Clarke 1957–see Swets 1964, Chap. 30). He also brought SDT to purely cognitive tasks with experiments in recognition memory (see Green and Swets 1966, Sect. 12.9). Applications were then made by others to those tasks, and also to tasks of conceptual judgment, animal discrimination and learning, word recognition, attention, visual imagery, manual control, and reaction time (see Swets 1996, Chap. 1). A broad sample of empirical ROCs obtained in these areas indicates their very similar forms (Swets 1996, Chap. 2). An Annual Review chapter reviews applications in clinical psychology, for example, to predicting acts of violence (McFall and Treat 1999).

9. *Applications in Diagnostics*

An analysis of performance measurement in information retrieval suggested that two-by-two contingency tables for any diagnostic task were grist for SDT's mill (Swets 1996, Chap. 9). This idea was advanced considerably by Lusted's (1968) application to medical diagnosis. A standard protocol for evaluating diagnostic performance via SDT methods, with an emphasis on medical images, was sponsored by the National Cancer Institute (Swets and Pickett 1982). By 2000, 'ROC' is specified as a key word in over 1000 medical articles each year, ranging from radiology to blood analysis. Other diagnostic applications are being made to aptitude testing, materials testing, weather forecasting, and polygraph lie detection (Swets 1996, Chap. 4).

A recent development is to use SDT to improve, as well as to evaluate, diagnostic accuracy. Observers' ratings of the relevant dimensions of a diagnostic task—e.g., perceptual features in an X-ray—are merged in a manner specified by the theory to yield an optimal estimate of the probability that a 'signal' is present (Swets 1996, Chap. 8). The latest work both in psychology and diagnostics has been described didactically (Swets 1998).

Signal Detection Theory: Multidimensional

Multidimensional signal detection theory (MSDT) is an extension of signal detection theory (SDT) to more than one dimension, with each dimension representing a different source of information along which the 'signal' is registered. The development of MSDT was motivated by psychologists who wanted to study information processing of more realistic, multidimensional stimuli, for example, the shape and color of geometric objects, or pitch, loudness, and timbre of tones. The typical questions of interest are: Are the dimensions (e.g., color and shape of an object) processed independently, or does the perception of one dimension (e.g., color) depend on the perception of the second (shape), and if so, what is the nature of their dependence? In MSDT, several types of independence of perceptual dimensions are defined and related to two sets (marginal and conditional) of sensitivity, d′, and response bias, β, parameters. This article gives the definitions, and outlines the uses in studying information processing of dimensions. MSDT is also known as General Recognition Theory (Ashby and Townsend 1986) or Decision Bound Theory (e.g., Ashby and Maddox 1994).

1. Introduction and Notation

Stimulus dimensions, A, B,…, represent different types of information about a class of stimuli, for example, in a two-dimensional (2-D) case, the shape (A) and color (B) of objects. The researcher specifies the levels on each dimension to study (e.g., square and rectangle are levels of shape, and blue, turquoise, and green are levels of color). A multidimensional 'signal' is stimulus A_iB_j, where the subscript indicates the specific level on the corresponding dimension (e.g., a green square is A_1B_3). For each physical stimulus dimension A (B,…), there is assumed a corresponding unique psychological or perceptual dimension X (Y,…).

The minimal stimulus set considered in this article consists of four 2-D stimuli, $\{A_1B_1, A_1B_2, A_2B_1, A_2B_2\}$, constructed by combining two levels on dimension A ($i = 1, 2$) with each of two levels on dimension B ($j = 1, 2$). For example, the set constructed from two levels of color (blue, green) and two levels of shape (square, rectangle) is {blue square, blue rectangle, green square, green rectangle}.

On a single trial, one stimulus is selected from the set at random, and it is presented to the observer whose task is to identify the stimulus. The presentation of a 2-D stimulus results in a percept, a point (x, y) in X-Y-perceptual space. The observer's response is based on the percept's location relative to the observer's placement of decision criterion bounds in the perceptual space, typically one bound per dimension, denoted c_A, c_B, … . These bounds divide the perceptual space into response regions such that if, for example, (x, y) falls above c_A and below c_B, the (2-D) response would be '21' (or any response that uniquely identifies it as A_2B_1).

As in unidimensional SDT, multiple presentations of a single stimulus are assumed to lead to a distribution of percepts, and one distribution (usually Gaussian) is assumed for each stimulus. An example with four 2-D stimuli is illustrated in Fig. 1. The bivariate joint densities, $f_{A_iB_j}(x, y)$, are represented more easily as equal-density contours (Fig. 1(b)), that are obtained by slicing off the tops of the joint densities in Fig. 1(a) at a constant height, and viewing the space

Figure 1
(a) The perceptual space showing four joint bivariate densities, $f_{A_iB_j}(x, y)$, that represent all possible (theoretical) perceptual effects for each of the four 2-D stimuli A_iB_j; (b) Equal density contours of the bivariate densities in (a) and the decision bounds c_A and c_B; (c) Marginal densities, $g_{A_iB_j}(x)$, representing perceptual effects for each stimulus A_iB_j on dimension A only. In this example, $g_{A_1B_1}(x) \neq g_{A_1B_2}(x)$ but $g_{A_2B_1}(x) g_{A_2B_2}(x)$

from 'above.' The joint density for each stimulus A_iB_j yields: (a) Marginal densities on each dimension, $g_{A_iB_j}(x)$ and $g_{A_iB_j}(y)$, obtained by integrating over all values of the second dimension (see Fig. 1(c) for marginal densities $g_{A_iB_j}(x)$ for dimension A); and (b) Conditional densities for each dimension (not shown), conditioning on the observer's response to the second dimension, and obtained by integrating only over values either *above* (or *below*) the decision bound on the second dimension, for example, $g_{A_iB_j}(x|y > c_B)$.

An observer's responses are tabulated in a 4×4 confusion matrix, a table of conditional probability estimates, $P(R_p|A_iB_j)$, that are proportions of trials that response R_p was emitted when stimulus A_iB_j was presented. These proportions estimate the volumes under each joint density in each response region. For example, the proportion of trials on which the observer responded '11' when in fact stimulus A_1B_2 was presented is

$$P(R_{11}|A_1B_2) = \int_{\infty}^{c_A} \int_{\infty}^{c_B} f_{A_1B_2}(x, y)\,\mathrm{d}x\,\mathrm{d}y \qquad (1)$$

2. *Definitions of Independence of Dimensions*

Several definitions of independence of dimensions are defined within MSDT. These are: perceptual separability (PS), decisional separability (DS), and perceptual independence (PI).

2.1 *Perceptual Separability (PS) and Decisional Separability (DS)*

Dimension A is PS from dimension B if the perceptual effects of A are equal across levels of dimension B, that is, $g_{A_iB_1}(x) = g_{A_iB_2}(x)$, for all values of x and both $i = 1$ and $i = 2$. Similarly, dimension B is perceptually separable from dimension A if $g_{A_1B_j}(x) = g_{A_2B_j}(x)$, for all y, and $j = 1, 2$.

DS is a similar type of independence of the *decisions* that the observer makes about the stimuli. DS holds for dimension A (or B) when the decision bound c_A (or c_B) is parallel to the Y- (or X-) perceptual axis.

PS and DS are global types of independence defined for perceptual dimensions across levels of the second dimension *for all stimuli in the set*. They can also be asymmetrical relations. In Fig. 1(b), for example, PS holds for dimension B across levels of dimension A, but PS fails for dimension A across levels of B; also, DS holds for dimension A but fails for dimension B.

2.2 *Perceptual Independence (PI)*

PI is distinguished from PS in that it is a local form of independence among dimensions *within a single stimulus*. PI holds within stimulus A_iB_j if

$$f_{A_iB_j}(x, y) = g_{A_iB_j}(x)\, g_{A_iB_j}(y)$$

for all (x, y). This is statistical independence, and it is a symmetric relation in a given stimulus.

The shape of an equal density contour describes the correlation among the perceived dimensions in one stimulus. A circle indicates PI in a stimulus with variances equal on the two dimensions. An ellipse with its major and minor axes parallel to the perceptual axes also indicates PI, but with unequal variances on the two dimensions. A tilted ellipse indicates failure of

PI, with the direction of the tilt (positive or negative slope of the major axis) indicating the direction of the dependence. In Fig. 1(b), stimuli A_1B_1 and A_2B_1 show PI, stimulus A_2B_2 shows a positive dependence, and stimulus A_1B_2 shows a negative dependence.

3. Marginal and Conditional d′s and βs

As in unidimensional SDT, sensitivity, d′, and response bias, β, are parameters that describe different characteristics of the observer. Two sets of these parameters are defined: (a) marginal d′s and βs, and (b) conditional d′s and βs. The marginal and conditional d′s and βs for the four-stimulus set discussed here can be generalized to any number of dimensions and any number of levels: for details, see Kadlec and Townsend (in Ashby 1992, Chap. 8).

3.1 Marginal d′s and βs

Marginal d′s and βs are defined using the marginal densities, $g_{A_iB_j}(x)$ and $g_{A_iB_j}(y)$. Let the mean vector and variance-covariance matrix of $f_{A_iB_j}(x, y)$, for stimulus $A_i\mathrm{B}_j$, be denoted by

$$\vec{\mu}_{(A_iB_j)} = \begin{bmatrix} \mu_{x(A_iB_j)} \\ \mu_{y(A_iB_j)} \end{bmatrix}$$

and

$$\Sigma_{(A_iB_j)} = \begin{bmatrix} \sigma^2_{x(A_iB_j)} & \sigma_{xy(A_iB_j)} \\ \sigma_{xy(A_iB_j)} & \sigma^2_{y(A_iB_j)} \end{bmatrix} \quad (2)$$

respectively. The marginal d′ for dimension A at level j of dimension B is

$$\mathrm{d}'(A \text{ at } B_j) = \frac{\mu_{x(A_2B_j)} - \mu_{x(A_1B_j)}}{\sigma_{x(A_1B_j)}} \quad \text{for} \quad j = 1, 2 \quad (3)$$

The subscript x indicates that for a d′ on dimension A, only the X-coordinates of the mean vectors and the standard deviation along the X-perceptual axis are employed. As in unidimensional SDT, the standard deviation of the 'noise' stimulus (here indicated as level 1 of dimension A) is used, and without loss of generality, it is assumed that $\mu_{(A_1B_1)} = [0\ 0]^T$ (^{T} denotes transpose) and $\Sigma_{(A_1B_1)} = \mathrm{I}$ (i.e., $\sigma^2_x = \sigma^2_y = 1$, and $\sigma_{xy} = 0$). Similarly, the marginal d′s for dimension B at level i of dimension A is

$$\mathrm{d}'(B \text{ at } A_i) = \frac{\mu_{y(A_iB_2)} - \mu_{y(A_iB_1)}}{\sigma_{y(A_iB_1)}} \quad \text{for} \quad i = 1, 2 \quad (4)$$

In a parallel fashion, marginal βs are defined as

$$\beta(A \text{ at } B_j) = \frac{g_{A_2B_j}(c_A)}{g_{A_1B_j}(c_A)} \quad \text{for} \quad j = 1, 2$$

and

$$\beta(B \text{ at } A_i) = \frac{g_{A_iB_2}(c_B)}{g_{A_iB_1}(c_B)} \quad \text{for} \quad i = 1, 2 \quad (5)$$

where c_A and c_B are the decision bounds for dimension A and B, respectively.

3.2 Conditional d′s and βs

In the four-stimulus set, two pairs of conditional d′s and βs are defined *for each dimension*, conditioning on the observer's response on the second. Using the terminology of unidimensional SDT for simplicity, with level 1 indicating the 'noise' stimulus and level 2 the 'signal' stimulus, one pair of conditional d′s for dimension A, with B presented at level 1, is: (a) d′(A|'correct rejection' on B)—conditioned on the observer's *correct* response that B was at level 1, defined using parameters of

$$g_{A_iB_1}(x|y < c_B),$$

i = 1 and 2 in Eqn. (3); and (b) d′(A|'false alarm' on B)—conditioned on the *incorrect* response that B was at level 1, using parameters of

$$g_{A_iB_1}(x|y > c_B)$$

in Eqn. (3). The second pair of conditional d′s for dimension A, with B presented at level 2, is: (c) d′(A|'hit' on B)—conditioned on the *correct* response that B was at level 2; and (d) d′(A|'miss' on B)—conditioned on the *incorrect* response that B was at level 1. Similar pairs are defined for conditional βs, and for d′s and βs for dimension B conditional on dimension A responses.

4. Using the d′s and βs to Test Dimensional Interactions

These d′ and β parameters are linked theoretically to PS, DS, and PI (Kadlec and Townsend 1992). Their estimates, obtained from the confusion matrix proportions (Eqn. (1)), can thus be used to draw tentative inferences about dimensional interactions (Kadlec 1999). DS for dimension A (or B) is inferred when c_A (c_B) estimates are equal at all levels of dimension B (A). Equal marginal d′s for a dimension across levels of the other are consistent with PS on that dimension. A stronger inference for PS on both dimensions can be drawn if the densities form a rectangle (but not a

parallelogram), and this condition is testable if DS and PI hold (Kadlec and Hicks 1998; see also Thomas 1999 for new theoretical developments). When DS holds, evidence for PI is gained if conditional d′s are found to be equal: Conversely, unequal conditional d′s indicate PI failure, and the direction of the inequality provides information about the direction of the dimensional dependencies in the stimuli. Exploring these relationships and looking for stronger tests of PS and PI is currently an active area of research.

MSDT is a relatively new development, and with its definitions of independence of dimensions, it is a valuable analytic and theoretical tool for studying interactions among stimulus dimensions. Current applications include studies of (a) human visual perception (of symmetry, Gestalt 'laws' of perceptual grouping, and faces); and (b) source monitoring in memory. It can be used in any research domain where the study of dimensional interactions is of interest.

Significance, Tests of

A recent article on the health benefits of herbal tea reported its use leading to a decreased incidence of insomnia in an experiment conducted at a sleep disorders clinic. Patients at the clinic were randomly assigned to daily consumption of herbal tea or a caffeine-free beverage of their choice, and were followed up for 10 months. The reported improvement was stated to be 'statistically significant ($p < 0.05$).' The implication intended was that the improvement should be attributed to the beneficial effects of the tea.

In fact, this article does not really exist, but examples of this sort are reported regularly in science articles in the press, and are very common in journal publications in a number of fields in science and social science. It has even been argued, in the press, that 'statistical significance' has become so widely used to give an *imprimatur* of scientific acceptability that it is in fact misused and should be abandoned (Matthews 1998).

A test of significance assesses the agreement between the data and an hypothesized statistical model. The magnitude of the agreement is expressed as an observed level of significance, or p-value, which is the probability of obtaining data as or more extreme than the observed data, if the hypothesized model were true. A very small p-value suggests that either the observed data are not compatible with the hypothesized model or an event of very small probability has been observed. A large p-value indicates that the observed data are compatible with the hypothesized model. Since the p-value is a probability, it must be between 0 and 1, and a very common convention is to declare values smaller than 0.05 as 'small' or 'statistically significant' and values larger than 0.05 as 'not statistically significant.' In this section we shall try to explain the historical rationale of this very arbitrary cut-off point.

To make these vague definitions more concrete, it is necessary to consider statistical models and the notion of a (simplifying) hypothesis within that model. The theory of this is outlined in Sect. 2 with some more advanced topics considered in Sect. 3. This section concludes with a highly idealized example to convey the idea of data being inconsistent with an hypothesized model.

Example 1. Students in a statistics class partake in an activity to assess their ability to distinguish between two competing brands of cola, and to identify their preferred brand from taste alone. Each of the 20 students expresses a preference for one brand or the other, but just one student claims to be able to discriminate perfectly between the two. Twenty cups of each brand are prepared by the instructor and labelled '1' and '2.' Each student is to record which label corresponds to Brand A. The result is that 12 students correctly the competing brands identify, although not the student who claimed a perfect ability to discriminate.

The labelling of the cups as 1 or 2 by the instructor was completely random, i.e., cup 1 was equally likely to contain Brand A or B. The students did not discuss their opinions with their classmates, and the taste testing was completed fairly quickly. Under these conditions, it is plausible that each student has a

Table 1
Probability of zero or one mistakes in n independent Bernoulli trials with probability of a mistake = 0.5

n	Probability
5	0.1875
6	0.1094
7	0.0625
8	0.0352
9	0.0195
10	0.0107
11	0.0059
12	0.0032
13	0.0017
14	0.0009
15	0.0002

probability of $\frac{1}{2}$ of identifying the brands correctly simply by guessing, so that about 10 students would identify the brands correctly with no discriminatory ability at all. That 12 students did so does not seem inconsistent with guesswork, and the p-value helps to quantify this. The probability of observing 12 or more correct results if one correct result has probability $\frac{1}{2}$ and the guesses are independent can be computed by the binomial formula as

$$\left\{\binom{20}{12}+\binom{20}{13}+\ldots+\binom{20}{20}\right\}(\tfrac{1}{2})^{20} = 0.34. \qquad (1)$$

This is not at all an unlikely event, so there is no evidence from these data that the number of correct answers could not have been obtained by guessing: in more statistical language, assuming a binomial model, the observed data is consistent with probability of success $\frac{1}{2}$.

The student who claimed to have perfect discrimination, but actually guessed incorrectly, argued that her abilities should not be dismissed on the basis of one taste test, so the class carried out some computations to see what the p-value for the same observed data would be if the number of trials was increased. The probability of one or zero mistakes in a set of n trials for various values of n, is given in Table 1. From this we see that, for example, one or no mistakes in five trials is consistent with guesswork, but the same result in 10 trials is much less so.

In both parts of this example we assumed a model of independent trials, each of which could result in a success or failure, with constant probability of success. Our calculations also assumed this constant probability of success was 0.5. This latter restriction on the model is often called a 'null hypothesis', and the test of significance is a test of this null hypothesis; the p-value measures the consistency of the data with this null hypothesis. In many applications the null hypothesis plays the role of a conservative position that the experimenter hopes to disprove, and one reason for requiring rather small p-values before declaring statistical significance is to raise the standard of proof required to replace a relatively simple working hypothesis with one that is possibly more complex and less well understood.

As formulated here, the hypothesis being tested is that the probability of a correct choice is 0.5, and not the other aspects of the model, such as independence of the trials, and unchanging probability of success. The number of observed successes does not measure such model features; it provides information; only on the probability of success. Functions of the data that do measure such model features can be constructed, and from these significance tests that assess the fit of an assumed model; these play an important role in statistical inference as well.

1. *Model Based Inference*

1.1 *Models and Null Hypothesis*

We assume that we have a statistical model for a random variable Y taking values in a sample space $\mathscr{Y}$, described by a parametric family of densities $\{f(y;\theta);\theta\in\Theta\}$. Tests of significance can in fact be constructed in more general settings, but this framework is useful for defining the main ideas. If Y is the total number of successes in n independent Bernoulli trials with constant probability of success, then

$$f(y;\theta) = \binom{n}{y}\theta^y(1-\theta)^{n-y} \qquad (2)$$

$\Theta = [0, 1]$ and $\mathscr{Y} = \{0, 1,\ldots, n\}$. If Y is a continuous random variable following a normal or bell curve distribution with mean θ_1 and variance θ_2^2, then

$$f(y;\theta) = \frac{1}{\sqrt{2\pi}\theta_2}\exp\left\{-\frac{1}{2\theta_2^2}(y-\theta_1)^2\right\} \qquad (3)$$

$\Theta = \Re\times\Re^+$, and $\mathscr{Y} = \Re$. The model for n independent observations from this distribution is

$$f(y_1,\ldots,y_n;\theta) = \frac{1}{(\sqrt{2\pi})^n\theta_2^n}\exp\left\{\frac{1}{2\theta_2^2}\sum_{i=1}^{n}(y_i-\theta_1)^2\right\} \qquad (4)$$

$\Theta = \Re\times\Re^+$, and $\mathscr{Y} = \Re^n$. For further discussion of statistical models, see *Statistical Sufficiency*; *Distributions, Statistical: Special and Discrete*; *Distributions, Statistical: Approximations*; *Distributions, Statistical: Special and Continuous*.

As noted above, we assume the model is given, and our interest is in inference about the parameter θ. While this could take various forms, a test of significance starts with a so-called *null hypothesis* about θ, of the form

$$H_0 : \theta = \theta_0 \tag{5}$$

or

$$H_0 : \theta \in \Theta_0. \tag{6}$$

In Eqn. (5) the parameter θ is fully specified, and H_0 is called a *point* null hypothesis or a *simple* null hypothesis. If θ is not fully specified, as in Eqn. (6) H_0 is called a *composite* null hypothesis. In the taste-testing examples the simple null hypothesis was $\theta = 0.5$. In the normal model, Eqn. (3), a hypothesis about the mean, such as $H_0 : \theta_1 = 0$, is composite, since the variance is left unspecified. Another composite null hypothesis is $H_0 : \theta_2 = \theta_1$, which restricts the full parameter space to a one-dimensional curve in $\mathscr{R} \times \mathscr{R}^+$.

A test is constructed by choosing a *test statistic* which is a function of the data that in some natural way measures departure from what is expected under the null hypothesis, and which has been standardized so that its distribution is known either exactly or to a good approximation under the null hypothesis. Test statistics are usually constructed so that large values indicate a discrepancy from the hypothesis.

Example 2. In the binomial model (2), the distribution of Y is completely specified by the null hypothesis $\theta = 0.5$ as

$$f(y) = \binom{n}{y} 2^{-n} \tag{7}$$

and consistency of a given observed value y_0 of y, is measured by the p-value $\sum_{y=y_0}^{n} \binom{n}{y} 2^{-n}$, the probability of observing a value as or more extreme than y_0. If y_0 is quite a bit smaller than expected, then it would be more usual to compute the p-value as $\sum_{y=0}^{y_0} \binom{n}{y} 2^{-n}$. Each of these calculations was carried out in the discussion of taste testing in Sect. 1.

Example 3. In independent sampling from the normal distribution, given in Eqn. (4), we usually test the composite null hypothesis $H_0 : \theta_1 = \theta_{10}$, by constructing the t-statistic

$$T = \sqrt{n}(\bar{Y} - \theta_{10})/S \tag{8}$$

where $\bar{Y} = n^{-1} \sum_{i=1}^{n} Y_i$ and $S^2 = (n-1)^{-1} \sum (Y_i - \bar{Y})^2$. Under H_0, T follows a t-distribution on $n-1$ degree of freedom, and the p-value is

$$\Pr\{T \geqslant \sqrt{n}(\bar{y} - \theta_{10})/s\}$$

where $\bar{y}$ and s are the values observed in the sample. This probability needs to be computed numerically from an expression for the cumulative distribution function of the t-distribution. Historically, tables of this distribution were provided for ready reference, typically by identifying a few critical values, such as $t_{0.10}$, $t_{0.05}$, and $t_{0.01}$ satisfying $\Pr\{T_\nu \geqslant t_\alpha\} = \alpha$, where T_ν is a random variable following a t-distribution on ν degrees of freedom. It was arguably the publication of these tables that led to a focus on the use of particular fixed levels for testing in applied work.

Example 4. Assume the model specifies that $Y_1, \ldots, Y_n$ are independent, identically distributed from a distribution with density $f(\cdot)$ on $\mathfrak{R}$ and that we are interested in testing whether or not $f(\cdot)$ is a normal density:

$$H_0 : f(y) = (\sqrt{2\pi})^{-1} \mathrm{e}^{-\frac{1}{2}y^2} \tag{9}$$

or

$$H_0 : f(y) = (\sqrt{2\pi})^{-1} \theta_2^{-1} \exp(-(1/2\theta_2^2)\{y - \theta_1\}^2) \tag{10}$$

the former is a simple and the latter is a composite null hypothesis. For this problem it is less obvious how to construct a test statistic or how to choose among alternative test statistics. Under Eqn. (9) we know the distribution of each observation (standard normal) and thus any function of the observations. The ordered values of Y, $Y_{(1)} \leqslant \cdots \leqslant Y_{(n)}$, could be compared to their expected values under Eqn. (9), for example by plotting one against the other, and deviation of this plot from a line with intercept 0 and slope 1 could be measured in various ways. In the case of the composite null hypothesis Eqn. (10), we could make use of the result that under H_0, $(Y_i - \bar{Y})/S$ has a distribution free of θ_1 and θ_2, and the vector of these residuals is independent of the pair $(\bar{Y}, S^2)$, and then for example compare the skewness $n^{-1} \sum \{(Y_1 - \bar{Y})/S\}^3$ with that expected under normality.

Example 5. Suppose we have a sample of independent observations $Y_1, \ldots, Y_n$ or a circle of radius 1 and our null hypothesis is that the observations are uniformly distributed on the circle. One choice of a test statistic is $T_1 = \sum_{i=1}^{n} \cos Y_i$, very large positive (or negative) values indicating a concentration of observations at angle 0 (or π). If, instead, we wish to detect clumps of observations at two angles differing by π, then $T_2 = \sum_{i=1}^{n} \{\cos(2Y_i) - 1\}$ would be more appropriate. The exact distribution of T_1 under H_0 is not available in closed form, but the mean and variance are readily computed as 0 and n, so a normal approximation might be used to compute the p-value.

In the examples described above, the test statistics are *ad hoc* choices likely to be large if the null hypothesis is not true; these are called pure tests of significance. Clearly, a more sensitive test can be constructed if we have more specific knowledge of the

likely form of departures from the null hypothesis. The theory of hypothesis testing formalizes this by setting up a null hypothesis and alternative hypothesis, and seeking to construct an optimal test for discriminating between them. See *Hypothesis Testing in Statistics*. In the remainder of this section we consider a less formal approach based on the likelihood function.

1.2 Significance Tests in Parametric Models

In parametric models, tests of significance are often constructed by using the likelihood function, and the p-value is computed by using an established approximation to the distribution of the test statistic. The likelihood function is proportional to the joint density of the data,

$$L(\theta; y) = c(y) f(y; \theta). \tag{11}$$

We first suppose that we are testing the simple null hypothesis $H_0 : \theta = \theta_0$ in the parametric model $f(y; \theta)$. Three test statistics often constructed from the likelihood function are the Wald or maximum likelihood statistic

$$w_e = (\theta - \theta_0)^T j(\hat{\theta})(\hat{\theta} - \theta_0), \tag{12}$$

the Rao or score statistic

$$w_u = U(\theta_0)^T \{ j(\hat{\theta}) \}^{-1} U(\theta_0), \tag{13}$$

and the likelihood ratio statistic

$$w = 2\{\ell(\hat{\theta}) - \ell(\theta_0)\} \tag{14}$$

where in Eqns. (12), (13), and (14) the following notation is used:

$$\sup_{\theta} L(\theta; y) = L(\hat{\theta}; y) \tag{15}$$

$$\ell(\theta) = \log L(\theta)$$

$$U(\theta) = \ell'(\theta) \tag{16}$$

$$j(\theta) = -\ell''(\theta). \tag{17}$$

The distributions of each of the statistics Eqns. (12), (13), and (14) can be approximated by a χ^2_k distribution, where k is the dimension of θ in the model. This relies on being able to apply a central limit theorem to $U(\theta)$, and to identify the maximum likelihood estimator $\hat{\theta}$ with the root of the equation $U(\theta) = 0$. The precise regularity conditions needed are somewhat elaborate; see, for example, Lehmann and Casella (1998, Chap. 6) and references therein. The important point is that under the simple null hypothesis the distributions of each of these test statistics is exactly known, and p-values readily computed.

In the case that the hypothesis is composite, a similar triple of test statistics computed from the likelihood function is available, but the notation needed to define them is more elaborate. The details can be found in, for example, Cox and Hinkley (1974, Chap. 9, Sect. 3) and the notation above follows theirs.

If θ is a one-dimensional parameter, then a one-sided version of the test statistics given in Eqns. (12), (13), and (14) can be used instead, since the square root of w_e, w_u, or w follows approximately a standard normal distribution.

It is rare that the exact distribution of test statistics can be computed, but the normal or chi-squared approximation can often be improved, and this has been a subject of much research in the theory of statistics over the past several years. A good book-length reference is Barndorff-Nielsen and Cox (1994). One result of this research is that among the three test statistics the square root of the likelihood-ratio statistic w is generally preferred on a number of grounds, including the accuracy of the normal approximation to its exact distribution. This is true for both simple and composite tests of a scalar parameter.

1.3 Significance Functions and Posterior Probabilities

We can also use a test of significance to consider the whole set or interval of values of θ that are consistent with the data. If θ is scalar, one of the simplest ways to do this is to compute $r(\theta) = \pm\sqrt{w(\theta)}$ as a function of θ, and tabulate or plot $\Phi\{r(\theta)\}$ against θ, choosing the negative root for $\theta < \hat{\theta}$, and the positive square root otherwise. This significance function will in regular models decrease from one to zero as θ ranges over an interval of values. The θ values for which $\Phi(r)$ is 0.975 and 0.025 provide the endpoints of an approximate 95 percent confidence interval for θ.

In a Bayesian approach to inference it is possible to make probability statements about the parameter or parameters in the model by constructing a posterior probability distribution for them. In a model with a scalar parameter θ based on a prior $\pi(\theta)$ and model $f(y; \theta)$ we compute a posterior density for θ as

$$\pi(\theta | y) \propto f(y; \theta)\pi(\theta) \tag{18}$$

and can assess any particular value θ_0 by computing

$$\int_{\theta_0}^{\infty} \pi(\theta | y) \mathrm{d}\theta$$

called the posterior probability of θ being larger than θ_0. This posterior probability is different from a p-

value: a p-value assesses the data in light of a fixed value of θ, and the posterior probability assesses a fixed value of θ in light of the probability distribution ascribed to the parameter. Many people find a posterior probability easier to understand, and indeed often interpret the p-value in this way. There is a literature on choosing priors called 'matching priors' to reconcile these two approaches to inference; recent developments are perhaps best approached from Kass and Wasserman (1996). See also *Bayesian Statistics*.

1.4 Hypothesis Testing

Little has been said here about the choice of a test statistic for carrying out a test of significance. The difficulty is that the theory of significance testing provides no guidance on this choice. The likelihood based test statistics described above have proved to be reasonably effective in parametric models, but in a more complicated problem, such as testing the goodness of fit of an hypothesized model, this approach is often not available. To make further progress in the choice of test statistics, the classical approach is to formulate a notion of a 'powerful' test statistic, i.e., one that will reliably led to small p-values when the null hypothesis is not correct. To do this in a systematic way requires specifying what model might hold if in fact the null hypothesis is incorrect. In parametric models where the null hypothesis is $H_0: \theta = \theta_0$ the alternative may well be $H_a: \theta \neq \theta_0$. In more general settings the null hypothesis might be H_0: 'the model is normal' and the alternative H_a: 'the model is not normal.' Even in the parametric setting if θ is a vector parameter it may be necessary to consider what direction in the parameter space away from θ_0 is of interest. The formalization of these ideas is the theory of hypothesis testing, which considers both null and alternative hypotheses, and optimal choices of test statistics. See *Hypothesis Testing in Statistics*; *Goodness of Fit: Overview*.

2. Further Topics

2.1 Combining Tests of Significance

The p-value is a function of the data, taking small values when the data are incompatible with the null hypothesis, and vice versa. As a function of y the p-value itself has a distribution under the model $f(y; \theta)$ and in particular under the null hypothesis H_0 has the uniform distribution on the interval (0, 1). In principle, then, if we have computed p-values from a number of different datasets the p-values can be compared to observations from a $U(0, 1)$ distribution with the objective of obtaining evidence of failure of the null hypothesis across the collection of datasets. This is one of the ideas behind meta analysis; see *Meta-analysis: Overview* and *Meta-analysis: Tools*. One difficulty is that the studies will nearly always differ in a number of respects that may mean they are not all measuring the same parameter, or measuring it in the same way. Another difficulty is that studies for which the p-value is not 'statistically significant' will not have been published, and thus are unavailable to be included in a meta analysis. This selection effect may seriously bias the results of the meta analysis.

2.2 Sample Size

The p-value is a decreasing function of the size of the sample, so that a very large study is more likely to show 'statistical significance' than a smaller study. This has led to considerable criticism of the p-value as a summary measure. Some statisticians have argued that, for this reason, posterior probabilities are a better measure of disagreement with the null hypothesis; see, for example, Berger and Sellke (1987).

To some extent the criticism can be countered by noting that the p-value is just one summary measure of a set of data, and excessive reliance on one measure is inappropriate. In a parametric setting it is nearly always advisable to provide, along with p-value for testing a particular value of the parameter of interest, an estimate of the observed effect and an indication of the precision of this estimate. This can be accomplished by reporting a significance function, if the parameter of interest is one-dimensional. At a more practical level, it should always be noted that a small p-value should be interpreted in the context of other aspects of the study. For example a p-value of less than 0.05 could be obtained by a very small difference in a study of 10,000 cases or a relatively larger difference in a study of 1,000. While a 1 percent reduction may be of substantial importance for some scientific contexts, this needs to be evaluated in its context, and not by relying on the fact that it is 'statistically significant.' Unfortunately, the notion that a study report is complete if and only if the p-value is found to be less than 0.05 is fairly widely ingrained in some disciplines, and indeed forms a part of the requirements of some government agencies for approving new treatments.

Another point of confusion in the evaluation of p-values for testing scalar parameters is the distinction sometimes made between one-sided and two-sided tests of significance. A reliable procedure is to compute the p-value as twice the smaller of the probabilities that the test statistic is larger than or smaller than the observed value, under the null hypothesis. This so-called two-sided p-value measures disagreement with the null hypothesis in two directions away from the null hypothesis, towards the alternative that the, say, new treatment is worse than the old treatment as well

Table 2
Hypothetical data from a small fictitious experiment on insomnia

	Decrease in insomnia reported	No decrease reported	No. of participants
Herbal tea	x	$10-x$	10
Other beverage	$13-x$	$x-3$	10
Total	13	7	20

as better. In the absence of very concrete *a priori* evidence that the alternative hypothesis is genuinely one-sided, this p-value is preferable.

In testing hypotheses about parameters of dimension larger than one, it can be difficult, as noted above, to define the relevant direction away from the null hypothesis. One solution is to identify the parameters of interest individually, and carry out separate tests on those parameters. This will usually be effective unless the dimension of the parameter of interest is unusually large, but in many applications it would be rare to have more than a dozen such parameters. Extremely large datasets such as arise in so-called data mining applications raise quite new problems of inference, however.

2.3 Fixed Level Testing

The problem of focusing on one or two so-called critical p-values is sometimes referred to as fixed-level testing. This was useful when computation of p-values was a very lengthy exercise, and it was usual to provide tables of critical values. It is now usually a very routine matter to compute the exact p-value, which is usually (and should be) reported along with other details such as sample size, estimated effect size, and details of the study design. There is still in some quarters a reliance on fixed level testing, with the result that studies for which the p-value is judged 'not statistically significant' may not be published. This is sometimes called the 'file drawer problem,' and a quantitative analysis was considered in Dawid and Dickey (1977).

More recently there has been a move to make the results of inconclusive studies available over the Internet, and if this becomes widespread practice will alleviate the file drawer problem. This issue is particularly important for meta analysis.

2.4 Achievable p-Values

In some problems where the distribution is concentrated on a discrete set, the number of available p-values will be relatively small. For example, Table 2 shows a hypothetical 2×2 table for the herbal tea experiment. The null hypothesis is that the two beverages are equally effective at reducing insomnia, and is here tested using Fisher's exact test. The relevant calculations are produced in Table 3, from which we see that the set of achievable p-values is relatively small.

Table 3
The set of achievable p-values from Table 2, as a function of x. The p-value for Table 2 is given by the formula $\sum_{s=x}^{\min(10,\,13-x)} p(s)$, where $p(s) = \binom{10}{s}\binom{10}{13-s}/\binom{20}{13}$. The mid p-value is given by $(1/2)p(x)+\sum_{s=x+1}^{\min(10,\,13-x)} p(s)$

	x			
	10	9	8	7
$p(x)$	0.0015	0.0271	0.1463	0.3251
p-value	0.0015	0.0286	0.1749	0.5000
Mid p-value	0.0007	0.0150	0.1018	0.3561

Some authors have argued that for such highly discrete situations a better assessment of the null hypothesis can be achieved by the use of Barnard's mid p-value, which is $(1/2)\Pr(X=x)+\Pr(X>x)$. See Agresti (1992) and references therein.

3. Conclusion

A test of statistical significance is a mathematical calculation based on a test statistic, a null hypothesis, and the distribution of the test statistic under the null hypothesis. The result of the test is to indicate whether the data are consistent with the null hypothesis: if they are not, then either we have observed an event of low probability, or the null hypothesis is not correct.

The choice of test statistic is in principle arbitrary, but in practice might be determined by convention in the field of application, by intuition in a relatively new setting, or by one or more considerations developed in statistical theory. It is convenient to use test statistics whose distributions can easily be calculated exactly or to a good approximation. It is useful to use a test statistic that is sensitive to the particular departures from the null hypothesis that are of particular interest in the application.

A test of statistical significance is just one component of the analysis of a set of data, and should be supplemented by estimates of effects of interest, considerations related to sample size, and a discussion of the validity of any assumptions of independence or underlying models that have been made in the analysis. A statistically significant result is not necessarily an important result in any particular analysis, but needs to be considered in the context of research in that field.

An eloquent introduction to tests of significance is given in Fisher (1935, Chap. 2). Kalbfleisch (1979,

Chap. 12) is a good textbook reference at an undergraduate level. The discussion here draws considerably from Cox and Hinkley (1974, Chap. 3), which is a good reference at a more advanced level. An excellent overview is given in Cox (1977). For a criticism of *p*-values see Schervish (1996) as well as Matthews (1998).

N. Reid

Simmel, Georg (1858–1918)

Georg Simmel was born in the heart of Berlin on March 1, 1858. He was the youngest son of Flora (born Bodstein) and Eduard Simmel, who, although coming from Jewish families, had been baptized into Christianity (he as a Catholic, she as a Protestant). Following the early death of Simmel's father in 1874, the family suffered serious financial difficulties, which, where the young Georg was concerned, were overcome thanks to Julius Friedländer, a friend of the family (co-founder of the music publishing company 'Peters'). Friedländer felt a strong sympathy for the young Simmel, and indeed took him under his wing as his protégé. Thus, Georg could attend high school and then university in Berlin, where he studied philosophy, history, art history, and social psychology (*Völkerpsychologie*). Simmel received his degree as Doctor of Philosophy in 1881, but not without difficulty: his first attempt at a doctoral thesis, '*Psychological and Ethnological Studies on the Origins of Music*,' was not accepted, and he had instead to submit his previous work on Kant, *On the Essence of Matter—Das Wesen der Materie nach Kant's Physischer Monadologie*, which had earned him a prize (Köhnke 1996). The *Habilitation* (postdoctoral qualification to lecture) came next in 1885, for which he also encountered some controversy, and after this his academic career began immediately as a *Privatdozent* (external lecturer). An extraordinary (*außerordentliche*) professorship without salary followed in 1901, and indeed he had to wait until 1914 before he was offered a regular professorship at the University of Strasbourg, where he remained until his death on September 26, 1918, shortly before the end of the First World War.

During his lifetime, Simmel was a well-known figure in Berlin's cultural world. He did not restrict himself merely to scientific or academic matters, but consistently showed great interest in the politics of his time, including contemporary social problems and the world of the arts. He sought to be in the presence of, and in contact with, the intellectuals and artists of his day. He married the painter Gertrud Kinel, with whom he had a son, Hans, and maintained friendships with Rainer Maria Rilke, Stefan George, and Auguste Rodin, amongst many others. At his home in Berlin, he organized private meetings and seminars (Simmel's *privatissimo*), whose participants he would choose personally.

1. Georg Simmel and the Social Sciences

Simmel's contributions to the social sciences are immeasurable. Nevertheless, most of them remain misunderstood, or have been separated from the intentions of their creator, and, thus, their origins have been forgotten. From system theory to symbolic interactionism, almost all sociological theories need to rediscover Simmel as one of their main founding parents.

Simmel's interest in the social sciences, especially in sociology, can be traced to the very beginning of his academic career. After attending seminars offered by Moritz Lazarus and Heymann Steinthal (founders of the *Völkerpsychologie*) during his student years, he became a member of Gustav Schmoller's circle, where he

became acquainted with the debates concerning the national economy of the time, and for whom he held a conference on *The Psychology of Money* (GSG2 1989, pp. 49–65), which would later constitute the first pillar of one of his major works, *The Philosophy of Money* (Frisby and Köhnke 1989). In both of these circles Simmel became more aware of, and sensitized towards, social questions. Schmoller's engagement with social questions, together with Lazarus' and Steinthal's emphasis on the level of '*Überindividualität*' (supraindividuality), and their relativistic worldview and insistence that ethical principles are not of universal validity, as well as Simmel's own interest in Spencer's social theory, all helped to shape the contours of his sociological approach. These various influences were melded together with Simmel's philosophical orientation, particularly his interest in Kant, which yielded a new and rather far-reaching sociological perspective that would evolve extensively throughout his life.

For example, Simmel's first sociological work, *On Social Differentiation* (*Über Sociale Differenzierung*: GSG2 1989), written at the very beginning of his academic career, was deeply influenced by Herbert Spencer and the ideas of Gustav Schmoller and his circle. Slowly, however, as the 1890s drew on, the admiration Simmel had felt for Spencer's theories turned into rejection, and he distanced himself from an evolutionary-organicist approach to sociology. In this rejection of such theories, he brought his knowledge of Kant to his sociological thinking, and this would become the basis of his later contact and dialogue with the members of the southern-German neo-Kantian school, such as Rickert, Windelband, and with the sociologist who was closest to their ideas: Max Weber. This contact with neo-Kantianism influenced Simmel's approach to the social sciences at the end of the nineteenth century and during the first years of the 1900s.

From contemporary testimonies we know that Simmel was in fact one of the greatest lecturers at the University of Berlin, and that his seminars were attended by a great number of students (Gassen and Landmann 1993). It is thus difficult to understand why Simmel did not have a more successful academic career. We know from his correspondences and from Gassen and Landmann's attempts to reconstruct Simmel's life and *oeuvre* that Georg Jellinek engaged himself, though with no positive results, in seeking to obtain an ordinary professorship for Simmel at the University of Heidelberg in 1908 (with, following Jellinek's death, a further attempt by Alfred Weber in 1912, and another in 1915). His converted Jewish background (i.e., assimilated into German society) surely played a significant role in the lack of recognition Simmel received from the academic system; but also his peculiar and original understanding of science, which diverged greatly from established patterns, as well as his characteristic mode of writing, using essays instead of more 'academic' and standardized forms, contributed to his not being accepted into the rather formal and classical German academic milieu. Both attempts at obtaining a professorship for Simmel were blocked by the bureaucracy of the Grand Dukedom of Baden. In fact the letter of evaluation written by the Berlin historian Schäfer regarding a possible professorship for Simmel in Heidelberg in 1908 has as the primary argument for denying Simmel's potential ability to be a good professor his 'Jewishness,' which, according to Schäfer, too obviously tinged Simmel's character and intellectual efforts with a strong relativism and negativity, which could not be good for any student (Gassen and Landmann 1993, Köhnke 1996). Throughout his life Simmel had to fight against these kinds of accusation, and he endeavored to build a 'positive relativism' in an attempt to show that he did not question 'absolute pillars' and thus leave us with nothing, but sought instead to show that this sense of 'absoluteness' was also a product of human reciprocal actions and effects (*Wechselwirkungen*), and was not fundamentally absolute. Such an argument was too much for the society and scientific milieu of the time to accept and forgive, even when Simmel later radically rejected his Introduction to the Moral Science (*Einleitung in die Moralwissenschaften*: GSG3 1989 GSG4, 1991), referring to it as a sin of his youth. This was the work in which his relativism, in the critical, 'negative' sense, had been most fully in bloom (Köhnke 1996).

Notwithstanding these varying approaches to sociology, Simmel's interest in the discipline persisted right through his career. When Simmel, in his letter to Célestin Bouglé of March 2, 1908, wrote: 'At the moment I am occupied with printing my *Sociology*, which has finally come to its end,' and, sentences later, added that work on this book 'had dragged on for fifteen years' (Simmel Archive at the University of Bielefeld) he indicated that his engagement with sociology was a long-term project. Considering that *Sociology* (*Sociologie*)was first published in 1908 (and therefore his work on it must have begun around 1893), we can find its first seed in his article *The Problem of Sociology* (*Das Problem der Sociologie*) originally published in 1894. Simmel must have thought this article a significant contribution to sociology, since he endeavored to spread it abroad as much as possible. Hence, the French translation of *The Problem of Sociology* appeared, simultaneously with the original German version, in September 1894. The American translation appeared in the *Annals of the American Academy of Political and Social Science* a year later, and, by the end of the century, the Italian and Russian translations were also in print. The American translation is of particular significance, since Simmel emphasized therein, in a footnote, that sociology involved an empirical basis and research, and should not be thought of as an independent offshoot from philosophy, but as a science concerning

the social problems of the nineteenth century. In the Italian translation he delivered an updated version of the text, wherein he introduced clear references to his theoretical polemic with Emile Durkheim. From his letter to Célestin Bouglé of February 15, 1894, we know that Simmel was, after the completion of *The Problem of Sociology*, quite excited by this new discipline, and that he did not foresee a shift away to any other fields of inquiry in his immediate future. During those years he worked on most of the key sociological areas of research, thus articulating the key social problems of his time within a sociological framework: for example, workers' and women's movements, religion, the family, prostitution, medicine, and ethics, amongst many others. He seemed deeply interested in putting his new theoretical proposals and framework for the constitution of sociology into practice. He realised the institutionalisation of the new discipline would be reinforced by the establishment of journals for the discipline; hence his participation in: the '*Institut Internationale de Sociologie*,' for whom he became vice-president; the *American Journal of Sociology*, and, although only briefly (due to differences with Emile Durkheim), *l'Année sociologique* (Rammstedt 1992, p. 4). He also played with the idea of creating his own sociological magazine. Another means of solidifying the role of sociology within the scientific sphere was through the academia, and he engaged himself in organising sociological seminars, offering them uninterruptedly from 1893 until his death in 1918. On June 15, 1898, he wrote to Jellinek 'I am absolutely convinced that the problem, which I have presented in the *Sociology*, opens a new and important field of knowledge, and the teaching of the forms of sociation as such, in abstraction from their contents, truly represents a promising synthesis, a fruitful and immense task and understanding' (Simmel Archive at the University of Bielefeld) Despite his original intention, it is clear Simmel did not work continuously on the *Sociology* for 15 years as, from 1897 to 1900, he worked almost exclusively on *The Philosophy of Money* (*Philosophie des Geldes*), and also found time for the writing and publication of his *Kant* (1904), as well as a reprint of his *Introduction to the Moral Sciences* (1904), which he had intended to rewrite, for he no longer accepted most of the ideas he had presented therein when it was first published in 1892 (although he did not achieve this); the revised edition of *The Problems of the Philosophy of History* (*Probleme der Geschichtsphilosophie* 1905), (*The Philosophy of Fashion* (*Philosophie der Mode* 1905), and *Religion Die Religion* 1906/1912) were all worked on by Simmel during this period too (Rammstedt 1992b). In *The Problem of Sociology* he questioned for the first time the lack of a theoretically well-defined object of study for the emerging discipline, and sought to develop a specific sociological approach, which would entail a distinct object of study, in order to bestow legitimacy and scientific concreteness to a discipline, under attack from different, and more settled, lines of fire. Fearing his call had not been heard, Simmel endeavored to prove his point by writing a broader work, within which he attempted to put into practice the main guidelines he had suggested as being central to the newly emerging discipline. In this way the *Sociology*, almost one thousand pages long, was cobbled together from various bits and pieces, taken from several essays he had written between the publication of *The Problem of Sociology* in 1894 and its final completion in 1908. Simmel, as can be understood from his letters, was aware of the incompleteness of this work, but rescued it by saying that it was an attempt to realise that which he had suggested almost 15 years earlier, for it had not been noticed enough by the scientific community. Simmel did not wish, by that time, to be thought of as only a sociologist. This was due to sociology not being an established discipline within the academic world, which therefore did not allow him to obtain a professorship in the field (i.e., offering very little recognition). Nevertheless he never quite abandoned the field of sociology and continued to write about religion, women's issues, and the family. He merely broadened his scope to include *Lebensphilosophie* (*the philosophy of life*) and cultural studies in general, whilst participating at the same time in the founding of the German Sociological Society (*Deutsche Gesellschaft für Soziologie*), for whom he served as one of the chairmen until 1913.

Sociology marks the end of Simmel's strongly Kantian period, and represents a turning point in his interests, for, from this moment onwards, he refused to be labeled as a sociologist, seeking instead to return to philosophy. Indeed, following the publication of the 'big' *Sociology*, as it is usually called by those who work in Simmel studies, he did not publish any sociological papers for nine years (although he continued, as has already been mentioned, to offer sociological seminars until his death), instead devoting his efforts to philosophy, history and the philosophy of art. Hence, as part of Simmel's output from these years we find, amongst other works, *Kant und Goethe* (*Kant und Goethe* 1906/1916), *Goethe* (1913), *Kant* (1904/1913/1918), *The Principal Problems of Philosophy* (*Hauptprobleme der Philosophie* 1911), *The Philosophical Culture* (*Philosophische Kultur* 1911/1918), and *Rembrandt* (1916). This new direction was accompanied and partly motivated by Simmel's acknowledgment of Henri Bergson's *hoeuvre*, and his inclination towards *Lebensphilosophie* (the philosophy of life; see Fitzi 1999, GSG16 1999). Thus, 'life' became the primary focus of Simmel's theoretical work, and consequently 'society' was pushed into a secondary role. During these years Simmel occupied himself with the study of artists, of their production, and how the relation between life and its formal expression is crystallised in their work. It was as if Simmel had lost interest in sociology, as he did not write a single line

concerning it for years. Yet, unexpectedly in 1917, a year before his death, he wrote *Grundfragen der Soziologie* (*Main Questions of Sociology*), the 'small sociology,' as it is called by Simmel scholars (i.e., in contrast to his 1908 work). The impetus for writing this book came from a publisher (Sammlung Göschen), who intended to print an introductory work to sociology, which he invited Simmel to write, because of the success other works of his had enjoyed for the same publisher. If Simmel had indeed distanced himself from all sociological questions, it is likely he would have merely reached for the shelf to his previous works and rewritten them in shorter form. But this was not the case, because, although he utilised older material, Simmel rewrote and redefined his perspective, and in the *Main Questions of Sociology*, scarcely 100 pages long, presented the final stage of his sociological reflections, which melded together his previous study of forms of sociation with a perspective from the philosophy of life. This approach to sociology fell into neglect after his death, awaiting revitalisation, harbouring a broad scope and original perspective for new generations of sociologists to rediscover (Simmel's last work was a philosophical contribution to *Lebensphilosophie*, the *Lebensanschauung—View of Life—1918*, GSG16 1999).

2. *The Object of Sociology*

At a time when sociology was still far from being an established discipline, instead seeking to stand up and open its eyes for the first time, Simmel sought to release it from the burden of being 'the science of society.' According to him this burden was an impossible one for the new-born discipline to carry, since being the science of society meant having to compete with already settled and established disciplines for the legitimacy of its object of study; law and history, psychology and ethnology, all could argue the case that society was their object, thus leaving sociology with the mere pretence of including elements from them all. Viewed from this perspective, as an object society was an all-encompassing matter but, at the same time, it eluded any scientific investigation, just like sand falling through our fingers. Simmel, as Max Weber two decades later, contributed to the demystification of 'society' as some kind of essential entity (as it appeared in nineteenth-century sociology, and remained as such in the sociology of Durkheim and Tönnies), instead explaining it as a dynamic process, a continuous happening, a continuous becoming, which is nothing more than the mere sum of the existing forms of sociation.

Individuals as well as society/ies are not units in and of themselves, though they may appear as self-sufficient units depending on the distance the observer interposes between him/herself and them (as observed objects). However, Simmel argued in his *Main Questions of Sociology* (GSG16 1999, pp. 62–8) that if we merely take individuals and pretend, through adopting a significant distance, to approach 'society,' or a social phenomenon, we will not reach our goal. Therefore, when conducting a sociological inquiry, what we must seek to do is base ourselves on the forms of sociation, which are built in *Wechselwirkung*. Simmel used this concept when either addressing 'interactions' or following the Kantian definition as 'reciprocal actions and effects' (Simmel 1978). The difference between the two possible meanings of this concept, or, more precisely, the differentiation of the two different concepts hidden behind the same word, has been addressed in the English translation of *The Philosophy of Money*; so the usual mistake of translating *Wechselwirkung* as a direct synonym for interaction has been corrected. According to Simmel, what actually takes place between individuals will be seen to be that which constitutes the object of sociology, not merely the individuals by themselves, or society as a whole, for, as previously mentioned, society is nothing but the sum of forms of sociation, a continuous process in and for which these forms intertwine and combine themselves to form the whole (GSG11 1992, p. 19). Thus, Simmel defined society as the sum of the forms of reciprocal actions and effects.

3. *The Concept of 'Form'*

If we take reciprocal actions and effects as our starting point, we achieve only a perspective common to all social and human sciences: sociology as method. In order to construct sociology as an independent discipline, with a specific object of study, it is necessary to analytically differentiate between form and content, that is, 'forms' as means and patterns of interaction between individuals, social groups or institutions, and 'contents' as that which leads us to act, the emotions or goals of human beings. Thus, social forms were conceived as being the object of analysis for a scientific sociology, which would only be possible empirically. Contents, on the other hand, should be left to other disciplines, such as psychology or history, to analyze.

Simmel's sociological theory is orientated towards these 'forms of sociation' (defined as such in the subtitle of *Sociology*). For individuals to become social, they need to rely on such forms in order to channel their contents, as forms represent their only means of participation in social interaction. Forms are independent from contents, and when analyzing them, it is necessary that they are abstracted from individual, particular participation in concrete interactions: the question of social forms does not include that regarding the specific relationships between the participants involved in concrete interactions; we are dealing only with that which is *between* them, as for an

analysis of social forms the particular individuals involved in them are irrelevant. Human beings, with their particular 'contents,' only become social when they seek to realise these contents, and then acknowledge this is only possible in a social framework: via 'exteriorising,' via acting through forms. Hence forms are social objectivations, which impose themselves, with their norms, upon particular individuals, an imposition which could only be annulled by isolation. These impositions and constraints are part of what sociation is, a concept which plays a key role in Simmel's theory, for he actually maintained that human beings are not social beings by nature. Simmel placed sociation, as a product of reciprocal actions and effects, at the centre of his formal, or pure (*reine*), sociology. The form of competition can be used as an example of what Simmel actually meant by 'forms.' Competition does not imply any specific contents, and remains the same, independent of those who are competing, or what they are competing for. Competition forms 'contents' (such as job seeking, or looking for the attention of a beloved person, amongst many others), limits the boundaries of actions, and actually brings them into being via giving them a framework and shape in which they can appear in the arena of actions and effects.

This situation of having the choice between multiple forms for channelling one content is stressed appreciatively in Simmel's sociology, particularly in his *Lebensphilosophie*, when he no longer contrasted the concept of form with the concept of content, but with life. In this later period, forms are the crystallization of the unretainable flow of life, yet also the channels of expressing life, for life cannot be expressed as only itself. Simmel explained this apparent paradox by asserting that life is 'more-life' and also 'more-than-life.' The concept of 'more-life' merely implies that this continuous flow connects every complete moment with the next; 'more-than-life' implies that life is not life if it does not transcend its boundaries, and becomes crystallized in a form. So life becomes art, or science, for example; life becomes externalised and crystallised and hence expressed and fulfilled. For instance, we should understand art as one form of expressing (*äussern*) life through (artistic, aesthetic) forms. Actually uncovering how this perspective can be applied to sociology may appear to be a difficult task; the first step towards clarifying this was made by Simmel himself in his *Main Questions of Sociology*.

4. *'Me' and 'You'*

Deliberately distancing himself from the concept of 'alter ego,' Simmel emphasized the signific1ance the concept of 'you' should have to all sociological theory. He articulated and embedded this concept within his—sociological—theory of knowledge. In parallel with Kant's question on nature, Simmel formulated this question as 'How is society possible?' the first and well known digression of his *Sociology*. In order to answer this question he proposed three *a priori*. According to the first, 'Me' and 'You' would see each other as 'to some extent generalised' (GSG11 1992, p. 47), and he therefore assumed that each individual's perception of the other (i.e., 'you') would also be generalized to a certain degree. The second *a priori* affirms that each individual as an 'element of a group is not only a part of the society, but, on top of this, also something else' (GSG11 1992, p. 51) that derives its own uniqueness, its individuality from the duality of being/not being sociated. The third *a priori* is related to the assignment of each individual to a position within their society (in the sense of the sum of highly differentiated reciprocal actions and effects): 'that each individual is assigned, according to his qualities, to a particular position within his social milieu: that this position, which is ideally suited to him, actually exists within the social whole—this is the supposition according to which every individual lives his social life' (GSG11 1992, p. 59); this is what Simmel meant when he wrote about the 'general value of individuality.'

These sociological *a priori*, orientated towards role, type, and individual/society, also allow us to understand the central aspects of Simmel's methodology, which can be framed together with the concepts of 'differentiation,' in the sense of division and difference, and of 'dualism,' in the sense of an irreconcilable, tragic opposition of the elements of a social whole.

5. *A Proposal for Three Sociologies*

According to Simmel sociology needed to stand as an autonomous science in close relationship with 'the principal problem areas' (GSG16 1999, pp. 76–84) of social life, even when these areas were distant from each other. Already in 1895 he asserted that just which name to give to any particular group was quite unimportant, since the real question was to state problems and to solve them, and not at all to discuss the names which we should give to any particular groups (1895, *Annals of the American Academy of Political and Social Science* **6**: 420). He stressed this orientation into problem areas again in 1917, when he returned to theorizing on the *Main Questions of Sociology*. Thus, as an attempt to approach these main questions (i.e., which relationships exist between society and its elements, individuals) he concentrated on three different sets of problems with concrete examples, particularly in the third part of the first chapter.The first focuses on objectivity as a component of the social sphere of experience; the second includes the actual facts of life, in which, and through which, social groups are realised; and the third emphasises the significance of society (Fitzi and GSG16 1999, p. 84) for grasping and understanding attitudes towards the world and life. These three problem areas correspond to his three proposed sociologies: the 'general sociology,' which, wherever society exists, deals with the

central relationships between the individuals and the social constructions resulting from them. The aim of general sociology is to show which reciprocally orientated values these social constructions and individuals possess. He gave an example for general sociology in the second chapter of the *Main Questions of Sociology*, by illustrating the relationships which exist between the 'social and the individual level,' a perspective which, at the same time, sociologizes the masses theory. The 'pure or formal' sociology focuses upon the multiple forms individuals use to embody contents, that is, emotions, impulses, and goals, in reciprocal actions and effects with others, be it with other people, social groups, or social organizations, and thus they constitute society. According to him, each form wins, entwined in these social processes, 'an own life, a performance, which is free from all roots in contents' (GSG16 1999, p. 106). The example Simmel chose for his formal sociology was the form of 'sociability' (*Geselligkeit*), which he presented in the third chapter of the *Main Questions of Sociology*. Finally, the 'philosophical sociology' circles the boundary of the 'exact, orientated towards the immediate understanding of the factual' (GSG16 1999, p. 84) empirical sociology: on the one hand the theory of knowledge (*Erkenntnistheorie*), on the other, the attempts to complement, through hypothesis and speculation, the unavoidably fragmentary character of factual, empirical phenomena (*Empirie*), in order to build a complete whole (GSG16 1999, p. 85). In the fourth chapter, entitled 'The Individual and Society in Eighteenth and Nineteenth Century Views of Life', Simmel illustrated the abstract necessity of individual freedom, which should be understood as a reaction to the contemporary, increasing, social constraints and obligations. Thus, reference is made to general conflicts between individual and society, which derive from the irreconcilable conflict between the idea of society as a whole, which 'requires from its elements the one-sidedness of a partial function,' and the individual, who knows him/herself to be only partially socialized, and 'him/herself who wants to be whole' (GSG16 1999, p. 123).

6. *Simmel and Modern Sociology*

Simmel's theoretical significance to contemporary sociology resides in the various theories, which built on his sociology. As examples, it will be sufficient to name symbolic interactionism, conflict theory, functionalism, the sociology of small groups, and theories of modernity. Simmel also introduced into sociology the essay as an academic form of analysis, whilst his digressions within *Sociology* should be mentioned as well, for they have become generally recognized as classical texts; see, for example, his digressions on 'The Letter' (*Brief*), 'Faithfulness' (*Treue*), 'Gratefulness' (*Dankbarkeit*), and 'The Stranger' (*Fremde*). But above all sociology owes Simmel the freedom he gave it from the fixation on the 'individual and society' as an ontic object—in hindsight, a point of no return.

Simulation and Training in Work Settings

Training is a set of activities planned to bring about learning in order to achieve goals often established using a training needs analysis. Methods of training include: behavior modeling, based on video or real activities; action training, which provides an opportunity to learn from errors; rule- and exemplar-based approaches that differ in terms of the extent to which theory is covered; and methods that aim to develop learning skills, the skills needed to learn in new situations. Simulation involves using a computer-based or other form of model for training, providing an opportunity for systematic exposure to a variety of experiences. Simulations are often used in training complex skills such as flying or command and control. Issues in training highlight the differing emphasis that can be placed on goals related to the process of learning or performance outcomes; motivation and self-management in training; and the transfer dilemma where effortful methods of training that enhance transfer may be less motivational. Finally organizational issues and training evaluation are discussed with a particular emphasis on the role of the environment and follow-up enhancing transfer of skills learned during training to the workplace.

1. Overview

Training is a set of planned activities organised to bring about learning needed to achieve organizational goals. Organizations undertake training as part of the socialization of newcomers. Even with the best selection systems a gap frequently remains between the knowledge, skills, and abilities (KSAs) required in a job, and those possessed by the individual. Training is used by organizations to improve the fit between what an individual has to offer and what is required. Training is also used when job requirements change such as with the introduction of new technology. Because of the frequency with which job requirements change, a major aim of training is to develop specific skills while also ensuring their transferability and adaptability. An ultimate aim is to increase learning skills where the emphasis in training is on learning to learn. Many methods of training are available (e.g. behavioral modeling, action, computer-based training), with an increasing trend toward incorporating evaluation as part of the training. Although simulations have been used in training for decades, the reduced cost and increased sophistication of simulations now make them more readily available for a wide range of situations. Simulations provide increased opportunities to train for transferable and adaptable skills because trainees can experiment, make errors, and learn from feedback on complex and dynamic real-time tasks. Evaluation of training programmes remains an important component of the training plan, and can be used to enhance transfer.

2. Training Needs Analysis

Most training starts with a training needs analysis, where the present and future tasks and jobs that people do are analyzed to determine the task and job requirements. The identified requirements are then compared with what the individual has to offer. This is done within a broader organizational context. Many different methods of job, task, and organizational analysis can be used, including observation, questionnaires, key people consultation, interviews, group discussion, using records, and work samples (that is, letting people perform a certain activity and checking what they need to know to perform well). A transfer of training needs analysis (Hesketh 1997a), places a particular emphasis on identifying the cognitive processes that must be practised during learning to ensure that the skills can be transferred to contexts and tasks beyond the learning environment.

3. The Training Plan and Methods

There has been an increase in the methods of training that can be used within a broader training plan that includes transfer and evaluation (Quinones and Ehrenstein 1997). The training plan provides a way of

combining the illustrative methods discussed below to ensure that the training needs identified in the analysis can be met.

3.1 Behavior Modeling

Behavior modeling is often combined with role-playing in training. A model is presented on video or in real life, and the rationale for the special behaviors of the model are discussed with the trainees. Trainees then role play the action or interaction, and receive feedback from the trainers and fellow trainees. This type of training is very effective as it provides an opportunity for practice with feedback (e.g. Latham and Saari 1979).

3.2 Action Training

Action training follows from action theory (Frese and Zapf 1994) and exploratory learning. Key aspects of action training involve active learning and exploration, often while doing a task. Action learning is particularly effective as a method of training (Smith et al. 1997). Another important aspect of action training involves obtaining a good mental model of the task and how it should be approached. A mental model is an abstraction or representation of the task or function. Trainees can be helped to acquire a mental model through the use of 'orientation posters' or advanced organizers, or through the provision of heuristic rules (rules of thumb) (Volpert et al. 1984). One of the advantages of action training is the opportunity to learn from feedback and errors. Feedback is particularly important in the early stages of learning, but fading the feedback at later stages of learning helps ensure that trainees develop their own self-assessment skills (Schmidt and Bjork 1992). Errors are central in action training since systematic exposure to errors during learning provides opportunities to correct faulty mental models while providing direct negative feedback. Although earlier learning theory approaches argued that there should be only positive feedback, active error training helps trainees develop a positive attitude toward errors because of their value in learning (Frese et al. 1991).

3.3 Rules versus Examples in Training

Although it has traditionally been assumed that rule-based training provides a sound basis for longer term transfer, recent research suggests that for complex nonlinear problems, exemplar training may be superior. Optimizing the combination of rules and examples may be critical. In order to facilitate transfer, examples should be chosen carefully to cover the typical areas of the problem. With only a few examples, the rule and the example are often confused. However, individual instances are difficult to recall if trainees are provided with too many examples (DeLosh et al. 1997), suggesting that care needs to be taken when deciding how many examples will be presented in training.

3.4 Developing Learning Skills: Learning to Learn

Downs and Perry (1984) offer a practical way of helping trainees develop learning skills such as knowing that there are different ways of learning (e.g., learning by Memorizing, Understanding and Doing, the MUD categories). Facts need to be memorized, concepts need to be understood and tasks such as driving a motor car need to be learned by doing. The approach stresses the importance of selecting the most appropriate method for the material to be learned so that learning skills can be trained while also developing content skills. Methods that typically encourage learning skills as well as content skills involve action learning, active questioning and discovery learning, rather than direct lecturing and instruction. The ideas in the learning to learn literature lead to issues such as developing self-management techniques and focusing on learning.

3.5 Simulation Training

Simulation involves developing a model of an on-the-job situation that can be used for training and other purposes. The advantages of using simulation for training include reduced cost, opportunity to learn from errors, and the potential to reduce complexity during the early stages of learning. Historically simulators have been used for training in military, industrial and transport industries, and in management training where business games are widespread.

Pilot training on simulators is well developed, to the extent that many pilots can transfer directly from a flight simulator to a real aircraft (Salas et al. 1998). Within the aviation industry, crew cockpit resource management training has also been undertaken using simulators. Driving simulators are not as well developed, and the transfer of skills learned on a driving simulator to the actual road remains to be established. Nevertheless, there is a view that attitudes and driving decisions can be trained on a simulator. Simulations of management decision situations and command and control in the military, police, and emergency personnel are well developed, and widely used for training. These simulations provide a miniaturized version of real crises, with key decision points extracted and shrunk

in time. They provide an opportunity for the trainee to experiment with decisions, make mistakes, and learn from these errors (Alluisi 1991). Simulation training has also been used to facilitate the acquisition of cross-cultural skills.

4. Issues in Training

4.1 Learning vs. Performance Goals

Whether the emphasis during learning is on performance or learning goals is used to explain differences in how people conceptualize their ability. Dweck and Leggett (1988) argue that some people conceptualize ability as increasing with learning (learning orientation), while others see ability as fixed (performance orientation). People with a learning orientation learn from mistakes and challenges. However, individuals with a performance orientation view mistakes as examples of poor performance and learn less from errors. Performance oriented people also tend to demonstrate a helpless response to problems and are therefore less likely to overcome challenges. Martocchio (1994) showed that ability self-conceptualization was related to computer anxiety and self-efficacy.

Motivation plays a key role in transfer of training (Baldwin and Ford 1988). Numerous motivation issues have been studied, the most important ones being self-efficacy, relapse prevention, perceived payoffs, goals, and the training contract. Self-efficacy is critical to transfer in that people will use a skill only if they believe that they can actually perform the appropriate behavior. Relapse prevention focuses on teaching solutions to those situations in which it may prove difficult to use the newly learned skills (Marx 1982). Trainees who receive relapse prevention training have been found to use their skills more often and perform their job better.

4.2 Self-management in Training

Self-management implies that one acquires the skills to deal with difficulties, reward oneself, and increase self-efficacy. Metacognitive strategies showing evidence of self-management and self-reward during training related to training performance. Furthermore, self-efficacy is related to increased post-training knowledge (Martocchio 1994) and transfer performance. Thus, self-efficacy functions as a predictor of both training and transfer performance.

4.3 Transfer Dilemma

Transfer is important to ensure that the skills learned in one context or on one task can be applied in a range of different contexts and tasks. For example fire fighters may learn how to fight fires in urban areas, but their skills must also transfer to the bush or rural areas where they are frequently required to work in emergencies. In the field of technology, training, in the use of one spreadsheet or database should lead to transfer to different spreadsheets and databases and a range of other software packages. Baldwin and Ford (1988) provide a model that highlights several factors that influence transfer, including the similarity of the training and transfer situation, the nature of the training methods used, and the extent to which environmental factors reinforce transfer. Annett and Sparrow (1986) explained that transfer would be best if the stimulus situations and behaviors trained shared identical elements with stimuli in the work environment and the behaviors required there. Because these are seldom identical it is important to use methods of training that encourage learners to bridge the gap and transfer their skills (Hesketh 1997b), and to create an environment that reinforces them for doing so. A transfer of training needs analysis can be used to discover how best to design training to increase transfer knowledge and skill (Hesketh 1997a). For example, a transfer of training needs analysis for a team leader in fire fighting would highlight the types of decisions that needed to be made in different fire incidents and the specific cues used in making the decisions. This information would be used to design training that emphasized practice of these decision processes in a range of systematically chosen contexts to facilitate transfer. This approach ensures that the cognitive skills required for transfer are practised during training, and that knowledge about transfer and likely barriers are discovered during training (Von Papstein and Frese 1988).

Druckman and Bjork (1992) has highlighted a dilemma in that the methods of training that trainees enjoy, and that often lead to better performance on the training task, are not necessarily the ones that enhance long term retention and transfer. Trainees enjoy methods of training that require less effortful cognitive processing. Yet to facilitate transfer, trainees need to engage in the problem solving and active processes that they will be required to do on transfer. This may create motivational difficulties. Designing the training to provide an appropriate level of challenge is important for both motivation and transfer.

4.4 Simulation and Transfer

Early debate about the appropriate level of physical and psychological fidelity of simulation for training remains important, but has been incorporated into the more general issue of transfer and generalization. A high fidelity simulation may facilitate transfer to a single context, but lower fidelity simulators may be more appropriate if transfer is required to a range of situations. Current research issues are addressing the

best ways of integrating simulation with other forms of training, and how to optimize the level of fidelity for the particular purpose and type of simulation. The debate is being informed by research on the best way of combining rules and examples for training. Simulators provide an ideal opportunity to structure systematic exposure to a carefully chosen set of exemplar situations.

Simulators have traditionally been used for training, but their potential use is much more widespread. Simulation may provide a more realistic selection task for situations that require dynamic decision-making. Simulations are also being used as a way of signing off competency levels. Questions remain about how to deal with re-testing with a simulator, e.g., whether the trainee should be given an opportunity to perform again on exactly the same sequence as used during an initial test or a transfer problem. Here the research on transfer of training is critical, and may be of use in resolving the reassessment debate. This illustrates the ways in which selection, assessment, and training are strongly related areas of research and practice.

4.5 Organizational Issues

Organizational characteristics often influence transfer success. Trainees develop expectations about whether or not it will pay off when they use what they have learned in training. Often, companies teach one thing and reward a completely different behavior. For example, trainees may learn to be cooperative in a training course, but may then be paid for their individual contribution in a highly competitive environment. In such situations there is no transfer. Trainees need to be reinforced for what they have learned, and to practise skills in circumstances where errors can be made without serious consequences. For example a practice niche can be created where a bank clerk who has learned a new program to calculate mortgages is provided with an opportunity to practise it first while answering written requests. Thus, the customer does not see all the mistakes the bank clerk makes when using the new program.

4.6 Evaluating Training

The importance of evaluation has always been emphasized in training, although until recently approaches were somewhat traditional and limited. The importance of training evaluation has been recognized because intuitive guesses about what works are often wrong. Druckman and Bjork (1991) concluded that many companies in the USA continue to use methods of training known to be suboptimal for transfer because they rely on short term reactions evaluation, rather than examining the longer term retention and transfer of skills. Training evaluation can also be used as a way of indicating the importance of the skills learned, and of providing an opportunity to practise. Integrating training evaluation into the training plan is the best way of achieving this. The more detailed understanding of ways in which knowledge structures change with skill acquisition has also provided a basis for evaluating training. For example, experts tend to have hierarchically organized knowledge structures, and are able to read off solutions to problems far more quickly. These ideas can be used to suggest innovative ways of evaluating training programs.

Simultaneous Equation Estimates (Exact and Approximate), Distribution of

A simple example of a system of linear simultaneous equations may consist of production and consumption functions of a nation: $Y = a + bK + cL +$ error, and $C = d + eY +$ error. The variables Y, K, L, and C represent the gross domestic product (GDP), the capital equipment, the labor input, and the consumption, respectively.

These variables are measures of the level of economic activity of a nation. In the production function, Y increases if the inputs K and/or L increase. C increases if Y increases in the consumption equation. Each equation is modeled to explain the variation in the left-hand side 'explained' variable by the variation in the right-hand side 'explanatory' variables. Error terms are added to analyze numerically the effect of the neglected factors from the right-hand side of the equation. These equations are different from the regression equations since the 'explained' variable Y is the 'explanatory' variable in the C equation, and Y and C are simultaneously determined by the two equations. Estimation of unknown coefficients and the properties of estimation methods are not straightforward compared with the ordinary least squares estimator.

In practice, this kind of simultaneous equation system is extended to include more than 100 equations, and regularly updated to measure the economic activities of a nation. It is indispensable to analyze numerically the effect of policy changes and public investments.

In this article, the statistical model and the estimation methods of all the equations are first explained, followed by the estimation methods of a single equation and their asymptotic distributions. Explained next are the exact distributions, the asymptotic expansions, and the higher order efficiency of the estimators.

1. *The System of Simultaneous Equations and Identification of the System*

We write the structural form of a system consisting of G simultaneous equations as

$$y_i = Y_i\,\beta_i + Z_i\,\gamma_i + u_i \equiv (Y_i\ Z_i)\delta_i + u_i, \qquad i = 1,\ldots, G \quad (1)$$

where y_i and Y_i are 1 and G_i subcolumns in the $T \times G$ matrix of whole endogenous variables $Y = (y_i, Y_i, Y_{ei})$, Z_i consists of K_i subcolumns in the $T \times K$ matrix of whole exogenous variables Z, β_i and γ_i are $G_i \times 1$ and $K_i \times 1$ column vectors of unknown coefficients, $\delta_i = (\beta_i', \gamma_i')'$, and u_i is the $T \times 1$ error term. This system of G equations with T observations is frequently summarized in a simple form

$$YB + Z\Gamma = U \quad (2)$$

the ith column of which is $y_i - Y_i\beta_i - Z_i\gamma_i = u_i$, i.e., Eqn. (1). The ith columns of B and Γ may be denoted as b_i and c_i where $(G - G_i - 1)$ and $(K - K_i)$ elements are zero so that $y_i - Y_i\beta_i - Z_i\gamma_i = Yb_i + Zc_i$. Zero elements are called zero restrictions. It is assumed that each row of U is independently distributed as $N(0, \Sigma)$. The reduced form of Eqn. (2) is

$$Y = Z\Pi + V \quad (3)$$

where the $K \times G$ reduced form coefficient matrix is $\Pi = -\Gamma B^{-1}$, and the $T \times G$ reduced form error term is $V = UB^{-1}$. Each row of V is assumed to be independently distributed as $N(0, \Omega)$, and then $\Sigma = B^{-1}, \Omega B^{-1}$.

The definition $\Pi = -\Gamma B^{-1}$, or $-\Pi B = \Gamma$ is the key to identify structural coefficients. Coefficients in β_i are identified if they can be uniquely determined by the equation $-\Pi b_i = c_i$ given Π. This equation is reduced to $-\Pi_0(1, \beta_i')' = 0$ denoting the $(K - K_i) \times (1 + G_i)$ submatrix in Π as Π_0. (Rows and columns are selected according to the zero elements in c_i and non-zero elements in b_i, respectively.) Given Π_0, this includes $(K - K_i)$ linear equations and G_i unknowns, and β_i is solvable if rank $(\Pi_0) = G_i$. This means $(K - K_i)$ must be at least G_i, or $L = K - K_i - G_i$ must be at least 0. If $L = 0$, β_i is uniquely determined. For the positive L, there are L linearly dependent rows in Π_0 since only G_i rows are necessary to determine β_i uniquely. Once β_i is determined, γ_i is determined by other K_i equations through $-\Pi b_i = c_i$. L is called the number of the degrees of overidentifiability of the ith equation.

Structural coefficients are not uniquely estimable if they are not identified (see *Statistical Identification and Estimability*).

2. *Estimation Methods of the Whole System and the Asymptotic Distribution*

The full information maximum likelihood (FIML) estimator of all nonzero structural coefficients δ_i, $i = 1,\ldots, G$, follows from Eqn. (3). Since it is in a linear regression form, the likelihood function can first be minimized with respect to Ω. Once Ω is replaced by the first-order condition, the likelihood function is concentrated where only B and Γ are unknown. The concentrated likelihood function is proportional to

$$\ln|\Omega_R|, \Omega_R = (Y-Z\Pi_R)'(Y-Z\Pi_R)/T, \quad \Pi_R = -\Gamma B^{-1}, \tag{4}$$

and all zero restrictions are included in B and Γ matrices. In the FIML estimation, it is necessary to minimize $|\Omega_R|$ with respect to all non-zero structural coefficients.

The FIML estimator is consistent, and the asymptotic distribution is derived by the central limit theorem. Stacking δ_i, $i = 1,\ldots, G$ in a column vector δ, the FIML estimator $\hat{\delta}$ asymptotically approaches $N(0, -I^{-1})$ as follows:

$$\sqrt{T}(\hat{\delta}-\delta)\xrightarrow{D}N(0, -I^{-1}), \quad I = \lim_{T\to\infty}\frac{1}{T}E\left(\frac{\partial^2\ln|\Omega_R|}{\partial\delta\,\partial\delta'}\right). \tag{5}$$

I is the limit of the average of the information matrix, i.e., $-I^{-1}$ is the asymptotic Cramer–Rao lower bound. Then the FIML estimator is the best among consistent and asymptotically normal (BCAN) estimators.

The right-hand side endogenous variable Y_i in (1) is defined by a set of G_i columns in (3) such as $Y_i = Z\Pi_i + V_i$. By the definition of V, Y_i or, equivalently, V_i is correlated with u_i since columns in U are correlated with each other. The least squares estimator applied to (1) is inconsistent because of the correlation between Y_i and u_i. Since Z is assumed to be not correlated with U in the limit, Z is used as K instruments in the instrumental variable method estimator. Premultiplying Z' to (1), it follows that

$$\begin{aligned} Z'y_i &= (Z'Y_i, Z'Z_i)\delta_i + Z'u_i \\ &= (0,\ldots, 0, Z'Y_i, Z'Z_i, 0,\ldots, 0)\delta + u_i^*, \\ &\qquad i = 1,\ldots, G \end{aligned} \tag{6}$$

where the $K\times 1$ transformed right-hand side variables $Z'Y_i$ is not correlated with u_i^* in the limit. Stacking all G transformed equations in a column form, the G equations are summarized as $w = X\delta + u^*$ where w and u^* stack $Z'y_i$ and u_i^*, $i = 1,\ldots, G$, respectively, and are $GK\times 1$. The covariance between u_i^* and u_j^* is $\sigma_{ij}(Z'Z)$ which is the ith row and jth column sub-block in the covariance matrix of u^*. (The whole covariance matrix can be written as $\Sigma\otimes(Z'Z)$ where $\otimes$ signifies the Kroneker product.) Once Σ is estimated consistently (by the 2SLS method explained in the next section), δ is efficiently estimated by the generalized least squares method

$$\hat{\delta}_{3\mathrm{SLS}} = \{X'[\hat{\Sigma}^{-1}\otimes(Z'Z)^{-1}]X\}^{-1}\{X'[\hat{\Sigma}^{-1}\otimes(Z'Z)^{-1}]w\}. \tag{7}$$

This is the three-stage least squares (3SLS) estimator by Zellner and Theil (1962). The assumption of the normal distribution error is not required in this estimation. The 3SLS estimator is consistent and is BCAN since it has the same asymptotic distribution as the FIML estimator.

3. *Estimation Methods of a Single Equation and the Asymptotic Distribution*

An alternative way of estimating structural coefficients is to pick up one structural equation, the ith, in a G-equation system, and estimate δ_i neglecting zero restrictions in other equations. Because of this, the other $(G-1)$ structural equations can be rewritten equivalently as $(G-1)$ reduced form equations. The limited information maximum likelihood (LIML) estimator by Anderson and Rubin (1949) applies the FIML method to a $(1+G_i)$-equation system consisting of (1) and $Y_i = Z\Pi_i + V_i$. This means the first column and the second G_i columns of B are $(1, -\beta_i')'$ and $(0, I)'$, respectively, and the first column and the second G_i columns of Γ are $(\gamma_i', 0')'$ and Π_i, respectively. (If we denote Y as (y_i, Y_i, Y_{ei}), Y_{ei} is weakly exogenous in estimating (1) or, equivalently, the structural and reduced form parameters of (y_i, Y_i) given Y_{ei} are variation-free from the reduced form coefficient of Y_{ei}. Then Y_{ei} is omitted from (2), (3), (4), and (8).) Using these limited information B and Γ matrices, we minimize $|\hat{\Omega}_R|$ with respect to δ_i and Π_i. Defining $P_F = F(F'F)^{-1}F'$ for any full column matrix F, $G = (y_i, Y_i)'(P_Z - P_{Z_i})(y_i, Y_i)$, and $C = (y_i, Y_i)'(I-P_Z)(y_i, Y_i)$, it turns out that β_i is estimated by minimizing the least variance ratio

$$\lambda(\beta_i) = \frac{(1, -\beta_i')G(1, -\beta_i')'}{(1, -\beta_i')C(1, -\beta_i')'}. \tag{8}$$

γ_i is estimated by the least squares method applied to (1) replacing β_i with the estimator.

The two stage least squares (2SLS) estimator is the generalized least squares estimator applied to Eqn. (6) using $Z'Z$ as the weight matrix. (See Eqn. (10), where k is set to 1.) The assumption of the normal distribution of the error term is not required in this estimation. Both LIML and 2SLS estimators are consistent, and the large sample distribution is

$$\sqrt{T}(\hat{\delta}_i - \delta_i)\xrightarrow{D}N(0, -I^{-1}(\delta_i, \delta_i)) \tag{9}$$

where I is calculated similarly to Eqn. (5) but Ω_R is defined using the limited information B and Γ matrices, and only the diagonal submatrix of I^{-1} which corresponds to δ_i is used. (Partial derivatives are calculated with respect to δ_i and columns in Π_i.) This asymptotic distribution is a particular case of Eqn. (5). Both estimators are consistent and BCAN under the zero restrictions imposed on Eqn. (1).

The k-class estimator $\hat{\delta}_i(k)$ unifies both LIML and 2SLS estimators (Theil 1961). It is

$$\hat{\delta}_i(k) = \begin{pmatrix} Y_i'P_Z Y_i - (k-1)Y_i(I-P_Z)Y_i & Y_i'Z_i \\ Z_i'Y_i & Z_i'Z_i \end{pmatrix}^{-1} \times \begin{pmatrix} Y_i'P_Z - (k-1)Y_i'(I-P_Z) \\ Z_i' \end{pmatrix} y_i. \quad (10)$$

This is the least squares estimator, the 2SLS estimator, and the LIML estimator when k is 0, 1, and $1+\lambda$, respectively. There are two important properties in the k-class estimator. It is consistent if $p\lim_{T\to\infty} k = 1$, and is BCAN if $p\lim_{T\to\infty}\sqrt{T}(k-1) = 0$. If k satisfies these conditions, the k-class estimator is consistent and BCAN even when $Y_i'(I-P_Z)Y_i$ and $Y_i'(I-P_Z)y_i$ are replaced with any matrix and a vector of order $O_P(T)$.

4. *Exact Distributions of the Single-equation Estimators*

Several early studies compared the bias and mean squared errors of OLS, LIML, 2SLS, FIML, and 3SLS estimators by the Monte Carlo simulations since all but OLS estimators are consistent and are indistinguishable. The OLS estimator was often found as reliable as other consistent estimators. Later, the studies went on to t ratios, and the real defect of OLS estimators was found: the deviation from the standard normal distribution is worse than any other simultaneous equation methods. See Cragg (1967) for related papers.

Drawing general qualitative comparisons from simulations is difficult since simulations require setting values of all population parameters. Simulation studies on the small sample properties led to the derivation of the exact distributions, which were expected to permit the drawing of general comparisons without depending on the particular parameter values.

If $n\times 1$ column vectors x_t, $t = 1,\ldots, T$ are independently distributed $N(m_t, \Omega)$, the density function of $\Sigma_{t=1,T}\, x_t x_t'$ is the non-central Wishart matrix denoted as $W_n(T, \Omega, M)$ where the non-centrality parameter is $M = \Sigma_{t=1,T}\, m_t m_t'$ (Anderson 1958, Chap. 13). The study of the exact distribution of the single-equation estimators started from the fact that $G = (G_{kl})$ and $C = (C_{kl})$, k, $l = 1,\ldots, 1+G_i$ in Eqn. (8) are the noncentral Wishart matrix $W_{1+G_i}(K-K_i, \Omega, M)$ with the noncentrality parameter matrix $M = \Pi_R' Z'(P_Z - P_Z)Z\Pi_R$, and the central Wishart matrix $W_{1+G_i}(T-K, \Omega, 0)$, respectively. The 2SLS, OLS, and LIML estimators of β_i are $G_{22}^{-1}\, G_{21}$, $(G_{22}+C_{22})^{-1}(G_{21}+C_{21})$, and $(G_{22}-\lambda C_{22})^{-1}(G_{21}-\lambda C_{21})$, respectively, and λ is the minimum root in the polynomial equation $|G-\lambda C| = 0$. Since all estimators are functions of elements in the G and C matrices, their distributions can be characterized by degrees of freedom of the two Wishart matrices, M and Ω matrices.

In deriving the exact density functions, the 2SLS and OLS estimators can be treated in a similar way. In the 2SLS estimator, the joint density of G is transformed into the joint density of $G_{22}^{-1}\, G_{21}$, $G_{11}-G_{12}G_{22}^{-1}\, G_{21}$, and G_{22}. Integrating out $G_{11}-G_{12}G_{22}^{-1}G_{21}$ and G_{22} results in the joint density of $G_{22}^{-1}G_{21}$. The resulting density function includes infinite terms, and zonal polynomials when G_i is greater than one. A pedagogical derivation is found in Press (1982, Chap. 5). In the LIML estimator, the joint density of G and C is transformed into that of characteristic roots and vectors. Since $\hat{\beta}$ is rewritten as a ratio of elements in a characteristic vector, the density function is derived by integrating out unnecessary random variables from the joint density function. However, the analytical operations are not easy when there are many endogenous variables. See Phillips (1983, 1985) to find comprehensive reviews on the 2SLS and LIML estimators, respectively.

It was somewhat fruitless to derive exact distributions because these include nuisance parameters and infinite terms. It was difficult to draw general conclusions on the qualitative properties of the estimators from the numerical evaluations of these distributions. See Anderson et al. (1982).

Qualitative properties of the estimators followed from the exact moments of estimators. Kinal (1980) proved that the (fixed) k-class estimator in a multiple endogenous variables case has moments up to $(T-K_i-G_i)$ if $0 \leqslant k < 1$, and up to L if $k = 1$. Mariano and Sawa (1972) proved that, in the $G_i = 1$ case, the mean and variance of the LIML estimator do not exit. (In Monte Carlo simulations, the bias of LIML estimators was often found to be smaller than that of others even though the exact mean is infinite. This showed the clear limitation of the simulation methods.)

5. *Asymptotic Expansions of the Distributions of the Single-equation Estimators*

Asymptotic expansion of the distribution was introduced as an analytical tool which is more accurate than the asymptotic distribution but is less complicated than the exact distributions. For instance, the

t ratio statistic, say X, which is commonly used in econometrics, has the density function $f(x) = c \cdot [1+(x^2/m)]^{-(1+m)/2}$ where c is a constant and m is the degree of freedom under conditions including the normally distributed error terms. Since the mean and variance of X is 0 and $m/(m-2)$, the standardized statistic $Z = \sqrt{(m-2)/m} \cdot X$ has the density $f(z) = c' \cdot [1+(z^2/(m-2))]^{-(1+m)/2}$ where c′ is a new constant. This density function is expanded to the third-order term as

$$f(z) = \phi(z)\{1+\frac{1}{4m}(z^4-6z^2+3)\}+o(m^{-1}) \quad (11)$$

where $\phi(z)$ is the standard normal density function, and the constant is adjusted so that the area under the curve is one. (Since the t distribution is symmetric around the origin, the $O(1/\sqrt{m})$ term does not appear in the right-hand side of the equation.) Rewriting in terms of X, the asymptotic expansion of the t statistic with m degrees of freedom is

$$f(x) = \phi(x)+\frac{1}{4m}(x^4-2x^2-1)\phi(x)+o(m^{-1}) \quad (12)$$

The first term in the right-hand side is the $n(0, 1)$ density function. The second term in the right-hand side converges to zero if the limit is taken with respect to m. This second term gives deviation of $f(x)$ from ϕ(x), and is called the third-order term. For finite m, the third-order term is expected to improve the standard normal approximation. The numerical evaluation of this expansion is easy.

The asymptotic expansions in the simultaneous equation estimators are long and include nuisance parameter matrices such as q below. See Phillips (1983) for a review and Phillips (1977) for the validity of expansion. The asymptotic expansion does not require the assumption of the normal distribution of the error term. Fujikoshi et al. (1982) gave the expansion of the joint density of the estimators of δ_i. In their study, the bias of the estimators is calculated from the asymptotic expansions as

$$AM(\sqrt{T}(\hat{\delta}_i-\delta_i)) = \frac{1}{\sqrt{T}}(dL-1)I^{-1}q+o(T^{-1}),$$

$$q = \frac{1}{\sigma^2}\begin{pmatrix} \varpi_{21}-\Omega_{22}\beta_i \\ 0 \end{pmatrix}, \quad (13)$$

where $\hat{\delta}$ is the estimator, d is 1 and 0 fo1r 2SLS and LIML estimators, respectively, and the Ω matrix is partitioned into submatrices conformable with the partitions of G and C matrices. $AM(\cdot)$ stands for the mean operator, but uses the asymptotic expansion for the density function. (Recall that the exact mean does not exist in the LIML estimator.) It is possible to compare the two estimators in terms of the calculated bias. For example, the bias of the 2SLS estimator is 0 when the degree of overidentifiability L is 1.

Further, the mean of the squared errors was calculated from the asymptotic expansions and used to compare estimators. It was proved that the mean squared error of the 2SLS estimator is smaller than that of the LIML estimator when L is less than or equal to 6. Historically, this kind of comparison of 'approximate' mean squared errors goes back to the 'Nagar expansion' by Nagar (1959) and the 'small disturbance expansion' by Kadane (1971). These qualitative comparisons gave researchers some guidance about the choice of estimators.

It was interesting to examine the accuracy of the approximations calculated by the asymptotic expansions of distributions. If the asymptotic expansions were accurate, calculation of the exact distributions could be avoided, and properties of estimators could be found easily from the approximations. However, the approximations were found not to be accurate enough to replace the exact distributions. There are many cases where the asymptotic expansion is accurate when the asymptotic distribution, the first term in the expansion, is already accurate; the asymptotic expansion is inaccurate when the asymptotic distribution is inaccurate. In particular, the asymptotic expansions are inaccurate when

(a) The value of asymptotic variance is small;
(b) The value of L is large; or
(c) The structural error term is highly correlated with the right-hand side endogenous variable.

It is noted, first, $Z'Z/T$ is assumed to converge a nonsingular fixed matrix in the asymptotic theory. Second, for an attempt to improve the accuracy of asymptotic distributions by incorporating large L values, see Morimune (1983). Third, the asymptotic expansions cannot trace closely the skewed exact distributions that happen particularly when the correlation is high.

6. *Higher-order Efficiency of the System and the Single-equation Estimators*

The asymptotic expansions of distributions can be used in comparing the probabilities of concentration of estimators about the true parameter values. One estimator is more desirable than another if its probability is greater than that of the other. This measure was used in comparing the single-equation estimators, and some qualitative results were derived.

Furthermore, the third-order efficiency criterion was brought in the comparisons. This criterion requires that estimators be adjusted to have the same asymptotic bias as in Eqn. (13). Then the adjusted estimators are compared, and the maximum likelihood

estimator is proved most efficient. It has the highest concentration about the true parameter values in terms of the asymptotic expansion of distribution to the third-order $O(1/T)$ terms. (Akahira and Takeuchi (1981), for example.) The adjusted maximum likelihood estimator has the smallest mean-squared error at the same time since the difference among estimators is found only in the mean-squared errors.

In whole system estimation, the FIML estimator is third-order efficient. The 3SLS estimator is less efficient than the FIML estimator in terms of the asymptotic probability of concentration once the bias of the two estimators is adjusted to be the same. Morimune and Sakata (1993) derived a simple adjustment of the 3SLS estimator so that the adjusted estimator has the same asymptotic expansion as the FIML estimator to the third-order $O(1/T)$ terms. This estimator is explained by modifying Eqn. (7). In Eqn. (6), Y_i is replaced by $\hat{Y}_i \equiv Z\,\hat{\Pi}_i = Z(Z'Z)^{-1} Z'Y_i$ so that the X matrix consists of $Z'\hat{Y}_i$ and $Z'Z_i$. In the modified estimator, we estimate Σ and Π by the first round 3SLS estimator and replace $\hat{Y}_i$ in X by $\tilde{Y}_i \equiv Z\tilde{\Pi}_i$ where $\tilde{\Pi}_i$ consists of proper subcolumns in $\tilde{\Pi} = -\hat{\Gamma}\hat{B}^{-1}$. The new X matrix is denoted as $\tilde{X}$. Finally, the new estimator is

$$\tilde{\delta}_{\mathrm{M3SLS}} = \{\tilde{X}'[\tilde{\Sigma}^{-1}\otimes(Z'Z)^{-1}]X\}^{-1}\{\tilde{X}'[\tilde{\Sigma}^{-1}\otimes(Z'Z)^{-1}]w\}. \quad (14)$$

This estimator has the same asymptotic expansion as the FIML estimator to the third-order terms and is third-order efficient.

The LIML and 2SLS estimators are simple cases of the FIML and 3SLS estimators, respectively. Then the modified 2SLS estimator which follows from Eqn. (14) has the same asymptotic expansion as the LIML estimator to the third-order term. The LIML estimator and the modified 2SLS estimator are third-order efficient in the single-equation estimation.

7. *Conclusion*

Laurence Klein received the 1980 Nobel prize for the creation of a macroeconometric model which is an empirical form of a simultaneous equation system, and for the application to the analysis of economic fluctuations and economic policies. The macroeconometric model became a standard tool to analyze the economies and policies of nations. Trygve Haavelmo received the 1989 Nobel prize for his contribution in the analysis of simultaneous structures. Haavelmo, together with other researchers at the Cowles Commission for Research in Economics, then at the University of Chicago, became the founders of simultaneous equation analysis in econometrics. Part of their research is collected in Hood and Koopmans (1953). Studies on the exact and approximate distributions of estimators came after the research conducted at the Cowles group, and helped to make econometrics rigorous.

Access to computers was the main concern when econometric model-building started spreading all over the world in the 1970s. Since then, computer facilities surrounding econometric model-building have changed greatly. Bulky mainframe computer have been replaced by personal computers. Computer programs were written individually, mostly in Fortran, and were used for regression analyses in model estimation as well as for simulation studies in econometrics theory. The packaged least squares programs replaced the individually written programs later in model estimation. They run on personal computers and have facilitated greatly the conducting of empirical studies.

Simultaneous Equation Estimation: Overview

Simultaneous equations are important tools for understanding behavior when two or more variables are determined by the interaction of two or more relationships in such a way that causation is joint rather than unidirectional. Such situations abound in economics, but also occur elsewhere. Haavelmo (1943, 1944) began their modern econometric treatment.

The simplest economic example is the interaction of buyers and sellers in a competitive market which jointly determines the quantity sold and price. Another important example is the interaction of workers, consumers, investors, firms, and government in determining the economy's output, employment, price level, and interest rates, as in macroeconometric forecasting models. Even when one is interested only in a single equation, it often is best interpreted as one of a system of simultaneous equations.

Strotz and Wold (1960) argued that in principle every economic action is a response to a previous action of someone else, but even they agreed that simultaneous equations are useful when the data are yearly, quarterly, or monthly, because these periods are much longer than the typical market response time.

This article discusses the essentials of simultaneous equation estimation using a simple linear example.

1. *A Simple Supply–Demand Example*

Let q and p stand for the quantity sold and price of a good, y and w for the income and wealth of buyers (assumed independently determined), u_1 and u_2 for unobservable random shocks, and Greek letters for unknown constant parameters. Suppose that market equilibrium, in which the price is such that suppliers want to sell the same quantity that demanders what to buy, is described by these linear equations:

$$\text{supply:} \quad q = \gamma_1 + \beta_1 p + u_1, \quad \beta_1 > 0 \tag{1}$$

$$\text{demand:} \quad q = \gamma_2 + \delta_2 y + \varepsilon_2 w + \beta_2 p + u_2, \quad \beta_2 < 0 \tag{2}$$

Neither equation alone can determine either p or q, because each equation contains both: these are *simultaneous equations*. Solve them for p and q thus:

$$p = \pi_{11} + \pi_{12} y + \pi_{13} w + (u_2 - u_1)/\Delta \tag{3}$$

$$q = \pi_{21} + \pi_{22} y + \pi_{23} w + (\beta_1 u_2 - \beta_2 u_1)/\Delta \tag{4}$$

where

$$\pi_{11} = (\gamma_2 - \gamma_1)/\Delta, \quad \pi_{12} = \delta_2/\Delta, \quad \pi_{13} = \varepsilon_2/\Delta \tag{5}$$

$$\pi_{21} = (\beta_1 \gamma_2 - \beta_2 \gamma_1)/\Delta, \quad \pi_{22} = \beta_1 \delta_2/\Delta, \quad \pi_{23} = \beta_1 \varepsilon_2/\Delta \tag{6}$$

and

$$\Delta = \beta_1 - \beta_2 \tag{7}$$

2. *Types of Variables: Structural and Reduced Form Equations*

The variables p and q which are to be explained by the model are *endogenous*. Equations (1) and (2) are structural equations. Each of them describes the behavior of one of the building blocks of the model, and (as is typical) contains more than one endogenous variable. Equations (3) and (4) are reduced form equations. Each of them contains just one endogenous variable, and determines its value as a function of parameters, shocks, and explanatory variables (here y and w).

The explanatory variables are predetermined if the shocks for any given period are independent of the explanatory variables for that period and all previous periods; they are *exogenous* if the shocks for each period are independent of the explanatory variables for every period. Thus all exogenous variables are predetermined, but not conversely. For example, the value of an endogenous variable from a previous period cannot be exogenous, but it is predetermined if the shocks are serially independent.

3. *The Need for Estimation of Parameters*

One job of a reduced form equation is to tell how an endogenous variable responds to a change in any predetermined or exogenous variable. Typically, no single structural equation can do this. Another job of

a reduced form equation is to forecast the value of an endogenous variable in a future period, based on expected future values of the predetermined and exogenous variables and of the shocks (the latter can safely be set at zero in most cases). Typically, no single structural equation can do this either. If the reduced form equations are to do these jobs, numerical values of their parameters are needed (in this example, values of the πs in Eqns. (3) and (4)).

Numerical values of the structural parameters are needed as well (in this example, the βs, γs, δ_2 and ε_2 in Eqns. (1) and (2)). There are several reasons. First, one wants to understand each of the system's separate building blocks in its own right. Second, in overidentified cases (see Sect. 7) better estimates of the reduced form can be obtained by solving the estimated structure (as in Eqns. (5)–(7) than by estimating the reduced form directly. Third, if forecasts made by the reduced form are poor, one wants to know which of the structural equations fit the forecast-period's data poorly, and which (if any) fit well. This is discovered by inserting observed values of the variables into each estimated structural equation to obtain an estimate of its forecast-period shock. Then one can revise the poorly-fitting structural equation(s) and so try to improve the model's accuracy (see Sect. 11). Fourth, if one wants to find the new values of the reduced form parameters after a change in a structural parameter, one needs to know the old values of all the structural parameters, as well as the new value of the one that has changed. In the example, one can then use Eqns. (5)–(7) to compute the reduced form parameters. The critique of Robert Lucas (1976) provides a warning about pitfalls in doing this.

4. *Least Squares Estimators*

Least squares (LS) estimators (see *Linear Hypothesis*) of an equation's coefficients are biased if the shocks in each period are not independent of the explanatory variables in all periods. Clearly this is true of Eqns. (1) and (2), since Eqns. (3) and (4) show that both u_1 and u_2 influence both p and q. This is typically true of LS estimators of simultaneous structural equations, However, LS estimators often have small variances, so they may sometimes have acceptably small expected squared errors even when they are biased.

LS estimators of the π's in the reduced form, Eqns. (3) and (4) are unbiased if the shocks in each period have zero mean and constant variance, and are independent of y and w for all periods (so that y and w are exogenous). They have minimum variance among unbiased estimators and are consistent if in addition the shocks are uncorrelated across time. They remain consistent if the shocks are uncorrelated across time but y and w are predetermined rather than exogenous.

The generalized least squares (GLS) method is minimum variance unbiased if the explanatory variables are exogenous but the shocks are correlated across time. This method requires information about the variances and covariances of the shocks.

5. *The Identifiability of Structural Parameters*

Having estimates of the reduced form parameters, one can try to make them yield estimators of the structural parameters. In the example this means trying to solve the estimated version of Eqns. (5) and (7) for estimators of the γ's, β's, δ_2 and ε_2. Denote the LS estimators of the π's by $\hat{\pi}$. Equations (5) and (6) show that $\hat{\pi}_{22}/\hat{\pi}_{12}$ is one estimator of β_1, and $\hat{\pi}_{23}/\hat{\pi}_{13}$ is another. Either of them leads to an estimator of γ_1 in Eqn. (1). These are indirect least squares (ILS) estimators. They are not unbiased, but they are consistent if the LS reduced form estimators are consistent. The supply parameters β_1 and γ_1 are *identified*, meaning that the data and the model reveal their values (subject to sampling variation). Indeed, they are *overidentified*, because in small samples the two ways to estimate β_1 from $\hat{\pi}$'s yield different results. (If either δ_2 and ε_2 were zero, there would be only one way, and the supply equation would be *just identified*. If both δ_2 and ε_2 were zero, there would be no way, and the supply equation would be *unidentified*.) Equations (5)–(7) have an infinite number of solutions for the demand parameters β_2, γ_2, δ_2 and ε_2. Hence the data and the model do not reveal their values; they are unidentified.

Another way to see this is to imagine price and quantity data being generated by intersections of the supply and demand curves in the pq plane. Ignoring shocks, the supply curve is fixed, but the demand curve shifts when y or w changes. Hence the intersections reveal the slope and position of the supply curve as the demand curve shifts. But they reveal nothing about the slope of the demand curve.

The identifiability of parameters is crucial: they cannot be estimated if they are not identified. Reduced form parameters are usually identified, except in special cases. But the identifiability of structural parameters should be checked before one tries to estimate them. The least squares formula can be applied to an unidentified structural equation such as Eqn. (2), but the result is not an estimator of that equation. For a more detailed and general discussion, see *Statistical Identification and Estimability*.

6. *Simultaneous Equations Estimation Methods*

Many methods have been developed for estimating identifiable parameters of simultaneous structural equations without the bias and inconsistency of LS. Most of them exploit the assumed independence between shocks and predetermined variables. Some estimate one equation at a time, and others estimate the whole system at once.

7. Estimating One Structural Equation at a Time

The ILS method mentioned above is one way of estimating one equation that is part of a system. A second way is the instrumental variables (IV) method (Durbin 1954). LS and IV will be shown for Eqn. (1). Denote the deviation of each variable from its sample mean by an asterisk, for example, $p^* = p - \bar{p}$. Now rewrite Eqn. (1) in terms of deviations from sample means, thus eliminating the constant term γ_1; multiply it by p^*; sum it over all the sample observations; and divide the sum by $\sum p^{*2}$. The result is the LS estimator of β_1:

$$\hat{\beta}_1 = \sum q^* p^* / \sum p^{*2} = \beta_1 + \sum u_1^* p^* / \sum p^{*2} \qquad (8)$$

It is biased and inconsistent because the shock u_1 influences p via Eqn. (3) so that the error term, the last term in Eqn. (8), does not equal zero in expectation or in probability limit.

Now rewrite Eqn. (1) as before in terms of deviations from sample means, but this time multiply it by y^*, sum it over all observations, and divide by $\sum p^* y^*$. The result is an IV estimator of β_1:

$$\hat{\beta}_{1y} = \sum q^* y^* / \sum p^* y^* = \beta_1 + \sum u_1^* y^* / \sum p^* y^* \qquad (9)$$

If y is predetermined it is an *instrument*. In this case the IV estimator is consistent if u_1 has zero mean and constant variance and is serially independent, because then $\sum u_1^* y^*$ is zero in probability limit and $\sum p^* y^*$ is not. Similarly, if w is predetermined it is another instrument, and another IV estimator of β_1 is $\hat{\beta}_{1w} = \sum q^* w^* / \sum p^* w^*$. Clearly, these IV estimators are equivalent to the ILS estimators of β_1 obtained earlier. For example, the one based on the reduced form coefficients of y is

$$\hat{\pi}_{22}/\hat{\pi}_{12} = (\sum q^* y^* / \sum y^{*2}) / (\sum p^* y^* / \sum y^{*2}) = \sum q^* y^* / \sum p^* y^* = \hat{\beta}_{1y} \qquad (10)$$

Similarly, the other one is $\hat{\pi}_{23}/\hat{\pi}_{13} = \hat{\beta}_{1w}$. For a reduced form equation, IV is the same as LS, because the instruments are precisely the equation's predetermined variables.

The two-stage least squares (2SLS) method (Theil 1972, Basmann 1957) is another way of estimating one structural equation at a time. For an overidentified equation it is superior to ILS or IV because it results in one estimator rather than two or more; for a just identified equation it reduces to ILS and IV. It first computes the LS estimator of the reduced form equation for each endogenous variable that appears on the right side of the structural equation to be estimated (this is stage 1); it then replaces the observed data for those endogenous variables by the values calculated from the reduced form, and computes the LS estimator for the resulting equation (this is stage 2). For Eqn. (1), stage 1 is to compute the least squares estimators of the π's in the price equation (3) of the reduced form; the second stage is to compute $\hat{p} = \hat{\pi}_{11} + \hat{\pi}_{12} y + \hat{\pi}_{13} w$, substitute this $\hat{p}$ for p in (1), and compute the LS estimator $\sum q^* \hat{p}^* / \sum \hat{p}^{*2}$, which is the 2SLS estimator of β_1. 2SLS is an IV estimator, its instruments are the observed values of the equation's predetermined variables and the reduced-form-calculated values of the endogenous variables from the equation's right side. 2SLS is a *generalized* method of moments (GMOM) estimator (Hansen 1982). LS and IV are plain MOM estimators.

The k-class estimator (Nagar 1959) includes as special cases LS, 2SLS, and the limited information maximum likelihood estimator (LIML) (Anderson and Rubin 1949, 1950). LIML is similar to 2SLS (the two are the same for infinitely large samples), but it has largely been displaced by 2SLS because it requires iterative computations which 2SLS does not, and because it often has a larger variance and sometimes yields outlandish estimates (Kadane 1971, Theil 1972).

For an identified structural equation, ILS, IV, LIML, and 2SLS are consistent if the model's explanatory variables are predetermined and the shocks have zero means and constant variances and covariances and are independent across time. An advantage of these methods is that, unlike LS, if applied to an unidentified structural equation they fail to yield estimates.

The Bayesian method of moments (BMOM) method (Zellner 1998) obtains estimators of linear reduced form and structural equations without making assumptions about the likelihood function of the data. It assumes that the posterior expectations of the shocks given the data are uncorrelated with the predetermined variables, and that the differences between actual and estimated shocks have a covariance matrix of a particular form. Zellner shows how to find optimum BMOM estimators for several different loss functions, including a *precision* loss function which is a weighted sum of squares and cross-products of errors. For this loss function, the optimum BMOM estimator of an identified structural equation belongs to the k-class; it turns out to be LS if the ratio of the sample size to the number of predetermined variables in the model is 2, and it approaches 2SLS in the limit as this ratio grows without limit.

When a structural equation is overidentified, restrictions are placed on the reduced form parameters (such as $\pi_{22}/\pi_{21} = \pi_{32}/\pi_{31}$ in the example, because both ratios must equal β_1), but LS estimators of the reduced form ignore this information. Better estimators of the reduced form, because they use this information, can then be obtained by solving the estimated structure (see Sect. 3).

8. Estimating a Complete System

If in an identified complete simultaneous equations system the shocks are normally distributed and other suitable conditions are satisfied, an asymptotically efficient but computationally complex method of estimating all the parameters of a complete system is the full information maximum likelihood (FIML) method (Koopmans 1950, Durbin 1988). It involves maximizing the joint likelihood function of all the data and parameters, and requires iterative computations. It has largely been displaced by the *three stage least squares* (3SLS) method (Zellner and Theil 1962), which is also asymptotically efficient but is much easier to compute. 3SLS is an application of the GLS method. 3SLS gets the required information on the shocks' covariances from 2SLS estimates of the shocks; hence the name 3SLS.

9. Cross-section vs. Time Series Studies

So far the treatment has concerned time series data, where the observations describe the same country, city, family, firm, or what not, at successive periods of time. The same type of analysis is appropriate for cross-section data, where the observations describe different countries, firms, or what not, at a single point of time, with obvious modifications. The analysis has also been extended to panel data, that is, a time series of cross-sections.

10. The Decline of Simultaneous Equations Models

In recent years the econometric literature has paid diminishing attention to simultaneous equations models and their identifiability. Many modern textbooks give these topics little space, and that only near the end of the book (Davidson and MacKinnon 1993). Perhaps one reason is that modern computers can handle the estimation of nonlinear models, for which identification criteria are much more complicated and for which lack of identifiability is a much rarer problem.

11. The Problem of Choosing and Testing a Model

Thus far it has been presumed that the model being estimated is an accurate representation of the real-world process that actually generates the data. This is far from certain; at best it is likely to be only approximately true. Any model has been chosen by someone, perhaps with the aid of economic theory about the maximization of profit or utility, or perhaps because it was suggested by previously observed data. But there is no guarantee that it contains the right variables, or that their endogeneity or exogeneity is correctly stated, or that the correct number of lagged variables has been chosen, or that its eqns. have the right mathematical form, or that the assumed distribution of its shocks is correct.

One can perform diagnostic tests to see whether the estimated model fits past data well, and whether its calculated past shocks have constant variance and are free of any obvious systematic behavior. But this does not assure that it will do well with future data. In my view, the most stringent and most important test of a model is to expose it to data that were not available when the model was formulated. If it does not describe these data well, it leaves something to be desired. The more new data it can describe well, the more confidence one can have in it. But at any point the best that can be said about a model is that it has done a good job of describing the data that are available thus far.

Single-case Experimental Designs in Clinical Settings

1. *Differing Research Traditions*

Two major research traditions have advanced the behavioral sciences. One is based on the hypothetico-deductive approach to scientific reasoning where a hypothesis is constructed and tested to see if a phenomenon is an instance of a general principle. There is a presumed *a priori* understanding of the relationship between the variables of interest. These hypotheses are tested using empirical studies, generally using multiple subjects, and data are collected and analyzed using group experimental designs and inferential statistics. This tradition represents current mainstream research practice for many areas of behavioral science. However, there is another method of conducting research that focuses intensive study on an individual subject and makes use of inductive reasoning. In this approach, one generates hypotheses from a particular instance or the accumulation of instances in order to identify what might ultimately become a general principle.

In practice, most research involves elements of both traditions, but the extensive study of individual cases has led to some of the most important discoveries in the behavioral sciences and therefore has a special place in the history of scientific discovery. Single-case or single-subject design (also known as 'N of one') research is often employed when the researcher has limited access to a particular population and can therefore study only one or a few subjects. This method is also appropriate when one wishes to make an intensive study of a phenomenon in order to examine the conditions that maximize the strength of an effect. In clinical settings one is frequently interested in describing which variables affect a particular individual rather than in trying to infer what might be important from studying groups of subjects and assuming that the average effect for a group is the same as that observed in a particular subject. In the current era of increased accountability in clinical settings, single-case design can be used to demonstrate treatment effects for a particular clinical case (Hayes et al. 1999 for a discussion of the changing research climate in applied settings).

2. *Characteristics of Single-case Design*

Single-case designs study intensively the process of change by taking many measures on the same individual subject over a period of time. The degree of control in single-case design experiments can often lead to the identification of important principles of change or lead to a precise understanding of clinically relevant variables in a specific clinical context. One of the most commonly used approaches in single-case design research is the interrupted time-series. A time-series consists of many repeated measures of the same variable(s) on one subject, while measuring or characterizing those elements of the experimental context that are presumed to explain any observed change in behavior. An by examining characteristics of the data before and after the experimental manipulation to look for evidence that the independent variable alters the dependent variable because of the interruption.

3. *Specific Types of Single-case Designs*

Single-case designs frequently make use of a graphical representation of the data. Repeated measures on the dependent variable take place over time, so the abscissa (X-axis) on any graph represents some sort of across time scale. The dependent measure or behavior presumably being altered by the treatment is plotted on the ordinate (Y-axis). There are many variations of single-case designs that are well described (e.g., Franklin et al. 1997, Hersen and Barlow 1976, Kazdin 1982), but the following three approaches provide an overview of the general methodology.

3.1 *The A-B-A Design*

The classic design that is illustrative of this approach is called the A-B-A design (Hersen and Barlow 1976, pp. 167–97) where the letters refer to one or another

Figure 1
A-B-A design

experimental or naturally observed conditions presumed to be associated with the behavior of importance. A hypothetical example is shown in Fig. 1. By convention, A refers to a baseline or control condition and the B indicates a condition where the behavior is expected to change. The B condition can be controlled by the experimenter or alternatively can result from some naturally occurring change in the environment (though only the former are true experiments). The second A in the A-B-A design indicates a return to the original conditions and is the primary means by which one infers that the B condition was the causal variable associated with any observed change from baseline in the target or dependent variable. Without the second A phase, there are several other plausible explanations for changes observed during the B phase besides the experimental manipulation. These include common threats to internal validity such as maturation or intervening historical events coincidental to initiating B.

To illustrate the clinical use of such an approach, consider the data points in the first A to indicate repeated observations of a child under baseline conditions. The dependent variable of interest is the number of disruptive behaviors per class period that the child exhibits. A baseline of disruptive behaviors is observed and recorded over several class periods. During the baseline observations, the experimenter hypothesizes that the child's disruptive behavior is under the control of contingent attention by the teacher. That is, when the child is disruptive, the teacher pays attention (even negative attention) to the child that unintentionally reinforces the behavior, but when the child is sitting still and is task oriented, the teacher does not attend to the child. The experimenter then trains the teacher to ignore the disruptive behavior and contingently attend to the child (e.g., praise or give some token that is redeemable for later privileges) when the child is emitting behavior appropriate to the classroom task. After training the teacher to reinforce differentially appropriate classroom behavior, the teacher is instructed to implement these procedures and the B phase begins.

Observations are made and data are gathered and plotted. A decrease in the number of disruptive behaviors is apparent during the B phase. To be certain that the decrease in disruptive behaviors is not due to some extraneous factor, such as the child being disciplined at home or simply maturing, the original conditions are reinstated. That is, the teacher is instructed to discontinue contingently attending to task-appropriate behavior and return to giving corrective attention when the child is disruptive. This second A phase is a return to the original conditions. The plot indicates that the number of disruptions returns to baseline (i.e., returns to its previous high level). This return to baseline in the second A condition is evidence that the change observed from baseline condition A to the implementation of the intervention during the B phase was under the control of the teacher's change in contingent attention rather than some other factor. If another factor were responsible for the change, then the re-implementation of the original baseline conditions would not be expected to result in a return to the original high levels of disruptive behavior.

There are many variations of the A-B-A design. One could compare two or more interventions in an A-B-A-C-A design. Each A indicates some baseline condition, the B indicates one type of intervention, and the C indicates a different intervention. By examining differences in the patterns of responding for B and C, one can make treatment comparisons. The notation of BC together, as in A-B-A-C-A-BC-A, indicates that treatments B and C were combined for one phase of the study.

3.2 The Multiple-baseline Design

An A-B-A or A-B-A-C design assumes that the treatment (B or C) can be reversed during the subsequent A period. Sometimes it is impossible or unethical to re-institute the original baseline conditions (A). In these cases, other designs can be used. One such approach is a multiple-baseline design. In a multiple-baseline design, baseline data are gathered across several environments (or behaviors). Then a treatment is introduced in one environment. Data continue to be gathered in selected other environments. Subsequently the treatment is implemented in each of the other environments, one at a time, and changes in target behavior observed (Poling and Grossett 1986).

In the earlier example, if the child had been exhibiting disruptive behavior in math, spelling, and social studies classes, the same analysis of the problem might be applied. The teachers or the researcher might not be willing to reinstitute the baseline conditions if

Figure 2
Example of multiple baseline design with same behaviour across different settings

improvements were noted because of its disruptive effects on the learning of others and because it is not in the best interests of the child. Figure 2 shows how a multiple-baseline design might be implemented and the data presented visually. Baseline data are shown for each of the three classroom environments.

While the initial level of disruptive behavior might be slightly different in each class, it is still high. The top graph in Fig. 2 shows the baseline number of disruptive behaviors in the math class. At the point where the vertical dotted line appears, the intervention is implemented and its effects appear to the right of dotted line. The middle and bottoms graphs show the same disruptive behaviors for the spelling and social studies class. No intervention has yet been implemented and the disruptive behavior remains high and relatively stable in each of these two classrooms. This suggests that the changes seen in the math class were not due to some other cause outside of the school environment or some general policy change within the school, since the baseline conditions and frequency of disruptive behaviors are unchanged in the spelling and social studies classes. After four more weeks of baseline observation, the same shift in attention treatment is implemented in the spelling class, but still not in the social studies class. The amount of disruptive behavior decreases following the treatment implementation in the spelling class, but not the social studies class.

This second change from baseline is a replication of the effect of treatment shown in the first classroom and is further evidence that the independent variable is the cause of the change. There is no change in the social studies class behavior. This observation provides additional evidence that the independent variable rather than some extraneous variable is responsible for the change in the behavior of interest. Finally, the treatment is implemented in the social studies class with a resulting change paralleling those occurring in the other two classes when they were changed. Rather than having to reverse the salutary effects of a successful treatment as one would in an A-B-A reversal design, a multiple baseline design allows for successively extending the effects to new contexts as a means of demonstrating causal control.

Multiple-baseline designs are used frequently in clinical settings because they do not require reversal of beneficial effects to demonstrate causality. Though Fig. 2 demonstrates control of the problem behavior by implementing changes sequentially across multiple settings, one could keep the environment constant and study the effects of a hypothesized controlling variable by targeting several individual behaviors. For example, a clinician could use this design to test whether disruptive behavior in an institutionalized patient could be reduced by sequentially reinforcing more constructive alternatives. A treatment team might target aggressive behavior, autistic speech, and odd motor behavior when the patient is in the day room. After establishing a baseline for each behavior, the team could intervene first on the aggressive behavior while keeping the preexisting contingencies in place for the other two behaviors. After the aggressive behavior has changed (or a predetermined time has elapsed), the autistic speech behavior in the same day room could be targeted, and so on for the odd motor behavior. The logic of the application of a multiple-baseline design is the same whether one studies the same behavior across different contexts or different behaviors across the same context. To demonstrate causal control, the behavior should change only when it is the target of a specific change strategy and other behaviors not targeted should remain at their previous baselines.

Interpretation can be difficult in multiple-baseline designs because it is not always easy to find behaviors that are functionally independent. Again, consider the disruptive classroom behavior described earlier. Even if one's analysis of teacher attention to disruptive behavior is reinforcing, it may be difficult to show change in only the targeted behavior in a specific classroom. The child may learn that alternative behaviors can be reinforced in the other classrooms and the child may

Figure 3
Example from an Alternating Treatment Design (ATD)

alter his or her behavior in ways that alter the teacher reactions, even though the teachers in the other baseline classes did not intend to change their behavior. Nevertheless, this design addresses many ethical and practical concerns about A-B-A (reversal) designs.

3.3 Alternating Treatment Design

The previous designs could be referred to as within-series designs because there are a series of observations within which the conditions are constant, an intervention with another series of observations where the new conditions are constant for the duration of series, and so on. The interpretation of results is based on what appears to be happening within a series of points compared with what is happening within another series. Another variation of the single-case design that is becoming increasingly recognized for its versatility is the alternating treatment design (ATD) (Barlow and Hayes 1979). The ATD can be thought of as a between-series design. It is a method of answering a number of important questions such as assessing the impact of two or more different treatment variations in a psychotherapy session. In an ATD, the experimenter rapidly and frequently alternates between two (or more) treatments on a random basis during a series and measures the response to the treatments on the dependent measure. This is referred to as a 'between-series' because the data are arranged by treatments first and order second rather than by order first, where treatments vary only when series change. There may be no series of one particular type of treatment, although there are many of the same treatments in a row.

To illustrate how an ATD might be applied, consider a situation where a therapist is trying to determine which of two ways of relating to a client produces more useful self-disclosure. One way of relating is to ask open-ended questions and the other is to ask direct questions. The dependent variable is a rating of clinically useful responsiveness from the client. The therapist would have a random order for asking one of the two types of questions. The name of the design does not mean that the questions alternate back and forth between two conditions on each subsequent therapist turn, but randomly change between treatments. One might observe the data in Fig. 3.

The X-axis is the familiar time variable and the Y-axis the rating of the usefulness of the client response. The treatment conditions are shown in separate lines. Note that points for each condition are plotted according to the order in which they were observed, but that the data from each condition are joined *as if* they were collected in one continuous series (even though the therapists asked the questions in the order of O-C-O-O-O-C-C-O …). The data in Fig. 3 indicate that both methods of asking questions produce a trend for the usefulness of the information to increase as the session goes on. However, the open-ended format produces an overall higher degree of utility.

4. Analyses

There are four characteristics of a particular series that can be compared with other series. The first is the level of the dependent measure in a series. One way in which multiple series may differ is with respect to the stable level of a variable. The second way in which multiple series may differ is in the trend each series shows. The third characteristic that can be observed is the shape of responses over time. This is also referred to as the *course* of the series and can include changes in cyclicity. The last characteristic that could vary is the variability of responses over time. Figure 4 shows examples of how these characteristics might show treatment effects. One might observe changes in more than one of these characteristics within and across series.

4.1 Visual Interpretation of Results

In single-case design research, there has been a long tradition to interpret the data visually once it has been graphed. In part, this preference emerged because those doing carefully controlled single-case research were looking for large effects that should be readily observable without the use of statistical approaches. Figure 4 depicts examples of clear effects. They demonstrate the optimal conditions for inferring a treatment effect, a stable baseline and clearly different responses during the post baseline phase. Suggestions for how to interpret graphical data have been described by Parsonson and Baer (1978).

However, there are many circumstances where patterns of results are not nearly so clear and errors in interpreting results are more common. When there are

Figure 4
Examples of changes observed in single-case designs

outlier data points (points which fall unusually far away from the central tendency of other points in the phase), it becomes more difficult to determine reliably if an effect exists by visual inspection alone. If there are carry-over effects from one phase to another that the experimenter may not initially anticipate, results can be difficult to interpret. Carry-over is observed when the effects of one phase do not immediately disappear when the experiment moves into another phase. For example, the actions of a drug may continue long after a subject stops taking the drug, either because the body metabolizes the drug slowly or because some irreversible learning changes occurred as a result of the drug effects. It is also difficult to interpret graphical results when there is a naturally occurring cyclicity to the data. This might occur when circumstances not taken into account by the experimenter lead to systematic changes in behaviors that might be interpreted as treatment effects. A comprehensive discussion of issues of visual analysis of graphical displays is provided by Franklin et al. (1996).

4.2 Traditional Measurement Issues

Any particular observation in a series is influenced by three sources of variability. The experimenter intends to identify systematic variability due to the intervention. However, two other sources of variability in an observation must also be considered. These are variability attributable to measurement error and variability due to extraneous sources, such as how well the subject is feeling at the time of a particular observation. Measurement error refers to how well the score on the measurement procedure used as the dependent measure represents the construct of interest. A detailed discussion of the reliability of measurement entails some complexities that can be seen intuitively if one compares how accurately one could measure two different dependent measures. If the experimenter were measuring the occurrence of head-banging behavior in an institutionalized subject, frequency counts would be relatively easy to note accurately once there was some agreement by raters on what constituted an instance of the target behavior. There would still be some error, but it would be less than if one were trying to measure a dependent measure such as enthusiasm in a classroom. The construct of enthusiasm will be less easily characterized and have more error associated with its measurement and therefore be more likely to have higher variability.

As single-case designs are applied to new domains of dependent measures such as psychotherapy research, researchers are increasingly attentive to traditional psychometric issues, including internal and external validity as well as to reliability. Traditionally, if reliability was considered in early applications of single-case designs, the usual method was to report interrater reliability as the percent agreement between two raters rating the dependent measure (Page and Iwata 1986). Often these measures were dichotomously scored counts of behaviors (e.g., a behavior occurred or did not occur). Simple agreement rates can produce inflated estimates of reliability. More sophisticated measures of reliability are being applied to single-case design research including kappa (Cohen 1960) and variations of intraclass correlation coefficients (Shrout and Fleiss 1979) to name a few.

4.3 Statistical Interpretation of Results

While the traditional method of analyzing the results of single-case design research has been visual inspection of graphical representation of the data, there is a growing awareness of the utility of statistical verification of assertions of a treatment effect (Kruse and Gottman 1982). Research has shown that relying solely on visual inspection of results (particularly

when using response guided experimentation) may result in high Type I error rates (incorrectly concluding that a treatment effects exists when it does not).

However, exactly how to conduct statistical analyses of time-series data appropriately is controversial. If the data points in a particular series were individual observations from separate individuals, then traditional parametric statistics including the analysis of variance, t-tests, or multiple regression could all be used if the appropriate statistical assumptions were met (e.g., normally distributed scores with equal variances). All of these statistical methods are variations of the general linear model. The most significant assumption in the general linear model is that residual errors are normally distributed and independent. A residual score is the difference between a particular score and the score predicted from a regression equation for that particular value of the predictor variable. The simple correlation between a variable and its residual has an expected value of 0. In single-case designs, it can be the case that any particular score for an individual is related to (correlated with) the immediately preceding observation. If scores are correlated with their immediately preceding score (or following score), then they are said to be serially dependent or autocorrelated. Autocorrelation violates a fundamental principle of traditional parametric statistics.

An autocorrelation coefficient is a slightly modified version of the Pearson correlation coefficient (r). Normally r is calculated using pairs of observations (X_i, Y_i) for several subjects. The autocorrelation coefficient (ρ_k) is the correlation between a score or observation and the next observation (Y_i, Y_{i+1}). When this correlation is calculated between an observation and the next observation, it is called a lag 1 autocorrelation. The range of the autocorrelation coefficient is from -1.0 to $+1.0$. If the autocorrelation is 0, it indicates that there is no serial dependence in the data and the application of traditional statistical procedures can reasonably proceed. As ρ_k increases, there is increasing serial dependence. As ρ_k becomes negative, it indicates that there is a rapid cyclicity pattern. A lag can be extended out past 1 and interesting patterns of cyclicity may emerge. In economics, a large value of ρ_k at a lag 12 can indicate an annual pattern in the data. In physiological psychology, lags at 12 or 24 may indicate a systematic diurnal or circadian rhythm in the data.

Statistical problems emerge when there is an autocorrelation among the residual scores. As the value of ρ_k increases (i.e., there is a positive autocorrelation) for the residuals, the computed values of many traditional statistics are inflated, and type I errors occur at a higher than expected rate. Conversely, when residuals show a negative autocorrelation, the resulting statistics will be too small producing misleading significance testing in the opposite direction. Suggestions for how to avoid problems of autocorrelation include the use of distribution-free statistics such as randomization or permutation tests. However, if the residuals are autocorrelated even these approaches may not give fully accurate probability estimates (Gorman and Allison 1996, p. 172).

There are many proposals for addressing the autocorrelation problem. For identifying patterns of cyclicity, even where cycles are embedded within other cycles, researchers have made use of spectral analysis techniques, including Fourier analysis. These are useful where there may be daily, monthly, and seasonal patterns in data such as one might see in changes in mood over long periods of observation.

The most sophisticated of these approaches is called the autoregressive integrated moving average analysis or ARIMA method (Box and Jenkins 1976). This is a regression approach that tries to model the value of particular observation as a function of the parameters estimating the effects of past observations (ϕ), moving averages of the influence of residuals on the series (θ), and the removal of systematic trends throughout the entire time series. The computation of ARIMA models is a common feature of most statistical computer programs. Its primary limitation is that it requires many data points, often more than are practical in applied or clinical research settings. Additionally, there may be several ARIMA models that fit any particular data set, making results difficult to interpret. Alternative simplifications of regression-based analyses are being studied to help solve the interpretive problems of using visual inspection alone as a means of identifying treatment effects (Gorman and Allison 1996).

4.4 Generalization of Findings and Meta-analysis

Although single-case designs can allow for convincing demonstrations of experimental control in a particular case, it is difficult to know how to generalize from single-case designs to other contexts. Single-case design researchers are often interested in specific effects, in a specific context, for a specific subject. Group designs provide information about average effects, across a defined set of conditions, for an average subject. Inferential problems exist for both approaches. For the single-case design approach, the question is whether results apply to any other set of circumstances. For the group design approach, the question is whether the average result observed for a group applies to a particular individual in the future or even if anyone in the group itself showed an average effect.

In the last two decades of the twentieth century, meta-analysis has become used as a means of aggregating results across large numbers of studies to summarize the current state of knowledge about a particular topic. Most of the statistical work has focused on aggregating across group design studies.

More recently, meta-analysts have started to address how to aggregate the results from single-case design studies in order to try to increase the generalizability from this type of research. There are still significant problems in finding adequate ways to reflect changes in slopes (trends) between phases as an effect size statistic, as well as ways to correct for the effects of autocorrelation in meta-analysis just as there are for the primary studies upon which a meta-analysis is based. There is also discussion of how and if single-case and group design results could be combined (Panel on Statistical Issues and Opportunities for Research in the Combination of Information, 1992).

5. *Summary*

Technical issues aside, the difference between the goal of precision and control typified in single-case design versus the interest in estimates of overall effect sizes that are characteristic of those who favor group designs makes for a lively discussion about the importance of aggregation across studies for the purpose generalization. With analytic methods for single-case design research becoming more sophisticated, use of this research strategy to advance science is likely to expand as researchers search for large effects under well specified conditions.

Single-subject Designs: Methodology

Science is about knowledge and understanding and is fundamentally a human enterprise. Adequate methodology is at the heart of scientific activity for it allows scientists to answer fundamental epistemic questions about what is known or knowable about their subject matter. This includes the validity of data-based conclusions, the generality of findings, and how knowledge may be used to achieve practical goals. Choice of methodology is critical in answering such questions with precision and scope, and the adequacy of a given methodology is conditional upon the purposes for which it is put. The purpose of this chapter is to provide a succinct description of a methodological approach well suited for work with single organisms, whether in basic research or applied contexts, and particularly where large N designs or inferential statistics are nonsensical and even inappropriate. This approach, referred to here as 'single-subject design' methodology, has a long history in the medical,

behavioral, and applied sciences and includes several design options, from the simple to the highly sophisticated and complex. As will be seen, all such designs involve a rigorous and intensive experimental analysis of a single case, and often replications across several individual cases. No attempt will be made here to describe all available design options, including available statistical tests, as excellent resources are available on both subjects (see Barlow and Hersen 1984, Busk and Marascuilo 1992, Hayes et al. 1999; Huitema 1986, Iversen 1991, Kazdin 1982, Parsonson and Baer 1992). Rather, the intent is to provide (a) an overview of single-subject design methodology and the rationale guiding its use in experimental and applied contexts; (b) a succinct description of the main varieties of single-subject designs, including basic guidelines for their application; and (c) to highlight recent trends in the use of such designs in applied contexts as a means to increase accountability.

1. *Single-subject Design: Overview and Rationale*

At the core, all scientists ultimately deal with particulars, whether cells, atoms, microbes, or the behavior of organisms. It is from such particulars that the facts of science and generality of findings are derived (Sidman 1960). This is true whether one aggregates a limited set of observations from a large sample of cases into groups that differ on one or more variables, or situations involving a few cases and a large number of observations of each over time (see also Hilliard 1993). The former is characteristic of hypothetico-deductive group design strategies that rely on inferential statistics to support scientific claims, whereas the latter idiographic and inductive approach is characteristic of single-subject methodology. As with other research designs, single-subject methodology is as much an approach to science as it is a set of methodological rules and procedures for answering scientific and practical questions. As an approach, single-subject designs have several distinguishing features.

1.1 *Subject Matter of Single-subject Designs*

Perhaps the most notable feature of single-subject methodology is its subject matter and sample characteristics; namely, the intensive study of the behavior of single (i.e., $N = 1$) organisms. This feature is also a source of great misunderstanding (Furedy 1999), particularly with regard to the generality and scientific utility of research based on an N of 1. It should be stressed that single-subject methodology gets its name not from sample size *per se*, but rather because the unit of analysis is behavior of individuals (Perone 1991), or what Gottman (1973) referred to as 'N-of-one-at-a-time' designs. Skinner (1966) described it this way: '… instead of studying 1000 rats for one hour each, or 100 rats for 10 hours each, the investigator is likely to study one rat for a 1000 hours' (p. 21); an approach that served as the foundation for operant learning (Skinner 1953, 1957) and one that, with the increasing popularity of behavior therapy, set the stage for a new approach to treatment development, treatment evaluation, and increased accountability (Barlow and Hersen 1984). Though single-subject research often involves more than one subject, the data are evaluated primarily on a case-by-case basis. The idiographic nature of this methodology is well suited for applied work where practitioners often attempt to influence and change problematic behavior(s) of individual clients (Hayes et al. 1999). Though not a requirement, the inclusion of more than one subject helps establish the robustness of observed effects across differentially imposed conditions, individuals, behaviors, settings, and/or time. Hence, direct or systematic replication serves to increase confidence in the observed effects and helps establish the reliability and generality of observed relations (Sidman 1960).

1.2 *Analytic Aims of Single-subject Designs: Prediction and Influence (Control)*

As with other experimental design strategies, the fundamental premise driving the use of single-subject methodology is to demonstrate control (i.e., influence) via the manipulation of independent variables and analysis of the effects of such variables on behavior (dependent variables). This emphasis on systematic manipulation of independent variables distinguishes single-subject designs from other small N research such as case reports, case studies, and the like which are often lucidly descriptive, but less controlled and systematic. With few exceptions (see Perone 1991), the general convention of single-subject design is to change one variable at a time and to evaluate such effects on behavior. This 'one-variable-at-a-time' rule positions the basic or applied researcher to make clear causal statements about the effects of independent variables compared with a previous state (e.g., naturally occurring behavior during baseline), to compare different independent variables across or within conditions, and only then to evaluate interaction effects produced by two or more independent variables together.

Indeed, single-subject methodology is unique in that it typically involves an intensive and rigorous experimental analysis of the behavior (i.e., thinking, emotional responses, overt motor acts) across time, and an equally rigorous attempt to isolate and control extraneous sources of variability (e.g., maturation, history) that may confound and/or mask any effects caused by systematic changes in the independent variable(s) across conditions and time (Sidman 1960). This point regarding the handling of extraneous sources of variability cannot be overstated. Iversen

(1991) and others (Barlow and Hersen 1984: Sidman 1960) have noted issues concerning how variability is handled in-group design research and single-subject methodology. With regard to such issues, Iverson put it this way:

> [in-group design research] the fit between theory and observation often is evaluated by means of statistical tests, and variability in data is considered a nuisance rather than an inspiration .... By averaging over *N* subjects the variability among the subjects is ignored *N* times. In other words, a data analysis restricted to only the mean generates *N* degrees of ignorance ... Single-subject designs are used because the data based on the individual subject are more accurate predictors of that individual's behavior than are data based on an averaging for a group of subjects (p. 194).

Though the issue of when and how to aggregate data (if at all) is controversial in single-subject research (Hilliard 1993), there is a consensus that variability is to be pinpointed and controlled to the extent possible. This is consistent with the view that variability is imposed and determined from without, and not an intrinsic property of the subject matter under study (Sidman 1960). Efforts are deliberately made to control such noise so that prediction and control can be achieved with precision and scope. Consequently, those employing experimental single-subject design methods are more likely to commit Type II errors (i.e., to deny a difference and claim that a variable is not exerting control over behavior, when it is) compared with more classic Type I errors (i.e., to claim that a variable is exerting control over behavior, when it is not; (see Baer 1977).

1.3 Single-subject Design: Measurement Issues

Single-subject design methodology also can be distinguished by the frequency with which behavior is sampled within conditions, and across differentially imposed conditions and time. It is common, for instance, for basic and applied researchers to include hundreds of samples of behavior across time (i.e., hours, days, weeks, and sessions) with individual subjects. Yet, a minimum of at least three data points is required to establish level, trend, and variability within a given phase or design element (Barlow and Hersen 1984, Hayes et al. 1999). Changes in level, trend, and at times variability from one condition to the next, and particularly changes that are robust, clear, immediate, and stable from behavior observed in a prior condition, help support causal inferences.

Here, stability is a relative term and should not be confused with something that is static or flat. Rather, stability provides a background by which to evaluate the reliability of changes produced by an independent variable across conditions and time. By convention, each condition is often continued until some semblance of stability is observed, at which point another condition is imposed, and behavior is evaluated relative to the previous condition or steady state (cf. Perone 1991). Such changes, in turn, are often evaluated visually and graphically relative to a prior less controlled state (i.e., baseline), or adjacent conditions involving another independent variable. In single-subject methodology, such stability can be evaluated within a condition (i.e., from one sample or observation to the next) and across conditions (i.e., changes in level, trend, and variability). The pragmatic appeal of such an approach, particularly in applied contexts, rests in allowing the practitioner to evaluate the effectiveness of imposed interventions in real time, and consequently to modify their intervention tactics as the data dictate. Indeed, unlike more formal group designs that are followed strictly once set in place, single-subject methodology is more flexible. Indeed, it is common for design elements to be added, dropped, and/or modified as the data dictate so as to meet scientific and applied goals. This feature has obvious parallels with how practitioners work with their clients in designing treatment interventions (see also Hayes et al. 1999).

In sum, all single-subject designs focus on individual organisms and aim to predict and influence behavior via: (a) repeated sampling and observation; (b) manipulation of one or more independent variables while isolating and controlling sources of extraneous variability to the extent possible; and (c) demonstration of stability within and across levels of imposed independent variables (see Perone 1991). Discussion will now turn to an enumeration of such features in the context of more popular single-subject designs.

2. Varieties of Single-subject Methodology

Most single-subject designs can be generally classified as representing two main types: within-series and between-series designs. Though each will be discussed briefly in turn, it is important to recognize that neither class of design precludes combining elements from the other (e.g., combined-series elements). In other words, a within-series design may, for some purposes, lead the investigator to add between-series elements and vice-versa, including other more complex elements (e.g., interaction effects, changing criterion elements).

2.1 Within-series Designs

The basic logic and structure of within-series designs are simple; namely, to evaluate changes within a series of data points across time on a single measure or set of related measures (see Hayes et al. 1999). Stability is judged for each data point relative to other data points that immediately precede and follow it. By convention, such designs include comparisons between a naturally occurring state of behavior (denoted by the letter A) and the effects of an imposed manipulation of an independent variable or intervention (denoted by different letters such as B, C, and so on). A simple A-B design involves sampling naturally occurring beha-

vior (A phase), followed by repeated assessment of responding when the independent variable is introduced (B phase). For example, suppose a researcher wanted to determine the effects of rational-emotive therapy on initiating social interactions for a particular client. If an A-B design were chosen, the rate of initiations prior to treatment would be compared with that following treatment in a manner analogous to popular pre-to-post comparisons in-group outcome research. It should be noted, however, that A-B designs are inherently weak in controlling for threats to internal validity (e.g., testing, maturation, history, regression to the mean). Withdrawal/reversal designs control for such threats, and hence provide a more convincing case of experimental control.

Withdrawal designs represent a replication of the basic A-B sequence a second time, with the term withdrawal representing the imposed removal of the active treatment or independent variable (i.e., a return to second baseline or A phase). For example, a simple A-B-A sequence allows one to evaluate treatment effects relative to baseline responding. If an effect due to treatment is present, then it should diminish once treatment is withdrawn and the subject or client is returned to an A phase. Other variations on withdrawal designs include B-A-B designs and A-B-A-B (reversal) designs (see Barlow and Hersen 1984, Hayes et al. 1999). A-B designs and withdrawal/reversal designs are typically used to compare the effects of a finite set of treatment variables with baseline response levels. Data regarding stable response trends are collected across several discrete periods (e.g., time, sessions), wherein the independent variable is either absent (baseline) or present (treatment phase). Phase shifts are data-driven, and response stability determines the next element added to the design, elements that may include other manipulations or treatments either alone (e.g., A-B-A-C-A-B-A) or in combination (e.g., A-B-A-B + C-A-B-A). As the manipulated behavior change is repeatedly demonstrated and replicated across increasing numbers of phase shifts and time, confidence in the role of the independent variable as a cause of such changes increases.

This basic logic of within-series single-subject methodology has been expanded in sophisticated and at times complex ways to meet basic and applied purposes. For instance, such designs can be used to test the differential effects of more than one treatment. Other reversal designs (i.e., B-C-B-C) involve the comparison of differential, yet consecutive, treatment interventions across multiple phase shifts. These designs are similar to the above reversals in how control is evaluated, but differ primarily in that baseline phases are not required. Designs are also available that combine features of withdrawal and reversal. For example, A-B-A-B-C-B designs allow one to compare A and B phases with each other (reversal; A-B-A-B), and a second treatment to B (reversal; e.g., B-C-B), or even to evaluate the extent to which behavior tracks a specified behavioral criterion (i.e., changing criterion designs; see Hayes et al. 1999). Changing criterion designs provide an alternative method for experimentally analyzing behavioral effects without subsequent treatment withdrawal. Criterion is set such that optimal levels given exposure can be met and then systematically increased (or decreased) to instill greater demand on acquiring new repertoires. For example, a child learning to add may be required to calculate 4 of 10 problems correctly to earn a prize. Once the child successfully and consistently demonstrates this level of responding, the demand increases to 6 of 10 correct problems. Changing criterion designs serve as a medium to demonstrate learning through achieving successive approximations of the end-state.

2.2 *Between-series Designs*

Between-series designs differ primarily from within-series designs in that data are first grouped and compared by condition, and then by time, whereas the reverse is true for within-series designs. Between-series designs need not contain phases, as evaluation of level, trend, and stability are organized by condition first, but not by time alone (Hayes et al. 1999, p.176). Designs within this category include 'alternating-treatment design' and 'simultaneous-treatment design.' The basic logic of both is the same, in that a minimum of two treatments are evaluated concurrently in an individual case. With alternating-treatments design, the concurrent evaluation is made between rapid and largely random alternations of two or more conditions (Barlow and Hayes 1979). Unlike within-series designs, alternating-treatment designs contain no phases (Hayes et al. 1999). The same is true for simultaneous-treatment designs; a design that is appropriate for situations where one wishes to evaluate the concurrent or simultaneous application of two or more treatments in a single case. Rapid or random alteration of treatment is not required with simultaneous-treatment design. What is necessary is that two or more conditions are simultaneously available, with the subject choosing between them. This particular design is not conducive for evaluating treatment outcome, but is appropriate for evaluating preference or choice (see Hayes et al. 1999). Alternating-treatment designs, by contrast, fit well with applied work, as therapists must often routinely target multiple problems concurrently, and thus need to switch rapidly between intervention tactics in the context of therapy.

2.3 *Combining Within- and Between-series Elements: Multiple-baseline Design*

Multiple-baseline designs build upon and integrate the basic logic and structure of within- and

between-series elements. The fundamental premise of multiple-baseline designs is to replicate phase change effects systematically in more than one series, with each subsequent uninterrupted series serving as a control condition for the preceding interrupted series. Series can be compared and arranged across behaviors, across settings, across individuals, or some combination of these (see Hayes et al. 1999). Such designs require that the series under consideration be independent (e.g., two functionally distinct behaviors), and that intervention be administered sequentially beginning with the first series, while others are left uninterrupted as controls. For example, a client might present with three distinct behavior problems all requiring exposure therapy. All behaviors would be monitored during baseline (A phase), and after some semblance of stability is reached the treatment (B phase) would be applied to the first behavior series, while the remaining two behaviors are continuously monitored in an extended baseline. Once changes in the first behavior resulting from treatment reach stability, the second series would be interrupted and treatment applied, while the first behavior continues in the B phase and the third behavior is monitored in an extended baseline. The procedure followed for the first two series elements is then repeated for the third behavior. This logic can be similarly applied to multiple-baseline designs across individuals or settings (see Barlow and Hersen 1984, Hall et al.). More complex within-series elements (e.g., A-B-A-B, or B-C-B, or counterbalanced phases such as B-A-B and A-B-A) can be evaluated across behaviors, settings, and individuals.

Note that with multiple-baseline designs the treatment is never withdrawn, rather, it is introduced systematically across a set of dependent variables. Independent variable effects are denoted from how reliably behavior change correlates with the onset of treatment for a particular dependent variable. For such reasons, multiple-baseline designs are quite popular, owing much to their ease of use, strength in ruling out threats to internal validity, built-in replication, and fit with the demands of applied practitioners working in therapy, schools, and institutions. Indeed, such designs can be useful when therapists are working with several clients presenting with similar problems, when clients begin therapy at different times, or in cases where targets for change in therapy occur sequentially.

3. *Recent Trends in the Application of Single-subject Methods*

Single-subject methodology has a long historic affiliation with basic and applied behavioral research, and the behavior therapy movement more generally (Barlow and Hersen 1984). Though the popularity of single-subject methods in published research appearing in mainstream behavior therapy journals appears to be on the decline relative to use of group design methodology (Forsyth et al. 1999), there does appear to be a resurgence of interest in single-subject methodology in applied work. There are several possible reasons for this renewed interest, but only two are mentioned here. First, trends in treatment-outcome research have increasingly relied on the now popular 'randomized clinical trial' group design methodology to establish empirical support for psychosocial therapies for specific behavioral disorders. Practitioners, who work predominantly with individual clients, are quick to point out that group-outcome data favoring a given intervention, however convincing statistically speaking, includes individuals in the group that did not respond to therapy. Moreover, the 'average' group response to treatment may not generalize to the specific response of an individual client to that treatment. Thus, practitioners have been skeptical of how such research informs their work with individual clients.

The second, and perhaps more important, reason for the renewed interest in single-subject methodology is driven by pragmatic concerns and the changing nature of the behavioral health care marketplace. Increasingly, third-party payers are requiring practitioners to demonstrate accountability. That is, to show that what they are doing with their clients is achieving the desired effect (i.e., good outcomes) in a cost-effective and lasting manner. Use of single-subject methodology has a place in assisting practitioners in making clinical decisions based on empirical data, in demonstrating accountability to third party payers and consumers. Further, such methodology, though requiring time and sufficient training to implement properly, is atheoretical and fits nicely with how practitioners from a variety of conceptual schools work routinely with their individual clients (Hayes et al. 1999). Thus, there is great potential in single-subject methodology for bridging the strained scientist–practitioner gap, and ultimately advancing the science of behavior change and an empirically-driven approach to practice and treatment innovation.

4. *Summary and Conclusions*

Methodology is a way of knowing. Single-subject methodology represents a unique way of knowing that has as its subject matter an experimental analysis of the behavior of individual organisms. Described here were the assumptions driving this approach and the main varieties of design options available to address basic experimental and applied questions. Perhaps the greatest asset of single-subject methodology rests with the flexibility with which such designs can be construc-

ted to meet the joint analytic goals of prediction and control over the behavior of individual organisms. This asset also represents one of the greatest liabilities of such designs in that flexibility requires knowledge of when and how to modify and/or add design elements to achieve analytic goals, and particularly skill in recognizing significant effects, sources or variability, and when one has demonstrated sufficient levels of prediction and control over the behavior of interest.

Situated Cognition: Contemporary Developments

Situate analyses of cognition that draw on the substantive aspects of Vygotsky's and Leont'ev's work (see *Situated Cognition: Origins*) did not become prominent in Western Europe and North America until the 1980s. Contemporary situated perspectives on cognition can be divided into two broad groups. One of these, cultural historical activity theory (CHAT), has developed largely independently of mainstream Western psychology by drawing inspiration directly from the writings of Vygotsky and Leont'ev. The other group, which I will call *distributed cognition*, has developed in reaction to mainstream cognitive science and incorporates aspects of the Soviet work.

1. Cultural Historical Activity Theory

It is important to clarify that the term 'activity' in the acronym in CHAT refers to cultural activity or, in other words, to cultural practice. The reference to history indicates a focus on both the evolution of the cultural practices in which people participate and the development of their thinking as they participate in them. Olson's (1995) analysis of the historical development of writing systems is paradigmatic of investigations that focus on the evolution of cultural practices at what might be termed the macrolevel of history writ large. Olsen's goal was not merely to document the first appearance of and subsequent changes in writing systems. Instead, he sought to demonstrate that changes in writing systems precipitated changes in thought that in turn made possible further developments in both writing and thinking. In doing so, he elaborated Vygotsky's claim that it was not until reasonably sophisticated writing systems had

emerged that people became consciously aware of language as a means of monitoring and regulating thought. As Olsen has made clear, the findings of his analysis have significant implications for children's induction into literacy practices in school.

Saxe's (1991) investigation of the body parts counting system of the Oksapmin people of Papua New Guinea provides a useful point of contrast in that it was concerned with cultural change at a more local level. As Saxe reports, the Oksapmin's counting system has no base structure and no distinct terms for numbers. Instead, the Oksapmin count collections of items (e.g., sweet potatoes) by beginning with the left index finger and naming various body parts as they move up the left arm, across the head and shoulders, and down the right arm, ending with the right index finger.

At the time that Saxe conducted his fieldwork, a new technology was being introduced, a base-10 currency system. Saxe documents that the Oksapmin with the greatest experience in using the currency, the owners of indigenous trade stores, had developed relatively sophisticated reasoning strategies that were based on the body parts system but that privileged 10 (e.g., transforming the task of adding nine and seven into that of adding ten and six by 'moving' a body part). Saxe's finding is significant in that it illustrates a general claim made by adherents of CHAT, namely that changes in the artifacts people use, and thus the cultural practices in which they participate, serve to reorganize their reasoning.

The two CHAT studies discussed thus far, those of Olsen and Saxe, investigated the evolution of cultural practices. A second body of CHAT research is exemplified by investigations that have compared mathematical reasoning in school with that in various out-of-school settings. Following both Vygotsky and Leont'ev, these investigations can be interpreted as documenting the fusion of the forms of reasoning that people develop with the cultural practices in which they participate. A third line of CHAT research has focused on the changes that occur in people's reasoning as they move from relatively peripheral participation to increasingly substantial participation in the practices of particular communities. In their overview of this type of research, Lave and Wenger (1991) clarify that the cultural tools used by community members are viewed as carrying a substantial portion of a practice's intellectual heritage. As Lave and Wenger note, this implies that novices' opportunities for learning depend crucially on their access to these tools as they are used by the community's old-timers. Lave and Wenger also make it clear that in equating learning with increasingly substantial participation, they propose to dispense with traditional cognitive analyses entirely. In their view, someone's failure to learn should be explained in terms of the organization of the community and the person's opportunities for access to increasingly substantial forms of participation rather than in terms of cognitive deficits that are attributed to the person. This is clearly a relatively strong claim in that it equates an analysis of the conditions for the possibility of learning with an analysis of learning.

It should be apparent from this overview that CHAT research spans a wide range of problems and issues. One theme that cuts across the three lines of work is a focus on groups of people's reasoning, whether they be people using different writing systems in different historical epochs, Oksapmin trade store owners compared to Oksapmin who have less experience with the new currency, the mathematical reasoning of people in school and nonschool settings, or novices versus old-timers in a community of practice. Differences in the reasoning of people as they participate in the same practices are therefore accounted for in terms of either (a) experience in participating in the practice, (b) access to more substantial forms of participation, or (c) differences in the history of their participation in other practices. Each of these types of explanations instantiates Leont'ev's dictum that the individual-in-cultural-practice rather than the individual *per se* is the appropriate unit of analysis.

2. *Distributed Cognition*

Whereas CHAT research often involves comparisons of groups of people's reasoning, work conducted within the distributed cognition tradition typically focuses on the reasoning of individuals or small groups of people as they solve specific problems or complete specific tasks. Empirical studies conducted within this tradition therefore tend to involve detailed microanalysis of either an individual's or a small group's activity. Further, whereas CHAT researchers often frame people's reasoning as acts of participation in relatively broad systems of cultural practices, distributed cognition theorists typically restrict their focus to the immediate physical, social, and symbolic environment. This circumscription of analyses to people's reasoning in their immediate environments is one indication that this tradition has evolved from mainstream cognitive science. Several of the leading scholars in this tradition, such as John Seeley Brown, Alan Collins, and James Greeno, initially achieved prominence within the cognitive science community before substantially modifying their theoretical commitments, in the process contributing to the emergence of a distributed perspective on cognition.

The term 'distributed intelligence' or 'distributed cognition' is most closely associated with Roy Pea (1993). Pea coined this term to emphasize that, in his view, cognition is distributed across minds, persons, and symbolic and physical environments. As he and other distributed cognition theorists make clear in their writings, this perspective directly challenges a

foundational assumption of mainstream cognitive science. This is the assumption that cognition is bounded by the skin or by the skull and can be adequately accounted for solely in terms of people's construction of internal mental models of an external world. Distributed cognition theorists instead see cognition as extending out into the immediate environment such that the environment becomes a resource for reasoning.

In coming to this conclusion, distributed cognition theorists have been influenced by a number of studies conducted by CHAT researchers, one of the most frequently cited investigations being that of Scribner (1984). In this investigation, Scribner analyzed the reasoning of workers in a dairy as they filled orders by packing products into crates of different sizes. Her analysis revealed that the loaders did not perform purely mental calculations but instead used the structure of the crates as a resource in their reasoning. For example, if an order called for 10 units of a particular product and six units were already in a crate that held 12 units, experienced loaders rarely subtracted six from 10 to find how many additional units they needed. Instead, they might realize that an order of 10 units would leave two slots in the crate empty and just know immediately from looking at the partially filled crate that four additional units are needed. As part of her analysis, Scribner convincingly demonstrated that the loaders developed strategies of this type *in situ* as they went about their daily business of filling orders. For distributed cognition theorists, this indicated that the system that did the thinking was the loader in interaction with a crate. From the distributed perspective, the loaders' ways of knowing are therefore treated as emergent relations between them and the immediate environment in which they worked.

Part of the reason that distributed cognition theorists attribute such significance to Scribner's study and to other investigations conducted by CHAT researchers is that they capture what Hutchins (1995) refers to as 'cognition in the wild.' This focus on people's reasoning as they engage in both everyday and workplace activities contrasts sharply with the traditional school-like tasks that are often used in mainstream cognitive science investigations. In addition to questioning whether people's reasoning on school-like tasks constitutes a viable set of cases from which to develop general models of cognition, several distributed cognition theorists have also critiqued current school instruction. In doing so, they have broadened their focus beyond cognitive science's traditional emphasis on the structure of particular tasks by drawing attention to the nature of the classroom activities within which the tasks take on meaning and significance for students.

Brown et al. (1989) developed one such critique by observing that school instruction typically aims to teach students abstract concepts and general skills on the assumption that students will be able to apply them directly in a wide range of settings. In challenging this assumption, Brown et al. argue that the appropriate use of a concept or skill requires engagement in activities similar to those in which the concept or skill was developed and is actually used. In their view, the well-documented finding that most students do not develop widely applicable concepts and skills in school is attributable to the radical differences between classroom activities and those of both the disciplines and of everyday, out-of-school settings. They contend that successful students learn to meet the teacher's expectations by relying on specific features of classroom activities that are alien to activities in the other settings. In developing this explanation, Brown et al. treat the concepts and skills that students actually develop in school as relations between students and the material, social, and symbolic resources of the classroom environment.

It might be concluded from the two examples given thus far, those of the dairy workers and of students relying on what might be termed superficial cues in the classroom, that distributed cognition theorists do not address more sophisticated types of reasoning. Researchers working in this tradition have in fact analyzed a number of highly technical, work-related activities. The most noteworthy of these studies is, perhaps, Hutchins's (1995) analysis of the navigation team of a naval vessel as they brought their ship into San Diego harbor. In line with other investigations of this type, Hutchins argues that the entire navigation team and the artifacts it used constitutes the appropriate unit for a cognitive analysis. From the distributed perspective, it is this system of people and artifacts that did the navigating and over which cognition was distributed. In developing his analysis, Hutchins pays particular attention to the role of the artifacts as elements of this cognitive system. He argues, for example, that the cartographer has done much of the reasoning for the navigator who uses a map. This observation is characteristic of distributed analyses and implies that to understand a cognitive process, it is essential to understand how parts of that process have, in effect, been sedimented in tools and artifacts. Distributed cognition theorists therefore contend that the environments of human thinking are thoroughly artificial. In their view, it is by creating environments populated with cognitive resources that humans create the cognitive powers that they exercise in those environments. As a consequence, the claim that artifacts do not merely serve to amplify cognitive process but instead reorganize them is a core tenet of the distributed cognition perspective.

3. *Current Issues and Future Directions*

It is apparent that CHAT and distributed cognition share a number of common assumptions. For example, both situate people's reasoning within encom-

passing activities and both emphasize the crucial role of tools and artifacts in cognitive development. However, the illustrations presented in the preceding paragraphs also indicate that there are a number of subtle differences between the two traditions. One concerns the purview of the researcher in that distributed cognition theorists tend to focus on social, material, and symbolic resources within the immediate local environment whereas CHAT theorists frequently locate an individual's activity within a more encompassing system of cultural practices. A second difference concerns the way in which researchers working in the two traditions address the historical dimension of cognition. Distributed cognition theorists tend to focus on tools and artifacts *per se*, which are viewed as carrying the reasoning of their developers from prior generations. In contrast, CHAT theorists treat artifacts as one aspect of a cultural practice, albeit an important one. Consequently, they situate cognition historically by analyzing how systems of cultural practices have evolved. Thus, whereas distributed cognition theorists focus on the history of the cognitive resources available in the immediate environment, CHAT theorists contend that this environment is defined by a historically contingent system of cultural practices. Despite these differences, it is possible to identify several current issues that cut across the two traditions. The two issues I will focus on are those of transfer and of participation in multiple communities of practice.

3.1 Transfer

As noted in the article *Situated Cognition: Origins*, the notion that knowledge is acquired in one setting and then transferred to other settings is central to the cognition plus view as well as to mainstream cognitive science. To avoid confusion, it is useful to differentiate between this notion of transfer as a theoretical idea and what might be termed the phenomenon called transfer. This term refers to specific instances of behavior that a cognition plus theorist would account for in terms of the transfer of knowledge from one situation to another. As will become clear, CHAT and distributed cognition theorists both readily acknowledge the phenomenon of transfer but propose different ways of accounting for it. An analysis developed by Bransford and Schwartz (1999) serves to summarize concerns about the traditional idea of transfer that underpins many cognitive science investigations.

Writing from within the cognition plus view, Bransford and Schwartz (1999) observe that the theory underlying much cognitive science research characterizes transfer as the ability to apply previous learning directly to a new setting or problem. As they note, transfer investigations are designed to ensure that subjects do not have the opportunity to learn to solve new problems either by getting feedback or by using texts and colleagues as resources. Although Bransford and Schwartz indicate that they consider this traditional perspective valid, they also argue for a broader conception of transfer that includes a focus on whether people are prepared to learn to solve new problems. In making this proposal, they attempt to bring the active nature of transfer to the fore. As part of their rationale, they give numerous examples to illustrate that people often learn to operate in a new setting by actively changing the setting rather than by mapping previously acquired understandings directly on to it. This leads them to argue that cognitive scientists should change their focus by looking for evidence of useful future learning rather than of direct application.

Bransford and Schwartz's proposal deals primarily with issues of method in that it does not challenge transfer as a theoretical idea. Nonetheless, their emphasis on preparation for future learning is evident in Greeno and MMAP's (1998) distributed analysis of the phenomenon of transfer. Greeno and MMAP contend that the ways of knowing that people develop in particular settings emerge as relations between them and the immediate environment. This necessarily implies that transfer involves active adaptation to new circumstances. As part of their theoretical approach, Greeno and MMAP analyze specific environments in terms of the affordances and constraints that they provide for reasoning. In the case of a traditional mathematics classroom, for example, the affordances might include the organization of lessons and of the textbook. The constraints might include the need to produce correct answers, the limited time available to complete sets of exercises, and the lack of access to peers and other resources. Greeno and MMAP would characterize the process of learning to be a successful student in such a classroom as one of becoming attuned to these affordances and constraints. From this distributed perspective, the phenomenon called transfer is then explained in terms of the similarity of the constraints and affordances of different settings rather than in terms of the transportation of knowledge from one setting to another.

The focus on preparation for future learning advocated by Bransford and Schwartz (1999) is quite explicit in Beach's (1995) investigation of the transition between work and school in a Nepal village where formal schooling had been introduced during the last 20 years of the twentieth century. Beach worked within the CHAT tradition when he compared the arithmetical reasoning of high school students who were apprentice shopkeepers with the reasoning of shopkeepers who were attending adult education classes. His analysis revealed that the shopkeepers' arithmetical reasoning was more closely related in the two situations than was that of the students. In line with the basic tenets of CHAT, Beach accounted for this finding by framing the shopkeepers' and students' reasoning as acts of participation in relatively global

cultural practices, those of shopkeeping and of studying arithmetic in school. His explanation hinges on the observation that the students making the school-to-work transition initially defined themselves as students but subsequently defined themselves as shopkeepers when they worked in a shop. In contrast, the shopkeepers continued to define themselves as shopkeepers even when they participated in the adult education classes. Their goal was to develop arithmetical competencies that would enable them to increase the profits of their shops. In Beach's view, it is this relatively strong relationship between the shopkeepers' participation in the practices of schooling and shopkeeping that explains the close relationship between their arithmetical reasoning in the two settings. Thus, whereas Greeno and MMAP account for instances of the phenomenon called transfer in terms of similarities in the affordances and constraints of immediate environments, Beach does so in terms of the experienced commensurability of certain forms of participation. In the case at hand, the phenomenon called transfer occurred to a greater extent with the shopkeepers because they experienced participating in the practice of shopkeeping and schooling as more commensurable than did the students.

The contrast between Beach's and Greeno and MMAP's analyses illustrates how general differences between the distributed cognition and CHAT traditions can play out in explanations of the phenomenon called transfer. However, attempts to reconceptualize transfer within these two are still in their early stages and there is every indication that this will continue to be a major focus of CHAT and distributed cognition research in the coming years.

3.2 Participating in Multiple Communities of Practice

To date, the bulk of CHAT research has focused on the forms of reasoning that people develop as they participate in particular cultural practices. For their part, distributed cognition theorists have been primarily concerned with the forms of reasoning that emerge as people use the cognitive resources of the immediate environment. In both cases, the focus has been on participation in well-circumscribed communities of practice or engagement in local systems of activity. An issue that appears to be emerging as a major research question is that of understanding how people deal with the tensions they experience when the practices of the different communities in which they participate are in conflict. The potential significance of this issue is illustrated by an example taken from education.

A number of studies reveal that students' home communities can involve differing norms of participation, language, and communication, some of which might be in conflict with those that the teacher seeks to establish in the classroom. Pragmatically, these studies lead directly to concerns for equity and indicate the importance of viewing the diversity of the practices of students' home communities as an instructional resource rather than an obstacle to be overcome. Theoretically, these studies indicate the importance of coming to understand how students attempt to resolve ongoing tensions between home and school practices. The challenge is therefore to develop analytical approaches that treat students' activity in the classroom as situated not merely with respect to the immediate learning environment, but with the respect to their history of participation in the practices of particular out-of-school communities. The classroom would then be viewed as the immediate arena in which the students' participation in multiple communities of practice play out in face-to-face interaction. This same general orientation is also relevant when attempting to understand people's activity in a number of other specific settings. As this is very much an emerging issue, CHAT and distributed cognition research on participation in multiple communities of practice is still in its infancy. The most comprehensive theoretical exposition to date is perhaps that of Wenger (1998). There is every reason to predict that this issue will become an increasingly prominent focus of future research in both traditions.

4. Concluding Comments

It should be apparent from this overview of contemporary developments in situated cognition that whereas CHAT researchers draw directly on Vygotsky's and Leont'ev's theoretical insights, the relationship to the Soviet scholarship is less direct in the case of distributed cognition research. Inspired in large measure by the findings of CHAT researchers, this latter tradition has emerged as a reaction to perceived limitations of mainstream cognitive science. As a consequence, distributed cognition theorists tend to maintain a dialog with their mainstream colleagues. In contrast, the problems that CHAT researchers view as significant are typically far less influenced by mainstream considerations.

The issue addressed in the previous section of this overview was that of the possible future directions for the two research traditions. It is important to note that the focus on just two issues—transfer and participation in multiple communities—was necessarily selective. It would have been possible to highlight a number of other issues that include the learning of the core ideas of academic disciplines and the design of tools as cognitive resources. In both cases, it can legitimately be argued that the CHAT and distributed cognition traditions each have the potential to make significant contributions. More generally, it can legitimately be argued that both research traditions are in progressive phases at the present time.

Situated Cognition: Origins

Situated cognition encompasses a range of theoretical positions that are united by the assumption that cognition is inherently tied to the social and cultural contexts in which it occurs. This initial definition serves to differentiate situated perspectives on cognition from what Lave (1991) terms the *cognition plus* view. This latter view follows mainstream cognitive science in characterizing cognition as the internal processing of information. However, proponents of this view also acknowledge that individual cognition is influenced both by the tools and artifacts that people use to accomplish goals and by their ongoing social interactions with others.

To accommodate these insights, cognition plus theorists analyze the social world as a network of factors that influence individual cognition. Thus, although the cognition plus view expands the conditions that must be taken into account when developing adequate explanations of cognition and learning, it does not reconceptualize the basic nature of cognition. In contrast, situated cognition theorists challenge the assumption that social process can be clearly partitioned off from cognitive processes and treated as external condition for them. These theorists instead view cognition as extending out into the world and as being social through and through. They therefore attempt to break down a distinction that is basic both to mainstream cognitive science and to the cognition plus view, that between the individual reasoner and the world reasoned about.

1. Situation and Context

I can further clarify this key difference between the situated and cognition plus viewpoints by focusing on the underlying metaphors that serve to orient adherents to each position as they frame questions and plan investigations. These metaphors are apparent in the different ways that adherents to the two positions use the key terms *situation* and *context* (Cobb and Bowers 1999, Sfard 1998). The meaning of these terms in situated theories of cognition can be traced to the notion of position as physical location. In everyday conversation we frequently elaborate this notion metaphorically when we describe ourselves and others as being positioned with respect to circumstances in the world of social affairs. This metaphor is apparent in expressions such as, 'My situation at work is pretty good at the moment.' In this and similar examples, the world of social affairs (e.g., work) in which individuals are considered to be situated is the metaphorical correlate of the physical space in which material objects are situated in relation to each other. Situated cognition theorists such as Lave (1988), Saxe (1991), Rogoff (1995), and Cole (1996) elaborate this notion theoretically by introducing the concept of participation in cultural practices (see Fig. 1). Crucially, this core construct of participation is not restricted to face-to-face interactions with others. Instead, all individual actions are viewed as elements or aspects of an

Figure 1
Metaphorical underpinnings of the cognition plus and situated cognition perspectives

encompassing system of cultural practices, and individuals are viewed as participating in cultural practices even when they are in physical isolation from others. Consequently, when situated cognition theorists speak of context, they are referring to a sociocultural context that is defined in terms of participation in a cultural practice.

This view of context is apparent in a number of investigations in which situated cognition theorists have compared mathematical reasoning in school with mathematical reasoning in various out-of-school settings such as grocery shopping (Lave 1988), packing crates in a dairy (Scribner 1984), selling candies on the street (Nunes et al. 1993, Saxe 1991), laying carpet (Masingila 1994), and growing sugar cane (DeAbreu 1995). These studies document significant differences in the forms of mathematical reasoning that arise in the context of different practices that involve the use of different tools and sign systems, and that are organized by different overall motives (e.g., learning mathematics as an end in itself in school vs. doing arithmetical calculations while selling candies on the street in order to survive economically). The findings of these studies have been influential, and challenge the view that mathematics is a universal form of reasoning that is free of the influence of culture.

The underlying metaphor of the cognition plus view also involves the notion of position. However, whereas the core metaphor of situated theories is that of position in the world of social circumstances, the central metaphor of the cognition plus view is that of the transportation of an item from one physical location to another (see Fig. 1). This metaphor supports the characterization of knowledge as an internal cognitive structure that is constructed in one setting and subsequently transferred to other settings in which it is applied. In contrast to this treatment of knowledge as an entity that is acquired in a particular setting, situated cognition theorists are more concerned with knowing as an activity or, in other words, with types of reasoning that emerge as people participate in particular cultural practices.

In line with the transfer metaphor, context, as it is defined by cognition plus theorists, consists of the task an individual is attempting to complete together with others' actions and available tools and artifacts. Crucially, whereas situated cognition theorists view both tools and others' actions as integral aspects of an encompassing practice that only have meaning in relation to each other, cognition plus theorists view them as aspects of what might be termed the stimulus environment that is external to internal cognitive processing. Consequently, from this latter perspective, context is under a researcher's control just as is a subject's physical location, and can therefore be systematically varied in experiments. Given this conception of context, cognition plus theorists can reasonably argue that cognition is not always tied to context because people do frequently use what they have learned in one setting as they reason in other settings. However, this claim is open to dispute if it is interpreted in terms of situated cognition theory where all activity is viewed as occurring in the context of a cultural practice. Further, situated cognition theorists would dispute the claim that cognition is partly context independent because, from their point of view, an act of reasoning is necessarily an act of participation in a cultural practice.

As an illustration, situated cognition theorists would argue that even a seemingly decontextualized form of reasoning such as research mathematics is situated in that mathematicians use common sign systems as they engage in the communal enterprise of producing results that are judged to be significant by adhering to agreed-upon standards of proof. For situated cognition theorists, mathematicians' reasoning cannot be adequately understood unless it is located within the context of their research communities. Further, these theorists would argue that to be fully adequate, an explanation of mathematicians' reasoning has to account for its development or genesis. To address this requirement, it would be necessary to analyze the process of the mathematicians' induction into their research communities both during their graduate education and during the initial phases of their academic careers.

This illustrative example is paradigmatic in that situated cognition theorists view learning as synonymous with changes in the ways that individuals participate in the practices of communities. In the case of research mathematics, these theorists would argue that mathematicians develop particular ways of reasoning as they become increasingly substantial participants in the practices of particular research communities. They would therefore characterize the mathematicians' apparently decontextualized reasoning as embedded in these practices and thus as being situated.

2. *Vygotsky's Contribution*

Just as situated cognition theorists argue that an adequate analysis of forms of reasoning requires that we understand their genesis, so an adequate account of contemporary situated perspectives requires that we trace their development. All current situated approaches owe a significant intellectual debt to the Russian psychologist Lev Vygotsky, who developed his cultural-historical theory of cognitive development in the period of intellectual ferment and social change that followed the Russian revolution. Vygotsky was profoundly influenced by Karl Marx's argument that it is the making and use of tools that serves to differentiate humans from other animal species. For Vygotsky, human history is the history of artifacts such as language, counting systems, and writing, that

are not invented anew by each generation but are instead passed on and constitute the intellectual bequest of one generation to the next. His enduring contribution to psychology was to develop an analogy between the use of physical tools and the use of intellectual tools such as sign systems (Kozulin 1990, van der Veer and Valsiner 1991). He argued that just as the use of a physical tool serves to reorganize activity by making new goals possible, so the use of sign systems serves to reorganize thought. From this perspective, culture can therefore be viewed as a repository of sign systems and other artifacts that are appropriated by children in the course of their intellectual development (Vygotsky 1978). It is important to understand that for Vygotsky, children's mastery of a counting system does merely enhance or amplify an already existing cognitive capability. Instead, children's ability to reason numerically is created as they appropriate the counting systems of their culture. This example illustrates Vygotsky's more general claim that children's minds are formed as they appropriate sign systems and other artifacts.

Vygotsky refined his thesis that children's cognitive development is situated with respect to the sign systems of their culture as he pursued several related lines of empirical inquiry. In his best known series of investigations, he attempted to demonstrate the crucial role of face-to-face interactions in which an adult or more knowledgeable peer supports the child's use of an intellectual tool such as a counting system (Vygotsky 1962). For example, one of the child's parents might engage the child in a play activity in the course of which parent and child count together. Vygotsky interpreted observations of such interactions as evidence that the use of sign systems initially appears in children's cognitive development on what he termed the 'intermental plane of social interaction.' He further observed that over time the adult gradually reduces the level of support until the child can eventually carry out what was previously a joint activity on his or her own. This observation supported his claim that the child's mind is created via a process of internalization from the intermental plane of social interaction to the intramental plane of individual thought.

A number of Western psychologists revived this line of work in the 1970s and 1980s by investigating how adults support or scaffold children's learning as they interact with them. However, in focusing almost exclusively on the moves or strategies of the adult in supporting the child, they tended to portray learning as a relatively passive process. This conflicts with the active role that Vygotsky attributed to the child in constructing what he referred to as the 'higher mental functions' such as reflective thought. In addition, these turn-by-turn analyses of adult–child interactions typically overlooked the broader theoretical orientation that informed Vygotsky's investigations. In focusing on social interaction, he attempted to demonstrate both that the environment in which the child learns is socially organized and that it is the primary determinant of the forms of thinking that the child develops. He therefore rejected descriptions of the child's learning environment that are cast in terms of absolute indices because such a characterization defines the environment in isolation from the child. He argued that the analyses should instead focus on what the environment means to the child. This, for him, involved analyzing the social situations in which the child participates and the cognitive processes that the child develops in the course of that participation.

Thus far, in discussing Vygotsky's work, I have emphasized the central role that he attributed to social interactions with more knowledgeable others. There is some indication that shortly before his death in 1934 at the age of 36, he was beginning to view the relation between social interaction and cognitive development as a special case of a more general relation between cultural practices and cognitive development (Davydov and Radzikhovskii 1985, Minick 1987). In doing so he came to see face-to-face interactions as located within an encompassing system of cultural practices. For example, he argued that it is not until children participate in the activities of formal schooling that they develop what he termed scientific concepts. In making this claim, he viewed classroom interactions between a teacher and his or her students as an aspect of the organized system of cultural practices that constituted formal schooling in the USSR at that time. A group of Soviet psychologists, the most prominent of whom was Alexei Leont'ev, developed this aspect of cultural-historical theory more fully after Vygotsky's death.

3. *Leont'ev's Contribution*

Two aspects of Leont'ev's work are particularly significant from the vantage point of contemporary situated perspectives. The first concerns his clarification of an appropriate unit of analysis when accounting for intellectual development. Although face-to-face interactions constitute the immediate social situation of the child's development, Leont'ev saw the encompassing cultural practices in which the child participates as constituting the broader context of his or her development (Leont'ev 1978, 1981). For example, Leont'ev might have viewed an interaction in which a parent engages a child in activities that involve counting as an instance of the child's initial, supported participation in cultural practices that involve dealing with quantities. Further, he argued that children's progressive participation in specific cultural practices underlies the development of their thinking. Intellectual development was, for him, synonymous with the process by which the child becomes a full participant in particular cultural practices. In other words, he viewed the development of children's minds and

their increasingly substantial participation in various cultural practices as two aspects of a single process. This is a strongly situated position in that the cognitive capabilities that children develop are not seen as distinct from the cultural practices that constitute the context of their development. From this perspective, the cognitive characteristics a child develops are characteristics of the child-in-cultural-practice in that they cannot be defined apart from the practices that constitute the child's world. For Leont'ev, this implied that the appropriate unit of analysis is the child-in-culture-practice rather than the child *per se*. As stated earlier, it is this rejection of the individual as a unit of analysis that separates contemporary situated perspectives from what I called the cognition plus viewpoint.

Leont'ev's second important contribution concerns his analysis of the external world of material objects and events. Although Vygotsky brought sign systems and other cultural tools to the fore, he largely ignored material reality. In building on the legacy of his mentor, Leont'ev argued that material objects as they come to be experienced by developing children are defined by the cultural practices in which they participate. For example, a pen becomes a writing instrument rather than a brute material object for the child as he or she participates in literacy practices. In Leont'ev's view, children do not come into contact with material reality directly, but are instead oriented to this reality as they participate in cultural practices. He therefore concluded that the meanings that material objects come to have are a product of their inclusion in specific practices. This in turn implied that these meanings cannot be defined independently of the practices. This thesis only served to underscore his argument that the individual-cultural-practice constitutes the appropriate analytical unit for psychology.

Situated Knowledge: Feminist and Science and Technology Studies Perspectives

The expression 'situated knowledge,' especially in its plural form 'situated knowledges,' is associated with feminist epistemology, feminist philosophy of science, and science and technology studies. The term was introduced by historian of the life sciences and feminist science and technology studies scholar Donna Haraway in her landmark essay *Situated Knowledges: The Science Question in Feminism and the Privilege of Partial Perspective* (Haraway 1991, pp. 183–201). The

essay was a response to feminist philosopher of science Sandra Harding's discussion of the 'science question in feminism' (Harding 1986). In her analysis of the potential of modern science to contribute to the goals of feminism, Harding noted three different accounts of objective knowledge in feminist epistemology: feminist empiricism, feminist standpoint, and feminist postmodernism (Harding 1986, pp. 24–6). Feminist empiricism attempted to replace more biased with less biased science. The feminist standpoint, echoing the Marxist tradition from which it derived, stressed the relevance of the social positioning of the knower to the content of what is known. Feminist postmodernism accentuated the power dynamics underlying the use of the language of objectivity in science. Haraway, taking off from Harding, diagnosed a 'Scylla and Charybdis' of temptations between which feminists attempt to navigate on the question of objectivity: radical constructionism and feminist critical empiricism. As she put it, what feminists wanted from a theory of objectivity was 'enforceable, reliable accounts of things not reducible to power moves and agonistic, high status games of rhetoric or to scientistic, positivist arrogance' (Haraway 1991, p. 188). Her notion of situated knowledges was her attempt to provide just such a theory of objectivity.

Despite the single author provenance, the term resonated with attempts by other scholars in the history, sociology, and philosophy of science to address similar epistemological tensions. The concept was quickly and fruitfully taken up in science and technology studies and feminist theory, provoking a certain amount of reworking in its turn.

1. *'Situated Knowledge' and Objectivity: Constructed Yet Real*

The term 'situated knowledge' derives its theoretical importance from its seemingly oxymoronic character, particularly when applied to knowledge about the natural world. It is common to think of modern scientific knowledge as universal, so that it has the same content no matter who possesses it. It is also almost definitional to hold that objective knowledge is warranted by the fact that it captures reality as it really is, rather than being warranted by the situational circumstances out of which the knowledge was generated or discovered (see Shapin 1994, pp. 1–8 for discussion of, and citations relevant to, various manifestations of these points). Thus, if the law of gravity enables us to make reliable experimental predictions, it is because there is such a thing as gravity that is adequately captured by our scientific understanding; in short, the truth of the knowledge is its own warrant. It is only in the case of false or superseded knowledge that we typically explain what went wrong by reference to faulty assumptions, sloppy work, ill-calibrated equipment, the *Zeitgeist*, or other aspects of the context of discovery. The idea of 'situated knowledge' contests these supposed concomitants of objective knowledge. It suggests that objective knowledge, even our best scientific knowledge of the natural world, depends on the *partiality* of its material, technical, social, semiotic, and embodied means of being promulgated.

Haraway's notion thus has affinities with other feminist epistemologies which have noted that facts can differ in their content from one time, place, and knower to another (e.g., Collins 1989). It also has sympathies in common with sociologists of science and scholars of science and technology studies who have suggested that capturing 'reality as it really is' may be dependent on institutional, technical, and cultural norms (Kuhn (1962/1970), on practice (Clarke and Fujimura 1992, Pickering 1992), and attempts to witness, measure, comprehend, or command assent to it (Latour 1987, Shapin 1994, Shapin and Schaffer 1985). All these scholars share a search for the theoretical resources to do justice to the embeddedness of science and truth. These challenges to conventional views of objectivity bring situated knowledges into conversation with key debates in the philosophy of science around the theory-ladenness of facts (Hesse 1980, pp. 63–110). Additionally, the suspicion of transcendent universalism entrains an epistemological and political distrust of clear-cut distinctions between subject and object, and a blurring of the distinction between context and content of knowledge or discovery.

Situated knowledges are as hostile to relativism as they are to realism. Haraway describes relativism as 'being nowhere while claiming to be everywhere equally' (Haraway 1991, p. 191) and realism as 'seeing everything from nowhere' (Haraway 1991, p. 189), and conceives of them both as 'god-tricks' promising total, rather than partial, located, and embodied, vision. In contrast to realist or relativist epistemologies, Haraway sees the possibility of sustained and rational objective inquiry in the epistemology of partial perspectives. This requires, she maintains, reclaiming vision as a series of technological and organic embodiments, as and when and where and how vision is actually enabled. This crafting of a feminist epistemology of situated knowledges on the basis of vision and partial perspective is noteworthy. The links in the history of science to militarism, capitalism, colonialism, and male supremacy have been theorized around the masculinist gaze of the powerful but disembodied knower disciplining and subjugating the weak by means of a multitude of technologies of surveillance. Feminists have lamented the privilege granted to the visual as a sure basis of knowledge and bemoaned the sidelining in modernity of what some cast as more feminine and less intrinsically violent ways of knowing involving emotion, voice, touch, and listening (Gilligan 1982). Haraway is concerned that feminists not cede power to those whose practices they wish

critically to engage. It is in this spirit that she grounds her feminist solution in an embrace of science and vision, 'the real game in town, the one we must play' (Haraway 1991, p. 184).

2. *The Feminist Roots of the Dilemma*

A tension between emancipatory empiricism and its associated egalitarian or socialist politics, and feminist postmodern constructionism and its associated identity politics, resonates throughout contemporary Western feminist theory. It is a recent hallmark of those engaged in feminist philosophical and social studies of science that they seek to resolve one or another version of this tension. One horn of the feminist dilemma, according to Haraway, represents the good feminist reasons to be attracted to radical constructionism. Feminist postmodernists, and analysts of science and technology influenced by semiotics (including Haraway herself), helped develop and often appeal to 'a very strong social constructionist argument for *all* forms of knowledge claims' including scientific ones (Akrich and Latour 1992, Haraway 1991, p. 184). This position has the benefit of showing the links between power—such things as status, equipment, rhetorical privilege, funding, and so on—and the production of knowledge and credibility. The downside, from the point of view of feminists interested in arguing for a better world, is that the radical constructionist argument risks rendering all knowledges as fundamentally ideological, with no basis for choosing between more and less just ideas, more and less true versions of reality. As Haraway provocatively expressed it, embracing this temptation seemed to leave no room for 'those of us who would still like to talk about *reality* with more confidence than we allow the Christian right's discussion of the Second Coming and their being raptured out of the final destruction of the world' (Haraway 1991, p. 185).

The second horn of the dilemma, according to Haraway, involves 'holding out for a feminist version of objectivity' through materialism or empiricism (Haraway 1991, p. 186). Haraway briefly discusses both Marxist derived feminisms and feminist empiricism. Feminisms with Marxist inspirations are several, and their genealogy can be traced in a number of ways. Feminists have long criticized Marxist humanism for its premise that the self-realization of man is dependent on the domination of nature, and for its account of the historical progression of modes of production that grants no historical agency to domestic and unpaid labor (Hartmann 1981). Some have responded by developing feminist versions of historical materialism (Hartsock 1983). Feminist standpoint theorists appropriated the general insight, inherited from both Marxist thought and the sociology of knowledge, that one's social-structural position in society—such things as one's class or relation to the means of production, or one's gender or ethnonational characteristics—determine or affect how and what one knows (Smith 1990).

Likewise, the idea that some social structural positions confer epistemological privilege has been widely adopted by standpoint theorists and feminist epistemologists arguing for specifically feminine ways of knowing (Rose 1983). 'Seeing from below,' that is, from a position of subordination, has commonly been theorized by feminists as the position of epistemological privilege, on the grounds that those with little to gain from internalizing powerful ideologies would be able to see more clearly than those with an interest in reproducing the status quo. In Patricia Hill Collins' version of standpoint theory, for example, these insights are used both to validate the knowledges of the historically disenfranchised, and to reverse the hegemonic ranking of knowledge and authority, and claim epistemological privilege for African–American women (Collins 1989).

Psychoanalytic theory, particularly anglophone object relations theory, inspired some of the early writings on gender and science (Chodorow 1978, Keller 1985). Object relations theory attempted to explain the different relation of women and men to objectivity, abstract thought, and science in modern societies. To account for this difference, the theory posited gender-based differences in the socialization of sons and daughters in Western middle class heterosexual nuclear families. Boys, according to this theory, are socialized to separate from the primary caregiver who is the mother in this normative family scenario. They thus learn early and well by analogy with their emotional development that relational thinking is inappropriate for them; separating themselves from the object of knowledge, as from the object of love, is good. Girls, on the other hand, are supposedly socialized to be like their primary caregiver, so that they can reproduce mothering when their turn comes. Relationality and connectivity, not abstraction and separation, are the analogous ordering devices of girls' affective and epistemological worlds. As applied to objectivity and scientific knowledge, object relations theory seemed to explain to feminists, without resort to distasteful biological determinisms denying women scientific aptitude, why women were excluded from much of science and technology. It also suggested that there were (at least) two distinct ways of knowing, and that much might have been lost in the violence and separation of masculinist science that could be restored by a proper valuation of the feminine values of connection and empathy (Harding 1986, Keller 1983). Like Marxism, psychoanalytic approaches to objectivity gave feminists a means to show the relevance of one's social position to knowledge. Like feminist empiricism, they encouraged the belief in the possibility of an improved, feminist, objectivity (Harding 1992).

The feminist canon contains a number of empirical studies that have revealed the negative effects of such things as colonialism and stereotypes about race and gender on the production of reliable science (Fausto-Sterling 1995, Martin 1991/1996, Schiebinger 1989, Traweek 1988). Evelyn Fox Keller's call for 'dynamic objectivity' (Keller 1985, pp. 115–26) and Sandra Harding's demand for 'strong objectivity' (Harding 1992, p. 244) are exemplary of the aspirations of theoretical feminist empiricism. These projects seek to prescribe scientific methods capable of generating accounts of the world that would improve upon disembodied, masculinist portrayals of science because they would be alert to the practices of domination and oppression inherent in the creation, dissemination, and possession of knowledge. Feminist empiricism nonetheless remains problematic because of its reliance on the dichotomies of bias vs. objectivity, use vs. misuse, and science vs. pseudoscience. The feminist insight of the 'contestability of every layer of the onion of scientific and technological constructions' (Haraway 1991, p. 186) flies in the face of leaving these epistemological dichotomies intact.

3. *Subjects, Objects, and Agency*

Haraway's notion of situated knowledges problematizes both subject and object. Unlike standpoint theories which attribute epistemological privilege to subjugated knowers, and the sociology of knowledge which attributes espitemological privilege to those in the right structural position vis-à-vis a given mode of production, Haraway attributes privilege to partiality. This shift underscores that 'situated knowledge' is more dynamic and hybrid than other epistemologies that take the position of the knower seriously, and involves 'mobile positioning' (Haraway 1991, p. 192)

In situated knowledges based on embodied vision, neither subjects who experience, nor nature which is known, can be treated as straightforward, pre-theoretical entities, 'innocent and waiting outside the violations of language and culture' (Haraway 1991, p. 109). Haraway maintains that romanticizing, and thus homogenizing and objectifying, the perfect subjugated subject position is not the solution to the violence inherent in dominant epistemologies. As feminists from developing countries have also insisted, there is no innocent, perfectly subjugated feminist subject position conferring epistemological privilege; all positionings are open to critical re-examination (Mohanty 1984/1991). Subjectivity is instead performed in and through the materiality of knowledge and practice of many kinds (Butler 1990, pp. 1–34).

Conversely, the extraordinary range of objects in the physical, natural, social, political, biological, and human sciences about which institutionalized knowledge is produced should not be considered to be passive and inert. Haraway says that situated knowledges require thinking of the world in terms of the 'apparatus of bodily production.' The world cannot be reduced to a mere resource if subject and object are deeply interconnected. Bodies as objects of knowledge in the world should be thought of as 'material-semiotic generative nodes,' whose 'boundaries materialize in social interaction' (Haraway 1991, p. 201). The move to grant agency to material objects places the epistemology of situated knowledges at the center of recent scholarship in science and technology studies (Callon 1986, Latour 1987).

4. *Uptake and Critique*

Donna Haraway's essay ranks among the most highly cited essays in science and technology studies and has been anthologized. As stated above, situated knowledges is a provocative and rich methodological metaphor with resonances in many quarters. The dialogue between Harding and Haraway continued after the publication of *Situated Knowledges* (Harding 1992, pp. 119–63). Her epistemology has directly influenced, and has in turn been influenced by, the recent work of sociologists and anthropologists of science (Clarke and Montini 1993, Rapp 1999), feminist philosophers of science (Wylie 1999), and practicing feminist scientists (Barad 1996). In addition, 'situated knowledges' is used as a standard technical term of the field by more junior scholars.

Critics of situated knowledges have been few. Timothy Lenoir has pointed out that many of the epistemological ideas behind Haraway's situated knowledges are found not only in other major strands of science and technology studies, but also in the work of continental philosophers such as Nietzsche. He likewise critiqued the idea of situated knowledges for its dependence on the apparatus of semiotics (Lenoir 1999, pp. 290–301). Historian Londa Schiebinger, in her recent book summarizing the effects of a generation of feminist scholarship on the practice of science, places Haraway's situated knowledges together with Harding's strong objectivity as attempts to integrate social context into scientific analysis (Schiebinger 1999). Implicit critiques have been leveled against the limitations of the idea of being situated, for example, in the development of De Laet's and Mol's mobile epistemology (De Laet and Mol 2000). Sheila Jasanoff and her colleagues have argued for bringing differently spatialized entities such as the nation, the local, and the global, into the epistemology of science and technology studies, while retaining the insights gained by paying attention to practice, vision, and measurement. These critiques stand more as continuing conversations with, than rebuttals of situated knowledges, however. Overall, the idea of situated knowledges remains central to feminist epistemology and science studies and to attempts to understand the role of modern science in society.

Situated Learning: Out of School and in the Classroom

Situated learning is not a unitary, well-defined concept. From an educational point of view, the core idea behind the different uses of this term is to create a situational context for learning that strongly resembles

possible application situations in order to assure that the learning experiences foster 'real-life' problem solving.

1. Situated Cognition–Situated Learning

Since 1985, the notion of situatedness of learning and knowing has become prominent in a variety of scientific disciplines such as psychology, anthropology, and computer science. In this entry, however, we focus only on situatedness approaches in education and educational psychology.

Since the late 1980s a particular educational problem has received much attention. In traditional forms of instruction, learners acquire knowledge that they can explicate, for example in examinations. When the learners are, however, confronted with complex 'real-life' problems, this knowledge is frequently not used, although it is relevant. Such knowledge is termed 'inert knowledge' (Renkl et al. 1996). This frequently found inertness phenomenon motivated some researchers to postulate that the whole notion of knowledge that is used in cognitive psychology as well as in everyday reasoning about educational issues is wrong (e.g., Lave 1988).

It has been argued that knowledge is not some 'entity' in a person's head that can be acquired in one situational context (e.g., classroom) and then be used in another context (e.g., workplace), but that instead it is context-bound. Hence, symbolic modeling of cognitive processes and structures is regarded as inappropriate. From a situatedness perspective, knowledge is generally constituted by the relation or interaction between an agent and the situational context they are acting in. Hence, it is proposed that we use the term 'knowing' instead of 'knowledge' in order to underline the process aspect of knowing/knowledge (Greeno et al. 1993). As a consequence of this conception of knowledge, learning must also be conceived as context-bound or situated. Thus, it is understandable that there is no transfer between such different contexts as the classroom and everyday life.

The theoretical assumption of the situatedness of knowing and learning also has consequences for research methodology. Laboratory experiments can no longer be seen as appropriate, because in this research strategy the phenomena are put out of their 'natural' context and their character is changed (e.g., Lave 1988). Situatedness proponents conduct primarily qualitative field studies.

Unfortunately, the term of situatedness is not well defined. One reason for the fuzziness of this construct is that its proponents differ in how far they depart from traditional cognitive concepts. Whereas Lave (1988), for example, radically rejects the notions of knowledge, transfer, and symbolic representations as not being sensible, other proponents, such as Greeno et al. (1993), hold a more modest position. Although they also stress the situatedness of knowing and learning, they aim, for example, to analyze conditions for transfer, or claim that representations can play a role in human activity. A factor that further contributes to the vagueness of the notion of situated learning is that it is used in two ways: descriptive and prescriptive. When descriptively used, situated learning means that learning is analyzed as a context-bound process. In the field of education, situated learning is, however, mostly used as prescriptive concept. It is argued that learning should be situated in a context that resembles the application contexts.

The prescriptive aspect of situated learning was quite appealing to the community of educational researchers in the 1990s. Hence, not only those who subscribe to the situated cognition perspective (i.e., rejection of cognitive concepts), but also people who still more or less remain within the traditional cognitive framework rely on this concept. The latter group often juxtapose situated learning with decontextualized (traditional) learning, in which concepts and principles are presented and acquired in an abstract way with little or no relation to 'real-world' problems. It is important to note that this 'assimilated' view, in principle, contradicts the more fundamental situatedness concept according to which there is no nonsituated learning. Even typical abstract school learning is situated in the very specific context of school culture, although this situatedness would usually be evaluated as unfavorable because of the differences between school and 'real-life' contexts. Hence, irrespective of the logical inconsistencies in the use of the notion of situated learning, the prescriptive notion of situated learning means that the learning and the application situations should be as similar as possible in order to assure that the learning experiences have positive effects on 'real-life' problem solving.

2. Learning and Problem Solving in School and Outside

From a situatedness perspective, typical school learning is not much help for problem solving in everyday or professional life because the contexts are too different. Based among others upon Resnick's (1987) analyses of typical differences between these contexts, the following main points are outlined:

(a) *Well-defined problems in school versus ill-defined problems outside*. For example, word problems in mathematics are usually well defined. It is clear what the problem is all about, all the necessary information is given in the problem formulation, there is usually only one way to arrive at the solution that is labeled as appropriate, and so on. Nontrivial, 'real-life' problems (e.g., improvement of an organization's communication structure) first often have to be defined more precisely for a productive solution: one has to decide whether one needs more information, one has to seek

information, one has to decide what is relevant and irrelevant information, there are multiple ways of solving a problem, and so on.

(b) *Content structured by theoretical systems in school versus structured by problems outside*. In traditional forms of instruction, content is structured according to theoretical systematizations (e.g., biological taxonomies). This helps learners to organize the content and to remember it. One very salient systematization of content is the distinction between different school subjects. When a 'real-life' problem (e.g., pollution in a city or evaluation of an Internet company's share) has to be solved, thinking within the boundaries of school subjects is often not helpful. Furthermore, the structure of concepts used in school is frequently not relevant to the problem at hand. In 'real life,' the nature of the problem to be solved determines what concepts and information are required and in which structure they are needed.

(c) *Individual cognition in school versus shared cognition outside*. In schools, the usual form of learning and performance is individualistic. Cooperation in examinations is even condemned. In professional or everyday life, in contrast, cooperation is valued and it is frequently necessary for solving problems.

(d) *Pure mentation in school versus tool manipulation outside*. In traditional instruction, pure 'thought' activities are dominating. Students should learn to perform without support of tools such as books, notes, calculators, etc. Especially in exams, tools are usually forbidden. In contrast, a very important skill in everyday or professional life is the competent use of tools.

(e) *Symbol manipulation in school versus contextualized reasoning outside*. Abstract manipulation of symbols is typical of traditional instruction. Students often fail to match symbols and symbolic processes to 'real-world' entities and processes. In ordinary life, on the other hand, not only are tools used, but reasoning processes are an integral part of activities that involve objects and other persons. 'Real-world' reasoning processes are typically situated in rich situational contexts.

(f) *Generalized learning in school versus situation-specific competencies outside*. One reason for the abstract character of traditional instruction is that it aims to teach general, widely usable skills and theoretical principles. Nobody can foresee what types of specific problem students will encounter in their later life. In everyday and professional life, in contrast, situation-specific skills must be acquired. Further learning is mostly aimed at competencies for specific demands (e.g., working with a new computer program).

On the one hand, this list is surely not complete and more differences could be outlined. On the other hand, this juxtaposition is somewhat oversimplifying. Nevertheless, there is a core of truth because *typical* learning in and out of school differs significantly. Given these differences, a consequence of situatedness assumptions is to claim that learning environments in school should strongly resemble application contexts or that learning should take place in the field (e.g., 'on the job'). A traditional model in which people acquire applicable skills in authentic contexts is apprenticeship learning.

3. *Apprenticeship Learning as Situated Learning*

The situatedness protagonists Lave and Wenger (1991) investigated out of school learning in the form of apprenticeship by means of qualitative analyses. They focused on people working in traditional skills, for example Indian midwives in Mexico, tailors in Liberia, and butchers in supermarkets. In these traditional apprenticeships, learners acquire mainly manual skills. In modern society, in contrast, 'cognitive' domains prevail (e.g., computer science, psychology), so that skilled activity is hardly 'visible.' Also in school learning, cognitive skills such as mathematical problem solving, reading, and writing dominate. Against this background, Collins et al. (1989) developed the instructional cognitive apprenticeship model. Herein the importance of explication or reification of cognitive processes (e.g., strategies, heuristics) during learning is stressed. Thus, cognitive processes can be approximately as explicit as the more manual skills trained in traditional apprenticeship.

The core of cognitive apprenticeship is a special instructional sequence and the employment of authentic learning tasks. Experts provide models in applying their knowledge in authentic situations. Thereby they externalize (verbalize) their reasoning. The learners then work on authentic tasks of increasing complexity and diversity. An expert or teacher is assigned an important role as a model and as a coach providing scaffolding. The learners are encouraged increasingly to take an active role, as the support by the expert is gradually faded out. Articulation is promoted so that normally internal processes are externalized and can be reflected. This means that one's own strategies can be compared with those of experts, are then open to feedback, and can be discussed. In addition, the student's own cognitive strategies can be compared with those of other students. In the course of interaction with experts and other learners, students can also get to know different perspectives on concepts and problems. As a result of this instructional sequence, the students increasingly work on their own (exploration) and may take over the role initially assumed by the expert. Lave and Wenger (1991) have characterized such a sequence as development from legitimate peripheral participation to full participation.

It is important to note that the type of apprenticeship learning that is envisioned by the proponents of the situatedness approaches implies much more than the acquisition of 'subject-matter knowledge.' It

is a process of enculturation. The learner gradually develops the competence to participate in a community of practice. Such participation presupposes more than the type of knowledge usually focused on in classroom learning. In addition, 'tricks of the trade' and knowledge of social norms, for example, are required.

4. Problem-based Learning as Situated Learning

Besides apprenticeship, problem-based learning is another possibility for implementing arrangements in accordance with a situatedness rationale. Learning should be motivated by a complex 'real-world' problem that is the starting point of a learning process. For example, Greeno and the Middle School Mathematics Through Applications Project Group (MMAP) (1998) designed learning arrangements in which mathematical reasoning is not triggered primarily in separate mathematics lessons, but within design activities in four domains: architecture, population biology, cryptography, and cartography. The design activities are supported by the employment of computer tools which are also typical of current situated learning arrangements. An instructional principle is to induce quantitative reasoning involving proportions, ratios, and rates during design activities that strongly resemble the activities of many everyday crafts and commercial practices. The mathematical reasoning within design activities can be quite sophisticated; however, it often remains implicit. The teachers' task is to uncover the mathematics the students are implicitly using. For this purpose, there are, among others, curricular materials for 'math extension' units (i.e., explicit mathematics lessons).

5. Common Critiques of the Situatedness Approach

The situatedness camp has criticized the fundamental assumptions of cognitively oriented educational research. Hence it is not surprising that the situatedness camp has also been heavily attacked. Three major objections against the situatedness approach and corresponding defending arguments should be outlined:

(a) *Faulty fundamental assumptions*: Anderson et al. (1996), in particular, have argued that the situatedness approach is based on wrong assumptions such as 'knowledge does not transfer between tasks' or 'training in abstraction is of little use.' Anderson et al. cited empirical studies that contradict these assumptions. In his reply, Greeno (1997) argues that the assumptions that Anderson et al. criticize are actually wrong, but that they are not the claims of the situativity approach. The core of a situativity theory is a different perspective on phenomena of learning. Instead of focusing on mental processes and structures, the situativity approach analyses '… the social and ecological interaction as its basis and builds toward a more comprehensive theory by … analyses of information structures in the contents of people's interactions' (Greeno 1997, p. 5).

(b) *Triviality*: It is also argued that there is nothing really new in the core arguments of the situatedness theories. For example, Vera and Simon (1993) argue that all findings of the situatedness research can be incorporated into the well-elaborated traditional framework of cognitive models (i.e., symbolic paradigm). From the situatedness perspective, however, analyzing symbolic structures and processes runs too short. They may just be a special case of activity (Greeno and Moore 1993). Another triviality argument is that many claims of the situatedness protagonists were already articulated long before, for example by Dewey, Piaget, and Vygotskji, so that they are hardly stating anything new (e.g., Klauer 1999). Renkl (2000) counters that it is to the merit of the situatedness protagonists that they have reactivated these classical ideas. Most of these ideas played only a very minor role in educational mainstream research before the situatedness approach emerged. Furthermore, situated learning approaches bring classical ideas together with new developments (e.g., learning with new technologies) to form new 'Gestalts.'

(c) *Weak methodology*: Klauer (1999) is one of many researchers who criticize that the situatedness protagonists employ purely qualitative research methods and that they often rely merely on anecdotes to support their claims of the situatedness of cognition and learning (e.g., the 'cottage cheese story'; cf. Lave 1988). Lave (1988), on the other hand, rejects the empirical-experimental paradigm as artificially decontextualizing phenomena in laboratory investigations. From a situatedness point of view, it is clear that results from laboratories are of questionable value for out-of-lab contexts. It is important to note that many researchers who merely assimilated the notion of situated learning, but do not subscribe to radical situatedness, keep on researching within the traditional empirical framework. Hence, the methodological critique aims at the more radical situatedness proponents.

6. Possible Futures of Situated Learning

On the one hand, at least some situatedness protagonists in the area of education make strong statements with respect to the advantage of their approach over the traditional one. On the other hand, the 'traditionalists' defend themselves. Against this background it is interesting to ask what the future will bring. Four main possibilities are discussed. (a) Critical traditionalists (Klauer 1999) argue that the situatedness approach and the discussion around it will disappear as other more or less fruitless debates (e.g., the person–situation debate in psychology) have done

before. (b) Others (e.g., Cobb and Bowers 1999) hope that the situatedness perspective will take the place of the cognitive paradigm in education, just as years ago the behavioral paradigm was driven out by the cognitive one. (c) Some 'observers' of the situatedness debate (e.g., Sfard 1998) argue that the two positions provide different metaphors for analyzing learning and that both are useful. Accordingly, they plea for a complementary coexistence. (d) Greeno and MMAP (1998) envision a very ambitious goal for their situativity approach; that is, to develop a situatedness approach that is a synthesis of the cognitive and the behavioral paradigm. Whatever possibility may become reality, there is at least consensus between the main opponents in the situatedness debate (cf. Anderson et al. 1997, Greeno 1997) on what the touchstone for the two approaches should be: the ability to improve education.

Situation Model: Psychological

> For, it being once furnished with simple ideas, it [the mind] can put them together in several compositions, and so make variety of complex ideas, without examining whether they exist so together in nature (John Locke 1690 *An Essay Concerning Human Understanding*).

When we read a story, we combine the ideas derived from understanding words, clauses, and sentences into mental representations of events, people, objects, and their relations. These representations are called situation models. Thus, situation models are not representations of the text itself; rather, they could be viewed as mental microworlds. Constructing these microworlds is the essential feature of understanding. At the most basic level, situation models are mental representations of events. Aspects of events that are encoded in situation models are: what their nature is, where, when, and how they occur, and who and what is involved in them. Single-event models are integrated with models of related events constructed based on the preceding text, such that situation models may evolve into complex integrated representations of large numbers of related events. This is what occurs when we comprehend extended discourse, such as news articles, novels, or historical documents.

1. Background

Situation models were introduced to cognitive psychology by van Dijk and Kintsch (1983) and are based on earlier research in formal semantics and logic (e.g., Kripke 1963). The concept is primarily used in research on language and discourse comprehension. For a good understanding, it is important to distinguish situation models from similar concepts, such as mental models, scripts, and frames.

2. How Situation Models Differ

2.1 Mental Models

Originally proposed by Craik (1943) and elaborated and introduced to cognitive psychology by Johnson-Laird (1983), mental models (see *Mental Models,*

Psychology of) are mental representations of real, hypothetical, or imaginary situations. Situation models can be viewed as a special type of mental model. Situation models are mental models of specific events. They are bound in time and space, whereas mental models in general are not. For example, heart surgeons have mental models of our blood circulatory system, but they construct a situation model of the state of patient X's coronary artery at time (t).

2.2 Scripts and Frames

Originally proposed in the artificial intelligence literature by Schank and Abelson (1977) and Minsky (1975), respectively, scripts and frames (see *Schemas, Frames, and Scripts in Cognitive Psychology*) are representations of stereotypical sequences of events, such as going to a restaurant and spatial layouts, such as that of a living room or the interior of a church. Comprehenders use scripts and frames to construct situation models. For example, the restaurant script can be used to construct a mental representation of your friend's visit to a local Italian restaurant last night. This is accomplished by filling in the slots of the script. Thus, scripts and frames can be considered types, whereas situation models are tokens. Furthermore, scripts and frames are semantic memory representations, whereas situation models are episodic memory representations.

3. Other Representations Constructed During Comprehension

It is often assumed that readers construct multilevel mental representations during text comprehension. Although there is no complete consensus as to what other types of mental representations, besides situation models, are constructed during text comprehension, empirical and intuitive evidence for the role of the following representations has been put forth. The surface structure is a mental representation of the actual wording of the text. Surface–structure representations are typically short-lived in memory, except when they have a certain pragmatic relevance (for example in the case of insults or jokes) or when the surface structure is constrained by prosodic features, such as rhyme and meter, as in some poetry.

The textbase is a mental representation of the semantic meaning of what was explicitly stated in the text. The textbase usually decays rather rapidly. That is, within several days, comprehenders are unable to distinguish between what they read and what they inferred (see *Memory for Meaning and Surface Memory*). Some researchers view the textbase simply as that part of the situation model that was explicitly stated (rather than implied) and thus deny the textbase a special status. Analyses of naturalistic discourse suggest that comprehenders not only construct a model of the denoted situation, but also construct a model of the communicative context. For example, they make inferences about the attitudes of writers regarding the situation they describe. Van Dijk (1999) calls this type of representation 'context model' and argues that no account of discourse comprehension is complete without the inclusion of a context model.

4. Why Situation Models are Needed to Explain Language Use

A task analysis of text comprehension shows the need for situation models. For example, when we comprehend the instructions that come with a household appliance, we form mental representations of the actions needed to operate or repair the device. It would be of little use to construct a mental representation of the wording of instructions themselves. Similarly, when we read newspaper articles, our usual goal is to learn and be updated about some news event. For example, we want to know how the United States House of Representatives responded to the latest budget proposal by the President or why the latest peace negotiations in the Middle East came to a halt. In these cases, we construct mental representations of agents, events, goals, plans, and outcomes, rather than merely mental representations of clauses and words.

5. Components of Situation Models

Situation models are models of events. Events always occur at a certain time and place. In addition, events typically involve participants (agents and patients) and objects. Furthermore, events often entertain causal relations with other events or are part of a goal-plan structure. Thus, time, place, participants, objects, causes and effects, and goals and plans are components of situations, with time and place being obligatory. As linguists have observed, most of these components are routinely encoded in simple clauses. Verbs typically describe events (although some events can also be described by nouns, e.g., explosion), while nouns and pronouns denote participants and objects (although pronouns can also denote events) and prepositions primarily denote spatial relations (although spatial relations can also be denoted by, for instance, verbs, as in 'The nightstand supported a lamp' and prepositions can be used to indicate temporal relationships, as in 'In an hour'). Temporal information can be expressed lexically in a variety of ways, but is also encoded grammatically in the form of verb tense and aspect in languages such as English, German, and French.

Causation and intentionality are denoted lexically by verbs (e.g., 'caused,' 'decided to') or adverbs (e.g., 'therefore,' 'in order to'), but are often left to be inferred by the comprehender. For example, there is no explicitly stated causal connection between following two events 'John dropped a banana peel on the floor. The waiter slipped,' yet comprehenders can easily infer the connection. Participants and objects may have various kinds of properties, such as having blue eyes or a cylindrical shape, and temporary features, such as being sunburnt or overheated. Finally, participants and objects may be related in various ways (e.g., kinship, professional, ownership, part–whole, beginning–end, and so on).

6. *A Simple Example*

A simple example illustrates these points. Consider the following clause:

(1) John threw the bottle against the wall.

This clause describes an event (throw) that involves a male agent (John), and two objects (bottle, wall). The simple past tense indicates that the event occurred prior to the moment at which the sentence was uttered (e.g., as opposed to *John will throw the bottle against the wall*). John's location is not explicitly stated, but we infer it is in relative proximity to the wall. We may draw inferences as to the causal antecedent and consequent of this event. A plausible antecedent is that John was angry. A plausible consequent is that the bottle will break.

Comprehenders are more likely to infer causal antecedents than causal consequences. Note that there are many other inferences that could be drawn. For example, one might infer that John is a middle-aged man and that the bottle was a wine bottle and that it was green and half-filled. One might also infer that the wall was a brick wall, and so on. Comprehenders typically make relatively few of this kind of elaborative inferences. Rather, they are focused on the causal chain of events (Graesser et al. 1994).

7. *Situation Models Establish Coherence*

A major role of situation models in discourse comprehension is to help establish coherence. Suppose sentence (1) were followed in the text by (2):

(2) It shattered into a thousand pieces.

How would this sentence be comprehended? If the two sentences are part of a discourse, rather than read in isolation, they would have to be integrated in some fashion. They are about some set of events. Comprehenders assume by default that a new sentence will describe the next event in the chronological sequence. Thus, they will assume that the event described in (2) directly follows that in (1). This implies temporal contiguity between (1) and (2). The use of the simple past tense is consistent with this assumption. Event 2 occurs prior to the moment of utterance, but after event 1. Given that no passage of time was mentioned, temporal contiguity is assumed.

The pronoun *it* in sentence (2) is taken to refer to some entity already in the situation model. There are three potential referents, John, the bottle, and the wall. John is not appropriate, because animate male human beings require the pronoun *he*. However, the bottle and the wall are both inanimate and thus compatible with the pronoun. Because there is no linguistic way to select the proper referent, the comprehender will use background knowledge that bottles are typically made out of glass, which is breakable, and walls out of harder materials, such as brick or concrete, to infer that it was the bottle that broke. The absence of a time lapse and the presence of an object from the previous event will cause the comprehender to assume that the second event takes place in roughly the same spatial region as the first, given that the same object cannot be at two different places at the same time.

Thus, the two events can now be integrated into a single situation model in which an agent, a male individual named John, at t1 threw a breakable object, a bottle, against a wall, presumably out of anger, which immediately, at t2, caused the bottle to break into pieces. This is how situation models provide coherence in discourse. Discourse is more than a sequence of sentences. Rather, it is a coherent description of a sequence of events that are related on several dimensions. Situation model theory attempts to account for how these events are successively integrated into a coherent mental representation.

8. *Situation Models Integrate Textual Information with Background Knowledge*

Another function of situation models is that they allow for the integration of text-derived information with the comprehender's background knowledge. Consider the following examples (from Sanford and Garrod 1998):

(3) Harry put the wallpaper on the table. Then he put his mug of coffee on the paper.

It is rather straightforward to integrate these sentences. They call for a spatial arrangement in which the paper is on top of the table and the mug on top of the paper and the coffee inside the mug. However,

consider the following sentence pair, which differs from (3) by only one word:

(4) Harry put the wallpaper on the wall. Then he put his mug of coffee on the paper.

Many readers will have difficulty integrating these sentences, because this discourse snippet describes an impossible set of circumstances. Realizing this impossibility relies critically on the activation of background knowledge. In this case the knowledge that putting wallpaper on a wall produces a vertical surface which would not support a mug of coffee. Thus, even though (or, rather, because) there are linguistic cues in the second sentence affording integration with the first—the pronoun can be taken to refer to Harry, and paper to wallpaper—this integration of text-derived information does not produce the correct understanding that the described situation is impossible. It is necessary to activate the requisite background knowledge to make this determination. By extension, the requisite background knowledge will help the comprehender construct an adequate representation in (3).

9. Other Functions of Situation Models

Situation models are needed in translation. Word-for-word translations yield nonsense in most cases. In order to arrive at a proper translation, one has to construct a situation model based on the source language and then convey this situation model in the target language.

Situation models are needed to explain learning from text. When we read a newspaper article about a current event, for example a war, we update our situation model of this event. We learn what the status of the actors and objects and their relations is at a new time. We would not learn by simply storing a mental representation of the text itself in long-term memory. In fact, what we know about a current and historical political situation, is usually an amalgam of information obtained from various sources (TV news, newspapers, magazines, encyclopedias, conversations with friends, and so on).

10. The Representational Format of Situation Models

Situation models often have an almost perceptual quality. In the example about the bottle, the first thing we construct is an agent, next is his action, next is the instrument of the action, and subsequently, we see the consequence of the action. There is a debate regarding the perceptual nature of situation models. Traditionally, an amodal propositional format has been proposed for situation models (van Dijk and Kintsch 1983, Kintsch 1998). However, others have proposed perceptual symbols (Barsalou 1999, Glenberg 1997, Johnson-Laird 1983).

In an amodal propositional representation, there is no analog correspondence between the mental representation and its referent. In a perceptual–symbol representation, there is. As a result, perceptual symbols represent more of the perceptual qualities of the referent than do amodal symbols, which are an arbitrary code. One of the major challenges of situation-model research will be to gather empirical evidence that speaks to the distinction between amodal and perceptual symbol systems as the representational format for situation models.

Both amodal and perceptual symbol systems allow for the possibility that information constructed from a text and activated background knowledge from long-term memory have the same representational format, such that they can be integrated quite easily. This is an important quality, because the integration of text-derived information with background knowledge is an essential feature of comprehension.

11. Empirical Evidence

There is a wealth of empirical evidence supporting the notion of a situation model (see Zwaan and Radvansky 1998 for a review). Most of this evidence consists of reaction times collected while people are reading texts. In addition, there is an increasing amount of electrophysiologal evidence (see, for example, Münte et al. 1998). Analyses of reading times, as well as electrophysiological measures suggest that comprehenders have difficulty integrating a new event into the situation model when that event has different situational parameters from the previously described event, for instance when it occurs in a different time frame or involves a new participant. Evidence suggests that ease of integration of an event depends on its relatedness to the evolving situation model on each of the five situational dimensions.

Probe-recognition studies show that the activation levels of concept decrease after a change in situational parameters (e.g., a shift in time, space, participant, or goal structure). For example, people recognize the word 'checked' more quickly after having read 'He checked his watch. A moment later, the doorbell rang' than after 'He checked his watch. An hour later, the doorbell rang.' Thus, the 'here and now' of the narrated situation tends to be more accessible to comprehenders than other information. This, of course, mimics our everyday interaction with the world.

Analyses of memory-retrieval data shows that people tend to store events together in long-term memory based on the time and location at which they occur, the participants they involve, whether they are causally related and whether or not they are part of the same goal-plan structure. There is evidence that

memory retrieval is influenced by a combination of the link strengths between events on the five situational dimensions. It has furthermore been shown that people's long-term memory for text typically reflects the situation that was described; memory representations for the discourse itself are much less resistant to decay or interference.

12. Computational Models

Kintsch (1998) has developed a computational model of text comprehension, the construction-integration model (see also *Text Comprehension: Models in Psychology*). In this model, a network consisting of nodes representing the surface structure, the textbase, and the situation models is successively constructed and integrated in a sequence of cycles. The construction of the network is done by hand. The nodes are propositions (or surface structure elements) and the links between them can be based on a variety of criteria, such as argument overlap, causal relatedness, or other aspects of situational relatedness. Integration occurs computationally by way of a constraint-satisfaction mechanism. Simulations using the construction–integration model have been most successful in (quantitatively) predicting text recall. In addition, the model has been shown to provide qualitative fit with a variety of findings in text comprehension, such as anaphoric resolution and sentence recognition. Similar models have been proposed by other researchers. Like the construction-integration model, these models include aspects of situation-model construction. However, there currently exists no full-fledged computational model of situation-model construction.

13. Beyond Language

Situation models have significance beyond the domain of text comprehension. Researchers are beginning to apply this concept to other domains of cognitive psychology, such as the comprehension of visual media (e.g., movies) and autobiographical memory. In the first case, situation models are acquired vicariously, as in language comprehension, but, in part, on nonlinguistic visual and auditory information. In the second case, they are acquired via direct experience. The question of whether and how the mode of acquisition affects the nature of situation models is a fruitful one.

Skinner, Burrhus Frederick (1904–90)

After J. B. Watson, the founder of the behaviorist movement, Skinner has been the most influential, and also the most controversial figure of behaviorism. His contributions to behavioral sciences are manifold: he designed original laboratory techniques for the study of animal and human behavior, which he put to work to produce new empirical data in the field of learning, and to develop a theory of operant behavior that led him eventually to a general psychological theory; he further elaborated the behaviorist approach, both refining and extending it, in a version of behavioral science which he labeled radical behaviorism; he

formulated seminal proposals for applied fields such as education and therapy and pioneered in machine assisted learning; finally, building upon his conception of the causation of behavior, he ventured into social philosophy, questioning the traditional view of human nature and of the relation of humans to their physical and social environment. This part of his work has been the main source of sometimes violent controversy.

1. Biographical Landmarks

Skinner was born on March 20, 1904 in Susquehanna (Pennsylvania, USA) in a middle-class family and experienced the usual childhood and adolescence of provincial American life. He attended Hamilton College, which was not a particularly stimulant institution to him. He was first attracted by a literary career, which he soon gave up, after traveling to Europe. He turned to psychology, and was admitted at Harvard in 1928. He obtained his Ph.D. in 1931, with a theoretical thesis on the concept of reflex—a first landmark in his reflections on the causation of behavior, an issue he was to pursue throughout his scientific career. He stayed at Harvard five more years, beneficiary of an enviable fellowship, affiliated to the physiology laboratory headed by Crozier. In 1936, he was appointed professor at the University of Minnesota where he developed his conditioning chamber for the study of operant behavior in animals—which was to be known as the Skinner box—and wrote his first book *The Behavior of Organisms* (1938). In 1945, he moved to Indiana University, as Chairman of the Department of Psychology. In 1948, he was offered the prestigious Edgar Pierce Professorship in Psychology at Harvard University, where he was to stay until his death on August 18, 1990.

Skinner received during his lifetime the highest national awards an American psychologist could receive, and he was praised as one of the most prominent psychologists of the century, in spite of harsh attacks against some of his ideas, from the most opposite sides of scientific and lay-people circles.

Although most of Skinner's laboratory research was carried out with animal subjects, mainly rats and pigeons, using the so-called operant procedure that will be described hereafter, essentially he was interested, not in animal behavior proper, but in behavior at large, and more specifically in human behavior. After the tradition of other experimental psychologists before him, such as Pavlov and Thorndike, and of most of his colleagues in the behaviorist school of thought, such as Hull, Tolman, or Guthrie, he resorted to animals as more accessible subjects than humans for basic studies on behavior, just as physiologists used to do quite successfully. The relevance of extrapolating from animals to humans is of course an important issue in psychology. However, Skinner's main concern was obviously with humans, as evidenced by his literary writings in the field of social philosophy—namely the utopian novel *Walden Two* (1948) and the essay, *Beyond Freedom and Dignity* (1971)—as well as by his theoretical endeavors to account for human behavior (*Science and Human Behavior* 1953) and for verbal behavior (*Verbal Behavior* 1957).

2. Operant Conditioning and the Skinner Box

The operant conditioning chamber, often called the Skinner box, is a laboratory device derived from Thorndike's puzzle box and from the mazes familiar to students of learning in rats by the time Skinner started his career. In its most common form, it consists of a closed space in which the animal moves freely; it is equipped with some object that the subject can manipulate easily—be it a lever for rats, or a small illuminated disk upon which pigeons can peck—and with a food dispenser for delivering calibrated quantities of food. By exploring spontaneously this particular environment, eventually with the help of the experimenter in shaping progressively its behavior, the subject will eventually discover the basic relation between a defined response—pressing the lever or pecking the key—and the presentation of a reinforcing stimulus—a small food reward. The basic relation here is between an operant response (i.e., a response instrumental to produce some subsequent event) and its consequence (i.e., the reinforcement), rather than between a stimulus and a response elicited by it, as in Pavlovian or respondent conditioning. This simple situation may be made more complex either by introducing so-called discriminative stimuli, the function of which is not to trigger the response at the manner of a reflex, but to set additional conditions under which the response will be reinforced, or by changing the basic one response-one reinforcement link to some more complicated contingencies, for instance requiring a given number of responses to one reinforcement, or the passing of some defined delay. A wide variety of schedules of reinforcement have been so studied, be it for their own sake as sources of information on the lawfulness of behavior (for instance modern research has applied optimization models borrowed from economics to the study of operant behavior), or as efficient tools for other purposes (such as the analysis of sensory functions in animal psychophysics, of the effects of drugs acting upon the Central Nervous System in experimental psychopharmacology, or of cognitive capacities).

The operant technique presented two important features by the time Skinner developed it from the thirties to the fifties. It emphasized the study of individual subjects through a long period of time rather than groups of subjects for a few sessions, as

used to be the case in maze studies and the like. This interest in individual behavior would favor later applications to human subjects in educational and clinical settings. Second, the operations involved soon were automatized by resorting to electromechanical circuits, to be replaced later by online computer control. This led to a level of efficiency and precision unprecedented in psychological research.

3. *The Evolutionary Analogy*

Skinner captured the essence of operant behavior in the formula 'control of behavior by its consequences,' and very early he pointed to the analogy between the selection of the response by the subsequent event and the mechanism at work in biological evolution. An increasingly large part of his theoretical contributions were eventually devoted to elaborating the evolutionary analogy (Skinner 1987). The generalization of the selectionist model to behavior acquisition at the individual level, initially little more than a metaphoric figure, has recently gained credentials with the theses of neurobiologists, such as Changeux's *Generalised Darwinism* (1983) or Edelman's *Neural Darwinism* (1987), who both have substantiated in ontogeny selective processes previously reserved to phylogeny. One of the main tenets of Skinner's theory converges with contemporary views in neurosciences.

Skinner extended the selectionist explanation to cultural practices and achievements, joining some schools of thought in cultural anthropology and in the history of science, such as Karl Popper's selectionist account of scientific hypotheses.

4. *Radical Behaviorism*

As a behaviorist, Skinner viewed psychology as a branch of natural sciences, more explicitly as a branch of biology, which can deal with its subject matter using the same principles as in other fields of life sciences, be it with specific implementations as required by its particular level of analysis.

Skinner defended a brand of behaviorism quite distinct from the dominant view that prevailed in the second quarter of the century. His radical behaviorism was opposed to methodological behaviorism. For most psychologists, defining their science as the science of behavior, after Watson's recommendation, did not really mean that they had abandoned mental life as the main objective of their inquiry; rather, they had simply resigned themselves to study behavior, because they had to admit that they had no direct access to mental life. Such methodological behaviorism, in fact, remained basically dualistic. In contrast, radical behaviorism is definitely monist, and it rejects any distinction between what is called mental and behavioral. Skinner is, in this respect, closer to Watson's view than to the position of other influent neobehaviorists of his generation, although he developed a far more sophisticated view of behavior than Watson's. For instance, he rejected the simplistic claim that thought is nothing more than subvocal language, and admitted that not all behavior is directly observable. Part of human behavior is obviously private, or covert, and raises difficult methodological problems of accessibility; but this is no reason to give it different status in a scientific analysis.

Skinner vigorously denounced mentalism not so much because it refers to events that would occur in another space and be of a different substance than behavior, but because it offers pseudo-explanations which give the illusion of understanding what in fact remains to be accounted for. Mentalistic explanations, very common in daily life psychology, were still quite frequent in scientific psychology. For example, in the field of motivation, all sorts of behavior were assigned internal needs as causal agents: not only do we eat *because* we are hungry—a simple statement which, at any rate from a scientist's point of view, requires qualification—but we exhibit aggressive behavior because of some aggression drive, we interact with social partners because of a need for affiliation, we work to successful and creative outcomes because of a need for achievement, etc. For Skinner, such explanations dispense us from looking for the variables really responsible for the behavior; these variables are more often than not to be found in the environment, and can be traced to the history of the individuals interacting with their environment, social and physical.

Combining this epistemological conception and the results of his empirical research, Skinner developed a theory of human behavior emphasizing the determining role of environmental contingencies on human actions. However, along the lines of the evolutionary analogy, he suggested a model that would account equally well for novelty and creative behavior, as exhibited in art and science productions, and for stabilized, persistent habits adapted to unchanging conditions.

Skinner devoted special attention to verbal behavior, the importance of which in the human species justified special treatment. He presented his book *Verbal Behavior* as 'an essay in interpretation,' proposing a functional analysis of the verbal exchanges composing the global episode of speaker-listener communication. In spite of the violent criticisms expressed by the linguist Chomsky (1959), Skinner's analysis foreshadowed some aspects of the pragmatic approach adopted some years later by many psycholinguists, aware of the insufficiency of formal grammars to account for central features characterizing the use of language. He viewed verbal behavior as shaped by the linguistic community, and exerting a genuine type of control over an individual's behavior, distinct from the action of the physical environment. A large part of human behavior is, in his terms, rule governed,

that is, controlled by words, rather than shaped by contingencies, that is, through direct exposure to the physical world. Many behaviors can have one or the other origin: avoidance of fire flame can derive from direct experience with fire, or from warnings received during education. Once endowed with verbal behavior, individuals can use it to describe and anticipate their own behavior, or to develop it in its own right, as in literary composition. Were it not for the unfortunate use of the term rule, which makes for confusion with the word as used in formal linguistics and with the notion of coercive control, what Skinner was pointing to was akin to a distinction now familiar to contemporary psychology and neurosciences between top-down vs. bottom-up causation.

5. *Education*

Skinner's interests in applications covered three main areas: education, psychological treatment, and social practices at large. He dealt with the first two in a technical manner, developing principles and techniques for improving educational and therapeutic practices. His treatment of the third one is more akin to social philosophy than to scientific application, although he viewed it as very consistently rooted in his scientific thinking. At a time school education in the US was criticized for its deficiencies and for its inefficiency in competing with technological achievements of the Soviet Union, Skinner, as many other American scientists, inquired into the reasons of that state of affairs. Observing what was going on in any normal classroom, including in reputed schools, he concluded that it was violating blatantly most basic principles of learning derived from laboratory analysis of the learning process. Pupils and students were passively exposed to teachers' monologues rather than actively producing behaviors followed by feedback; there was no attempt to adjust the teacher's actions to individual level and rhythm of learning; negative evaluation based on mistakes and errors prevailed over positive evaluation pointing to progresses achieved; punitive controls, known to be poorly effective in shaping and maintaining complex behavior, was still widely used; general conditions and teaching practices were far from favorable to developing individual talents and creativity. Such criticisms had been made by others, but Skinner differed from them in the analysis of the causes and in the remedies proposed. He did not question the importance of endowing the students with basic knowledge and skills that they need if they are to engage in more complex and original activities. But he thought such skills could be mastered using more efficient methods than those currently in use in the classroom. This was the origin of teaching machines, a term that would raise strong objections on the ground that machines could not lead but to dehumanising teaching. In fact, Skinner's idea has been implemented since then in computer assisted learning, which is now widely accepted—with little reference to the pioneering projects of the behaviorist psychologist. The device he designed in the 1950s appears quite primitive compared with modern computers: it was an electromechanical machine—adapted from a record player—built in such a way that it would present in a window to the student successive small frames of the material to be learned, each frame requiring an active answer from the learner. The latter could learn at his or her own individual rhythm, ideally with no or few errors, and eventually reach the end of the program, with the guarantee that the subject matter had been mastered from end to end. Good programs would make exams useless, if exams are just a way to control that the material has been covered and understood. Most important, student and teachers would not waste the few hours they could work together in tasks easily fulfilled using teaching devices; they could devote the time so spared to more constructive activities requiring direct human contact.

In spite of numerous attacks in educational circles, Skinner's project inspired many applications, such as programmed instruction in book form, until modern computers would offer the elegant solution we know today. It also contributed to the development of individualized teaching approaches that favor methods allowing students to learn at their own pace in an autonomous and active way.

Teaching machines are but one aspect of Skinner's contribution to education. In a number of his writings, including his utopian novel, Skinner (1968, 1978) did express his reflections on educational issues. He was concerned especially with the disproportion between the resources devoted to education and the poor outcomes; with the tendency to level down individual differences; with the increasing distance between the school environment and real life; with violence in schools, and other matters which remain crucial issues today, with little improvement.

6. *Behavior Therapy*

Treatment of psychological disturbances was another field of application to which Skinner (1955, 1989) made influent contributions. By the middle of the twentieth century, psychopathology had elaborated refined descriptive systems of psychological disturbances and equally sophisticated explanatory models such as the psychoanalytic theory. Contrasting with these, methods for treatment were scarce and their results poor. Psychoanalytic treatment had limited indications and practical limitations. Rogers's non-directive therapy, though quite popular, did not provide convincing results. Psychopharmacology was still in the air.

Skinner did not question the classical categorization of mental illnesses, nor did he propose miracle remedies. He simply suggested to look at them as disturbances in behavior, rather than alterations of hypothetical mental structures, such as the psychic apparatus appealed to by psychoanalysis, of which abnormal behavior would be but observable indicators, or symptoms. Consequently, he proposed to attempt to change undesirable behavior by acting directly upon it, rather than upon underlying structures supposedly responsible for it. This approach was not totally new: behavior therapy had its origins in John Broadus Watson's attempts to treat fear in children by resorting to Pavlovian conditioning and in the theoretical work of some neobehaviorists aimed at transposing some psychoanalytical concepts into learning theory models. What Skinner added was his genuine theoretical elaboration, especially based on his antimentalist stand, and techniques of behavior modification drawn from the operant laboratory, supplementing Pavlovian techniques in use up to then. He also brought into the clinical field a sense of rigor transferred from the laboratory, perfectly compatible with the study of single cases.

Skinner did not practice behavior therapy himself. His influence in the field was indirect, by stimulating pioneering research on psychotic patients and mentally deficient people. He gave a decisive impulse to the development of the behavioral approach to treatment, which soon acquired a major position in clinical psychology and counseling, and which eventually merged, somewhat paradoxically, with cognitively oriented practices into what are labeled behavioral-cognitive therapies.

7. *Social Philosophy*

Skinner's social philosophy was based in a deep confidence that only science would help us in solving the problems we are facing in our modern societies. What is needed is a science of behavior, which in fact is now available, he thought, and could be applied if only we would be ready to abandon traditional views of human nature. He first expressed his ideas in the novel *Walden Two* (1948). Written two years after the end of the World War Two, the book describes a utopian community run after the principles derived from the psychological laboratory. It is by no means a totalitarian society, as some critics have claimed. Looked at retrospectively, it is surprisingly premonitory of social issues that are still largely unsolved half a century later. For instance, working schedules at *Walden Two* have been arranged so that all tasks needed for production of goods and good functioning of the community are distributed among members according to a credit system which results in an average amount of 24 hours per week, avoiding unemployment, abolishing any social discrimination between manual and intellectual work, and leaving many free hours for leisure activities such as sports, arts, and scientific research. Emphasis is put on active practice rather than passive watching, on co-operation rather than competition. The community is not isolated culturally: cultural products from outside such as books or records are of course welcome, but radio programs are filtered to eliminate publicity. Education is active; the school building symbolically has no door separating it from the life and work community; there are no age classes, no humiliating ranking; all learn at their own rhythm, in whatever orientation they feel appropriate, throughout their life time. Women enjoy complete equality with men. Waste of natural resources is avoided. Special charges in the management of the community are strictly limited in time, eliminating any risk of political career.

Similar themes, plus the frightening concerns with pollution, violence, uncontrolled population growth, nuclear weapons, and the like, are further elaborated in the essay *Beyond Freedom and Dignity* (1971) and a number of later articles. In an alarming tone, Skinner points to what he feels is the core of our inability to deal with these issues, that is our obstinacy in keeping a conception of human nature which scientific inquiry shows us to be wrong, and which bar any solution to the problems we are confronted with. We still stick to a view of humans as being the center of the universe, free and autonomous, dominating nature, while we are but one among many elements of nature. As a species, we are the product of biological evolution; as cultural groups, the result of our history; and as individuals the outcome of our interactions with the environment. Because we fail to admit this dependency, and draw the consequences of it, we might put in danger our own future. Freedom, autonomy, and merit are no absolute values: they were forged throughout history, and more often than not they are used to disguise insidious controls, the mechanisms of which should be elucidated if we want to develop counter-controls eventually allowing for the survival of our species.

Skinner viewed these various facets of his work as closely related, making for a highly consistent theory of human behavior, in which the critical analysis of social processes in modern society was deeply rooted in the experimental analysis of the behavior of animal subjects in the laboratory. So global an ambition has been criticised, and clearly various aspects of his contribution did not have the same fate. If the operant technique is now a widely used procedure to many purposes in experimental research in psychology and related fields, if his early attempts to build teaching machines appear now as ancestors of computer assisted learning and teaching, if a number of principles of contingencies analysis are now currently put in practice in behavior therapies, radical behaviorism has been seriously questioned and even shaken by the rise of the cognitivist approach in psychology, while

Skinner's social philosophy has been attacked from different fronts both on ideological and scientific grounds.

As most great theory builders of the twentieth century in psychology, from Sigmund Freud and Watson to Jean Piaget, Skinner may be blamed for having reduced the explanation of human nature to a very limited set of concepts and findings, namely those he had forged and observed in his own restricted field of research and reflection, ignoring even other concepts and facts in neighboring fields of psychology, leaving alone of other sciences. It is clear that Skinner has made no attempt at integrating, for example, contributions of developmental or of social psychology, nor those of sociology, cultural anthropology, or linguistics. Such neglects might have been deliberate, legitimated by the will to concentrate on what were, in Skinner's mind, essential points left out by other branches of psychology or other sciences dealing with human societies. However, they might appear as sectarianism to those who favor an integrative and plurisdisciplinary approach to the complex objects of human sciences. It cannot be decided whether his influence would have been larger or smaller had he adopted a less exclusive stand.

Slavery as Social Institution

Slavery is the most extreme form of the relations of domination. It has existed, at some time, in most parts of the world and at all levels of social development. This article examines five aspects of the institution: Its distinguishing features; the means by which persons were enslaved; the means by which owners acquired them; the treatment and condition of slaves; and manumission, or the release from slavery.

1. The Distinctive Features of Slavery

The traditional, and still conventional, approach is to define slavery in legal–economic terms, typically as 'the status or condition of a person over whom any or all the powers attaching to the right of ownership are exercised' (League of Nations 1938, Vol. 6). In this view, the slave is, quintessentially, a human chattel. This definition is problematic because it describes adequately mainly Western and modern, capitalistic systems of slavery. In many nonWestern parts of the world, several categories of persons who were clearly not slaves, such as unmarried women, concubines, debt bondsmen, indentured servants, sometimes serfs, and occasionally children, were bought and sold. Conversely, in many slave-holding societies certain categories of slaves, such as those born in the household, were not treated as chattels.

Slavery is a relation of domination that is distinctive in three respects. First, the power of the master was usually total, if not in law, almost always in practice. Violence was the basis of this power. Even where laws forbade the gratuitous killing of slaves, it was rare for masters to be prosecuted for murdering them, due to the universally recognized right of masters to punish their slaves, and to severe constraints placed on slaves in giving evidence in courts of law against their masters, or free persons generally.

The totality of the master's claims and powers in them meant that slaves could have no claims or powers in other persons or things, except with the master's permission. A major consequence of this was that slaves had no custodial claims in their children; they were genealogical isolates, lacking all recognized rights of ancestry and descent. From this flowed the hereditary nature of their condition. Another distinctive consequence of the master's total power is the fact that slaves were often treated as their surrogates, and hence could perform functions for them as if they were legally present, a valuable trait in premodern societies with advanced commodity production and long-distance trading, such as ancient Rome, where laws of agency, though badly needed, were nonexistent or poorly developed.

Second, slaves were universally considered as outsiders, this being the major difference between them and serfs. They were natally alienated persons, deracinated in the act of their, or their ancestors', enslavement, who were held not to belong to the societies in which they lived, even if they were born there. They lacked all legal or recognized status as independent members of a community. In kin-based societies, this was expressed in their definition as kinless persons; in more advanced, state-based societies, they lacked all claims and rights of citizenship. Because they belonged only to their master, they could not belong to the community; because they were bonded only to their master's household, they could share no recognized bond of loyalty and love with the community at large. The most ancient words for slaves in the Indo-European and several other families of languages translate to mean, 'those who do not belong,' or 'not among the beloved,' in contrast with free members of the community, who were 'among the beloved,' and 'those who belonged.'

Third, slaves were everywhere considered to be dishonored persons. They had no honor that a nonslave person need respect. Masters could violate all aspects of their slaves' lives with impunity, including raping them. In most slave-holding societies, injuries against slaves by third parties were prosecuted, if at all, as injuries against the person and honor of the master. Where an honor-price or *wergild* existed, as in Anglo-Saxon Britain and other Germanic lands, its payment usually went to the master rather than to the injured slave. Universally, slavery was considered the most extreme form of degradation, so much so that the slave's very humanity was often in question.

For all these reasons, there was a general tendency to conceive of slaves symbolically as socially dead persons. Their social death was often represented symbolically in ritual signs and acts of debasement, death and mourning: In clothing, hairstyles, naming practices, and other rituals of obeisance and nonbeing.

2. *The Modes of Enslavement*

Free persons became slaves in one of eight ways: capture in warfare; kidnapping; through tribute and taxation; indebtedness; punishment for crimes; abandonment and sale of children; self-enslavement; and birth. Capture in warfare is generally considered to have been the most important means of acquiring slaves, but this was true mainly of simpler, small-scale societies, and of certain volatile periods among politically centralized groups. Among even moderately advanced premodern societies, the logistics of warfare often made captivity a cumbersome and costly means of enslaving free persons.

Kidnapping differed from captivity in warfare mainly in the fact that enslavement was its main or sole objective, and that it was usually a private act rather than the by-product of communal conflict. Other than birth, kidnapping in the forms of piracy and abduction was perhaps the main form of enslavement in the ancient Near East and the Mediterranean during Greek and Roman times; and this was true also of free persons who were enslaved in the transSaharan and transatlantic slave trades.

Debt bondage, which was common in ancient Greece up to the end of the seventh century BC, the ancient Near East, and in South East Asia down to the twentieth century, could sometimes descend into real slavery, although nearly all societies in which it was practiced distinguished between the two institutions in at least three respects: Debt-bondage was nonhereditary; bondsmen remained members of their community, however diminished; and they maintained certain basic rights, both in relation to the bondholder and to their spouses and children.

Punishment for crimes was a major means of enslavement in small, kin-based societies; China, and to a lesser extent, Korea, were the only advanced societies in which it remained the primary way of becoming a slave. Nonetheless, it persisted as a minor means of enslavement in all slaveholding societies, and became important historically in Europe as the antecedent of imprisonment for the punishment of crimes.

The enslavement of foundlings was common in all politically centralized premodern societies, though rarely found in small-scale slaveholding communities. It was the humane alternative to infanticide and was especially important in China, India, European antiquity, and medieval Europe. It has been argued that

it ranked second to birth as a source of slaves in ancient Rome from as early as the first century CE until the end of the Western empire.

Self-enslavement was rare and was often the consequence of extreme penury or catastrophic loss.

In nearly all slave-holding societies where the institution was of any significance, birth rapidly became the most important means by which persons became slaves, and by which slaves were acquired. Contrary to a common misconception, this was true even of slave societies in which the slave population did not reproduce itself naturally. The fact that births failed to compensate for deaths, or to meet the increased demand for slaves—which was true of most of the slave societies of the New World up to the last decades of the eighteenth century—does not mean that birth did not remain the main source of slaves.

However, the role of birth as a source of slaves was strongly mediated by the rules of status inheritance, which took account of the complications caused by mixed unions between slaves and free persons. There were four main rules.

(a) The child's status was determined by the mother's status only, regardless of the father's status. This was true of most modern and premodern Western slave societies, and of nearly all premodern non-Western groups with matrilineal rules of descent.

(b) Status was determined by the father only, regardless of the mother's status. This unusual pattern was found mainly among certain rigidly patrilineal groups, especially in Africa, where it was the practice among groups such as the Migiurtini Somali, the Margi of northern Nigeria, and among certain Ibo tribes. The practice, however, was not unknown in the West. It was the custom in Homeric Greece and was the norm during the seventeenth century in a few of the North American colonies such as Maryland and Virginia, and in South Africa and the French Antilles up to the 1680s.

(c) Status was determined by the principle of *deterior condicio*, that is, by the mother or father, whoever had the lower status. This was the harshest inheritance rule and was the practice in China from the period of the Han dynasties up to the reforms of the thirteenth and fourteenth centuries. It found its most extreme application in Korea, where it was the dominant mode down to 1731. The rule also applied in Visigothic Spain, and medieval and early modern Tuscany. The only known case in the New World was that of South Carolina in the early eighteenth century.

(d) The fourth principle of slave inheritance, that of *melior condicio*, is in direct contrast with the last mentioned, in that the child inherited the status of the free parent, whatever the gender of the parent, as long as the father acknowledged his paternity. This is the earliest known rule of slave inheritance and may have been the most widely distributed. It was the norm in the ancient Near East and, with the exception of the Tuareg, it became the practice among nearly all Islamic societies. The rule was supported among Muslims by another Koranic prescription and practice: The injunction that a slave woman was to be freed, along with her children, as soon as she bore a son for her master.

The only known cases in Europe of the *melior condicio* rule both emerged during the thirteenth century. In Sweden, it was codified in the laws of Ostergotland and Svealand as part of a general pattern of reforms. In Spain, religion was the decisive factor in the appearance of a modified version of the rule. Baptized children of a Saracen or Jewish owned slave and a Christian were immediately freed. Throughout Latin America, although the legal rule was of the first type—the children of slave women were to become slaves—the widespread custom of concubinage with slave women, coupled with the tendency to recognize and manumit the offspring of such unions, meant that, in practice, a modified version of the *melior condicio* rule prevailed where the free person was the father, which was usually the case with mixed unions.

3. *The Acquisition of Slaves*

Slaves not born to, or inherited by, an owner were acquired mainly through external and internal trading systems; as part of bride and dowry payments; as money; and as gifts. There were five major slave trading systems in world history. The Indian Ocean trade was the oldest, with records dating back to 1580 BC, and persisted down to the twentieth century AD. Slaves from subSaharan Africa were transported to the Middle and Near East as well as Southern Europe. It has been estimated that between the years 800 AD and 1800 approximately 3 million slaves were traded on this route, and over two million were traded during the nineteenth century.

The Black Sea and Mediterranean slave trade supplied slaves to the ancient European empires and flourished from the seventh century BC through the end of the Middle Ages. Over a quarter of a million slaves may have been traded in this system during the first century of our era. The European slave trade prospered from the early ninth century AD to the middle of the twelfth, and was dominated by the Vikings. One of the two main trading routes ran westward across the North Sea; the other ran eastward. Celtic peoples, especially the Irish, were raided and sold in Scandinavia. Most slaves traded on the eastern routes were of Slavic ancestry. It was the Viking raiding, and wide distribution, of Slavic slaves throughout Europe that accounts for the common linguistic root of the term 'slave' in all major European languages.

The transSaharan trade has persisted from the mid-seventh century AD down to the twentieth and involved the trading of subSaharan Africans throughout North Africa and parts of Europe. It has been

estimated that some 6.85 million persons were traded in this system up to the end of the nineteenth century. Although it declined substantially during the twentieth century, largely under European pressure, significant numbers of Africans are still being traded in Sudan and Mauritania.

The transatlantic slave trade was the largest in size and certainly the most extensive of all these systems. The most recent evidence suggests that between the years 1500 and 1870, some 11 million Africans were taken to the Americas. Of the 10.5 million who were forced from Africa between 1650 and 1870, 8.9 million survived the crossing. Although all the maritime West European nations engaged in this trade, the main traders were the British, Portuguese, and French. Four regions account for 80 percent of all slaves going to the New World: the Gold Coast (Ghana), the Bights of Benin and Biafra, and West-Central Africa. Forty percent of all slaves landed in Brazil; and 47 percent in the Caribbean. Although only 7 percent of all slaves who left Africa landed in North America, by 1810 the United States had, nonetheless, one of the largest slave populations due to its unusual success in the reproduction of its slave populations. For the entire three and a half centuries of the Atlantic slave trade, approximately 15 percent of those forced from Africa died on the Atlantic crossing (some 1.5 million) with losses averaging between 6000 and 8000 per year during the peak period between the years 1760 and 1810.

4. *The Treatment of Slaves*

It is difficult to generalize about the treatment of slaves, since this not only varied considerably between societies but also within them. There was no simple correlation of favorable factors. Furthermore, the same factor may operate in favor of slaves in one situation, but against them in the next. Thus, in many small, kin-based societies, slaves were relatively well treated and regarded as junior members of the master's family, but could nonetheless be sacrificed brutally on special occasions. In advanced premodern societies such as Greece and Rome, as well as modern slave societies such as Brazil, slaves in the mines or latifundia suffered horribly short lives, while skilled urban slaves were often virtually free and sometimes even pampered. In the Caribbean, the provision ground system, by which slaves supported themselves, led to high levels of malnutrition compared to the US South, where masters provided nearly all the slaves' provision. Nonetheless, Caribbean slaves cherished the provision ground system for the periods of self-determination and escape from the master's direct control that it offered.

In general, the most important factors influencing the condition of slaves were the uses to which they were put, their mode of acquisition, their location—whether urban or rural—absenteeism of owners, proximity to the master, and the personal characteristics of the slaves. Slaves were acquired for purely economic, prestige, political, administrative, sexual, and ritual purposes. Slaves who worked in mines or in gangs on highly organized farming systems were often far worse off than those who were employed in some skilled craft in urban regions, especially where the latter were allowed to hire themselves out independently. Slaves acquired for military or administrative purposes, as was often the case in the Islamic world—the Janissaries and Mameluks being the classic examples—were clearly at an advantage when compared with lowly field hands or concubines. Newly bought slaves, especially those who grew up as free persons and were new to their masters' society, usually led more wretched lives than those born to their owners. High levels of absenteeism among owners—which was true of the owners of slave latifundia in ancient Rome as well as the Caribbean slave societies and some parts of Latin America—often meant ill-usage by managers and overseers paid on a commission basis.

Proximity to the master cut both ways with respect to the treatment of slaves. Slaves in the household were usually materially better off, and in some cases close ties developed between masters and these slaves, such as those between masters and their former nannies, or with a favored concubine. However, proximity meant more sustained and direct supervision, which might easily become brutal.

Ethnic and somatic or perceived racial differences between masters and slaves operated in complex ways. Intra-ethnic slavery was uncommon in world history, although by no means nonexistent, while that between peoples of different perceived 'racial' groups was frequent. The common view that New World slavery was distinctive in that masters and slaves belonged to different perceived races is incorrect. Where there were somatic differences, the treatment of the slave depended on how these differences were perceived and, independently of this, how attractive the slave was in the eyes of the master. Scandinavian women were prized in the slave harems of many Islamic Sultans, but so were attractive Ethiopian and subSaharan women. Furthermore, in Muslim India and eighteenth-century England and France, dark-skinned slaves were the most favored, especially as young pages. In the New World, on the other hand, mulatto and other light-skinned female slaves were often better treated than their more African-looking counterparts.

Two other factors should be mentioned in considering the treatment of slaves: Laws and religion. Slightly more than a half of all slave societies on which data exist had some kind of slave laws, in some cases elaborate servile codes, the oldest known being those of ancient Mesopotamia. Slightly less than a half had none. Laws did make a difference; a much higher proportion of societies without any slave codes tended to treat slaves harshly. Nonetheless, the effectiveness

of laws were mediated by other factors such as the relative size of the slave population, and religion.

The degree to which religion, especially Islam and Christianity, influenced the treatment of slaves is a controversial subject. Islam had explicit injunctions for the treatment of slaves, and these were sometimes influential, especially those relating to manumission. Although racism and strong preference for light complexion were found throughout the Islamic lands, it is nonetheless the case that Islam as a creed has been more assimilative and universalist than any other of the world religions, and has rarely been implicated in egregiously racist movements similar to those that have tarnished the history of Christianity such as apartheid, the Ku Klux Klan, Southern Christianity during the era of segregation, and the ethnic cleansing of Eastern Europe. However, Islam never developed any movement for abolition, and, in general, strongly supported the institution of slavery, especially as a means of winning converts.

For most of its history up to the end of the eighteenth century, Christianity simply took slavery for granted, had little to say about the treatment of slaves, and generally urged slaves to obey their masters. This changed radically with the rise of evangelical Christianity in the late eighteenth and early nineteenth centuries, during which it played a critical role in the abolition of both the slave trade and of slavery in Europe and the Americas. Throughout the world, Christianity appealed strongly to slaves and ex-slave populations, and in the Americas their descendants are among the most devout Christians. While Christianity may have had conservative influences on converted slaves, it is also the case that nearly all the major slave revolts from the late eighteenth century were influenced strongly by rebel leaders, such as Daddy Sharp in Jamaica and Nat Turner in America, who interpreted the faith in radical terms, or by leaders of syncretic Afro-Christian religions.

5. *Manumission as an Integral Element of Slavery*

With a few notable exceptions, manumission, the release from slavery, was an integral and necessary element of the institution wherever it became important. The reason for this is that it solved the incentive problem implicit in slavery. The promise of redemption proved to be the most important way of motivating the slaves to work assiduously on their masters' behalf.

Slaves were manumitted in a wide variety of ways, the most important being: Self-purchase or purchase by others, usually free relatives; through the post-mortem or testamentary mode; through cohabitation or sexual relations; through adoption; through political means or by the state; and by various ritual or sacral means. Self-purchase or purchase by relatives or friends of the slave into freedom was by far the most important means in the advanced slave economies of Greece and Rome, and in the modern capitalistic slave regimes. However, it was not the most widespread in other kinds of slave systems, and in parts of the world such as Africa it was uncommon. Post-mortem manumission by wills and other means was common in Islamic lands and in many parts of Africa. This form of manumission was usually intimately linked to religious practices and with expectations of religious returns for what was often defined as an act of piety.

As indicated earlier, in many slave societies slave concubines sometimes gained their freedom for themselves and their children from the master. Manumission by the state for acts of heroism or for military action was an important, though episodic, form of manumission not only in the ancient world, but in many New World slave societies. Thousands of slaves gained their freedom in this way, not only in Latin America, but also in North America during the American war of independence and in wars against Spain in the southern USA. Manumission by adoption was unusual, but in certain societies, such as ancient Rome, it constituted the most complete form of release from slavery.

Slaves were sometimes manumitted for ritual or religious reasons, or on special celebratory occasions. Although thousands of slaves were manumitted at Delphi, ostensibly by being sold to Apollo, such manumissions had become merely legal formalism by the second century BC, although the practice may have harked back to an earlier era when they were genuinely religious in character. In other societies, religious or ritual manumissions were often substitutes for earlier practices in which slaves were sacrificed. Since manumission meant the negation of slavery, for many peoples, freeing slaves was symbolically identical to killing them. Such practices were common in some parts of Africa and the Pacific islands, and among some indigenous tribes of the Northwest Coast of America slaves were either killed or given away in potlatch ceremonies. There is an extension of this primitive symbolic logic in Christianity, where Christ's sacrificial death is interpreted as a substitute for the redemption of mankind from enslavement to sin and eternal death, 'redemption' (from Latin *redemptio*) literally meaning 'to purchase someone out of slavery.'

In all slave societies, certain categories of slave were more likely to be manumitted than others. The most important factors explaining the incidence of manumission were: Gender, the status of parents, age, skill, residence and location, the means of acquisition and, where relevant, skin color. These factors are similar to those influencing the treatment of slaves and will not be discussed further.

They were also important in explaining varying rates between societies. Thus societies with relatively higher proportions of skilled slaves, a greater location

of slaves in urban areas, higher ratios of female to male slaves, and higher rates of concubinage between masters and slaves were more likely to have higher rates of manumission than those with lower levels of these attributes. Added to this is another critical variable: The availability of slaves, either internally or externally, to replace manumitted slaves. As long as such sources existed and the replacement value of the manumitted slave was less than the price of manumission, it suited slave-owners to manumit slaves, especially when the manumitted slaves were nearing, or had already reached, the end of their useful life.

However, on rare occasions the supply of slaves was cut off when demand remained high or was on the increase. This always resulted in very low rates of manumission. The most striking such case in the history of slavery was the US South, where the rise of cotton-based, capitalistic slavery in the early nineteenth century came within a few years of the termination of the Atlantic slave trade to America. Planters responded by reducing the manumission rate to near zero. A similar situation, though not as extreme, developed in the Spanish islands of the Caribbean during the nineteenth century, when the plantation system developed in the context of British enforcement of the abolition of the slave trade in the region. The result was that previously high rates of manumission plunged to very low rates.

A final point concerns the status of freed persons. This varied considerably across slave societies and bore little relation to the rate of manumission. Thus manumission rates were high in the Dutch colonies of Curaçao and in nineteenth-century Louisiana, but the condition of freedmen was wretched. Conversely, in the British Caribbean, where manumission rates were low, the condition of freedmen was relatively good, some groups achieving full civil liberties before the end of slavery. The main factor explaining the difference in treatment was the availability of economic opportunities for freedmen, and the extent to which the dominant planter class needed them as allies against the slaves. In the Caribbean, the small proportion of slaveholders and Europeans and the existence of a vast and rebellious slave population gave much political leverage to the small but important freed population. No such conditions existed in the United States, where the free and white population greatly outnumbered the slaves, and conditions for rebellion were severely restricted. In the ancient world, ethnic barriers meant generally low status and few opportunities for the manumitted in the Greek states, in contrast with Rome, where cultural and economic factors favored the growth and prosperity of a large freedmen class, a class that eventually came to dominate Rome demographically and culturally, with major implications for Western civilization.

Slavery: Comparative Aspects

In the comparative study of slavery it is important to distinguish between slave holding societies and large-scale, or what Moses Finley called 'genuine,' slave societies (Finley 1968). The former refers to any society in which slavery exists as a recognized institution, regardless of its structural significance. Genuine slave societies belong to that subset of slave holding societies in which important groups and social processes become heavily dependent on the institution.

The institution of slavery goes back to the dawn of human history. It remained important down to the late nineteenth century, and persisted as a significant mode of labor exploitation in some Islamic lands as late as the second half of the twentieth century. Remnants of it are still to be found in the twenty-first century in a few areas. Yet it was only in a minority of cases that it metastasized socially into genuine slave societies, though in far more than the five cases erroneously claimed by Keith Hopkins (1978). Thus, the institution existed throughout the ancient Mediterranean, but only in Greece and Rome (and, possibly, Carthage) did genuine slave societies emerge. It was found in every advanced precapitalist society of Asia, but only in Korea did it develop into large-scale slavery. All Islamic societies had slavery, but in only a few did there emerge structural dependence on the institution. In all, there were approximately 50 cases of large-scale slavery in the precapitalist world. With the rise of the modern world, slavery became the basis of a brutally efficient variant of capitalism. There were at least 40 such cases, counting the Caribbean slave colonies as separate units (for the most complete list, see Patterson 1982, App. C)

This article examines two sets of problems. The first concerns those factors associated with the presence of institutionalized slaveholding. The critical question here is: why is the institution present in some societies yet not in other, apparently similar, ones? The second set of problems begins with the assumption that slavery exists, and attempts to account for the growth in significance of slavery. More specifically, such studies attempt to explain the origins, structure, dynamics, and consequences of genuine slave societies.

1. Comparative Approaches to Slaveholding Societies

There is now a vast and growing body of literature on slavery (Patterson 1977a, Miller 1993, Miller and Holloran 2000). Yet, with the notable exception of certain anthropological studies (to be considered shortly) relatively few recent works are truly comparative in that they aim to arrive at general conclusions about the incidence, nature, and dynamics of slavery. Even those few works that compare two slaveholding societies tend to be concerned more with highlighting, through contrast, the distinctive features of the societies under consideration. This highly particularistic trend marks a regrettable departure from earlier studies of slavery.

The evolutionists of the nineteenth century were the first to offer explanations for the presence of slaveholding. Their basic proposition—that there was a close relationship between stages of socioeconomic development and the rise of slavery—has received no support from modern comparative studies (Pryor 1977). However, some of their less grandiose views have survived later scrutiny. One was their emphasis on warfare, and the demand for labor at certain crucial points in their scales of development as the important factors (Biot 1840, Westermarck 1908). The other was their finding that the socioeconomic role of women was critical. It was claimed, for example, that the subjection of women provided both a social and an economic model for the enslavement of men (Biot 1840, Tourmagne 1880).

The most important of the early-twentieth-century theorists was H. J. Nieboer (1910), who broke with the evolutionists with his open-resource theory. His work, which is still influential, was unusual also in its reliance on statistical data. His main hypothesis was that slavery existed to a significant degree only where land or some other crucial resource existed in abundance relative to labor. In such situations, free persons cannot be induced to work for others, so they must be forced to do so. The theory has had lasting appeal, especially for economic historians, since it is both testable and consistent with marginal utility theory. It was revived by Baks (1966) and by the MIT economist, Domar (1970). However, the theory has been shown to have little empirical support from modern cross-cultural data (Patterson 1977b, Pryor 1977); and Engerman (1973) has questioned seriously its theoretical consistency.

In the course of criticizing Nieboer, Siegel (1945) proffered a functionalist theory which claimed that chattel slavery may be expected to occur in those societies where there is a tendency to reinforce autocratic rule by means of wealth symbols, and where the process results in a rather strongly demarcated class structure. There is little empirical support for this theory, and it verges on circularity. In many premodern hierarchical societies with wealth symbols, it was slavery which was the main cause of increased stratification.

The best recent comparative work on slavery has come from historical anthropologists studying Africa. Meillassoux (1975, 1991) and his associates have

demonstrated ably from their studies of West Africa and the Sahel just how valuable a nondogmatic Marxian approach can be in understanding the dynamics of trade, ethnicity, status, and mode of production in complex lineage-based societies. The anthropologist Jack Goody (1980), drawing on Baks (1966), began by arguing that 'slavery involves external as well as internal inequality, an unequal balance of power between peoples.' From this unpromising start he enriches his analysis with both the ethnohistorical data on Africa and the cross-cultural statistical data from the Murdock Ethnographic Atlas. Central to his analysis is the role of women. The complex facts of slavery cannot be explained, he argues, 'except by seeing the role of slaves as related to sex and reproduction as well as to farm and production, and in the case of eunuchs, to power and its non-proliferation.' While being valuable, Goody's arguments are confined to Africa, and even with respect to this continent they are insufficient to explain why it was that some African societies came to rely so heavily on the institution while closely related neighboring groups did not.

The economist Frederic Pryor (1977) has come closest to formulating a general theory of premodern slavery using modern statistical techniques applied to cross-cultural data. He distinguishes between social and economic slavery, and argues that different factors explain the presence of one or the other. Central to his theory is the nineteenth-century idea that there is a correspondence or 'homologism' between male domination of women and masters' domination of slaves. He tried to demonstrate that economic slavery was most likely to occur 'in societies where women normally perform most of the work so that the slave and the wife act as substitutes for each other,' whereas social slavery was related to 'the role of the wife in a polygynous situation.' The theory is interesting and robustly argued but is problematic. Where women dominated the labor force there was no need for men to acquire slaves for economic purposes. On the contrary, it was precisely in such situations that slaves, when used at all, were acquired for social purposes. The presumed correspondence between wives and slaves is also questionable. There were profound differences between these two roles. Wives everywhere belonged to their communities, and were intimately kin-bound, whereas slaves everywhere were deracinated and kinless. Wives always had some rights, some power, at least in the protection of their kinsmen, in relation to their husbands and could rarely be killed with impunity, which was not true of slaves. Wives everywhere had honor, while slaves had none.

Far more comparative work is needed for an understanding of the institutionalization of slavery. The main variables involved in any explanation are now well known. They are: The economic and social role of women; polygyny; internal and external warfare; the mode of subsistence (mainly whether pastoral or agricultural); and the mode of political succession. However, the causal role and direction of each of these variables is complex, and their interaction with each other even more so. To take the role of women as an example, in some cases it is their role as producers that is important; in others, their role as reproducers. It is also difficult using static cross-cultural data to ascertain whether low female participation in production is the result of slavery or its cause.

2. *Approaches to the Study of Genuine Slave Societies*

Marxist scholars were the first to take seriously the problem of the origins, nature, and dynamics of large-scale slavery (for a review, see Patterson 1977a). Engels's (1962) periodization view that large-scale slavery constituted an inevitable stage in the development of all human societies was merely one version of nineteenth-century evolutionism, discussed earlier. It dominated East European thought until the deStalinization movement, and is still the orthodox view in mainland China.

More sophisticated, but no less problematic, have been attempts of modern Marxists to formulate a 'slave mode of production.' The most empirically grounded of these attempts is that of Perry Anderson (1974) who argued that 'the slave mode of production was the decisive invention of the Graeco-Roman world, which provided the ultimate basis both of its accomplishments and its eclipse.' There is now no longer any doubt that slavery was foundational for both Athens and Rome, and that these were the first societies in which large-scale or genuine slavery emerged. However, the concept of the 'slave mode of production' overemphasizes the materialistic aspects of slavery, making it of limited value for the comparative study of slavery. Slaves were indeed sometimes used to generate new economic systems—as in Rome and the modern plantation economies—but there are many cases where, even when used on a large scale, there was nothing innovative or distinctive about the economic structure. The narrow materialist focus not only leads to a misunderstanding of the relationship between slavery and technology in the ancient world, but more seriously, it fails to identify major differences between the Greek and Roman cases, and it is of no value in the study of genuine slave societies in which the structurally important role of slaves was noneconomic, as was true of most of the Islamic slave systems.

Several non-Marxist historical sociologists, drawing also on the experience of ancient Europe, have made important contributions to our understanding of genuine slave societies. According to Weber (1964) slavery on a large scale was possible only under three conditions: '(a) where it has been possible to maintain slaves very cheaply; (b) where there has been an

opportunity for regular recruitment through a well-supplied slave market; (c) in agricultural production on a large scale of the plantation type, or in very simple industrial processes.' However suggestive, there is little support for these generalizations from the comparative data. Medieval Korea (Salem 1978) and the US South (Fogel and Engerman 1974) disprove (a) and (b). And work on urban slavery in the modern world as well as the relationship between slavery and technology in the ancient world disprove (c) (Finley 1973).

Finley (1960, 1973, 1981) was the first scholar to grapple seriously with the problem of defining genuine slave societies, which he explicitly did not confine to those in which the slaves were economically important. He also cautioned correctly against too great a reliance on numbers in accounting for such societies. His emphasis on the slave as a deracinated outsider led him to the conclusion that what was most advantageous about slaves was their flexibility, and their potential as tools of change for the slaveholder class. Finlay also offered valuable pointers in his analyses of the relationship between slave and other forms of involuntary labor. And in criticizing Keith Hopkins's (1978) conquest theory of the emergence of genuine slave societies, persuasively he encouraged an emphasis on demand, as opposed to supply factors in the rise of slave society. Romans, he argued, captured many thousands of slaves during the Italian and Punic wars because a demand for them already existed and 'not the other way around.' He postulated three conditions for the existence of this demand: private ownership of land, and some concentration of holdings; 'a sufficient development of commodity production of markets'; and 'the unavailability of an internal labor supply.'

3. *A Framework for the Study of Slave Societies*

It is useful to approach the comparative study of slave society with an understanding of what structural dependence means. There are three fundamental questions. First, what was the *nature* of the dependence on slavery; second, what was the *degree* of dependence; and third, what was the *direction* of dependence. Answers to these three questions together determine what may be called the *modes of articulation* of slavery.

The nature of dependence on slavery may have been primarily economic or social, political or militaristic, or a combination of these. Economic dependence was frequently the case, especially in ancient Rome and in the modern capitalistic slave systems. Here the critical questions are: What were the costs and benefits of imposing and maintaining an economy based on slave labor? Stanley Engerman (1973) has written authoritatively on this subject. He distinguishes between the costs of imposition, of enforcement, and of worker productivity. Lower maintenance costs, more constant supply of labor, greater output due to the neglect of the non-pecuniary costs of labor, higher participation rates and greater labor intensity, and economies of scale, are the main factors proposed by Engerman in explaining the shift to slave labor. They apply as much to ancient Rome as they do to the modern capitalistic slave systems of America and the Caribbean.

Military and bureaucratic dependence were the main noneconomic forms, and they could be as decisive for societies as was economic dependence. The rise of Islam was made possible by the reliance on slave soldiers, and the Abbasid Caliphate, along with other Islamic states, was maintained by slave and ex-slave soldiers and bureaucrats. Although there was little economic dependence on slaves in most Islamic states—with the notable exception of ninth-century Iraq—many of them qualify as genuine slave societies as a result of the politico-military dependence of these regimes on slavery, and the ways in which slaves influenced the character of their cultures, many of the literati also being slaves or descendants of slaves (see Pipes 1981, Crone 1981, Marmon 1999).

The degree of dependence must be taken into account, although it is sometimes difficult to quantify. There has been a tendency to emphasize the size of the slave population over other variables, and while demography is important it can sometimes be misleading. Thus, it has been noted that no more than one in three adults were slaves in Athens at the height of its slave system in the late fifth century BCE as a way of playing down the importance of slavery. But as M. I. Finley liked to point out, the same was true of most parts of the American Slave South, and no one has ever questioned the fact that it was a large-scale slave system.

Finally, there is the direction of dependence. Even where a society had a high functional dependence on slavery it was not necessarily the case that slavery played an active, causal role in the development of its distinctive character. The institution, though important, was not structurally transformative. In ancient Rome, the Sokoto Caliphate and the slave societies of the Caribbean, the American South and Brazil, slavery was *actively articulated* and transformative. In other cases, however, it was *passively articulated*, the classic instance being Korea during the Koryo and Yi periods where, although a majority of the rural population were at times slaves, there was no significant transformation of the economy, and no impact on the regime's government and culture. The same was true of several of the modern Spanish colonies of Central and South America. During the sixteenth and seventeenth centuries there was marked structural dependence on slavery in Mexico and Central America as well as Peru, and the urban areas of Chile and Argentina, but the institution was not determinative in the course of development of these societies and, as in Korea, when slavery ended it left hardly a trace, either

cultural or social (Mellafe 1975, Palmer 1976, Klein 1986, Blackburn 1997).

These three factors together determined a finite set of modes of articulation, which is a sociologically more useful construct than that of the so-called 'slave mode of production.' Space permits only the most cursory mention of some of the most important such modes of articulation.

The *lineage mode of articulation* refers to those kin-based societies in which large-scale slavery was related critically to the rise to dominance of certain lineages in the process of class and state formation. In some cases, slavery originally served primarily economic ends; in others, mainly social and political ones; but in the majority the institution became multifunctional. This kind of genuine slave society was most commonly found in western and west-central Africa. Warfare, combined with some critical internal factor such as demographic change accounted for the rise of slavery (see Miller 1977 for the Kongo kingdom). The ideal case of this mode of articulation was the Asante state (Wilks 1975, Klein 1981). Slaves were originally incorporated as a means of expanding the number of dependents, a tendency reinforced by the matrilineal principle of descent. The growing number of slaves enhanced the lineage heads who owned them, and facilitated the process of lineage hierarchy and state formation. Later, the role of slaves was greatly expanded to include a wide range of economic activities, including mining.

The *predatory circulation mode* refers to those slave societies in which warfare and raiding mainly for slaves were the chief occupations of a highly predatory elite. The warrior class was usually assisted by a commercial class which traded heavily in slaves. There was usually a high rate of manumission of slaves, who not only contributed to the production of goods, but in their role as freedmen soldiers helped the ruling class to produce more slaves. Thus there was a continuous circulation of persons in and out of slave status as outsiders were incorporated as loyal freedmen retainers, creating a constant need for more enslaved outsiders. Slaves and freedmen often played key roles in, and sometimes even dominated, the palatine service and elite executive jobs.

The contiguous existence of pastoral and sedentary agricultural peoples with different levels of military might was the major factor in the development of this mode of articulation of slavery. The mode is strongly associated with Islam, and there are many examples of it in the Sahel and North Africa. The west–east spread of the Fulani over an area of some 3,000 miles over a period of 800 years provides one of the best cases of this mode, on which there is an abundance of historical and anthropological data (Lovejoy 2000, Pipes 1981, Meillassoux 1975, 1991).

The *embedded demesne mode* embraces those patrimonial systems dominated by large landed estates in which slaves were incorporated on a substantial scale to cultivate the demesne land of the lords. Serf or tenant laborers continued, in most cases, to be the primary producers of food for the society, and their rents or appropriated surpluses remained a major source of wealth for the ruling class. However, slaves were found to be a more productive form of labor on the home farms of the lords for the cost–benefit reasons analyzed by Engerman, mentioned above. The landowners got the best of both types of labor exploitation. This was a particularly valuable arrangement where a landed aristocracy needed to change to a new crop but was not prepared to contest the technical conservatism of serfs; where there was a supply of cheap labor across the border; or where there was a high level of internal absenteeism among the landed aristocracy.

This is the least understood or recognized form of advanced slave systems, perhaps because its mode of articulation was usually passive. Many of them were to be found in medieval Europe, especially in France, Spain, and parts of Scandinavia (Dockes 1982, Verlinden 1955, 1977, Bonassie 1985, Anderson 1974, Patterson 1991). The slave systems of the western 'states' of eleventh-century England, where slave populations were as high as 20 percent of the total are likely examples. So, possibly, was Viking Iceland, which may well have had similar proportions of slaves (Williams 1937, Foote and Wilson 1970). However, the ideal case of embedded demesne slavery was to be found in Korea, especially during the Koryo and early Yi periods. Here the slave population sometimes exceeded that of other forms of bonded labor (Salem 1978, Wagner 1974, Hong 1979).

The *urban–industrial modes* of articulation were those in which the urban elites came to rely heavily on slaves for support. Slaves played a relatively minor role in agriculture, although they may well have dominated the 'home farms' of certain segments of the ruling urban elites. Slave labor was concentrated in urban craft industries which produced goods for local consumption and exports, as well as the mining sector where it existed.

Slavery emerged on a large scale in such systems as a result of a combination of factors among which were the changing nature and frequency of warfare, conquest of foreign lands, the changing tastes of the ruling class, crises in the internal supply of labor, shifts in food staples, growing commercial links with the outside world, and demographic changes.

This mode of articulation could be either passive or active. To the extent that the character of the urban civilization depended on its urban economy, and to the extent that the economy depended on slave laborers, both manual and technical, to that degree were these systems active in their articulation. The classic case of the active mode of slave articulation were the ancient Greek slave systems, especially Athens of the fifth and fourth centuries BC (Finley 1981, Garlan 1982, De Ste. Croix 1981). Typical of the

passive mode of urban–industrial articulation were several of the Spanish slave systems of Central and South America during the sixteenth and seventeenth centuries, mentioned above.

The *Roman or urban–latifundic mode*: ancient Roman slavery stands in a class by itself, having no real parallels in either the ancient, medieval, or modern worlds. It came the closest to a system of total slavery in world history. It was distinctive, first, in the sheer magnitude of its imperial power and the degree of dependence on slavery, both at the imperial center and in its major colonial sectors. Second, Rome was unique in the extent of its reliance on slavery in both its rural and urban–industrial sectors. Third, the articulation of slavery was more actively transformative than in any other system, entailing what Hopkins (1978) called an 'extrusion' of free, small farmers and their replacement by slaves organized in gangs on large latifundi. Rome was unusual too, not only for its high levels of manumission, but for the extent to which slaves and slavery came to influence all aspects of its culture.

The *capitalist plantation mode*: contrary to the views of early economic theorists such as Adam Smith, and of Marxist scholars until fairly recently (Genovese 1965), modern plantation slavery was in no way incompatible with capitalism. Indeed, the rise of capitalism was intimately bound up with this mode of articulation of slavery, and at its height in nineteenth-century America was as profitable as the most advanced industrial factories of Europe or the northern United States (Fogel and Engerman 1974). Plantation slavery constituted one version of the worldwide systemic spread of capitalism, in which capital accumulation was advanced through the use of slaves in the peripheral colonial regions, complementing the use of so-called free labor in the metropolitan centers, and of serf and other forms of dependent labor in the semi-peripheral areas of Eastern Europe and Latin America (Wallerstein 1974, Blackburn 1997).

While plantation slavery bore some organizational resemblance to the ancient slave latifundia, and indeed can be traced historically to late medieval and early modern variants of the ancient model (see Solow 1991), it was distinctive in its complex, transnational system of financial support, in its production for international export, its heavy reliance on a single crop, its advanced organizational structure, which in the case of sugar involved innovative agri-industrial farms, in the vast distances from which slaves were imported, entailing a complex transoceanic slave-trading system, and in its reliance on slaves from one major geographic region who differed sharply from the slaveholding class in ethnosomatic terms.

However, it is important to recognize that there existed concurrently with the capitalistic plantation mode several other modes of slave articulation that were either precapitalist or at best protocapitalist. As has already been noted, many of the Spanish colonial systems in the Americas relied on forms of slavery that were nonaccumulative and distinctly premodern in their articulation, for example the urban–industrial modes of Mexico and parts of South America which were focused heavily on mining. In the Spanish Caribbean up to the third quarter of the eighteenth century a peculiar premodern form of agri-pastoral slavery prevailed which had little in common with the highly capitalistic slave plantation systems of the neighboring French and British islands, and which had to be dismantled at considerable political and socioeconomic cost in order to make way for the belated capitalistic slave systems that were imposed forcefully during the nineteenth century (Knight 1970).

While slavery was largely abolished in the Americas through the course of the nineteenth century (Blackburn 1988, Davis 1975), pockets of the institution persist into the twenty-first century in northern Africa and parts of Asia (Stearman 1999). With the possible exception of Mauritania, however, in none of these societies do we find genuine slave systems. It can be claimed, with cautious optimism, that this most inhuman form of societal organization has vanished from the world.

O. Patterson

Slaves/Slavery, History of

Slavery comes in many culturally specific forms. Common to all these different forms is the fact that slaves are denied the most basic rights. Slaves remain outside the social contract that binds the other members of a given society; they are people without honor and kin, subject to violent domination. They are objects of the law, not its subjects, considered as property, or chattel. Hence, we may describe slavery with Orlando Patterson as a form of 'social death,' and slaves as outsiders kept in a position of institutionalized marginality. In many languages, the term for foreigner also denoted slaves. Nowadays slavery is considered a most inhumane practice. The United Nations Universal Declaration of Human Rights proclaims: 'No one shall be held in slavery or servitude; slavery and the slave trade shall be prohibited in all their forms.' Signing the slavery conventions of 1926 and 1956, 122 states have committed themselves to abolish slavery and similar practices such as debt bondage, serfdom, servile marriage, and child labor.

In historical times, however, slavery as an institution was accepted in many societies with a minimum of social stratification all over the world, from early Mesopotamia and Pharaonic Egypt to ancient China, Korea, India, medieval Germany, and Muscovite Russia, from the Hebrews to the Aztecs and Cherokees. Yet, according to Moses Finley there were only five full-fledged slave societies with slaves constituting the majority of people and their work determining the whole economy. All five were located in what we tend to call the West, two in antiquity: Athenian Greece and Rome between the second century BC and the fourth century AD, three in modern times: Brazil, the Caribbean, and the southern US. The Ottoman Empire was notorious for its slave soldiers, the janissary, taken from its Slavic neighbors to the north and from Africa. The most exploitative form of chattel slavery emerged in the plantation economies of the New World under the aegis of European colonial rule with the UK playing a dominant role. Interestingly, this happened at the time when the medieval concept of labor as a common community resource was progressively replaced by a free labor regime in the UK. Ultimately, and for the first time in history, employer and employed in Europe were equal before the law, while slavery with its extreme status differential prevailed in the new world. The ensuing contradictions eventually led to the rise of an abolitionist movement in Europe and to the progressive banning of slavery in the nineteenth and twentieth centuries.

The last to make slavery illegal were the governments on the Arabian Peninsula. They did so in 1962.

Where there are slaves, there are people arguing about slavery, some rationalizing it, others denouncing it, and yet others to better demarcate the duties and rights of those involved. There is an extensive Islamic literature about slavery, paying particular attention to the question of who may, and who may not, be enslaved, to the duties of slave owners and the terms of manumission. Many classical and Christian authors dealt with the same problems. The abolitionist movement generated a literature of its own, stressing the horrors of slavery as in 'Oronooko,' the justly famous play by Aphra Behn, and the life narrative of Olaudah Equiano, who was taken captive as a child in his native Igbo village in what is now Nigeria. A common aspect of all these contributions written by contemporaries is their normative approach, based either in religion or moral philosophy, their focus on institutional and legal matters, and not the least on their reliance on anecdotal evidence and personal experience. In ancient Greece and in Rome, slaves were perceived as captives of war even when bought and defined as things until the Code of Justinian defined slaves as persons. Christian and Islamic thought highlighted religious difference. Slavery was primarily the fate of non-believers taken captive in 'just' wars. Yet, neither Christianity nor Islam prevented the enslavement of coreligionists, and if conversion obliged Islamic slave owners to manumit their slaves, it did not change the slaves' status in Christian societies. Later authors rather emphasized property relations. The same line of argument informs the 1926 League of Nations slavery convention which defines slavery as the 'status or condition of a person over whom any or all the powers attaching to the right of ownership are exercised.'

European and American scholars pioneered the historical study of slavery. Taking their cues from Greece, Rome, and medieval European experiences, they tended to interpret slavery as an intermediate stage in the general process of historical development. G. W. F. Hegel construed slavery as a sort of development aid for the benefit of Africans. Classical social sciences from Adam Smith to Max Weber identified slavery with backwardness. Marxist thinkers were even more explicit, positing primitive society, slavery, feudalism, capitalism, and communism as five consecutive stages of world history. Thus, slavery and capitalism, slavery and markets, and slavery and technological innovations were considered utterly incompatible. How then can one explain the rise of racial slavery in the plantation economies of the New World? From about 1500 to the late nineteenth century Portuguese, British, Dutch, French, Danish, Spanish, and American vessels carried some 12 million plus Africans across the Atlantic to be used mainly as field hands for the production of sugar, coffee, tobacco, rice, indigo, and cotton. Others were put to work in the gold and silver mines of Spanish America. Together they constituted by far the largest forced migration the world has known. Moreover, how should one interpret slavery in the South of the US, the first modern nation, if it is in opposition to capitalist logic?

Studies of US and West Indian slavery have dominated the field of slave studies from its very beginning. They set the agenda for research into other domains, such as: the transatlantic slave trade and its precedents in the Mediterranean and the Black Sea during the Middle Ages and the Renaissance. In the Italian city-states slaves were common until the fourteenth century, on the Iberian Peninsula up to the sixteenth century, many of them Moslems. Christian sailors, captured on the seas, ended up in North African slavery. Later, researchers shifted their attention to plantation slavery in other areas of the New World, and finally to slavery in various non-Western societies.

In the beginning, scholars studying Southern slavery followed an institutional approach, describing plantation slavery as a closed system of generalized violence and totalitarian control with dehumanizing effects similar to Nazi concentration camps. Slaves in these pioneering interpretations were victims, devoid of any power and will of their own. All the power was said to be vested in the slave owners who treated their slaves as mere chattel; whipping them into submission and keeping them at starvation level, even working them to death; denying them any family life and breeding them like cattle, buying and selling the slaves at their will and pleasure. Then came Eugene D. Genovese's monumental historical anthropology of plantation life in the American South. A Marxist himself, Genovese held on to the idea that the planters constituted a pre-capitalist class. Yet he showed that the slaves, although people without rights or hardly any rights, were not people without will. Quite to the contrary, they were even able to shape the structures of the system as a whole. Using cunning and other weapons of the weak in the daily transactions at the work place, they moved their owners to accept their humanity and some minimal duties. The outcome was a paternalist system with some give and take between slave-owner and slave.

With this new paradigm slaves got their agency back. Slavery as such came to be seen as a negotiated relationship and as an intrinsically unstable process, the terms of which varied with time and place. This process spanned different stages from enslavement and transporation to life in slavery and possible, yet by no means inevitable social re-integration. There were different ways to overcome the outsider status: resistance and flight, manumission or the purchase of freedom. Prompted by the American civil rights movement, slave lives, slave culture, and slave resistance developed into privileged subjects of study. Herbert G. Gutman showed that slaves against all odds were living in families, creating enduring networks of kinship and self help. Religion proved to be

another major sphere where slaves gained some cultural autonomy. Integrating Christian teachings and African beliefs they developed a richly textured religious life with dance and song as integral parts of worship.

As to resistance, scholars had to contend with the fact that apart from the Haitian Revolution, slave rebels were nowhere able to end slavery. Studies of slave rebellions nonetheless brought to the fore numerous instances of organised resistance. A more salient aspect of these studies pioneered by John Hope Franklin was the insight into the complexities of resistance which ranged from mocking tales and mimicking dances to the deliberate cultivation of African customs, to go slow tactics and flight and the establishment of so-called Maroon societies. These societies developed into refuges for other slaves. Most of them had only a limited life span, some, however, such as the seventeenth century kingdom of Palmares in the hinterland of Pernambuco evolved into autonomous centers of power at the margins of the colonial system, often cultivating their own forms of slavery. Most successful were the rebels in relatively weak colonial states with open frontiers such as Brazil, Spanish America, and Surinam where the Saramaka fought a successful war of liberation against the Dutch, lasting more than 100 years.

A major advance in the study of slavery was achieved when historians shifted their focus from the interpretation of anecdotal literary evidence to the analysis of statistical material and other mass data with the help of economic modeling techniques. Philip D. Curtin was the first to attempt a census of the transatlantic slave trade using customs records from the Americas. His calculations have later been complemented and refined, yet his general insights withstood any later scrutiny and still hold true at the beginning of the twenty-first century. Others tried to extend his census to the much longer established Trans-Saharan, Indian Ocean, and Red Sea trades although there is no comparable database for these regions. Current estimates stand at 12 million plus Africans transported along these routes from the seventh to the twentieth century. Others reconstructed slave prices at the points of purchase and sale, carefully tracing changes over time, and studying all the other aspects of slave trading and the plantation business. These endeavors engendered seminal new insights. Scholars were able to prove that the length of a voyage was the single most important factor determining mortality during the voyage across the sea, the ghastly Middle Passage, with death rates ranging from 10 to 20 percent and more. They showed that pricing was competitive and that supply was responsive to changes in price and that the transatlantic slave trade continued well into the nineteenth century. It ended when Brazil and Cuba emancipated their slaves in the 1880s, the last to do so in the Western hemisphere. Scholars also discovered that markets shifted eastwards and southwards along the West African coast, from Senegambia and the Upper Guinea coast to the Bight of Biafra and northwestern Angola. Imports into Africa varied over time and from place to place with cotton goods, brandy, guns, and iron tools in high demand everywhere along the coast. With the recent publication of more than 27,000 Atlantic slave trading voyages in one single data set, even non-specialists have access to parts of the evidence used in the econometric computations.

Taken together, the studies of the new economic history show that the Marxist thesis of an inherent contradiction between slavery and capitalism is untenable is untenable as both slave trading and plantation economies were capitalist to the core, with prices set by the laws of supply and demand. In a major reinterpretation of slavery in the antebellum South Robert William Fogel and Stanley L. Engerman also convincingly demonstrated that during the reign of 'King Cotton,' the planters acted as capitalist entrepreneurs who were ready to innovate when it paid to do so and who rather used incentives than the whip to drive their slaves. They even ventured the thesis that in material terms (diet, clothing, housing, and life expectancy) slaves in the South were better off than many peasants and workers in Europe and the northern US. Moreover, the system was well and flourishing to the end with high levels of productivity. Parallel quantitative studies of the plantation economies in the West Indies arrived at similar conclusions: abolition came not in the wake of economic decline, but rather in spite of economic success. Seymour Drescher even coined the term econocide.

A major contentious issue among scholars has been the significance of slavery for the Industrial Revolution. In 1947 Eric Williams argued that the profits from the 'triangular trade' had financed the Industrial Revolution in the UK, adding that abolition was a consequence of economic decline. This double-pronged 'Williams thesis' became a central tenet of dependency theory. A close look at hundreds and thousands of slave voyages, however, showed that average profits were smaller than scholars had previously assumed and could never explain why the UK achieved the stage of self-sustained growth in the latter half of the eighteenth century. New data on capital formation in that period points in the same direction. Nevertheless, slavery and the plantation economies contributed to British economic growth and the advent of modernity. Slavery reduced the cost of sugar and tobacco for European consumers and it made great fortunes; it created markets for cheap industrial mass-products, and sugar plantations with their gang-labor system may even be interpreted as 'factories in the fields' with a work discipline prefiguring that of modern industrial plants. The impact of slavery was also felt in the realm of ideas and ideology. It furthered a racially informed negative perception of all things African in the West and set the stage for racism, a most

tragic legacy of more than 400 years of slave trading, that the West has not yet come to terms with. The rise of racial slavery in the Atlantic system is a reminder of the fact that economic self-interest and markets, when left to themselves, can produce the most immoral and humanly destructive institutions. The term 'racial slavery' refers to the fact that almost all slaves employed in the Americas hailed from Africa as the Spanish had banned the enslavement of Amerindians already by the 1540s.

The impact of slavery on Africa is also very controversially debated. Yet, once again a change of perspective has led to a shift of emphasis. An earlier generation of scholars with first-hand experience of colonial domination saw African societies mainly as victims of external forces. They singled out the transatlantic slave trade as a first step towards underdevelopment as it depopulated whole areas, or so ran the argument, and induced African rulers to engage in wars for the sake of making prisoners for sale in exchange for guns, which then triggered new wars. This set of ideas informed dependency theory as well as world-system analysis and the early nationalist African historiography. Walter Rodney even argued that African slavery on the Guinea coast was a result of external demand.

Quantitative studies shattered some of these assumptions. The gun-slave-cycle could not be substantiated. In addition, historical demography, although a risky business, points to demographic stagnation from 1750 to 1850, with population losses in the areas directly affected by slaving when other continents were beginning to experience demographic growth. The causal link between the slave trade and Africa's economic backwardness as posited by Joseph E. Inikori is a contested issue. A better understanding of the complexities of African politics has furthermore led scholars to argue that most African wars of the period were independent of the external demand for slaves, although the slave trade generated income, strengthening some polities while weakening others. Asante, Dahomey, and the Niger Delta city-states were among the main beneficiaries while the kingdom of Benin was one of those who abstained from participating in the slave trade. Slave sales shifted with the vagaries of African politics, not to forget the cycles of drought with the ensuing threats of starvation, which also led people into slavery. In other cases, slavery was a punishment for the crimes people had committed.

To stay in business, European and American slave traders had to adapt to local circumstances. They were at the mercy of local merchants and local power holders. They hardly ever ventured beyond the ports of call and the forts they built along the West African coast. They also bought women and children, although the planters considered them second choice to men, and people from other areas than those that the planters preferred. Women constituted up to a third of those sent to the Americas. The female ratio among slaves was higher than among early European immigrants. It ensured an enduring African physical presence. It is also a further proof that African cultural and political parameters had the power to shape the Atlantic system, an argument best developed by David Eltis.

Studies of African slavery have furthered the understanding of these cultural parameters. Slavery was widespread in precolonial Africa and expanded in the nineteenth century despite, or rather because of, the abolition of the transatlantic slave trade by the UK in 1807. Some scholars even argue that West African societies then developed into fully-fledged slave societies with 50 percent and more of their population kept in bondage. First among these were the Sudanic societies from the Futa Jallon to Sokoto and Adamawa, where Islamic revolutions and state-building initiated more intense slave raiding than ever before. Yet, African slavery, often referred to as 'household slavery,' markedly differed from chattel slavery. As elsewhere, slaves had to do the hardest work and their owners treated them as outsiders, the first to be sacrificed in public rituals and put to death at the whim of their owner. However, it was common to find slaves in positions of albeit borrowed authority, such as traders, officers, and court officials. Elsewhere slave and slave owner worked side by side. Alternatively, slaves lived in villages of their own. They owned property and in some cases, even slaves of their own. More importantly, the slave status was not a fixed status; rather it changed over time along a slave to kinship continuum, with people born into slavery exempt from further sale. Recent scholarship has stressed that women were the pre-eminent victims of slavery in Africa as they were valued for their labor power and for the offspring they might give birth to. Moreover, one should never forget that power and prestige in African societies rather depended on the number of followers someone could count on, than the control of land which was not a scarce resource yet, or not everywhere. According to H. J. Nieboer agricultural slavery developed wherever land was plentiful and the productivity of agricultural labour was low.

The slave to kinship paradigm as expounded most forcefully by Igor Kopytoff and Suzanne Miers has lost some of its appeal when scholars discovered that in many places a slave past carries a social stigma to this day. Yet Africa is a continent with a wide spectrum of cultures. Hence, what prevails at one place may be contradicted at another. Nonetheless, the general rule of slavery getting more exploitative and more strictly closed when used for the production of export staples and in societies with strong state structures holds true for Africa as well as for the Americas. A case in point is slavery on the East African coast and the island of Zanzibar during the clove boom of the mid-nineteenth century. In West Africa too, slavery turned more adversarial when set to the production of palm oil in

the aftermath of the abolition of the transatlantic slave trade, called the period of legitimate trade. The less centralized power in a society was, the easier it was for slaves to overcome their outsider status. This, however, meant integration into a land-holding kin group as access to women and land, the keys to reproduction, was generally controlled by these. In modern Europe, on the other hand, property rights in human labor, one's own or others, were vested in the individual. Hence freedom in Africa, and other non-Western societies, meant belonging, but independence in Europe.

Colonialism also helped to keep the memory of slavery alive. In the early nineteenth century, the UK had done its best to end the slave trade. It even stationed a naval squadron for this purpose in West African waters and concluded anti-slave trade treaties with African rulers who had trouble seeing the benefits of abolition. The European public later tended to take the imperialist scramble for Africa as an anti-slavery crusade, but colonial administrations, while forcefully suppressing the slave trade, were reluctant to fight slavery as a social system; rather they closed their eyes and did their best to freeze existing social relations while claiming to bring progress to Africa. When slavery finally ended in Africa, it did so not so much as the result of conscious acts of emancipation but rather because of the emergence of a colonial labor market, with the socially defined older mechanisms for the integration of outsiders easing the transition. The men and women held in bondage eagerly took up alternatives wherever they were viable.

The cultural turn in social sciences has deeply influenced slave studies. There is no end to quantitative analyses. However, scholars have discovered that cultural parameters are important variables affecting what people do, even when they operate under the impress of a market system. Even *Homo oeconomicus* has to consider cultural values. Gender and slave memories have also attracted much more attention than before. The 41 volumes of interviews with former slaves conducted in the 1920s and 1930s in the US remain unrivalled, yet cf. the splendid collection of peasant narratives from Niger presented by Jean Pierre Olivier de Sardan. Archeologists have started to investigate slave material culture. Others have begun to retrace the construction of different Creole identities and cultures in the Americas so rich in imaginative creativity. They all encounter the same problem: as slaves by definition were people without voice, what they experienced and what they thought is to a great extent buried in the documents written by the perpetrators of slavery. To give the slaves their voice back is one of the nobler tasks of historical scholarship, but it is immensely difficult.

While studies of slavery become ever more detailed and localized, historians have come to realize that the Middle Passage is more a bridge than an abyss or a one-way street, binding different cultures together, a point first made by the anthropologist Melville J. Herskovits. Slaves came with a history of their own to the Americas, returning Africans and children of former slaves such as Olaudah Equiano, Wilmot Blyden, and James Africanus Horton were among the first to consciously define themselves as Africans. Hailing from different regions of Africa, yet sharing a common plight, they developed an awareness of a common African identity. The books they wrote helped to lay the foundations for Panafricanism, a strand of ideas and a political movement central to the freedom struggle of Africans in the twentieth century.

David Brion Davis noted a similar correlation between slavery and freedom in Western religious, legal, and philosophical discourses. Hence the double paradox and legacy of slavery: it inflicted death and hardship on millions and millions of people of mostly African descent for the benefits of a few; and while it was instrumental for the rise of racial prejudice, it also shaped the notion of freedom and equality as we know and cherish it today. To consider these global dimensions, is the challenge of any further research into the history of slavery even when dealing with very specific local aspects of the problem. But this is easier said than done because it requires historians to venture beyond the deeply rooted traditions of privileging the history of a particular nation-state, usually their own, into the open sea of a new comparative history. The fight against slavery is not won so long as debt bondage, servile marriage, forced labor, child labor, trafficking of women, forced prostitution, and other forms of bondage exist in many societies, including the very rich countries of the West.

Sleep and Health

1. Sleep Physiology

Sleep is a ubiquitous mammalian phenomenon which is associated with diminished responsiveness to external stimuli and a familiar and delightful sense of restoration under the circumstances of a normal night of sleep. The importance of sleep in daily living can

Figure 1
The distribution of sleep stages over the course of a normal night of sleep

easily be discerned when an individual has even a modest restriction in a normal night of sleep. This has been well documented to be associated with performance decrement and alterations in mood. The mysteries of sleep are many, and how it produces its restorative effects remain vague, but it is clear that it is at the core of mental and physical well being. Biological functioning cannot be thoroughly appreciated without integrating sleep and sleep biology into our understanding of waking biology. It is obvious now to the layman and professional sleep researcher both that sleeping behavior effects waking behavior, and waking behavior effects sleeping behavior.

In the mid-1950s, some of the mysteries of sleep began to unravel by a series of discoveries by Nathaniel Kleitman, William Dement, and Eugene Aserinsky at the University of Chicago (Dement 1990). These individuals produced a series of studies which delineated the brain wave patterns associated with different stages of sleep, and the unique stage of sleep which was termed rapid eye movement (REM) sleep, shown to be associated with dreaming. These stages of sleep were determined by the concomitant recording of the electroencephalogram (EEG), electro-octulogram (EOG), and the electromyogram (EMG). The stages of sleep are characterized by a pattern of activity in each of these variables. Brain wave activity changes dramatically from waking to the deep stages of sleep (stages 3 and 4) with high voltage slow waves becoming increasingly dominant. These stages are distributed throughout the night in a well-defined pattern of activity associated with REM periods approximately every 90 minutes (Fig. 1). REM periods are interspersed with stages 2, 3, and 4 such that stages 3 and 4 are identified largely in the first third of the night, with relatively little noted in the last third of the night. REM sleep is accumulated with episodes occurring every 90 minutes as noted, but as the night progresses, the REM periods become progressively longer, thus producing very long REM periods in the last third of the sleeping interval. Thus, REM sleep is identified primarily in the last third of the night, with relatively little in the first third of the night (Carskadon and Dement 1994).

Of interest, is the fact that REM sleep is associated with some unique physiologic changes. Thermoregulatory and respiratory functioning are markedly compromised during REM sleep. For example, the vasomotor mechanisms necessary to respond appropriately to increases and decreases in ambient temperature in order to maintain a normal core body temperature are suspended during REM sleep. This renders the mammalian organism poikilothermic, or cold blooded, during REM sleep. In addition, appropriate respiratory compensatory responses to both hypoxemia and hypercapnia are substantially blunted during REM sleep. These data combine to suggest that even under normal circumstances, REM sleep is a period of physiologic risk woven into the fabric of a normal night of sleep.

Other phenomena associated with REM sleep are of considerable interest. For example, it is known that REM sleep is associated with a skeletal muscle paralysis. This has been substantiated by the documentation of hyperpolarization of motor neurons during REM sleep in cats. In addition, REM sleep is generally associated with thematic dreaming, and it is felt that the inhibition of skeletal muscles prevents the 'acting out' of dreams. Also during each REM period penile tumescence occurs, resulting in a normal full erection in males (Carskaden and Dement 1994).

Non-REM (NREM) sleep, alternatively, is associated with a slowing of physiological processes to include heart rate, blood pressure, and general metabolic rate compared to the waking state. During the first episode of slow wave sleep (stages 3 and 4) there is a dramatic increase in the secretion of growth hormone. This has been shown to be specifically linked to the first episode of slow wave sleep, rather than a circadian phenomenon. No other hormone is quite so precisely identified with secretion during a specific stage of sleep.

2. *Subjective Aspects of Sleep*

The quality of sleep, and the physiologic parameters which produce 'good sleep' or a feeling of restoration in the morning are not understood. Deprivation of REM sleep as opposed to non-REM sleep does not appear to differentially affect subsequent mood or performance. It is well established that older adults have characteristic alterations in their sleep patterns, i.e., a marked diminution in stages 3 and 4 sleep, which are quite characteristically associated with complaints of nonrestorative, or poor sleep. Determining the physiologic characteristics of the subjective elements of 'good sleep' is difficult in that it is well known that the subjective and physiologic aspects of sleep can be

easily disassociated. It is not unusual, for example, for individuals with significant complaints of insomnia or poor sleep to have essentially normal physiological sleep patterns. Sleep is well known to be easily disturbed by mood and psychological state. Sleep is clearly disturbed by anxiety and in patients with generalized anxiety disorder. Characteristically this is associated with prolonged sleep onset latency and multiple awakenings subsequent to sleep onset. In addition, a well-recognized prodrome to a clinically significant depressive episode is an alteration in sleep pattern which includes an early onset of REM sleep and early morning awakenings with difficulty falling back to sleep. There are also data which document the fact that REM deprivation in depressed patients can produce a significant antidepressant effect (see *Depression*).

Good sleep is commonly associated with good health and a sense of well being. Measures of overall functional status have been known to be significantly correlated with both subjective and objective measures of daytime sleepiness. Other studies have shown that sleep disordered breathing is associated with lower general health status, with appropriate controls for body mass index, age, smoking status, and a history of cardiovascular conditions. Even very mild degrees of sleep disordered breathing have been shown to be associated with subjective decrements in measures of health status which are comparable to those individuals with chronic disease such as diabetes, arthritis, and hypertension.

Complaints of poor sleep and/or insomnia, and daytime sleepiness and fatigue are common. A recent Gallop survey in the USA indicated that approximately one third of Americans have insomnia. Thirty-six percent of American adults indicated some type of sleep problem. Approximately 27 percent reported occasional insomnia, while 9 percent indicated that their sleep-related difficulty occurs on a regular, chronic basis. In a study of a large sample of Australian workers, the prevalence of a significant elevation in the Epworth Sleepiness Scale was just under 11 percent. These data were not related significantly to age, sex, obesity, or the use of hypnotic drugs. Perhaps the most common cause of daytime fatigue and sleepiness, aside from self-imposed sleep restriction, is obstructive sleep apnea. The *sine qua non* of this sleep disorder is persistent sonorous snoring. Snoring itself is the most obvious manifestation of an increase in upper airway resistance, and as it progresses to more significant levels, the upper airway gradually diminishes in cross-sectional diameter and may produce a complete occlusion. Sonorous snoring can exist as a purely social nuisance or it can be associated with multiple episodes of partial and complete upper airway obstruction during sleep associated with dangerously low levels of oxygen saturation. This sleep-related breathing disorder is also associated with complaints of daytime fatigue and sleepiness that may be only minimally obvious to some individuals, but can be quite severe and debilitating in others (Orr 1997).

3. *Sleep Disorders*

There are a variety of documented sleep disorders which have been described in a diagnostic manual which can be obtained through the American Academy of Sleep Medicine. This manual describes the diagnostic criteria of a plethora of sleep disorders ranging from disorders which manifest themselves primarily as symptoms, i.e., insomnia, narcolepsy, to physiologic disorders which can be defined only through a polygraphic sleep study such as sleep apnea, periodic limb movements during sleep, and nocturnal gastroesophageal reflux. The prevalence of these disorders varies from narcolepsy (5–7 cases per 10,000) to OSAS (2–4 cases per 100) to insomnia which may be as high as 25 percent of the general population who report occasional problems with this disorder. Space constraints do not permit a discussion of all of these disorders, therefore we will touch only on the most commonly encountered sleep disorders.

Clearly, sleep disorders have well-documented consequences with regard not only to health but to daytime functioning. Perhaps the most common of all relates to the behavioral consequences of sleep fragmentation or sleep restriction. Either as a result of anxiety, or a physiologic sleep disturbance, sleep restriction and sleep fragmentation can produce documentable declines in performance, and increases in daytime sleepiness. The effects of even minimal sleep restrictions are cumulative across nights, but the effects can be quickly reversed in a single night of normal sleep. Sleep restriction is commonly noted in shift workers; it is estimated that approximately 30 percent of the American work force works rotating shifts, or a permanent night shift. Even permanent night shift workers rarely obtain 'normal' sleep in the daytime, and complaints of inadequate or non-restorative sleep are persistent in this group of workers. Studies have shown that accidents are 20 percent higher on the night shift, and 20 percent of night shift workers report falling asleep on the job. The demands of our increasingly complex technologic society have created a workforce that is under greater stress, obtaining less sleep, and clearly increasing prevalence of sleep complaints and sleep disorders.

An epidemiological study has estimated the prevalence of sleep disordered breathing (defined as five obstructive events per hour or greater) was 9 percent for women and 24 percent for men (Young et al. 1993). It was estimated that 2 percent of women and 4 percent of middle-aged men meet the minimal diagnostic criteria for sleep apnea, which includes five obstructive events per hour with the concomitant symptom of daytime sleepiness. Although, obstructive

sleep apnea syndrome (OSAS) is felt to be a predominantly male phenomenon, the incidence rises sharply among postmenopausal women. Persistent, loud snoring, and the concomitant upper airway obstruction, has been shown to carry with it a variety of medical and behavioral risks. Various studies have shown that snoring is a significant predictor of hypertension, angina, and cerebral vascular accidents independent from other known risk factors. One study has shown in a multiple regression analysis that snoring was the only independent risk factor which differentiated stroke occurring during sleep and stroke occurring at other times of the day. Other studies have documented a higher mortality rate in patients with moderate to severe OSAS compared to those with a less severe manifestation of this disorder. Furthermore, other studies have shown that in individuals with curtailed life expectancy secondary to OSAS, the most common cause of death was myocardial infarction. Other studies have confirmed that more aggressive treatment of OSAS reduces the incidence of vascular mortality (Hla et al. 1994).

The issue of the relationship between snoring, OSAS, and hypertension is somewhat controversial. The frequent association of significant OSAS with male gender, and obesity make it difficult to determine the relative contribution of each variable to hypertension. One large population study of 836 males from a general medical practice in England revealed a significant correlation between overnight hypoxemia and systemic blood pressure, but this could not be determined to be independent of age, obesity, and alcohol consumption (Stradling and Crosby 1990). No significant relationship was found with snoring. Alternatively, another excellent study which actually utilized overnight polysomnography and 24-hour ambulatory blood pressure monitoring did find an association between hypertension and sleep apnea which is independent of obesity, age, and sex in a nonselected community based adult population (Hla et al. 1994). Clinically, it is recognized that appropriate treatment of OSAS will often result in a notable reduction in blood pressure, often independent of weight loss. In a recent National Institute of Health supported project on sleep and cardiovascular functioning, preliminary data have shown that 22 to 48 percent of hypertensive patients have been observed with significant OSA, and 50 to 90 percent of sleep apnea patients have been documented to have hypertension.

Perhaps the most well-known 'sleeping disorder' or 'sleep sickness' is narcolepsy. Long assumed to be synonymous with uncontrollable daytime sleepiness, narcolepsy is now known to be a neurological disorder, and genetic abnormalities have recently been described in a canine model of narcolepsy. This disorder is associated with an extraordinary degree of daytime sleepiness but that alone does not define the syndrome. Many individuals with OSAS also have an equivalent degree of daytime sleepiness. Narcolepsy is identified by other ancillary symptoms. Perhaps the most common and dramatic is cataplexy in which individuals have a partial or complete loss of skeletal muscle control in the face of emotional stimuli such as fear, anger, or laughter. In the sleep laboratory, narcolepsy is associated with a unique pattern of sleep where an onset of REM sleep is noted usually within 10 to 15 minutes after sleep onset. This is considered to be a pathognomonic sign of narcolepsy. Unfortunately, there is no cure for narcolepsy at the present time, and treatment is limited to the symptomatic improvement of daytime sleepiness with stimulant medication, and the control of the ancillary symptoms primarily via tricyclic antidepressant medication.

The results of the Gallop survey indicated that 36 percent of American adults suffer from some type of sleep problem. Approximately 25 percent reported occasional insomnia, while 9 percent said that their sleep-related difficulty occurs on a regular or chronic basis. In addition, the survey documented that insomniacs were 2.5 times more likely than noninsomniacs to report vehicle accidents in which fatigue was a factor. In addition, compared to noninsomniacs, insomniac patients reported a significantly impaired ability to concentrate during the day. The well-documented excessive daytime sleepiness in patients with obstructive sleep apnea has been documented in several studies to result in a significant increase in traffic accidents, as well as at-fault accidents (Findley et al. 1989). The extreme sleepiness noted in patients with OSAS is almost certainly the result of an extreme degree of sleep fragmentation secondary to arousals from sleep by repeated events of obstructed breathing. Furthermore, it is well established that the sleepiness experienced by patients with OSAS is completely reversible by appropriate therapy which resolves the sleep related breathing disorder. The most common approach to therapy currently is the application of a positive nasal airway pressure via a technique referred to as continuous positive airway pressure (CPAP).

The effects of sleep deprivation, either as a result of willful sleep restriction, poor sleep secondary to insomnia, or fragmented sleep secondary to OSAS, has substantial effects on physical and behavioral health as noted above. Studies on chronic sleep deprivation have shown minimal physiologic effects, but have documented dose related effects in performance decrements and decreased alertness. More recently, however, an extraordinary set of studies has demonstrated that long-term sleep deprivation does have very significant effects in rats, and can ultimately result in death. The most likely explanation of death appears to be the result of a profound loss of thermal regulation (Rechtschaffen 1998). Also of interest, are recent studies which suggest alterations in immune function secondary to chronic sleep deprivation in humans.

In conclusion, the intuitive notion that sleep has important consequences with regard to one's health

appears to be clearly documented. Alterations in sleep producing a fragmentation of sleep or restriction in the normal duration of sleep have been shown to have significant consequences with regard to waking behavior. In addition, sleep disorders which fragment sleep such as obstructive sleep apnea produce effects that relate not only to waking behavior, but also have significant consequences with regard to both cardiovascular and cerebral vascular complications as well as producing a significant increase in mortality. Perhaps, the most important message to be gleaned from the remarkable increase in our knowledge of sleep is that sleeping behavior affects waking behavior and waking behavior affects sleeping behavior.

Sleep Disorders: Psychiatric Aspects

Complaints of too little sleep (insomnia) or too much sleep (hypersomnia), or of sleep that is not restorative enough, are termed dyssomnias. This chapter is intended to give an overview on the frequency and risk factors of dyssomnias, and on the psychiatric conditions that may be associated with them, and the physiopathological concepts related to sleep changes in depression. Of the greater than 30 percent of the general population who complain of insomnia during the course of one year, about 17 percent report that it is 'serious.' Insomnia is encountered more commonly in women than men and its prevalence increases with age. Insomnia represents one of the major features of depression and appears to be one type of the prodromal symptoms and risk factors for the development of major depression. Since chronic dyssomnia most often occurs as a comorbid disturbance of psychiatric and physical conditions, a thorough evaluation of the patient and his/her sleep complaints is needed to lay the foundation for accurate diagnosis and effective treatment.

The diagnosis of insomnia is based upon the subjective complaint of sleeping too little. Patients report difficulties in initiating or maintaining sleep or of non-restorative sleep, i.e., not feeling well rested after sleep that is apparently adequate in amount, and tiredness during the day. Insomnia may occur as primary or as secondary disorder due to other psychiatric conditions, due to general medical conditions, and/or due to substance misuse. Compared to secondary insomnia, the prevalence of primary insomnia is relatively small.

Hypersomnia includes complaints of excessive sleepiness characterized either by prolonged sleep episodes and/or excessive sleepiness during the day. These symptoms may interfere with social, occupational, and/or other areas of functioning. Like insomnia, hypersomnia may occur as a primary disorder or as a secondary disorder due to psychiatric and/or medical conditions, and/or due to substance misuse. Especially among patients encountered in psychiatric practices and hospitals, secondary sleep disturbances are more common than primary sleep disturbances. This is particularly important to bear in mind when evaluating a patient with sleep complaints. Dyssomnia is particularly often associated with psychiatric disorders such as depression, schizophrenia, anxiety disorders, or personality disorders, and with misuse of drugs and/or alcohol. Whenever possible, it is clinically useful to assess which is the primary and which is the secondary disturbance. This will facilitate clinical treatment and management and improve preventive measures.

1. Frequency and Risk Factors

Somnipathies are among the most frequent complaints a general practitioner must deal with. According to epidemiological studies, 19–46 percent of the population report sleep problems. Of these, 13 percent suffer from moderate or severe disturbances. In terms of the narrow definition of diagnostic criteria, that is, initial insomnia, interrupted sleep and disturbance of daily well being, 1.3 percent of the population suffers from somnipathies.

Risk factors for somnipathies are psychological stress or psychiatric illness. A high prevalence of

	Wake Predominantly alpha waves, high muscle tone.
	Stage 1 ~ 5%, EEG slowing at the transition from waking to sleeping, muscle tone (EMG) decreases, slow (rolling) eye movements (EOG).
	Stage 2 ~ 45-50%, progressive slowing of the EEG, intermittent theta and alpha waves, occurrence of sleep spindles and K-complexes.
	Stage 3 ~ 5-10%, predominantly delta waves.
	Stage 4 ~ 25%, increased occurrence of delta waves (stages 3+4 = slow wave sleep [SWS] or delta sleep).
	REM sleep ~ 20-25%, EEG is activated and ressembles that during waking; muscle tone is relaxed, rapid eye movements.

Figure 1
Sleep stages according to Rechtschaffen and Kales (1968)

somnipathies was reported by volunteers suffering from stress, tension, solitude, or depression. More severe sleep problems were found to be clearly related to psychiatric illness such as depression and anxiety disorders as well as substance misuse.

A recent World Health Organization (WHO) collaborative study in 15 different countries found that insomnia is more common in females than males and increases with age. In fact, it is thought that half of the population over 65 years of age suffers from chronic sleep disturbances. The WHO study also found that 51 percent of people with an insomnia complaint had a well defined *International Classification of Diseases-10* (*ICD-10*) mental disorder (mainly depression, anxiety, alcohol problems). Although many somnipathies develop intermittently, 70–80 percent of the surveyed subjects had been suffering from sleeping problems for more than one year. Disturbances of concentration and memory, difficulties in getting on with daily activities, and depressive mood changes were among the problems most often related to insomnia. The pressure imposed by their ailment leads many patients to seek help in alcohol and drugs.

Insomnia has also costly financial consequences. The economical impact of insomnia can be divided into direct and indirect costs. Direct costs of insomnia include outpatient visits, sleep-recordings, and medications directly devoted to insomnia. There is too little knowledge about the exact figures. However, the direct costs of insomnia in the US has been estimated in 1990 to be $10.9 billion (with $1.1 billion devoted to substances used to promote sleep and $9.8 billion associated with nursing home care for elderly subjects with sleep problems). The direct costs related to the evaluation of sleep disorders by practitioners seem to be a small part of the total costs of insomnia. The indirect costs of insomnia include the presumed secondary consequences of insomnia such as health and professional problems, and accidents. The exact quantification of these costs is, however, controversial. It is often not known if sleep disorders are the cause or the consequence of various medical or psychiatric diseases. For instance, it has been observed that insomniacs report more medical problems than good sleepers do and have twice as many doctor visits per year than good sleepers do. Furthermore, subjects with severe insomnia appear to be hospitalized about twice as often as good sleepers. It has also been observed that insomniacs consume more medication for various problems than good sleepers do.

These results confirm previous observations showing that insomnia is statistically linked with a worse health status than individuals with good sleep. Again, it can not be established whether insomnia is the cause or the result of this worse status. For instance, one could reasonably hypothesize that insomnia promotes fatigue that could increase the risk of some diseases, or more simply decrease the threshold of others that could more easily develop.

2. *Regulation of Normal Sleep*

The quantity and quality of sleep is measured with polysomnographic recordings (PSG) that include the electroencephalogram (EEG), electromyogram (EMG), and electrooculogram (EOG). Human sleep consists of two major states, the Rapid-Eye-Movement (REM) sleep, and the nonREM (nonREM) sleep (Fig. 1). NonREM sleep is characterized by increasing EEG synchronization and is divided into stages 1–4. Stages 3 and 4 are also termed slow wave sleep (SWS) or delta sleep ('delta waves'). REM sleep has also been termed paradoxical sleep because of its wake-like desynchronized EEG pattern combined with an increased arousal threshold. Typical nocturnal sleep is characterized by 3-5 cycles of non-REM and REM sleep phases of about 60–100 minutes duration. At the beginning of the night, the cycles contain more non-REM sleep, particularly more SWS. Towards the end of the night, the amounts of REM sleep increases and the amount of SWS decreases. The following standard terms are used to describe quality and quantity of sleep: sleep continuity refers to the balance between sleep and wakefulness (i.e., initiating and maintaining sleep), and sleep architecture refers to the amount, distribution, and sequencing of specific sleep stages. Measures of sleep continuity include sleep latency (usually defined as the duration between lights out and the first occurrence of stage 2 sleep), intermittent wake after sleep onset, and sleep efficiency (ratio of the time spent asleep to total time spent in bed). REM latency refers to the elapsed time between sleep onset and the first occurrence of REM sleep. The amount of each sleep stage is quantified by its percentage of the total sleep time. REM density is a measure of eye movements during REM sleep; typically this is low in early REM sleep periods and increases in intensity with successive REM sleep periods. In normal sleep, the cycle of non-REM and REM sleep lasts approximately 60–100 minutes. Sleep usually begins with the non-REM sleep stage 1 and progresses to stage 4 before the appearance of the first REM period.

The duration of the REM sleep episodes and REM density usually increases throughout subsequent sleep cycles. As shown in Fig. 2, the pattern of nocturnal growth hormone secretion is associated with the development of SWS during the first non-REM sleep period. Cortisol secretion, on the other hand, appears to be associated with increased amount of REM sleep. Several non-REM and REM sleep measures including the amount of SWS, REM latency and density may be particularly altered in affective and schizophrenic disorders, in aging, and with the administration of certain drugs.

Figure 2
Bidirectional interaction between sleep EEG and nocturnal hormone secretion

At least three major processes are involved in the regulation of normal sleep. According to the Two-Process-Model of sleep regulation, sleep and wakefulness are influenced by both a homeostatic and a circadian process that interact in a complex way. The homeostatic Process S (related to SWS) increases with the duration of wakefulness prior to sleep onset and augments sleep propensity. The circadian Process C, driven by the internal clock located in the suprachiasmatic nuclei (SCN), describes the daily cycle of sleepiness and wakefulness and is also related to REM sleep. The third process is the ultradian rhythm of non-REM and REM sleep. The electrophysiological measures are associated with endocrinological and other physiological events.

Wakefulness, non-REM sleep, and REM sleep appear to be controlled by interacting neuronal networks, rather than by unique necessary and suffic-

Figure 3
Neuroanatomy of sleep–wake regulation

ient centers. A simplified neuroanatomy of sleep–wakefulness is shown in Fig. 3. The non-REM–REM sleep cycle is regulated within the brainstem. According to current concepts, REM sleep is initiated and maintained by cholinergic neurons originating within the lateral dorsal tegmental and pedunculopontine nuclei in the dorsal tegmentum, and is inhibited by noradrenergic and serotonergic neurons originating in the locus coeruleus and dorsal raphe nuclei. Human pharmacological data are consistent with the neurophysiological concepts of the control of REM and non-REM sleep.

In contrast to the brain-activated state of REM sleep, non-REM sleep is characterized by synchronized, rhythmic inhibitory–excitatory potentials in large numbers of neurons in cortical and thalamic regions. Other areas implicated in the control of non-REM sleep include cholinergic and noncholinergic neurons in the basal forebrain, the hypothalamus, and the area of the solitary tract.

In addition to neuronal mechanisms in the control of sleep, more than 30 different endogenous substances have been reported to be somnogenic. These include delta sleep-inducing peptide, prostaglandin D_2, vasoactive intestinal peptide, adenosine, growth hormone-releasing hormone, and several cytokines including interleukins, tumor necrosis factor-α, and interferons. The significance of endogenous sleep factors in normal sleep physiology remains to be proven, but the possibility has interesting implications. As the Two Process Model of sleep regulation suggests, increased sleep propensity with progressive duration of wakefulness might be associated with the accumulation of a sleep factor and the homeostatic function of sleep or at least delta sleep might reflect its 'catabolism.'

3. *Sleep and Psychiatric Disorders*

Polygraph sleep research helped paving the way to the modern age of scientific, biological psychiatry. Much of the early sleep research beginning in the mid-1960s was descriptive mapping of events taking place during sleep and laid out the currently rich picture of polysomnographic features in the different psychiatric disorders. Although many of the objective sleep abnormalities associated with psychiatric disorders appear not to be diagnostically specific, these studies have also established sleep measures as neurobiological windows into the underlying pathophysiology associated with psychiatric illnesses.

Psychiatric disorders are among the most common primary causes of secondary sleep complaints, particularly of insomnia. Sleep abnormalities may be caused by central nervous system abnormalities associated with psychiatric illnesses as well as by accompanying

Typical EEG sleep findings in psychiatric disorders (meta-analysis by Benca et al. 1992)

behavioral disturbances. Patients with depression, anxiety disorders, misuse of alcohol or drugs, schizophrenia and personality disorders may complain of difficulty falling asleep, staying asleep, or of inadequate sleep. Although specific sleep patterns are not necessarily diagnostic of particular psychiatric disorders, there are relationships between certain sleep abnormalities and categories of psychiatric disorders (Table 1).

A review of the literature on sleep in psychiatric disorders showed that EEG sleep in patients with affective disorders differed most frequently from those of normal control subjects.

4. *Sleep Abnormalities in Depression*

Sleep abnormalities in patients with major depressive disorders, as assessed by laboratory studies, can be classified as difficulties of sleep continuity, abnormal sleep architecture, and disruptions in the timing of REM sleep. Sleep initiation and maintenance difficulties include prolonged sleep latency (sleep onset insomnia), intermittent wakefulness and sleep fragmentation during the night, early morning awakenings with an inability to return to sleep, reduced sleep efficiency, and decreased total sleep time. With regard to sleep architecture, abnormalities have been reported in the amounts and distribution of nonREM sleep stages across the night and include increased shallow stage 1 sleep and reductions in the amount of deep, slow-wave (stages 3 + 4) sleep. REM sleep disturbances in depression include a short REM latency ($<$ 65 minutes), a prolonged first REM sleep period, and an increased total REM sleep time, particularly in the first half of the night.

Sleep disturbances are generally more prevalent in depressed inpatients, whereas only 40–60 percent of outpatients show sleep abnormalities. Moreover, a recent meta-analysis indicated that no single polysomnographic variable might reliably distinguish depressed patients from healthy control subjects or from patients with other psychiatric disorders. Table 1 gives an overview of the typical EEG sleep changes in major psychiatric conditions. This prompted some researchers to conclude that clusters or combinations of sleep variables better describe the nature of sleep disturbances in depression.

Although there is some disagreement as to which specific sleep EEG variables best characterize depressed patients, the importance of sleep to depression is clear. Persistent sleep disturbance is associated with significant risk of both relapse and recurrence, and increased risk of suicide. Sleep variables such as REM latency has also been shown to predict treatment response and clinical course of illness in at least some studies. It has also recently been suggested that the nature of the sleep disturbance at initial clinical presentation may be relevant to the choice of antidepressant medications and the likelihood of experiencing treatment-emergent side effects.

One of the most sensitive parameter for discrimination of patients with major depression from patients with other psychiatric disorders and healthy subjects is REM density which is substantially elevated only in depressed patients. The persistence of a depression-like sleep pattern in fully remitted depressed patients suggests that the pattern is a trait characteristic of the sleep measurements. However, in the past, subjects have undergone investigations only after the onset of the disorder, and therefore the altered sleep pattern may merely represent a biological scar. The answer to the question 'trait or scar' lies in the investigation of potential patients before the onset of the disorder. The EEG sleep patterns of subjects without a personal history but with a strong family history of an affective disorder differed from those of the controls without any personal history of family history of psychiatric disorders showing a depression-like sleep pattern with diminished SWS and increased REM density. Follow-up studies will determine whether the sleep pattern indeed represents a trait marker indicating vulnerability.

The importance of sleep in depression is also shown in other ways. Many well-documented studies show that total and partial sleep deprivation or selective REM sleep deprivation has antidepressant effects. Additionally, following total or partial sleep deprivation, patients with depression appear to be uniquely susceptible to clinical mood changes when they return to sleep. Patients who have shown a clinically significant antidepressant response to sleep deprivation are

at risk of awakening depressed again, even after very short naps (see *Depression*; *Antidepressant Drugs*).

5. *Neurobiology of Sleep: Relevance to Psychiatric Disorders*

Inspired by the growing knowledge of the underlying neurobiology of sleep, investigators proposed theories into the pathophysiology of psychiatric disorders. Because depression has been studied more than any other psychiatric syndrome in recent decades, the models have attempted to explain features of sleep in depression, such as short REM latency, decreased delta sleep, and the antidepressant effects of sleep deprivation in depressed patients.

Among the most prominent models of sleep changes in depression are the cholinergic–aminergic imbalance hypothesis for depression, the Two-Process-Model of sleep regulation, the Phase Advance Hypothesis, the Overarousal hypothesis, and the REM sleep hypothesis.

The 'cholinergic–aminergic imbalance hypothesis' for depression postulates that depression arises from an increased ratio of cholinergic to aminergic neurotransmission in critical central synapses. Because various features of the sleep of depressed patients (decreased REM latency and delta sleep) have been simulated in normal volunteers by pharmacological probes, the reciprocal interaction hypothesis from basic sleep research and the cholinergic–aminergic imbalance model from clinical psychiatry have been correlated. The reciprocal interaction model assumes that the cycling alternating pattern of non-REM and REM sleep is under the control of noradrenergic/serotonergic and cholinergic neuronal networks. Linking these concepts it is suggested if depression results from diminished noradrenergic and serotonergic neurotransmission, cholinergic activity would be expected to increase and lead therefore to the sleep disturbances of depression.

In recent years the role of serotonin in the regulation of sleep has afforded increased attention. Among other neurotransmitters, serotonin plays a role in the pathophysiology of depression and its treatment; chiefly all antidepressants ultimately lead to an enhancement of serotonergic neurotransmission that is believed to be associated with clinical improvement. Depression is associated with a disinhibition of REM sleep (shortened REM latency, increased REM density) and serotonin leads to a suppression of REM sleep. Furthermore, there is evidence that the antidepressant effect of sleep deprivation is related to a modification of serotonergic neurotransmission, thus sleep regulation and depression share common physiopathological mechanisms at the serotonergic level.

According to the 'Two-Process-Model of sleep regulation,' depression is thought to result from, or is associated with, a deficiency of Process S. This model was supported by evidence that EEG power density in the delta frequencies was decreased during sleep in depressed patients compared with controls and by the fact that sleep deprivation increases both Process S and mood. In the 'Extended Two-Process-Model of sleep regulation' the interaction of hormones with EEG features has been integrated. Preclinical investigations and studies in young and elderly normal controls and in patients with depression demonstrate that neuropeptides play a key role in sleep regulation. As an example, growth hormone releasing hormone (GHRH) is a common stimulus of SWS and growth hormone release, whereas corticotropin-releasing hormone (CRH) exerts opposite effects. It is suggested that an imbalance of these peptides in favor of CRH contribute to changes in sleep EEG and endocrine activity during depression. Based on the findings that the hypothalamic–pituitary–adrenocortical (HPA) axis is disregulated in depression, and that CRH produces EEG sleep changes reminding to depression on one hand (SWS reduction, REM sleep disinhibition), and that the somatotrophic system reciprocally interacts with the HPA system (decreased GHRH and SWS), it has been postulated that deficient Process S is associated with deficient GHRH and an overdrive of CRH. Although abnormally high values of cortisol secretory activity normalize after recovery from depression, growth hormone release and several characteristic disturbances of the sleep EEG may remain unchanged. These putative trait-dependent alterations suggest that strategies aiming at restoration of these sleep changes are worthy of exploration for their potential antidepressant effect.

The depressed state appears not only to be associated with a disturbance of sleep-wake homeostasis but also of circadian function or of their interaction. The 'Phase Advance Hypothesis' suggests that the phase position of the underlying circadian oscillator is 'phase advanced' relative to the external clock time. This is supported by studies showing that short REM latency could be simulated in normal controls by appropriate phase shifts of hours in bed.

As mentioned above, sleep deprivation has potent antidepressant effects in more than half of all depressed patients. This observation has prompted the hypothesis that depressed patients are 'overaroused.' Later, the 'Overarousal Hypothesis' has been forwarded and was supported by psychological self-rating studies suggesting that clinical improvement to sleep deprivation in depression may be associated simultaneously with subjective feelings of more energy (arousal), less tension, and more calmness (dearousal). Other data consistent with this hypothesis include the short, shallow, and fragmented sleep patterns, lowered arousal thresholds, and elevated nocturnal core body temperature often seen in depressed patients. This hypothesis has been tested by means of studies of localized cerebral glucose metabolism with ^{18}F-deoxyglucose positron emission tom-

ography in separate studies in depression, sleep deprivation, and the first non-REM period of the night. In these studies it was found that elevated brain metabolism prior to sleep deprivation predicted clinical benefits in depressed patients and that normalization of these measures is associated with clinical improvement. It was also found that local cerebral glucose metabolism in cingulate and amygdala at baseline was significantly higher in clinical responders than in nonresponders or normal controls. Furthermore, it was shown that glucose metabolic rate was increased during the first non-REM period in depressed patients compared with normal controls. Moreover, these studies demonstrated significant 'hypofrontality,' that is; reduced ratio of frontal to occipital activity compared with normal controls.

The 'REM sleep hypothesis' of depression has been based on the findings that REM sleep is enhanced in depression and that virtually all antidepressant drugs suppress REM sleep. Early, however not replicated, studies have shown that a sustained remission from depression may be achieved by selective REM sleep deprivation carried out repeatedly every night during about two weeks. This treatment modality was not followed because the long-term REM sleep deprivation was too exhausting for the patients. Recently, researchers have proposed a treatment modality that combined some of the above hypotheses. The so-called 'Sleep-Phase-Advance' protocol, that is scheduling sleeping times in a way that minimizes the occurrence of REM sleep, has been shown to produce a sustained antidepressant effect. However, also this treatment modality is demanding for both the patients and the institutional staff.

6. *Future Perspectives*

We have outlined just some aspects of sleep research that are relevant to depression. Linking basic and clinical approaches has been one of the 'royal roads' to the neurobiological underpinnings of psychiatric diseases and their treatment in the past, and to narrow the gap between bench and bedside. One of the most impressing links between sleep and depression is the fact that sleep deprivation alleviates depressive symptoms within hours and that sleep may restore the initial symptoms within hours or even minutes. Given the fact that the core symptoms of only few psychiatric and medical conditions may be 'switched' on and off, one promising lead of future research in depression is the quest to understanding the mechanisms underlying the neurobiological processes associated with sleep and wakefulness. In the future it is hoped that the rapidly evolving progress in basic neuroscience including recent molecular biology with systematic screening of gene expression and functional brain imaging techniques will help us in progressively uncovering the mystery of sleep, and ultimately improving treatment strategies of depression.

Sleep Disorders: Psychological Aspects

1. *Definition*

Good sleep is usually defined by its consequences. It is the amount and quality of sleep that results in the ability to feel and function well the next day. In contrast, a sleep disorder is a disturbance in the quantity or quality of sleep that interferes with waking performance and/or feelings of well-being. Psychological factors play a role in both the etiology and maintenance of many of the 84 sleep disorders recognized in the *The International Classification of Sleep Disorders Diagnostic Coding Manual* (1997). These in turn have both short-term and long-term effects on the psychological functioning of patients.

2. *Background*

Historically, sleep has not been an area of concern in psychology. Aside from psychoanalytic theory, which placed a good deal of emphasis on the role of unconscious motivation in explaining behavior, most psychological theory was based on behavior that was objectively observable. With the discovery in the early 1950s of rapid eye movement (REM) sleep, and its

close association with the distinctive mental activity, dreaming, a good deal of work was undertaken to explore whether and how this interacted with waking behavior. The question of whether dreaming has some unique psychological function was driven by the observation that this phenomenon was universal, regularly recurring, and persistent when experimentally suppressed.

Initially it was speculated that the study of dreaming might lead to better understanding of the psychoses. Was the hallucination of mental illness a misplaced dream? Was the high degree of brain activation in REM sleep conducive to memory consolidation of new learning? Did dreaming play a role in emotional adaptation? When, after some 25 years of experimentation, no clear consequences for waking behavior could be attributed to the suppression of REM sleep, interest in this area faded. Loss of REM sleep did not appear to interfere with memory consolidation, nor did it promote waking hallucinations. Its role in emotional adaptation remained speculative. Foulkes's (1982) study of children's dream development concluded that dream construction was not something special. It could be explained by the periodic internal activation of the brain stimulating bits of sensory memory material represented at the same level of cognitive sophistication as the child was capable of achieving in waking thought. Adult dreams were further diminished in importance by the Activation-Synthesis hypothesis of Hobson and McCarley (1977), whose work pinpointed the area of the brain where REM sleep turns on as, not where the higher mental processes take place, but in the lower brain stem. In this theory dreams only acquire meaning after the fact, by association to what are initially, unplanned, random sensory stimuli.

3. *Current Research*

Interest in the 24-hour mind, the interaction of waking–sleeping–waking behavior came back into focus with the development of the field of sleep disorder medicine. The impact of disordered sleep on psychological functioning is documented most convincingly through large epidemiological studies of insomnia and hypersomnia that involved extensive follow up. The findings of Ford and Kamerow (1989) that both insomnia and hypersomnia are significant risk factors for new psychiatric disorders have now been replicated in several large studies. Further work has established that the onset of a new episode of waking major depression can be predicted from the presence of two weeks of persistent insomnia (Perlis et al. 1997). These findings have sparked the development of psychological interventions for the control of insomnia in an effort to prevent the development of these psychiatric disorders. Some of these are behavioral programs that work directly to manipulate sleep to improve its continuity, others are psychotherapeutic in nature such as interpersonal therapy and cognitive behavioral therapy which address the interaction patterns, emotional and cognitive styles that are dysfunctional in depressed persons.

Again, it was the observation that morning mood on awakening in major depression was frequently low, that suggested an investigation of the REM sleep and dreaming of the depressed person to test whether defects in this system prevented overnight mood regulation or emotional adaptation. The work of Kupfer and his colleagues (Reynolds and Kupfer 1987) established that there are several REM sleep deviations associated with major depression not seen in normal individuals. This leads to a variety of manipulations in an attempt to correct these. Vogel's (Vogel et al. 1975) studies of extensive REM deprivation interspersed with recovery nights were most successful in improving waking mood and in bringing about remission without further treatment. Cartwright's work (Cartwright et al. 1998) on the effect on morning mood of various within-night dream affect patterns, showed that a 'working through' pattern, from dreams expressing negative mood to those with predominantly positive affect, predicted later remission from depression.

The recurring nightmares characteristic of post-traumatic stress disorder (PTSD) has stimulated renewed interest in addressing dreams directly in treatment programs, especially for those with long-lasting symptoms of this disorder. These methods typically involve active rehearsal of mastery strategies for the control of the disturbing dream scenario.

A good deal of effort is now being addressed to discovering those attitudes, beliefs, and habitual behaviors that are implicated in maintaining poor sleep patterns since the correction of these may help to restore normal sleep and abort the development of a major psychiatric disorder.

Studies of the psychological profiles of those exhibiting various sleep disorders have most often employed the Minnesota Multiphasic Personality Inventory (MMPI). These show insomnia patients have more scale elevations above the norms especially of those indicating neurotic personality characteristic, such as phobias and obsessive compulsive disorders, than do matched controls. Generally, insomnia patients appear to internalize tensions rather than express them and may often somaticize these and express them as pain syndromes. In terms of demographic variables most studies report more women than men complain of insomnia. Rates are higher in those who are separated or widowed rather than single or married, and among the unemployed. In addition, insomnia is more common in those of middle to lower socioeconomic status than in the highest class. This picture suggests that a loss of the time structure of work and of a love relationship may be precipitating psychological factors in disrupting sleep/wake rhythms.

Other sleep disorders, such as periodic limb movements of sleep, and sleep-related breathing disorders, are not related to personality, but do have an impact on relationships, due to an inability to share the bed at night, and on waking performance. Severe levels of any sleep disorder, whether insomnia or hypersomnia, limits work efficiency, cognitive clarity, and emotional stability.

4. *Methodological Issues*

Technological problems still hamper the progress in this field. Sleep laboratory studies are expensive and in many ways unnatural. Home studies while possible are unable to make repairs or adjustments as needed. Subjects must be awakened to obtain reports of their ongoing mental activity to investigate dream content. This aborts the end of each REM period, thus truncating the dream story. Dream reports are also limited by the subject's ability to translate his/her sensory experience during sleep into waking verbal terms.

Recent studies using positive emission tomography (PET) to image the brain activity during REM sleep have established that dreaming sleep differs from waking and from non-REM in the activation of the limbic and paralimbic systems in the presence of lower activity in the dorsal–lateral frontal areas (Maquet et al. 1996, Nofzinger et al. 1997). This is interpreted as confirming that dreaming engages the emotional and drive-related memory systems in the absence of higher systems of planning and executive control. This gives new impetus to the study of dreams as a unique mental activity whose place in the 24-hour psychology may now move ahead on firmer ground.

5. *Probable Future Directions*

Work initiated by Solms (1997) on the effect of localized brain lesions on dream characteristics suggests a new line of investigation in mapping how the brain constructs dreams. This strategy may give more power to understand some of the dream disorders currently less well understood; perhaps even the hallucinations of psychoses.

Sleep States and Somatomotor Activity

The drive to sleep has an awesome power over our lives. If we go without sleep or drastically reduce it, the desire to sleep quickly becomes more important than life itself. The willingness to go to extraordinary efforts in order to obtain even a little sleep demonstrates vividly that sleep is a vital and necessary behavior. In fact, we often allow ourselves to be placed in life-threatening situations in order to satisfy the need to sleep.

But what is sleep, really? All of us feel, at some basic level, that we really do understand what sleep is all about. We certainly know how it feels, and the 'meaning' of the word is generally accepted in ordinary conversation. But, in point of fact, no one knows what sleep really is. Once we proceed beyond a simple description of an apparently quiet state that is somehow different from wakefulness, we find that the following major questions about the nature of sleep are largely unanswered: Why do we sleep?; What is (are) the function(s) of sleep?; What are the mechanisms that initiate and sustain sleep?; and, How, when and why do we wake up?

In order to understand 'sleep,' we must clarify the key processes and mechanisms that initiate and maintain this state. From a purely descriptive point of view, we simply need to know what is going on in the brain

(and body) during sleep. But first, we must agree on how to describe and/or define those behaviors that we intuitively understand as constituting the sleep states.

1. NREM and REM Sleep

Traditionally, three physiological measures are employed for describing the states of sleep in controlled laboratory situations. They are the EEG (electroencephalogram, which reflects the electrical activity of the cerebral cortex), the EOG (electrooculogram, which is a recording of eye movements), and the EMG (electromyogram, which is an indication of the degree of muscle activity, i.e., contraction). Together, these measures are used to define and differentiate sleep in mammals, which is comprised of two very different states. These states are called nonrapid eye movement (NREM) sleep and rapid eye movement (REM) sleep: each is nearly as different from the other as both are distinct from wakefulness.

Generally speaking, the EEG during NREM sleep consists of slow large-amplitude waves. Involuntary, slow, rolling, eye movements occur during the transition from drowsy wakefulness to NREM sleep; otherwise, NREM essentially lacks eye movements. Few motor events occur during NREM sleep; however, body repositioning and occasionally some motor behavior, such as sleepwalking, talking, eating or cooking, take place during NREM sleep. In general, motor processes that occur during NREM sleep are comparable to those present during very relaxed wakefulness.

The cortical EEG during REM sleep closely resembles the EEG of active wakefulness, i.e., it is of low voltage and high frequency. This is a surprising finding, considering that these two states are so dramatically different from a behavioral point of view. Bursts of rapid eye movements occur phasically during REM sleep. These eye movements are similar to those which would occur during wakefulness if one were looking at an object that went from right to left and then from left to right, rapidly and continuously, for a couple of seconds at a time. During REM sleep there is also a nonreciprocal flaccid paralysis, i.e., atonia, of the major muscle groups (with the principal exception being certain muscles used in respiration). However, at intervals that usually coincide with the phasic periods of rapid eye movements, there are brief muscle twitches that involve principally, but not exclusively, the distal muscles (e.g., the muscles of the fingers, toes, and face).

REM sleep is subdivided into 'phasic' and 'tonic' periods. During phasic REM sleep periods there are brief episodes of rapid eye movements and muscle twitches as well as muscle atonia (Fig. 1). Tonic REM

Figure 1
Intracellular recording from a trigeminal jaw-closer motoneuron: correlation of membrane potential and state changes. The membrane potential increased rather abruptly at 3.5 min in conjunction with the decrease in neck muscle tone and transition from quiet (NREM) to active (REM) sleep. At 12.5 min, the membrane depolarized and the animal awakened. After the animal passed into quiet sleep again, a brief, aborted episode of active sleep occurred at 25.5 min that was accompanied by a phasic period of hyperpolarization. A minute later the animal once again entered active sleep, and the membrane potential increased. EEG trace, marginal cortex, membrane potential band pass on polygraphic record, DC to 0.1 Hz. PGO, ponto-geniculo-occipital potential (reprinted from Chase MH, Chandler SH, Nakamura Y 1980 Intracellular determination of membrane potential of trigeminal motoneurons during sleep and wakefulness. *Journal of Neurophysiology* **44**: 349–58)

periods occur when the preceding phasically occurring eye and muscle twitches are absent, but there is still persistent muscle atonia.

2. *Somatomotor Activity During REM Sleep*

Because there is very little motor behavior during NREM sleep, the present overview of somatomotor activity during sleep consists mainly of a description of motor events which take place during REM sleep and entails: (a) an exploration of the mechanisms that control muscle activity during this sleep state, and (b) a description of the 'executive' mechanisms that are responsible for these REM sleep-related patterns of motor control (Chase and Morales 1994).

In order to understand the mechanisms responsible for the control of motor activity during REM sleep, it is important to first describe the changes in muscle fiber activity that occur during this state. The passage from wakefulness to NREM sleep is accompanied by a decrease in the degree of contraction of somatic muscle fibers, that is, there is a decrease in muscle tone, i.e., hypotonia. Surprisingly, during the state of REM sleep there occurs somatomotor atonia, or the complete lack of tone of many somatic muscles (Fig. 1). In order to understand how atonia of the somatic musculature during REM sleep is achieved, it is necessary to understand how the activity of muscle fibers are, in general, controlled.

First of all, muscles (i.e., muscle fibers) do one thing, they contract/shorten. When muscle fibers contract, they do so because command signals, which are really trains of action potentials, travel from the cell bodies of motoneurons along their axons to activate muscle fibers by changing the permeability of the muscle fiber membrane. A great many muscle groups are constantly contracting, at least to some degree, when we maintain a specific posture or perform a movement when we are awake. Thus, *tone* or some degree of muscle fiber contraction is dependent on the asynchronous, sustained discharge of motoneurons and the action potentials that travel down their axons to initiate the contraction of muscle fibers.

There is a gradual, but slight decline in muscle tone during NREM sleep compared with wakefulness. During REM sleep, there is such a strikingly potent suppression of muscle activity and motoneuron discharge. This results in a complete loss of muscle tone, or atonia. Thus, the key to understanding atonia during REM sleep resides in understanding the manner in which the activity of motoneurons is reduced or eliminated during this state.

There are two basic mechanisms that could, theoretically, be responsible for the elimination of motoneuron discharge during REM sleep: one is the direct inhibition of motoneurons (i.e., postsynaptic inhibition) and the second is a cessation of excitatory input to motoneurons (i.e., disfacilitation). Experimentally, these processes have been explored in the laboratory by recording, intracellularly, from individual motoneurons during REM sleep.

Figure 2
High-gain intracellular recording of the membrane potential activity of a tibial motoneuron during wakefulness (A), quiet (NREM) sleep (B), and active (REM) sleep (C). Note the appearance, *de novo* during active sleep, of large-amplitude, repetitively occurring inhibitory postsynaptic potentials. Two representative potentials, which were aligned by their origins, are shown at higher gain and at an expanded time base (C1, 2). These potentials were photographed from the screen of a digital oscilloscope. The analog to digital conversion rate was 50 μs/min. During these recordings the membrane potential during active sleep was −67.0 mV; the antidromic action potential was 78.5 mV (reprinted from Morales FR, Boxer P, Chase MH 1987 Behavioral state-specific inhibitory postsynaptic potentials impinge on cat lumbar motoneurons during active sleep. *Experimental Neurology* **98**: 418–35)

During REM sleep, it has been found that motoneurons become hyperpolarized, and as a consequence, they become relatively unresponsive to excitatory input. Analyses of the various membrane properties of these motoneurons indicate that their lack of responsiveness is due primarily to postsynaptic inhibition (Fig. 1). Thus, it is clear that postsynaptic

Figure 3
Action potential generation during wakefulness (A) and a rapid eye movement period of active (REM) sleep (B). Gradual membrane depolarization (bar in A′) preceded the development of action potentials during wakefulness, whereas a strong hyperpolarizing drive was evident during a comparable period of active sleep (bar in B′). This difference was also observed preceding the subsequent generation of each action potential during the rapid eye movement episode. Action potentials in A′ and B′ are truncated owing to the high gain of the recording. Resting membrane potentials are −58 mV in (A) and −63 mV in (B). Data are unfiltered; records were obtained from a single tibial motoneuron (reprinted from Chase MH, Morales FR 1982 Phasic changes in motoneuron membrane potential during REM periods of active sleep. *Neuroscience Letters* **34**: 177–82)

inhibition is the primary mechanism that is responsible for atonia of the somatic musculature during this state.

Postsynaptic inhibition of motoneurons during REM sleep occurs when certain neurons which are located in the brainstem liberate glycine at their point of contact with motoneurons, which is called the synapse. When glycine is liberated, motoneurons respond by generating changes in their membrane properties and their ability to discharge, which are recorded as 'inhibitory' postsynaptic potentials.

In an effort to elucidate the bases for motoneuron inhibition (which is viewed behaviorally as atonia) during REM sleep, spontaneous postsynaptic potentials, recorded from motoneurons, were examined. A unique pattern of sleep-specific inhibitory postsynaptic potentials was found to bombard motoneurons during REM sleep; they were of very large amplitude and occurred in abundant numbers (Fig. 2). Thus, it is clear that there is a unique set of presynaptic cells that are responsible for the REM sleep-specific inhibitory postsynaptic potentials that bombard motoneurons. For brainstem motoneurons (and likely for spinal cord motoneurons as well), these presynaptic inhibitory neurons are located in the ventromedial medulla.

In summary, postsynaptic inhibition is the principal process that is responsible for the atonia of the somatic musculature during REM sleep. This postsynaptic process is dependent on the presence of REM sleep-specific inhibitory potentials, which arise because glycine (an inhibitory neurotransmitter) is released by presynaptic neurons onto the surface of postsynaptic motoneurons.

All of the inhibitory phenomena that have been described in the previous sections are not only present but also enhanced during the phasic rapid eye movement periods of REM sleep. How, then, could there be twitches and jerks of the eyes and limbs during phasic rapid eye movement periods when there is also enhanced inhibition? The answer is simple: most of these periods are accompanied not only by increased motoneuron inhibition but also by potent motor excitatory drives that impinge on motoneurons. Thus, during these phasic periods of REM sleep, even though there is a suppression of the activity of motoneurons, there occurs, paradoxically, the concurrent excitation of motoneurons whose discharge results in the activation of muscle fibers (which leads to twitches and jerks, mainly of the limbs and fingers) (Fig. 3). These patterns of activation reflect descending excitatory activity emanating from different nuclei in the pons and possibly from the forebrain as well.

Consequently, from time to time, and for reasons as yet unknown, during REM sleep excitatory drives overpower the enhanced inhibitory drives. When this occurs, motoneurons discharge and the muscle fibers that they innervate contract. Thus, there is an increase in excitatory drives that is actually accompanied by an increase in inhibitory drives (Fig. 3). When motoneurons discharge during the REM periods of active sleep, contraction of the muscles that they innervate is unusual because the resultant movements are abrupt, twitchy, and jerky; they are also without apparent purpose.

Thus, from the perspective of motoneurons, REM sleep can be characterized as a state abundant in the availability of strikingly potent patterns of postsynaptic inhibition and, during REM periods, by new periods of excitation and also by enhanced postsynaptic inhibition.

3. The Executive Control Mechanism for Somatomotor Activity During REM Sleep

The preceding description of the neural control of somatomotor control during REM sleep can also be viewed from the perspective of the central nervous system executive mechanisms that are responsible this physiological pattern of activity. A critical structure

that is involved in the generation and/or maintenance of REM sleep, and especially, the motor inhibitory aspects of this state, is the nucleus pontis oralis, which is located in the rostral portion of the pontine reticular tegmentum. This area is thought to be activated by cholinergic fibers that arise from cell bodies that are located in the laterodorsal pontine tegmentum and the pedunculo pontine tegmentum.

There is evidence that a neuronal mechanism that resides within or is part of the nucleus pontis oralis is involved in the generation of wakefulness (and motor excitation) as well as REM sleep (and motor inhibition). For example, studies of the nucleus pontis oralis have shown that it is central to the phenomenon of reticular response reversal. This is a phenomenon wherein stimulation of this pontine nucleus results in an increase in somatic reflex activity during wakefulness, but remarkably, the identical stimulus during REM sleep yields potent postsynaptic inhibition of the same somatic reflexes.

We have suggested the existence of a neuronal switch, based on the phenomena of reticular response reversal, that is responsible for controlling the animal's state and somatomotor inhibitory processes during wakefulness as well as REM sleep. The existence of this switch is based on the hypothesis that wakefulness occurs when inhibitory (GABAergic) neurons in the nucleus pontis oralis suppress the activity of REM sleep neurons that are also located in, or in the vicinity of, the nucleus pontis oralis (Xi et al. 1999). Thus, when REM sleep-controlling neurons discharge in this and related areas the result is the generation of this state and its attendant patterns of somatomotor inhibition.

In support of the preceding hypothesis, we have found that when the inhibitory neurotransmitter GABA is placed in the nucleus pontis oralis, prolonged periods of wakefulness and heightened motor activity are elicited in cats. Conversely, the application of bicuculline, a $GABA_A$ antagonist, results in the occurrence of episodes of REM sleep and somatomotor inhibition of very long duration. We therefore conclude that a pontine GABAergic system plays a critical role in the control of wakefulness and REM sleep.

There are also recent data which demonstrates that when cells of the nucleus pontis oralis discharge, they initiate a cascade of events, the first one being the excitation of a group of premotor inhibitory neurons in the lower part of the brainstem, i.e., in the medulla (Morales et al. 1999). Fibers from these medullary neurons release glycine onto motoneurons, which results in atonia of the somatic musculature.

When the motor inhibitory mechanisms of REM sleep cease to function properly, and there is still ongoing motoneuron excitation (and/or enhanced motor excitation during the phasic periods of REM sleep), a syndrome occurs in cats that is called 'REM without atonia.' In humans, a comparable syndrome is called 'REM Behavior Disorder.' When humans and cats with this syndrome enter REM sleep, they begin to twitch violently, jump about and appear to act out their dreams; their sleep is quite disrupted and they are certainly a threat both to themselves and, of course, to others.

It is clear that the motor inhibition that occurs during REM sleep plays a critical role in the maintenance of this state. There is also no doubt that the simple release of glycine onto motoneurons during REM sleep, which results in atonia, i.e., a lack of muscle activity, has importance and implications of far-reaching and widespread proportions.

Sleep: Neural Systems

Since we spend roughly one third of our lives asleep, it is remarkable that so little attention has been paid to the capacity of sleep to organize the social behavior of animals including humans. To grasp this point, try to imagine life without sleep: no bedrooms and no beds; no time out for the weary parent of a newborn infant; and nothing to do all through the long, cold, dark winter nights. Besides demonstrating the poverty of the sociobiology of sleep, this thought experiment serves to cast the biological details which follow in the broader terms of social adaptation. Family life, reproduction, childrearing, and even economic commerce all owe their temporal organization to the power of sleep. The dependence of these aspects of our

lives on sleep also underlines its importance to deeper aspects of biological adaptation—like energy regulation—that are only beginning to be understood by modern scientists.

1. Behavioral Physiology of Sleep

Sleep is a behavioral state of homeothermic vertebrate mammals defined by: (a) characteristic relaxation of posture; (b) raised sensory thresholds; and (c) distinctive electrographic signs.

Sleep tends to occur at certain times of day and becomes more probable as sleeplessness is prolonged. These two organizing principles are the pillars of Alex Borbely's two-factor model: factor one captures the temporal or 'circadian' aspect while factor two captures the energetic or 'homeostatic' aspect (see *Sleep Behavior*). Sleep is usually associated with a marked diminution of motor activity and with the assumption of recumbent postures. Typically the eyes close and the somatic musculature becomes hypotonic. The threshold to external stimulation increases and animals become progressively less responsive to external stimuli as sleep deepens.

The differentiation of sleep from states of torpor in animals that cannot regulate core body temperature has an important phylogenetic correlation with the neural structures mediating the electrographic signs of sleep. These include the cerebral cortex and thalamus whose complex evolution underlies the distinctive electroencephalographic features of sleep in the higher vertebrate mammals. Sleep also constitutes the state of entry to and exit from hibernation in mammalian species that regulate temperature at lower levels during winter.

In humans, who can report upon the subjective concomitants of these outwardly observable signs of sleep, it is now clear that mental activity undergoes a progressive and systematic reorganization throughout sleep. On first falling asleep, individuals may progressively lose awareness of the outside world and experience microhallucinations and illusions of movement of the body in space; after sleep onset, mental activity persists but is described as thoughtlike and perseverative, if it can be recalled at all upon awakening. (For a description of the subsequent changes in mental activity, see the entry on dreaming.)

2. Electro-physiological Aspects of Sleep

There is a complex organization of behavioral, physiological, and psychological events within each sleep bout. To detect this organization, it is necessary to record the electroencephalogram (EEG) from the surface of the head (or directly from the cortical structures of the brain), to record the movement of the eyes by means of the electrooculogram (EOG), and to record muscle tone by means of the electromyogram (EMG). These three electrographic parameters allow one to distinguish sleep from waking and to distinguish two distinctive and cyclically recurrent phases within sleep: NREM (non-rapid eye movement) and REM (rapid eye movement) sleep. NREM, also known as synchronized or quiet sleep, is characterized by a change in the EEG from a low-amplitude, high-frequency to a high-amplitude, low-frequency pattern (see Fig. 1a).

The degree to which the EEG is progressively synchronized (that is, of high voltage and low frequency) can be subdivided into four stages in humans: In stage one, the EEG slows to the theta frequency range (4–7 cycles per second or cps) and is of low voltage (< 50 mV and arrhythmic). Stage two is characterized by the evolution of distinctive sleep spindles composed of augmenting and decrementing waves at a frequency of 12–15 cps and peak amplitudes of 100 mV. Stage three is demarcated by the addition to the spindling pattern of high voltage (> 100 mV) slow waves (1–4 cps), with no more than 50 percent of the record occupied by the latter. In stage four, the record is dominated by high-voltage (150–250 mV) slow waves (1–3 cps). At the same time that the EEG frequency is decreasing and the voltage increasing, muscle tone progressively declines and may be lost in most of the somatic musculature. Slow rolling eye movements first replace rapid saccadic eye movements of waking and then also subside, with the eyes finally assuming a divergent upward gaze (Fig. 1a).

After varying amounts of time, the progressive set of changes in the EEG reverses itself and the EEG finally resumes the low-voltage, fast character previously seen in waking. Instead of waking, however, behavioral sleep persists; muscle tone, at first passively decreased, is now actively inhibited; and there arise in the electrooculogram stereotyped bursts of saccadic eye movement called rapid eye movements (the REMs, which give this sleep state the name REM sleep). Major body movements are quite likely to occur during the NREM–REM transition. The REM phase of sleep has also been called activated sleep (to signal the EEG desynchronization) and paradoxical sleep (to signal the maintenance of increased threshold to arousal in spite of the activated brain). Human consciousness is associated with the low-voltage, fast EEG activity of waking and REM sleep but its unique character in dreaming depends upon other aspects of REM neurophysiology (see Fig. 1b).

In all mammals (including aquatic, arboreal, and flying species) sleep is organized in this cyclic fashion: sleep is initiated by NREM and punctuated by REM at regular intervals. Most animals compose a sleep bout out of three or more such cycles, and in mature humans the average nocturnal sleep period consists of four to five such cycles, each of 90–100 minutes

Figure 1
(a) Behavioral states in humans. The states of waking, NREM, and REM sleep have behavioral, polygraphic, and psychological manifestations which are depicted here. In the behavioral channel, posture shifts- detectable by time lapse photography or video- can be seen to occur during waking and in concert with phase changes of the sleep cycle. Two different mechanisms account for sleep immobility: disfacilitation (during stages I–IV of NREM sleep) and inhibition (during REM sleep). In dreams, we imagine that we move, but we do not. The sequence of these stages is schematically represented in the polygraph channel and sample tracings are also shown. Three variables are used to distinguish these states: the electromyogram (EMG) which is highest in waking, intermediate in NREM sleep, and lowest in REM sleep; the electroencephalogram (EEG) and electrooculogram (EOG) which are both activated in waking and REM sleep, and inactivated in NREM sleep. Each sample record is about 20 s long. Other subjective and objective state variables are described in the three lower channels. (*b*) Sample records of human sleep (Snyder and Hobson)

duration. After a prolonged period of wake activity (as in humans) the first cycles are characterized by a preponderance of high-voltage, slow wave activity (i.e., the NREM phase is enhanced early in the sleep bout) while the last cycles show more low-voltage, fast wave activity (i.e., the REM phase is enhanced late in the sleep bout). The period length is fixed across any and all sleep periods in a given individual but is shorter in immature and smaller animals indicating a correlation of NREM–REM cycle length with brain size.

3. *Neural Mechanisms of Sleep*

In all animals, sleep is one of a number of circadian behavioral functions controlled by an oscillator in the suprachiasmatic nucleus of the hypothalamus. It is the interaction of the intrinsic propensity to sleep at about 24 hour (i.e., circadian) intervals with the daily cycles of extrinsic light and temperature that gives sleep its diurnal organization. The exact mechanism by which hypothalamic structures act to potentiate sleep at one or another diurnal period is unknown, but increasing evidence suggests that peptide hormones are involved in regulating this coordination.

The hypothesis that sleep is hormonally regulated is an old one and is linked to the subjective impression of fatigue with its implied humoral basis. The fact that the sleep drive increases with the duration of time spent awake in both normal and sleep-deprived animals clearly indicates the homeostatic regulation function of sleep, and experiments begun by Pieron at the beginning of the twentieth century suggested that a circulating humoral factor might mediate this propensity. Subsequent efforts to test the humoral hypothesis have involved the isolation of an S-muramyl peptide as a slow wave sleep-enhancing factor found both in the cerebrospinal fluid of sleep-deprived animals and in normal human urine. It remains to be established that this so-called factor S is involved in physiological sleep mediation; this is most important since factor S is known to be a product of bacterial cell walls but is not produced by the brain.

Whatever its mediating mechanism, the onset of sleep has long been linked by physiologists to the concept of deafferentation of the brain. In early articulations of the deafferentation hypothesis it was thought that the brain essentially shut down when deprived of external inputs. This idea was put forth by Frederic Bremer to explain the results of midcollicular brain stem transection after which the forebrain persistently manifested the EEG synchronized pattern of slow wave sleep. Bremer thought that the so-called *cerveau isolé* (or isolated forebrain) preparation was asleep because it had been deprived of its afferent input. That interpretation was upset by Bremer's own subsequent finding that transection of the neuraxis at C-1 produced intense EEG desynchronization and hypervigilance in the so-called *encephale isolé* (or isolated brain) preparation.

The possibility that active neural mediation of arousal by brain stem structures situated somewhere between the midcollicular and high spinal levels was thus suggested. The faint possibility that afferent input (via the trigeminal nerve) might account for the difference between the two preparations was eliminated by Giuseppe Moruzzi's finding that the mediopontine pretrigeminal transected preparation was also hyperalert. Thus the notion of sleep mediation via passive deafferentation was gradually replaced by the idea of sleep onset control via the active intervention of brain stem neural structures. This new idea does not preclude a contribution from deafferentation. And indeed, they appear to be complementary processes.

The clear articulation of the concept of active brain stem control of the states of sleep and waking came from the 1949 finding by Giuseppe Moruzzi and Horace Magoun that high-frequency stimulation of the mid-brain reticular formation produced immediate desynchronization of the electroencephalogram and behavioral arousal in drowsy or sleeping animals. The most effective part of the reticular activating system was its rostral pole in the diencephalon where the circadian clock is located.

These data indicated that wakefulness was actively maintained by the tonic firing of neurons in an extensive reticular domain. Arousal effects could be obtained following high-frequency stimulation anywhere in the reticular formation from the medullary to the pontine to the midbrain and diencephalic levels. The activating effect was thought to be mediated by neurons in the thalamus, which in turn relayed tonic activation to the entire neocortex. This concept has been recently confirmed at the cellular level by Mircea Steriade, following up on the earlier work of Dominic Purpura which had indicated that the spindles and slow waves of NREM sleep were a function of a thalamocortical neuronal interaction that appeared whenever brain stem activation subsided.

Once Moruzzi and Magoun had substantiated the concept of active neural control of the states of waking and sleep, other evidence supporting this notion promptly followed. For example, it was found by Barry Sterman and Carmine Clemente that high-frequency stimulation of the basal forebrain could produce slow wave sleep in waking animals. When the same region was lesioned by Walle Nauta, arousal was enhanced. The cellular basis of these basal forebrain effects and their possible link to both the circadian oscillator of the hypothalamus and the arousal system of the reticular activating system are currently under intense investigation.

The second dramatic demonstration that sleep states were under active neural control was Michel Jouvet's lesion and transection work suggesting a role of the pontine brain stem in the timing and triggering of the REM phase of sleep. The pontine cat preparation

Figure 2
(a) Schematic representation of the REM sleep generation process. A distributed network involves cells at many brain levels (left). The network is represented as comprising 3 neuronal systems (center) that mediate REM sleep electrographic phenomena (right). Postulated inhibitory connections are shown as solid circles; postulated excitatory connections as open circles. In this diagram no distinction is made between neurotransmission and neuromodulatory functions of the depicted neurons. It should be noted that the actual synaptic signs of many of the aminergic and reticular pathways remain to be demonstrated, and, in many cases, the neuronal architecture is known to be far more complex than indicated here (e.g., the thalamus and cortex). Two additive effects of the marked reduction in firing rate by aminergic neurons at REM sleep onset are postulated: disinhibition (through removal of negative restraint) and facilitation (through positive feedback). The net result is strong tonic and phasic activation of reticular and sensorimotor neurons in REM sleep. REM sleep phenomena are postulated to be mediated as follows: EEG desynchronization results from a net tonic increase in reticular, thalamocortical, and cortical neuronal firing rates. PGO waves are the result of tonic disinhibition and phasic excitation orf burst cells in the lateral pontomescencephalic tegmentum. Rapid eye movements are the consequence of phasic firing by reticular and vestibular cells; the latter (not shown) directly excite oculomotor neurons. Muscular atonia is the consequence of tonic postsynaptic inhibition of spinal anterior horn cells by the pontomedullary reticular formation. Muscle twitches occur when excitation by reticular and pyramidal tract motorneurons phasically overcomes the tonic inhibition of the anterior horn cells. Anatomical abbreviations: RN, raphe nuclei; LC, locus coeruleus; P, peribrachial region; FTG, gigantocellular tegmental field; FTC, central tegmental field; FTP, parovocellular tegmental field; FTM, magnocellular tegmental field; TC, thalamocortical; CT, cortical; PT cell, pyramidal cell; III, oculomotor; IV, trochlear; V, trigmenial motor nuclei; AHC, anterior horn cell. (Modified from Hobson et al. 1986)
(b) Synaptic modifications of the original reciprocal interaction model based upon recent findings. Reported data from animal (cat and rodent) are shown as solid lines and some of the recently proposed putative dynamic relationships are shown as dotted lines. The exponential magnification of cholinergic output predicted by the original model can also occur in this model with mutually excitatory cholinergic-non-cholinergic interactions (7.) taking the place of the previously postulated, mutually excitatory cholinergic-cholinergic interactions. The additional synaptic details can be superimposed on this revised reciprocal interaction model without altering the basic effects of aminergic and cholinergic influences on the REM sleep cycle. For example: i. Excitatory cholinergic-non-cholinergic interactions utilizing ACh and the excitatory amino acid transmitters enhance firing of REM-on cells (6., 7.) while inhibitory noradrenergic (4.), serotonergic (3.) and autoreceptor cholinergic (1.) interactions suppress REM-on cells. ii. Cholinergic effects upon aminergic neurons are both excitatory (2.), as hypothesized in the original reciprocal interaction model and may also operate via presynaptic influences on noradrenergic-serotonergic as well as serotonergic-serotonergic circuits (8.). iii. Inhibitory cholinergic autoreceptors (1.) could contribute to the inhibition of LDT and PPT cholinergic neurons which is also caused by noradrenergic (4.) and serotonergic (3.) inputs. iv. GABAergic influences (9., 10.) as well as other neurotransmitters such as adenosine and

(with ablation of all forebrain structures above the level of the pontine tegmentum) continued to show periodic abolition of muscle tone and rapid eye movements at a frequency identical to the REM periods of normal sleep. The implications were (a) that the necessary and sufficient neurons for timing and triggering by REM were in the pons and (b) that this system became free-running when the pontine generator was relieved of circadian restraint from the hypothalamus.

Small lesions placed in the pontine tegmentum between the locus coeruleus and the pontine reticular formation resulted in periods of REM sleep without atonia: the cats exhibited all the manifestations of REM sleep except the abolition of muscle tone, indicating that intrapontine connections were essential to mediate and coordinate different aspects of the REM sleep period.

4. *A Cellular and Molecular Model of the Sleep–Wake Cycle*

Microelectrode studies designed to determine the cellular mechanism of these effects have indicated that REM sleep is actively triggered by an extensive set of executive neurons ultimately involving at least the oculomotor, the vestibular, and the midbrain, pontine, and medullary reticular nuclei (see Fig. 2). The intrinsic excitability of this neuronal system appears to be lowest in waking, to increase progressively throughout NREM sleep, and to reach its peak during REM sleep. Cells in this system have thus been designated REM-on cells. In contrast, neurons in the aminergic brain stem nuclei (the serotoninergic dorsal raphe and the catacholaminergic locus coeruleus and peribrachial region) have reciprocally opposite activity curves. These aminergic REM-off cells fire maximally in waking, decrease activity in NREM sleep, and reach a low point at REM onset.

The reciprocal interaction model of state control ascribes the progressive excitability of the executive (REM-on) cell population to disinhibition by the modulation (REM-off) cell population. How the aminergic systems are turned off is unknown, but Cliff Saper has recently suggested that GABA-ergic inhibition may arise from neurones in the hypothalamic circadian control system.

5. *Cholinergic REM Sleep Mediation*

Confirming the early studies of Jouvet and Raul Hernandez-Peon, numerous investigations have found prompt and sustained increases in REM sleep signs when cholinergic agonist drugs are microinjected into the pontine brain stem of cats. The behavioral syndrome produced by this treatment is indistinguishable from the physiological state of REM sleep, except that it is precipitated directly from waking with no intervening NREM sleep. The cats can be aroused but revert to sleep immediately when stimulation abates. This drug-induced state has all the physiological signs of REM sleep (such as the low voltage fast EEG, EMG atonia, REM, and ponto-geniculo-occipital (PGO) waves), suggesting that it is a valid experimental model for physiological REM. Humans who are administered cholinergic agonist by intravenous injection during the first NREM cycle also show potentiation of REM sleep; this cholinergically enhanced REM sleep is associated, as usual, with dreaming.

Mixed nicotinic and muscarinic agonists (e.g., carbachol), pure muscarinic agonists (e.g., bethanechol) and dioxylane are equally effective potentiators of REM sleep and recent results suggest that activation of the M2 acetylcholine receptor suffices to trigger REM sleep behavior. The inference that acetylcholine induces REM sleep is suggested by Helen Baghdoyan's finding that neostigmine, (an acetylcholinesterase inhibitor which prevents the breakdown of endogenously released acetylcholine) also potentiates sleep after some delay. All of these effects are dose-dependent and are competitively inhibited by the acetylcholine antagonist atropine.

REM sleep induction is obtained only by injection of cholinergic agonists into the pons: Midbrain and medullary injections produce intense arousal with incessant turning and barrel-rolling behavior, respectively. Within the pons, the response pattern differs according to the site of injection, with maximal effects obtained from a region anterodorsal to the pontine reticular formation and bounded by the dorsal raphe and the locus coeruleus nuclei.

In the peribrachial pons, where both aminergic and cholinergic neurons are intermingled, carbachol injection produces continuous PGO waves by activating the cholinergic PGO burst cells of the region. But agonist induction of these drug-induced waves is state-independent and REM sleep is not potentiated in the

Figure 2

nitric oxide (see text) may contribute to the modulation of these interactions. Abbreviations: open circles, excitatory postsynaptic potentials; closed circles, inhibitory postsynaptic potentials; mPRF, medial pontine reticular formation; PPT, pedunculopontine tegmental nucleus; LDT, laterodorsal tegmental nucleus; LCα, peri-locus coeruleus alpha; 5HT, serotonin; NE, norepinephrine; ACh, acetylcholine; glut, glutamate; AS, aspartate; GABA, gamma-aminobutyric acid

first 24 hours following drug injection. It is only later that REM sleep increases reaching its three- to fourfold peak at 48–72 hours and thereafter remaining elevated for 6–10 days. By injection of carbachol into the sub- and peri-locus coeruleus regions of the pontine reticular formation, where tonic, neuronal activity can be recorded during REM sleep, atonia may be generated, while waking persists, suggesting a possible animal model of human cataplexy.

Cholinergic cells of the PGO wave generator region of the peribrachial pons are known to project to both the lateral geniculate nucleus and the perigeniculate sectors of the thalamic reticular nucleus, where they are probably responsible for the phasic excitation of neurons in REM sleep. This supposition is supported by the finding that the PGO waves of the LGN are blocked by nicotinic antagonists.

Wolf Singer's recent work suggests the functional significance of these internally generated signals. Singer proposes that the resulting resonance contributes to the use-dependent plasticity of visual cortical networks. Besides providing evidence that REM sleep signs are cholinergically mediated, these recent pharmacological results provide neurobiologists with a powerful experimental tool, since a REM-sleeplike state can be produced at will. Thus Francisco Morales and Michael Chase have shown that the atonia produced by carbachol injection produces the same electrophysiological changes in lumbar motoneurons as does REM sleep: a decrease in input resistance and membrane time constant, and a reduction of excitability associated with discrete IPSPs. These findings facilitate the exploration of other neurotransmitters involved in the motorneuronal inhibition during REM sleep which is mediated, at least in part, by glycine.

Another important advance is the intracellular recording of pontine reticular neurons in a slice preparation by Robert McCarley's group. Neuronal networks can be activated cholinergically, producing the same electrophysiological changes as those found in REM sleep of intact animals. A low threshold calcium spike has been identified as the mediator of firing pattern alterations in brain-stem slice preparations.

The activation process within the pons itself has also invited study, using carbachol as an inducer of REM sleep. Using the moveable microwire technique, Peter Shiromani and Dennis McGinty showed that many neurons normally activated in REM sleep either were not activated or were inactivated by the drug. Ken-Ichi Yamamoto confirmed this surprising finding and found that the proportion of neurons showing REM-sleeplike behavior was greatest at the most sensitive injection sites.

To achieve greater anatomical precision in localizing the carbachol injection site, James Quattrochi conjugated the cholinergic agonist carbachol to fluorescent microspheres, thereby reducing the rate of diffusion tenfold and allowing all neurons projecting to the injection site to be identified by retrograde labeling. Surprisingly, the behavioral effects are no less potent despite the reduced diffusion rate of the agonist. They are maximized by injection into the same anterodorsal site described by Helen Baghdoyan. That site receives input from all the major nuclei implicated in control of the sleep cycle; the pontine gigantocellular tegmental field (glutamatergic), the dorsal raphe nuclei (serotonergic), the locus coeruleus (noradrenergic), and the dorsolateral tegmental and pedunculo-pontine nuclei (cholinergic). Thus the sensitive zone appears to be a point of convergence of the neurons postulated to interact reciprocally in order to generate the NREM–REM sleep cycle. Whether this is also a focal point of reciprocal projection back to those input sites can now be investigated.

6. *Conclusions*

Because sleep occurs in a social context, and because sleep actively determines many aspects of that context, its study constitutes fertile ground for integration across domains of inquiry. At the basic science level, the cellular and molecular mechanisms emphasized here reach inexorably down, to the level of the genome. The upward extension of sleep psychophysiology to the psychology of individual consciousness, to dreaming, and hence to the mythology that guides cultures is also advancing rapidly. Altogether absent is a sound bridge to the social and behavioral realms where sleep has been ignored almost as if it were a non-behavior and hence devoid of social significance. Yet when, where, and especially with whom we sleep roots us profoundly in our domestic and interpersonal worlds.

Small-group Interaction and Gender

When people interact together in groups that are small enough to allow person-to-person contact (2 to 20 people), regular patterns of behavior develop that organize their relations. The study of gender in this context examines how these patterns of behavior are affected by members' social locations as men or women and the consequences this has for beliefs about gender differences and for gender inequality in society.

1. *The Emergence of the Field*

The systematic, empirical study of small group interaction and gender (hereafter, gender and interaction) developed during the 1940s and 1950s out of the confluence of a general social scientific interest in small groups and structural-functionalist theorizing about the origin of differentiated gender roles for men and women. Parsons and Bales (1955) argued that small groups, like all social systems, must manage instrumental functions of adaptation and goal attainment while also attending to expressive functions of group integration and the well-being of members. Differentiated instrumental and expressive gender roles develop to solve this problem in the small group system of the family. Children internalize these functionally specialized roles as personality traits that shape their behavior in all groups.

Although eventually discredited on logical and empirical grounds, the functional account of gender roles stimulated broader empirical attention to gender and interaction, not only within the family but also in task-oriented groups such as committees and work groups. Evidence accumulated that gender's effects on interaction are complex and quite context specific (see Aries 1996; Deaux and LaFrance 1998). This evidence is inconsistent with the view that gender is best understood as stable individual traits that affect men and women's behavior in a consistent manner across situations.

These findings on interaction contributed to a gradual transformation of social scientific approaches to gender. From an earlier view of gender as a matter of individual personality and family relations, social science has increasingly approached gender as a broad system of social difference and inequality that is best studied as part of social stratification as well as individual development and family organization.

Considering gender in a broader context draws attention to how the interactional patterns it entails are both similar to and different from those that characterize other systems of difference and inequality such as those based on race, ethnicity, or wealth. While interaction occurs between the advantaged and the disadvantaged on each of these forms of social difference, the rate of interaction across the gender divide is distinctively high. Gender divides the population into social categories of nearly equal size; it cross-cuts kin and households and is central for reproduction. Each of these factors increases the frequency with which men and women interact and the intimacy of the terms on which they do so. Furthermore, research on social cognition has shown that people automatically sex categorize (i.e., label as male or female) any concrete person with whom they interact. As a consequence, gender is potentially at play in all interaction and interactional events are likely to be important for the maintenance or change of a society's cultural beliefs and practices about gender. West and Zimmerman (1987) argue that for gender to persist as a social phenomenon, people must continually 'do gender' by presenting themselves in ways that allow others to relate to them as men or women as that is culturally defined by society.

Recognition of these distinctive aspects of gender has increased attention to the role that gendered patterns of interaction play in gender inequality. Interaction mediates the process by which people form social bonds, are socially evaluated by others, gain influence, and are directed towards or away from positions of power and valued social rewards. Interaction also provides the contexts in which people develop identities of competence and sociality. To the extent that gender moderates these interaction processes, it shapes the outcomes of men and women as well as shared beliefs about gender.

2. *Current Theories*

Four theoretical approaches predominate. Two, social role theory and expectation states theory, single out a society's cultural beliefs about the nature and social value of men's and women's traits and competencies as primary factors that create gendered patterns of interaction in that society. The theories conceptualize these beliefs in slightly different terms (i.e., as gender stereotypes or gender status beliefs) but are in substantial agreement about their explanatory impact on interaction through the expectations for behavior that develop when these beliefs are evoked by the group situation. The remaining theories take somewhat different approaches.

2.1 *Social Role Theory*

Eagly's (1987) social role theory argues that widely shared gender stereotypes develop from the gender

division of labor that characterizes a society. In western societies, men's greater participation in paid positions of higher power and status and the disproportionate assignment of nurturant roles to women have created stereotypes that associate agency with men and communion with women. In addition, the gendered division of labor gives men and women differentiated skills. When gender stereotypes are salient in a group because of a mixed sex membership or a task or context that is culturally associated with one gender, stereotypes shape behavior directly through the expectations members form for one another's behavior. When group members enact social roles that are more tightly linked to the context than gender, such as manager and employee in the workplace, these more proximate roles control their behavior rather than gender stereotypes. Even in situations where gender stereotypes do not control behavior, however, men and women may still act slightly differently due to their gender differentiated skills.

Social role theory has a broad scope that applies to interaction in all contexts and addresses assertive, power related behaviors as well as supportive or feeling related behaviors (called socioemotional behaviors). The explanations offered by the theory are not highly specific or detailed, however. The theory predicts that women will generally act more communally and less instrumentally than men in the same context, that these differences will be greatest when gender is highly salient in the situation, and that gender differences will be weak or absent when people enact formal, institutional roles.

2.2 *Expectations States Theory*

Another major approach, Berger and co-worker's expectation states theory, offers more detailed explanations within a narrower scope. The theory addresses the hierarchies of influence and esteem that develop among group members in goal-oriented contexts and makes predictions about when and how gender will shape these hierarchies due to the status value gender carries in society (see Ridgeway 1993; Wagner and Berger 1997). It does not address socioemotional behavior. Gender status beliefs are cultural beliefs that one gender (men) is more status worthy and generally more competent than the other (women) in addition to each having gender specific competencies. When gender status beliefs become salient due to the group's mixed sex or gender associated context, they create implicit expectations in both men and women about the likely competence of goal oriented suggestions from a man compared to those from a similar woman. These often unconscious expectations shape men and women's propensity to offer their ideas to the group, to stick with those ideas when others disagree, to positively evaluate the ideas of others, and to accept or resist influence from others, creating a behavioral influence hierarchy that usually advantages men over women in the group.

In mixed sex groups with a gender-neutral task, the theory predicts that men will participate more assertively and be more influential than women. If the group task or context is culturally linked to men, their influence advantage over women will be stronger. If the task or context is associated with women's culturally expected competencies, however, the theory predicts that women will be somewhat more assertive and influential than men. There should be no gender differences in assertive influence behavior between men and women in same sex groups with a gender-neutral task, since gender status beliefs should not be salient.

2.3 *Structural Identity Theories*

A set of symbolic interactionist theories, including Heise and Smith-Lovin's affect control theory and Burke's identity theory forms the structural identity approach (see Ridgeway and Smith-Lovin (1999) for a review). It, too, emphasizes shared cultural meanings about gender but focuses on the identity standards those beliefs create for individuals in groups. People learn cultural meanings about what it is to be masculine or feminine and these meanings become a personal gender identity standard that they seek to maintain through their actions. Identity standards act like control systems that shape behavior. If the context of interaction causes a person to seem more masculine or feminine than his or her gender identity standard, the person reacts with compensatory behaviors (e.g., warm behaviors to correct a too masculine impression). Consequently, different actions serve to express and maintain gender identities in different situational contexts.

Since people automatically sex categorize one another, this approach assumes that gender identity standards affect behavior in all interaction, although the extent of their impact varies with gender's salience in the context. Gender is often a background identity that modifies other, more situationally prominent identities, such as woman judge. Unlike the other theories, the predictions of structural identity theories focus primarily on the behavioral reactions gender produces to events in small groups.

2.4 *Two-cultures Theory*

Maltz and Borker's (1982) two cultures theory, popularized by Tannen (1990), takes a different approach. It limits its scope to informal, friendly interaction. People learn rules for friendly conversation from peers in childhood, it argues. Since these peer groups tend to

be sex-segregated and because children exaggerate gender differences in the process of learning gender roles, boys and girls groups develop separate cultures that are gender-typed. Girls learn to use language to form bonds of closeness and equality, to criticize in nonchallenging ways, and to accurately interpret the intentions of others. Boys learn to use speech to compete for attention and assert positions of dominance. In adult mixed sex groups, these rules can cause miscommunication because men and women have learned to attribute different meanings to the same behavior. Men and women's efforts to accommodate each other in mixed-sex interaction, however, modifies their behavior slightly, reducing gender differences. In same sex interaction, gendered styles of interaction are reinforced. Thus, two cultures theory predicts greater gender differences in behavior between men and women in same-sex groups than in mixed sex groups. The theory has been criticized for ignoring status and power differences between men and women and oversimplifying childhood interaction patterns (see Aries 1996).

3. *Research Findings*

The body of systematic evidence about men and women's behaviors in small group interaction is large and growing. Several methodological concerns must be kept in mind in order to interpret this evidence and infer general patterns.

3.1 *Methodological Issues*

Interaction in small groups is an inherently local phenomenon that is embedded within larger socio-cultural structures and affected by many aspects of those structures besides gender. Three methodological problems result. First, care is required to ascertain that behavioral differences between men and women in a situation are indeed due to their gender and not to differences in their other roles, power, or statuses in the situation. Second, reasonably large samples of specific interactional behaviors are necessary to infer gendered patterns in their use. Third, attention must be paid to the specific cultural context within in which the group is interacting. At present, almost all systematic research has been based on small groups in the US composed predominately of white, middle class people. Since several theories emphasize the importance of cultural beliefs about gender in shaping interaction, researchers must be alert to subcultural and cross-cultural variations in these beliefs and appropriately condition their empirical generalizations about gendered patterns of interaction. The available studies that compare US populations such African–Americans whose gender beliefs are less polarized than the dominant beliefs find that gender differences in interaction are also less for these populations (Filardo 1996).

3.2 *Empirical Patterns in North American Groups*

Taking these methodological concerns into account, narrative and meta-analytic reviews of research suggest several provisional conclusions about gender and interaction in groups governed by the dominant culture of North American society. Aries (1996), Deaux and La France (1998), and Ridgeway and Smith-Lovin (1999 provide reviews of the research on which these conclusions are based.

Gender differences in behavior do not always occur in small groups and vary greatly by context. Behavioral expectations associated with the specific focus and institutional context of the small group (e.g., the workplace, a committee, a friendship group, a student group) generally are more powerful determinants of both men's and women's behavior than gender. When gender differences occur, they tend to be small or moderate in effect size, meaning that there is usually at least a 70 percent overlap in the distributions of men's and women's behavior.

When men and women are in formal, prescribed roles with the same power and status, there are few if any differences in their behavior. Research has shown that men and women in equivalent leadership or managerial roles interact similarly with subordinates of either sex. On the other hand, when women are gender atypical occupants of positions of power, they are sometimes perceived by others as less legitimate in those roles and elicit more negative evaluations when they behave in a highly directive, autocratic way than do equivalent men. These findings are in accord with the predictions of social role theory and expectations states theory.

Influence over others and assertive, goal-directed behavior such as participation rates, task suggestions, and assertive patterns of gestures and eye gaze are associated with power and leadership in small groups. In mixed sex groups with a gender-neutral task, men have moderately higher rates of assertive behaviors and influence than do women who are otherwise their peers. When the group task or context is culturally linked to men, this gender difference increases. When the task or context is one associated with women, however, women's rates of assertive behaviors and influence are slightly higher than men's. When performance information clearly demonstrates that women in a mixed sex group are as competent as the men, gender differences in assertiveness and influence disappear. In same sex groups, there are no differences between men's and women's rates of assertive behaviors or influence levels. These patterns closely match the predictions of expectations states theory, are

consistent with social role theory, and inconsistent with two cultures theory. They suggest that gender status beliefs in society and the expectations for competence in the situation that they create are an important determinant of gender differences in power and assertiveness in groups, independent of men and women's personalities or skills. They indicate as well that both men and women act assertively or deferentially depending on the situational context.

Men, like women, show higher rates of socioemotional behaviors when they are in subordinate rather than superordinate positions in groups. These are verbal and nonverbal behaviors that support the speech of others, express solidarity, and show active, attentive listenership. In mixed sex groups, women engage in slightly more socioemotional behavior than men. However, women engage in the highest rates of socioemotional behaviors, and men the lowest, in same sex groups. The latter findings are the only ones in partial accord with the two-cultures theory. That theory, however, does not account for the partial association of socioemotional behaviors with lower status positions.

Status factors alone, however, do not explain women's increased socioemotional behaviors in female groups. Assertive, instrumental behaviors appear to reflect power, competence, and status equally for men and women and, thus, do not reliably mark gender identity for the actor. To the extent that people signal gender identity consistently across interaction contexts, they appear to do so primarily through socioemotional behaviors that are less associated with instrumental outcomes.

4. Conclusions

Both the gender division of labor and gender inequality in a society depend on its cultural beliefs about the nature and social value of gender differences in competencies and traits. Such taken for granted beliefs allow actors to be reliably categorized as men and women in all contexts and understood as more or less appropriate candidates for different roles and positions in society. For such cultural beliefs to persist, people's everyday interactions must be organized to support them. The empirical evidence from North America suggests that unequal role and status relationships produce many differences in interactional behavior that are commonly attributed to gender. Network research suggests that most interactions between men and women actually occur within the structural context of unequal role or status relations (see Ridgeway and Smith-Lovin 1999). These points together may account for the fact that people perceive gender differences to be pervasive in interaction, while studies of actual interaction show few behavioral differences between men and women of equal status and power. Small group interaction is an arena in which the appearance of gender differences is continually constructed through power and status relations and identity marking in the socioemotional realm.

Theory and research on gender and interaction have focused on the way cultural beliefs about gender and structural roles shape interaction in ways that confirm the cultural beliefs. New approaches investigate the ways that interactional processes may perpetuate or undermine gender inequality in a society as that society undergoes economic change. If the cultural beliefs about gender that shape interaction change more slowly than economic arrangements, people interacting in gendered ways may rewrite gender inequality into newly emerging forms of socioeconomic organization in society. On the other hand, rapidly changing socioeconomic conditions may change the constraints on interaction between men and women in many contexts so that people's experiences undermine consensual beliefs about gender and alter them over time.

Smith, Adam (1723–90)

Adam Smith was born in Kirkcaldy, in the County of Fife, and baptized on June 5, 1723 (the date of birth is unknown). He was the son of Adam Smith, Clerk to the Court-Martial, later Comptroller of Customs in the town, and of Margaret Douglas of Strathendry.

1. *Early Years*

Smith entered Glasgow University in 1737—at the not uncommon age of 14. He was fortunate in his mother's choice of University and in the period of his attendance. The old, nonspecialised, system of 'regenting' had been replaced in the late 1720s by a new arrangement whereby individuals professed a single subject. There is little doubt that Smith benefited from the teaching of Alexander Dunlop (Greek) and of Robert Dick (Physics).

But two men in particular are worthy of note in view of Smith's later interests. The first is Robert Simson (1687–1768) whom Smith later described as one of the 'greatest mathematicians that I have ever had the honour to be known to, and I believe one of the two greatest that have lived in my time' (TMS, III.2.20). Smith could well have acquired from Simson and Matthew Stewart (father of Dugald) his early and continuing interest in mathematics. Dugald Stewart recalled in his memoir (Stewart 1977) that Smith's favorite pursuits while at university were mathematics and natural philosophy.

Campbell and Skinner noted that 'Simson's interests were shared generally in Scotland. From their stress on Greek geometry the Scots built up a reputation for their philosophical elucidation of Newtonian fluxions, notably in the *Treatise on Fluxions* (1724) by Colin Maclaurin (1698–1746), another pupil of Simson's who held chairs of mathematics in Aberdeen and Edinburgh (1982, p. 20).

But important as it undoubtedly was Simson's influence upon Smith pales by comparison with that exerted by Francis Hutcheson (1694–1746). A student of Gerschom Carmichael, the first Professor of Moral Philosophy, Hutcheson succeeded him in 1729. A great stylist, Hutcheson lectured in English (rather than Latin) 3 days a week on classical sources and 5 days on Natural Religion, Morals, Jurisprudence, and Government. As Dugald Stewart was to observe, Hutcheson's lectures contributed to diffuse, in Scotland, the taste for analytical discussion, and a spirit of liberal enquiry.

It is believed that Smith graduated from Glasgow in 1740 and known that he was elected to the Snell Exhibition (scholarship) in the same year. He matriculated in Balliol College on July 7, and did not return to Scotland until 1746—the year that ended the Jacobite Rebellion and saw the death of Hutcheson. The 6 years spent in Oxford were often unhappy. Smith had a retiring personality, his health was poor, and the College was pro-Jacobite and 'anti-Scottish.' Some members were also 'unenlightened'; a fact confirmed by the confiscation by one tutor of David Hume's *Treatise on Human Nature*.

And yet Smith was to write to the Principal of Glasgow University (Archibald Davidson), on the occasion of his election as Lord Rector (letter 274, dated November 16, 1787):

> No man can owe greater obligations than I do to the University of Glasgow. They educated me, they sent me to Oxford, soon after my return to Scotland they elected me one of their members, and afterwards preferred me to another office, to which the abilities and virtues of the never to be forgotten Dr Hutcheson had given a superior degree of illustration.

The reference to Oxford was no gilded memory.

Balliol had one of the best libraries in Oxford. Smith's occasional ill-health may be explained by his enthusiastic pursuit of its riches. It has been assumed that Smith developed an interest in Rhetoric and *Belles Lettres* during this period, although it now seems likely, in view of his later career, that he also further developed longer standing interests in literature, science, ethics, and jurisprudence.

2. *Professor in Glasgow*

Smith returned to Kirkcaldy in 1746 without any fixed plan. But his wide-ranging interests must have been known to his friends, three of whom arranged a program of public lectures which were delivered in Edinburgh between 1748 and 1751. The three friends were Robert Craigie of Glendoick, James Oswald of Dunnikier, and Henry Home, Lord Kames.

The lectures were of an extramural nature and delivered to a 'respectable auditory.' They probably also included material on the history of science (astronomy), jurisprudence, and economics.

The success of Smith's courses in Edinburgh no doubt led to his appointment to the Glasgow Chair of Logic and Rhetoric in 1751—where once again he

enjoyed the support of Henry Home, Lord Kames. Evidence gathered from former pupils confirms that Smith did lecture on rhetoric but also that he continued to deploy a wide range of interests, leading to the conclusion that he continued to lecture on the history of philosophy and science in the Glasgow years (Mizuta 2000, p. 101).

Smith attached a great deal of importance to his essay on the history of Astronomy (Corr, letter 137) the major part of which may well have been completed soon after leaving Oxford (Ross 1995, p. 101).

Adam Smith was translated to Hutcheson's old chair of Moral Philosophy in 1752. As John Millar recalled to Dugald Stewart, the course was divided into four parts: natural theology, ethics, jurisprudence, and expediency (economics). Millar also confirmed that the substance of the course on ethics reappeared in *The Theory of Moral Sentiments* (1759) and that the last part of the course featured in the *Wealth of Nations* (1776). We know from Smith's own words that he hoped to complete his wider plan by writing a 'sort of Philosophical History of all the different branches of literature, of philosophy poetry and eloquence' together with 'a sort of theory and history of law and government' (Corr, letter 248).

Smith returned to this theme in the advertisement to the sixth and final edition of TMS in noting that TMS and WN were parts of a wider study. 'What remains the theory of jurisprudence, which I have long projected, I have hitherto been hindered from executing, by the same occupations which had till now prevented me from revising the present work.' But the outlines of the projected study are probably revealed by the content of LJ(A) and LJ(B), and by those passages in WN which can now be recognized as being derived from them (e.g., WN, III, and V.i.a.b).

The links between the parts of the great plan are many and various. The TMS, for example, may be regarded as an exercise in social philosophy, which was designed in part to show the way in which so self-regarding a creature as man, erects (by natural as distinct from artificial means) barriers against his own passions, thus explaining the observed fact that he is always found in 'troops and companies.' The argument places a good deal of emphasis on the importance of general rules of behaviour which are related to experience and which may thus vary in content, together with the need for some system of government as a precondition of social order.

The historical analysis, with its four socioeconomic stages, complements this argument by formally considering the origin of government and by explaining to some extent the forces which cause variations in accepted standards of behavior over time. Both are related in turn to Smith's treatment of political economy.

The most polished accounts of the emergent economy and of the psychology of the 'economic man' are to be found, respectively, in the third book of WN and in Part VI of TMS that was added in 1790. Yet both areas of analysis are old and their substance would have been communicated to Smith's students and understood by them to be what they possibly were: a preface to the treatment of political economy.

From an analytical point of view, Smith's treatment of economics in the final part of LJ was not lacking in sophistication, which is hardly surprising in view of his debts to Francis Hutcheson, and through him, to Gerschom Carmichael, and thus to Pufendorf.

3. *The French Connection*

Despite his anxieties, the TMS proved to be successful (Corr, letter 31) and attracted the attention of Charles Townshend, the statesman, who set out to persuade Smith to become tutor to the young Duke of Buccleuch. Smith eventually agreed, and left Glasgow with two young charges to begin a stay of almost 2 years in France. Smith resigned his Chair in February 1764 (Corr, letter 87). The party spent many months in Toulouse before visiting Avignon and Geneva (where Smith met the much-admired Voltaire) prior to reaching Paris to begin a stay of some 10 months.

From an intellectual point of view, the visit was a resounding success and arguably influential in the sense that Smith was able to meet, amongst many others, Francois Quesnay and A. R. J. Turgot. Quesnay's economic model dates from the late 1750s but it is noteworthy that he was working on a new version of the *Tableau*, the *Analyse*, during the course of Smith's visit. It is also known that Smith met Turgot at this time and that the latter was at work on the *Reflections*.

While Smith wrote a detailed commentary on Physiocratic teaching (WN IV.ix), his lectures on economics, as delivered in the closing months of 1763, did not include a model of the kind which he later associated with the French Economists—thus suggesting that he must have found a great deal to think about in the course of 1766. But there were more immediate concerns. The young Duke was seriously ill in the summer, leading Smith to call upon the professional services of Quesnay. Smith's distress was further compounded by the illness and death of the younger brother, Hew Scott. The visit to Paris was ended abruptly. Smith spent the winter of 1766 in London and returned to Kirkcaldy in the following Spring to begin a stay of more than 6 years during which he worked upon successive drafts of the WN.

4. *London 1773–76*

Smith left Kirkcaldy in the spring of 1773 to begin a stay of some 3 years in London. David Hume assumed that publication of WN was imminent, but in fact, the

book did not appear until March 1776. The reason may well be that Smith was engaged in systematic revision of a complex work. But he was also concerned with two sophisticated areas of analysis.

The first of these questions related to Smith's interest in the optimal organization of public services, notably education, and features in a long letter addressed to William Cullen dated September 1774. The issue of public services was one of the topics that Smith addressed during his stay in London. Cullen had written to Smith seeking his opinion on proposals from the Royal College of Physicians in Edinburgh. The petition suggested that doctors should be graduates, that they should have attended College for at least 2 years, and that their competence be confirmed by examination. Smith opposed this position, arguing that universities should not have a monopoly of provision and in particular that the performance of academic staff should be an important factor in determining salaries. In sum, an efficient system of higher education requires: a state of free competition between universities and private teachers; a capacity effectively to compete in the market for men of letters; freedom of choice for students as between teachers, courses, and colleges, together with the capacity to be sensitive to market forces, even if those forces were not always themselves sufficient to ensure the provision of the basic infrastructure. Smith also argued that education should be paid for through a combination of private and public funding (WN, V.i.i.5). Smith was arguing in favour of the doctrine of 'induced efficiency' and applied the principles involved to the whole range of public services (Skinner 1996, chap. 8).

At the same time, Smith also addressed another complex question, which was considered at great length in WN (Book IV, vii), namely the developing tensions with the American Colonies. Indeed, Hume believed that Smith's growing preoccupation with the Colonial Question was the cause of the delay in the publication of the book (Corr, letter 139).

Smith's long analysis of the issues involved provides the centerpiece of his critique of the 'mercantile' system of regulation (WN, IV, v.a.24). On Smith's account the Regulating Acts of Trade and Navigation in effect confined the Colonies to the production of primary products, while the 'mother country' concentrated on more refined manufacturers—thus creating a system of complementary markets which benefited both parties. But it was Smith's contention that the British economy could not sustain indefinitely the cost of colonial administration and that in the long run the rate of growth in America would come into conflict with restrictions currently imposed.

Smith, therefore, argued that Great Britain should dismantle the Acts voluntarily with a view to creating a single free trade area, in effect an Atlantic Economic Community, with a harmonized system of taxation, possessing all the advantages of a common language and culture.

Smith accepted the principle that there should be no taxation without representation. In this connection, he noted that:

> In the course of little more than a century perhaps the produce of American might exceed that of British taxation. The seat of empire would then naturally remove itself to that part of the empire which contributed most to the general defence of the whole (WN IV, vii.c.79).

Hugh Blair, Professor of Rhetoric in Edinburgh, objected to Smith's inclusion of this material on the grounds that 'it is too much like a publication for the present moment' (Corr, 151). Others were more perceptive, recognizing that Smith was applying principles drawn from his wider system to the specific case of America (e.g., Thomas Pownall, Corr, ap.A). Pownall, a former Governor of Massachusetts, was an acute critic of Smith's position (Skinner 1996, chap. 8) but recognized that Smith had sought to produce 'an institute of the Principia of *those laws of motion*, by which the operations of the community are directed and regulated, and by which they should be examined' (Corr p. 354).

5. *The Wealth of Nations*

Dugald Stewart, Professor of Moral Philosophy in Edinburgh, noted that: 'It may be doubted, with respect to Mr Smith's Inquiry, if there exists any book beyond the circle of the mathematical and physical sciences, which is at once so agreeable in its arrangement to the rules of a sound logic and so accessible to the examination of ordinary readers' (Stewart 1977, IV22).

This is a complement which Smith would have appreciated, conscious as he was of the 'beauty of a systematical arrangement of different observations connected by a few common principles' (WN, V.i.f. 25).

But there are really two systems in WN. The first is a model of 'conceptualised reality' (Jensen 1984) which provides a description of a modern economy, which owed much to the Physiocrats. The second system is analytical and builds upon the first.

5.1 *A Model of Conceptualized Reality*

If the *Theory of Moral Sentiment* provides an account of the way in which people erect barriers against their own passions, thus meeting a basic precondition for economic activity, it also provided an account of the psychological judgments on which that activity depends. The historical argument on the other hand explains the origins and nature of the modern state and provides the reader with the means of understanding the essential nature of the exchange economy. For Smith: 'the great commerce of every civilised society, is that carried on between the inhabitants of

the town and those of the country ... The gains of both are mutual and reciprocal, and the division of labour is in this, as in all other cases, advantageous to all the different persons employed in the various occupations into which it is subdivided' (WN, III.i.1).

The concept of an economy involving a flow of goods and services, and the appreciation of the importance of intersectoral dependencies, were familiar in the eighteenth century. Such themes are dominant features of the work done, for example, by Sir James Steuart and David Hume. But what is distinctive about Smith's work, at least as compared to his Scottish contemporaries, is the emphasis given to the importance of three distinct factors of production (land, labor, capital) and to the three categories of return (rent, wage, profit) which correspond to them. What is distinctive to the modern eye is the way in which Smith deployed these concepts in providing an account of the flow of goods and services between the sectors involved and between the different socio-economic groups (proprietors of land, capitalists, and wage-labor). The approach is also of interest in that Smith, following the lead of the French Economists, worked in terms of period analysis— typically the year was chosen, so that the working of the economy is examined within a significant time dimension as well as over a series of time periods. Both versions of the argument emphasise the importance of capital, both fixed and circulating.

5.2 A Conceptual Analytical System

The 'conceptual' model which Smith had in mind when writing the *Wealth of Nations* is instructive and also helps to illustrate the series of separate, but interrelated problems, which economists must address if they are to attain the end which Smith proposed, namely an understanding of the full range of problems which have to be encountered. Smith, in fact, addressed a series of areas of analysis which began with the problem of value, before proceeding to the discussion of the determinants of price, the allocation of resources between competing uses, and, finally, an analysis of the forces which determine the distribution of income in any one time period and over time.

The analysis offered in the first book enabled Smith to proceed directly to the treatment of macroeconomic issues and especially to a theory of growth which provides one of the dominant features of the work as a whole (c.f. Skinner 1996, chap. 7). The idea of a single, all-embracing conceptual system, whose parts should be mutually consistent is not an ideal which is so easily attainable in an age where the division of labor has increased significantly the quantity of science through specialization. But Smith becomes even more informative when we map the content of the 'conceptual (analytical) system' against a model of the economy, which is essentially descriptive.

Perhaps the most significant feature of Smith's vision of the 'economic process,' to use Blaug's phrase, lies in the fact that it has a significant time dimension. For example, in dealing with the problems of value in exchange, Smith, following Hutcheson, made due allowance for the fact that the process involves judgments with regard to the utility of the commodities to be received, and the disutility involved in creating the commodities to be exchanged. In the manner of his predecessors, Smith was aware of the distinction between utility (and disutility) anticipated and realized, and, therefore, of the process of adjustment which would take place though time. Young (1997, p. 61) has emphasized that the process of exchange may itself be a source of pleasure (utility).

In an argument which bears upon the analysis of the TMS, Smith also noted that choices made by the 'rational' individual may be constrained by the reaction of the spectator of his conduct—a much more complex situation than that which more modern approaches may suggest. Smith makes much of the point in his discussion of Mandeville's 'licentious' doctrine that private vices are public benefits, in suggesting that the gratification of desire is perfectly consistent with observance of the rules of propriety as defined by the 'spectator,' that is, by an external agency. In an interesting variant on this theme, Etzioni (1988, pp. 21–4) noted the need to recognize 'at least two irreducible sources of valuation or utility; pleasure and morality.' He added that modern utility theory 'does not recognise the distinct standing of morality as a major, distinct, source of valuations' and hence as an explanation of 'behaviour' before going on to suggest that his own 'deontological multi-utility model' is closer to Smith than other modern approaches.

Smith's theory of price, which allows for a wide range of changes in taste, is also distinctive in that it allows for competition among and between buyers and sellers, while presenting the allocative mechanism as one which involves simultaneous and interrelated adjustments in both factor and commodity markets.

As befits a writer who was concerned to address the problems of change and adjustment, Smith's position was also distinctive in that he was not directly concerned with the problem of equilibrium. For him the 'natural' (supply) price was: 'as it were, the central price, to which the prices of all commodities are continually gravitating ... whatever may be the obstacles which hinder them from settling in this center of repose and continuance, they are constantly tending towards it' (WN, I.vii.15).

The picture was further refined in the sense that Smith introduced into this discussion the doctrine of 'net advantages' (WN, I.x.a.1). This technical area is familiar to labor economists, but in Smith's case it becomes even more interesting in the sense that it provides a further link with the TMS, and with the discussion of constrained choice. It was Smith's contention that men would only be prepared to

embark on professions that attracted the disapprobation of the spectator if they could be suitably compensated (Skinner 1996, p. 155) in terms of monetary reward.

But perhaps the most intriguing feature of the macroeconomic model is to be found in the way in which it was specified. As noted earlier, Smith argued that incomes are generated as a result of productive activity, thus making it possible for commodities to be withdrawn from the 'circulating' capital of society. As he pointed out, the consumption of goods withdrawn from the existing stock may be used up in the present period, or added to the stock reserved for immediate consumption, or used to replace more durable goods which had reached the end of their lives in the current period. In a similar manner, undertakers and merchants may add to their stock of materials, or to their holdings of fixed capital while replacing the plant which had reached the end of its operational life. It is equally obvious that undertakers and merchants may add to, or reduce, their inventories in ways that will reflect the changing patterns of demand for consumption and investment goods, and their past and current levels of production.

Smith's emphasis upon the point that different 'goods' have different life-cycles means that the pattern of purchase and replacement may vary continuously as the economy moves through different time periods, and in ways which reflect the various age profiles of particular products as well as the pattern of demand for them. If Smith's model of the 'circular flow' is to be seen as a spiral, rather than a circle, it soon becomes evident that this spiral is likely to expand (and contract) through time at variable rates.

It is perhaps this total vision of the complex working of the economy that led Mark Blaug to comment on Smith's sophisticated grasp of the economic process and to distinguish this from his contribution to particular areas of economic analysis (c.f. Jensen 1984, Jeck 1994, Ranadive 1984).

What Smith had produced was a model of conceptualized reality, which is essentially descriptive, and which was further illuminated by an analytical system which was so organized as to meet the requirement of the Newtonian model (Skinner 1996, chap.7). Smith's model(s) and the way in which they were specified confirmed his earlier claim that government's ought not to interfere with the economy—a theme stated in the 'manifesto of 1775' (Stewart 1977, IV.25), repeated in LJ, confirmed by Turgot, and even more eloquently defended in WN (IV.ix.51).

Smith would no doubt be gratified that Hume had lived to see the publication of WN and pleased with the assessment that it has 'Depth and Solidity and Acuteness' (Corr, letter 150). Hume died in the summer of 1776. Two years later Smith was asked by a former pupil, Alexander Wedderburn, Solicitor-General in Lord North's administration, to advise on the options open to the British Government in the aftermath of Bourgoyne's surrender at Saratoga. Smith returned to his old theme of Union, but recognized that the most likely outcome was military defeat (Corr, app B). In February of the same year, Smith was appointed Commissioner of Customs and of the Salt Duties that gave him an income of £600pa to be added to the £300 which he still received from the Duke.

Smith then moved to Edinburgh where he lived with his mother and a cousin. He died in 1790 after instructing his executors, Joseph Black and James Hutton, to burn the bulk of his papers. We may believe that the pieces which survived (which include the *Astronomy*) and which were later published in the *Essays on Philosophical Subjects*, were all specified by Smith.

6. *Influence*

Adam Smith's influence upon his successors is a subject worthy of a book rather than a few concluding paragraphs. But there are some obvious points to be made even if the list can hardly be exhaustive.

If we look at the issues involved from the standpoint of economic theory and policy, the task becomes a little simpler.

On the subject of policy, Teichgraeber has noted that Smith's advocacy of free trade or economic liberalism did not 'register any significant victories during his life-time' (1987, p. 338). Indeed, Tribe has argued that 'until the final decade of the eighteenth century, Sir James Steuart's Inquiry was better known than Smith's *The Wealth of Nations*' (1988, p. 133). The reason is that Steuart's extensive and unique knowledge of conditions in Europe, gained as a result of exile, made him acutely aware of problems of immediate relevance; problems such as unemployment, regional imbalance, underdeveloped economies and the difficulties which were presented in international trade as a result of variations in rates of growth (Skinner 1996, chap. 11). In view of later events, it is ironic to note that Alexander Hamilton considered Steuart's policy of protection for infant industries to be more relevant to the interests of the young American Republic than the 'fuzzy philosophy of Smith' (Stevens 1975, pp. 215–7).

But the situation was soon to change. In the course of a review of the way in which WN had been received, Black noted that:

> On the side of policy, the general impression left by the historical evidence is that by 1826 not only the economists but a great many other influential public men were prepared to give assent and support to the system of natural liberty and the consequent doctrine of free trade set out by Adam Smith' (1976, p. 47).

Black recorded that the system of natural liberty attracted attention on the occasion of every anni-

versary. But a cautionary note was struck by Viner (1928). Having reviewed Smith's treatment of the function of the state in *Adam Smith and Laisser-Faire*, a seminal article, Viner concluded:

> Adam Smith was not a doctrinaire advocate of laisser-faire. He saw a wide and elastic range of activity for government, and was prepared to extend it even further if government, by improving its standards of competence, honesty and public spirit, showed itself entitled to wider responsibilities' (Wood 1984, i.164).

But this sophisticated view, which is now quite general, does not qualify Robbins' point that Smith developed an important argument to the effect that economic freedom 'rested on a two fold basis: belief in the desirability of freedom of choice for the consumer and belief in the effectiveness, in meeting this choice, of freedom on the part of the producers' (Robbins 1953, p. 12). Smith added a dynamic dimension to this theme in his discussion of the Corn Laws (WN, IV.v.b). The thesis has proved to be enduringly attractive.

Analytically, the situation is also intriguing. Teichgraeber's research revealed that there 'is no evidence to show that many people exploited his arguments with great care before the first two decades of the nineteenth century (1987, p. 339). He concluded: 'It would seem at the time of his death that Smith was widely known and admired as the author of the Wealth of Nations. Yet it should be noted too that only a handful of his contemporaries had come to see his book as uniquely influential' (1987, p. 363).

Black has suggested that for Smith's early nineteenth-century successors, the WN was 'not so much a classical monument to be inspected, but as a structure to be examined and improved where necessary' (1984, p. 44). There were ambiguities in Smith's treatment of value, interest, rent, and population theory. These ambiguities were reduced by the work of Ricardo, Malthus, James Mill, and J. B. Say, making it possible to think of a classical system dominated by short-run self-equilibrating mechanisms and a long-run theory of growth.

But there was one result of which Smith would not have approved in that the classical orthodoxy made it possible to think of economics as quite separate from ethics and history. In a telling passage reflecting upon the order in which Smith developed his argument (ethics, history, economics), Hutchison concluded that Smith was unwittingly led, as if by an Invisible Hand, to promote an end which was no part of his intention, that 'of establishing political economy as a separate autonomous discipline' (1988, p. 355).

But the economic content of WN did, after all, provide the basis of classical economics in the form of a coherent, all-embracing account of 'general interconnexions' (Robbins 1953, p. 172). As Viner had earlier pointed out, the source of Smith's originality lies in his 'detailed and elaborate application to the wilderness of economic phenomena of the unifying concept of a co-ordinated and mutually interdependent system of cause and effect relationships which philosophers and theologians had already applied to the world in general' (Wood 1984, i.143).

Down the years it is the idea of system which has attracted sustained attention perhaps because it is now virtually impossible to duplicate a style of thinking which becomes more informative the further we are removed from it. No one who is familiar with the Smithian edifice can fail to notice that he thought mathematically and in a manner which reflects his early interest in related disciplines, including the life sciences—all mechanistic, evolutionary, static, and dynamic, which so profoundly affected the shape assumed by his *System of Social Science*.

Smoking and Health

1. Introduction

Worldwide, 1.1 billion people use tobacco products, primarily cigarettes. An estimated four million die annually as a consequence. By the year 2030, an estimated 1.6 billion will consume tobacco and tobacco's death toll will have skyrocketed to 10 million per year, making tobacco the leading behavioral cause of preventable premature death throughout the world. Tobacco already claims that dubious distinction in the world's developed countries (World Health Organization 1997).

The causes of this pandemic of avoidable disease and death are a complex web of physiological, psychological, social, marketing, and policy factors. Social and behavioral scientists of all disciplinary stripes have contributed to identifying and disentangling these factors, although no single model has yet adequately characterized the interactions of these determinants. Social and behavioral scientists have also elucidated important mechanisms by which both private sector and governmental intervention can discourage the initiation of smoking and encourage quitting.

After a brief description of the burden of smoking and how epidemiological science unearthed the principal tobacco-related disease connections, the causes of tobacco consumption are summarized. The efforts of social and behavioral scientists to improve the ability of smokers to quit smoking are then described, including better theoretical characterization of the determinants of quitting success and the development of more effective cessation interventions. Next examined is how social and behavioral scientists have analyzed the effects of selected important tobacco control measures, and thereby contributed to the formulation and implementation of tobacco control programs and policies. Finally, the future contribution of the social and behavioral sciences to dealing with a potentially even more cataclysmic crisis in world health during the twenty-first century is considered.

Traditional methods of youth smoking prevention, such as school health education and enforcement of minimum age-of-purchase laws, are only touched on due in part to limited scientific understanding of how initiation can be effectively discouraged, and due to its coverage elsewhere (Lantz et al. 2000; see *Substance Abuse in Adolescents, Prevention of*; *Smoking Prevention and Smoking Cessation*; *Health Promotion in Schools*).

2. Cigarette Smoking and Disease: Making the Connection

In the major industrialized nations, smoking causes from a sixth to a fifth of all mortality. The two major smoking-related causes of death are lung cancer and coronary heart disease (CHD). In the United States, epidemiologists estimate that smoking accounts for approximately 90 percent of all lung cancer deaths, with lung cancer the leading cancer cause of death in both men and women. Smoking is credited with better than a fifth of CHD deaths. In addition, smoking causes four-fifths of all chronic obstructive pulmonary disease mortality and just under a fifth of all stroke deaths (US Department of Health and Human Services 1989). The exposure of nonsmokers to environmental tobacco smoke is also a cause of disease and death (American Council on Science and Health 1999).

The toll of smoking is proportionately smaller in developing countries, reflecting the more recent rise and lesser intensity of smoking to this point. However, projections indicate a future chronic disease epidemic quite comparable to that now experienced in the world's more affluent nations (World Health Organization 1997).

Although the health hazards of tobacco smoking have been suspected for centuries, serious interest is a twentieth-century phenomenon, coincident with the advent of cigarette smoking. Prior to the twentieth century, tobacco was smoked primarily in pipes and cigars, chewed, or used nasally as snuff. Harsh tobaccos made deep inhalation of tobacco smoke difficult. Tobacco likely exacted a modest toll through the nineteenth century.

In the US, four factors combined in the early twentieth century to make cigarette smoking the most popular, and lethal, form of tobacco consumption. Perfection of the Bonsack cigarette rolling machine in 1884 introduced relatively inexpensive and neater cigarettes to the market. Discovery of the American blend of tobaccos (combining more flavorful tobaccos from Turkey and Egypt with milder American tobaccos) made deep inhalation of cigarette smoke feasible. The development and marketing of Camel cigarettes in 1913, the first American blend cigarette, introduced this new-generation product to the American public with an advertising campaign often credited as inaugurating modern advertising. Finally, cigarettes were included in soldiers' rations during World War I, permitting soldiers a quick and convenient battlefield tobacco break. Considered effeminate and unattractive prior to the war, cigarette smoking came home a 'manly' behavior. Since then, cigarette smoking has dominated all other forms of tobacco use by far in the US and in most countries of the world.

Lung cancer was virtually unknown at the beginning of the twentieth century. By 1930, it had become the sixth leading cause of cancer death in men in the United States. Less than a quarter of a century later, lung cancer surpassed colorectal cancer to become the leading cause of male cancer death. It achieved the same status among American women in the mid-1980s, surpassing breast cancer (US Department of Health and Human Services 1989).

The rapidly growing rate of lung cancer in the early decades of the century spurred a number of epidemiologists and laboratory scientists to begin investigating the relationship between smoking and cancer. In 1950, Wynder and Graham published a now classic retrospective epidemiologic analysis that strongly linked the behavior to the disease. Throughout the decade, a series of articles documented similar findings from major prospective (cohort) mortality studies in the US and the UK. Scientific groups in both countries soon thereafter published seminal public health documents indicating smoking as the major cause of lung cancer and a cause of multiple other diseases (Royal College of Physicians of London 1962, US Public Health Service 1964, US Department of Health and Human Services 1989).

By the end of the twentieth century, approximately 70,000 studies in English alone associated cigarette smoking with a wide variety of malignant neoplasms and cardiovascular and pulmonary diseases, as well as numerous other disorders. The modern plague of tobacco-produced disease is now rapidly metastasizing—both figuratively and literally—to the world's poorer nations, where increasing affluence and western image-making have combined to place cigarettes in the mouths of a sizable majority of men and a growing minority of women.

3. *The Causes of Smoking*

Smoking affords users a very mild 'high' and addresses a number of often seemingly competing physical and psychological needs, for relaxation or stimulation, distraction or concentration, for example. The crucial ingredient in the sustained use of cigarettes is the addictiveness of the nicotine in tobacco smoke. Once addicted, as most regular smokers are, smoking serves the physiological purpose of avoiding nicotine withdrawal. Nicotine affects brain receptors in much the same manner as other addictive substances, and withdrawal shares many of the same unpleasant characteristics (US Department of Health and Human Services 1988).

In many countries, smoking is initiated during the teen and even pre-teen years. At the time of initiation, new smokers typically do not appreciate the nature of addiction, much less the addictiveness of nicotine. Further, they tend to be short sighted, unconcerned about potential distant adverse health consequences (US Department of Health and Human Services 1994). The combination translates into a large pool of new smokers who have adopted the behavior, and become addicted, without considering either the danger or addictiveness of smoking, a situation that most will come to regret.

The physical effects of nicotine notwithstanding, history teaches that virtually all drug use is socially conditioned; tobacco smoking is no exception. The use of tobacco in the Americas prior to the arrival of Europeans demonstrates this vividly. Although tobacco played a prominent role in most native societies, in some tobacco smoking was restricted exclusively to the shaman, who used it for medicinal and relig-ious purposes. In other societies, tobacco smoking anointed official nonsectarian functions of tribal leaders (such as the famous 'peace pipe'). In still others, nearly all males smoked tobacco frequently, for personal and social reasons (Goodman 1993).

In contemporary society, the initiation of cigarette smoking is often viewed as a rite of passage to adulthood. In many poorer societies, smoking is seen as a symbol of affluence. In virtually all cases, smoking results from role modeling, of parents, prominent celebrities, or youthful peers.

Many tobacco control advocates attribute much of smoking's holding power to sophisticated tobacco industry marketing campaigns. In the United States alone, the industry spends over $5 billion per year on

advertising and other forms of marketing. The industry insists that the purpose of its advertising is solely to vie for shares of the existing market of adult smokers, a claim greeted with derision by the public health community. With US smokers exhibiting strong brand loyalty and two companies controlling three-quarters of the US market, marketing directed at brand switching (or its defensive analog, maintaining brand loyalty) would appear to be a relatively fruitless investment. Tobacco control advocates thus believe that much of the industry's marketing effort is directed toward attracting new smokers, primarily children but also groups of first- and second-generation American adults not yet fully acculturated into American society (e.g., Hispanic females, who have a very low smoking prevalence).

Similarly, the introduction of aggressive Western cigarette marketing into Asian societies and Eastern European and African countries has been attacked by the public health community as spurring the growth of smoking among children and other traditionally non-smoking segments of society (e.g., Asian females). In many of these countries, cigarette advertising was nonexistent or restricted to modest use of print media prior to the introduction of advertising by the major multinational tobacco companies. Before dissolution of the Soviet Union, there was virtually no advertising of the state-produced cigarettes in the Eastern European countries. That ended with a flourish when multinational tobacco companies entered the newly liberated economies and, in some instances, took over cigarette production from the inefficient state-run enterprises. In Japan, the state tobacco monopoly had never bothered to advertise on television prior to the entry of the multinationals. In short order, competition from the advertising of Western cigarette brands led to cigarettes becoming the second most advertised product on Japanese television. In Africa, the advertising media portray smoking as the indulgence of the much admired affluent set, with billboards in desperately poor villages depicting high-society Africans smoking and smiling in convivial social settings (McGinn 1997).

Although many tobacco control advocates find advertising a convenient villain to attack, widespread smoking has often preceded formal marketing. Tobacco smoking spread like wildfire through much of Europe in the sixteenth and seventeenth centuries. Similarly, male smoking rates in Russia and the Eastern European countries were very high prior to the fall of Communism and the advent of modern cigarette marketing. The effects of advertising are further examined below in Sect. 5.

4. *The Art and Science of Smoking Cessation*

In countries in which the hazards of smoking have been well publicized, surveys find that most smokers would like to quit and most have made at least one serious quit attempt, yet relatively few of those who try to quit succeed on any given attempt. In the US, for example, approximately three-quarters of smokers report they want to stop and as many as a third try each year. Yet only 2.5–3 percent succeed in quitting each year. Combined with persistent cessation efforts by many smokers, this modest quit rate has created a population in the US in which there are as many former smokers as current smokers (US Department of Health and Human Services 1989, 1990). In the aggregate, thus, quitting has significantly reduced the toll of smoking, but the toll remains stubbornly high due to the difficulty of quitting.

Although most former smokers quit without the aid of formal programs or products, the widespread desire to quit, paired with its difficulty, has created a small but thriving market for smoking cessation. Formal cessation interventions range from the distribution of how-to-quit booklets, to mass media cessation campaigns, to individual and group counseling programs, to self-administered nicotine replacement therapy (NRT) products, to use of cessation pharmaceuticals combined with clinical counseling. The efficacy of interventions ranges from sustained quit rates of about 5–7 percent for the most general and least resource-intensive interventions (e.g., generic cessation booklets) to 30 percent or more for the most resource-intensive programs that combine sophisticated counseling with the use of pharmaceuticals (Agency for Health Care Policy and Research 1996).

Over the years, behavioral scientists have helped refine smoking cessation techniques by evaluating interventions and developing theory applied to smoking cessation. Pre-eminent in the domain of theory have been models that characterize how smokers progress, through a series of 'stages,' to contemplate, attempt, and eventually succeed or fail in quitting, with cessation maintenance also examined (Prochaska and DiClemente 1983). Relating cessation advice to smokers' stages of readiness to change constitutes one way of 'tailoring' cessation messages. Another involves tying cessation advice to the specific motivations of individual smokers to quit and their specific concerns. For example, consider a smoker motivated to quit primarily by the high cost of smoking but also concerned about gaining weight. Armed with this knowledge, a cessation counselor can develop specific information on the financial savings the smoker can expect once he or she quits, while suggesting specific strategies to avoid weight gain (or to deal with it if it occurs).

Tailored cessation messages have the obvious virtue of meeting the idiosyncratic needs of individual smokers. In the absence of computer technology, however, they would entail the substantial cost of collecting information on individuals' needs and concerns and then developing individualized (tailored) cessation advice for them. Computers, however, per-

mit simple and inexpensive collection and translation of information into tailored cessation materials, such as individualized advice booklets and calendars with specific daily advice and reminders (Strecher 1999). Health informatn kiosks placed in malls and other public locations can provide instant tailored suggestions to help people quit smoking. The concept of tailoring holds great potential to enhance quit rates both in individual counseling situations and in low-cost nontreatment settings, such as these kiosks.

Social and behavioral scientists have also played a central role in defining appropriate medical treatment of smokers. The US Agency for Health Care Policy and Research (1996) clinical guideline for smoking cessation was produced by an expert committee including social and behavioral scientists who had worked on smoking cessation as service providers or developers or evaluators of interventions. The guideline urges physicians to regularly counsel their smoking patients about the implications of the behavior and to encourage them to quit. It concludes that a highly effective cessation approach involves physician counseling to quit, supplemented with use of cessation pharmaceuticals and maintenance advice through follow-up contacts. A cost-effectiveness analysis of the guideline added economics to the social sciences contributing to understanding optimal smoking cessation therapy (Cromwell et al. 1997).

Despite substantial improvements in the efficacy of cessation treatments, in any given year only a small fraction of the smokers who say they want to quit succeed in doing so, and only a small fraction of these have employed professional or programmatic assistance. As such, in any short-run period of time, the contribution of smoking cessation interventions to reducing the health toll of smoking is modest at best. This source of frustration has led a subset of smoking cessation professionals to explore methods of achieving 'harm reduction' that do not depend on smokers completely overcoming their addictions to nicotine. Harm reduction techniques range from helping smokers to reduce their daily consumption of cigarettes to encouraging consideration of the long-term use of low-risk nicotine-delivery devices, such as nicotine 'gum' or the patch. Though fraught with problems, harm reduction may be an idea whose time has come (Warner 2001).

5. *Analysis of the Effects of Tobacco Control Policies*

Another way to grapple with the toll created by smoking is to develop policies that discourage the initiation or continuation of smoking, or that restrict it to areas in which it will not impose risk on nonsmokers. Social and behavioral scientists have devoted substantial effort to studying the impacts of policies, as well as the processes by which such policies come to be adopted. This section examines the former. (For the latter, see, e.g., Fritschler and Hoefler 1996, Kagan and Vogel 1993.)

The World Health Organization and the World Bank have described and evaluated a wide array of tobacco control policies in countries around the globe (Roemer 1993, Prabhat and Chaloupka 1999). Three that have commanded the greatest amount of research attention are taxation, restricting or banning advertising and promotion, and limiting smoking in public places.

5.1 *Taxation*

Research performed primarily by economists has established that taxing cigarettes is among the most effective measures to decrease smoking (Chaloupka and Warner 2000, Prabhat and Chaloupka 1999). Because the quantity of cigarettes consumed declines by an amount proportionately smaller than the associated tax rise, taxation increases government revenues at the same time that it decreases smoking. In developed countries, economists find that a 10 percent increase in cigarette price induces approximately a 4 percent decrease in quantity demanded. In developing countries, the demand impact may be twice as large. Effective dissemination of research findings has made taxation one of the central tenets of a comprehensive tobacco control program.

Although the 'bottom line' about taxation is well established, research by economists and others points to concerns that remain unanswered. For example, does taxation discourage the initiation of smoking? Although evidence preponderantly suggests that it does, recent studies challenge the conventional view (Chaloupka and Warner 2000, Chaloupka 1999). 'Side effects,' or subtle unanticipated impacts of taxation, warrant additional attention as well. Notably, cigarette tax increases in the US cause some smokers to switch to higher nicotine cigarettes to get their customary dose of nicotine from fewer cigarettes, particularly among younger smokers (Evans and Farrelly 1998).

In the emerging field of 'behavioral economics,' a small cadre of psychologists is studying experimentally how smoking responds to incentives. For example, investigators give subjects a daily 'budget' (e.g., play money) with which to buy cigarettes, food, and other commodities, at prices established by the investigators, and evaluate the effects of 'taxation' by raising the price of cigarettes. Findings generally have been quite consistent with those in the mainstream economics literature (Chaloupka et al. 1999).

Behavioral economics can investigate questions not addressable using existing real world data, but also has decided limitations in predicting how people will

respond to price changes in that real world. By learning from each other, the two fields can enrich the evidentiary base for future tobacco tax policy.

5.2 Advertising

A diverse group of sociologists, psychologists, economists, marketing specialists, and public health scholars has studied the effects of marketing on smoking. Research by several scholars concludes that modern Western-style advertizing creates an imagery that many people, including large proportions of children, find easily recognizable and attractive. There is a strong correlation between children's interest in cigarette marketing campaigns and their subsequent smoking behavior. Temporally, advertising campaigns directed at specific segments of a population have often been followed by significant growth in smoking in the targeted groups, including women in the US in the 1960s, young women in Asia in the 1990s, and children in many countries (Warner 2000 McGinn 1997).

Whether any of these associations constitutes a causal relationship is the essential question. The same unidentified factor that makes cigarette advertising attractive to certain children could account for their subsequent smoking, independent of the advertising *per se*. Similarly, cigarette marketers might foresee an (independently occurring) expansion of a market segment and dive into the advertising void to compete for shares of that new market.

In the absence of the ability to run randomized controlled trials, empirical analysis of the relationship between cigarette advertising and consumption has been unable to prove a causal connection or to estimate its likely extent (US Department of Health and Human Services 1989, Warner 2000). However, strong new evidence supporting causality comes from a study re-examining data on the relationship between countries' policies with regard to cigarette advertising (ranging from no restrictions to complete bans) and levels of smoking within those societies (Saffer and Chaloupka 1999). Blending marketing theory with empirical analysis, this study concluded that a complete ban on cigarette advertising would decrease smoking by about 6 percent, while partial bans (e.g., banning cigarette ads on the broadcast media) would be unlikely to have an impact on cigarette consumption.

Combined with the previously existing evidence, the new research leads to the most plausible interpretation of the relationship between advertising and cigarette consumption. It is a conclusion that likely will satisfy neither tobacco industry defenders of the 'brand-share only' argument, nor tobacco control advocates who condemn marketing efforts as a principal cause of smoking. Cigarette advertising and other forms of marketing likely do increase the amount of smoking in a statistically significant manner, possibly accounting for as much as 10 percent of cigarette consumption. (This figure is likely to vary among societies, depending on the maturity of the smoking market and on familiarity with large-scale marketing campaigns.) The converse, of course, is that advertising and marketing almost certainly do not account for the majority of cigarettes consumed. For these, one must turn to other influences, all less policy tractable than advertising, including role modeling, peer behavior, and the addictiveness of nicotine and smoking.

5.3 Restrictions on Smoking in Public Places

'Clean indoor air laws,' which restrict or prohibit smoking in public places and workplaces, grew out of concerns that the exposure of nonsmokers to environmental tobacco smoke (ETS) could create a risk of disease, leading in the US to rapid diffusion of state laws, beginning in 1973. A decade later, similar laws emerged at the local level of government, where most of the legislative action in the US has remained since then (Brownson et al. 1997).

The scientific knowledge base actually followed early diffusion of legislation, with a number of studies of the relationship between ETS exposure and the risk of lung cancer published in the 1980s (Brownson et al. 1997). By the 1990s, the research base had become sufficiently strong that the US Environmental Protection Agency (EPA) declared ETS a 'Class A Carcinogen,' a proved environmental cause of cancer in nonsmoking humans. The EPA estimated that ETS caused approximately 3,000 lung cancer cases annually in the US, and also detailed nonfatal respiratory disease effects of ETS, particularly in children (US Environmental Protection Agency 1992). More recently, research has implicated ETS in heart disease deaths in adult nonsmokers, possibly an order of magnitude greater than the lung cancer impact (American Council on Science and Health 1999).

Social and behavioral scientists have informed the debate by studying the process of the emergence and diffusion of clean indoor air laws and, subsequently, the effects of such laws on nonsmokers' exposure to ETS and on smokers' smoking behavior. Studies have found generally high levels of compliance with the laws, even in bars (where low compliance was anticipated by many) (Warner 2000), and reductions in employees' exposure to ETS, as measured both by self-reports, air sampling, and examination of employees' body burdens of cotinine, a nicotine derivative.

Less obvious is whether clean indoor air laws discourage smoking or merely 'reallocate' it to times and places in which smoking is permitted. According to several studies, the laws do discourage smoking

among workers in regulated workplaces, producing increased quit rates and lower daily consumption among continuing smokers (Brownson et al. 1997).

5.4 Interaction of Policies

As policy research becomes more sophisticated, the relationships among policies and their impacts will come to be better understood. Illustrative is research examining the joint effects of tax increases and the adoption of clean indoor air laws. For example, some of the smoking decline credited to tax increases might be associated with a citizenry more interested in reducing smoking. In turn, the latter could be reflected in the adoption of clean indoor air laws. Examining the joint effects of the two policies confirmed researchers' suspicions, thereby suggesting a reduced (but still quite substantial) impact of taxation on smoking. Similarly, disentangling the impacts of state-level tobacco control programs that mix tax increases with media antismoking campaigns is important but analytically challenging. Recent research paves the way toward better evaluation of multiple-component policies (Chaloupka 1999, Chaloupka and Warner 2000).

6. The Future of Social and Behavioral Science Contributions to Tobacco Control

Social and behavioral science have contributed greatly toward understanding how and why the epidemic of smoking has evolved throughout the twentieth century. They have also elucidated a set of tools that can help society to extricate itself from the tenacious grip of this public health disaster.

With innovations in information and pharmacological technology combining with better insights into human behavior, further improvements in assisting smokers to quit appear to be virtually certain. Although the long-range goal must focus on preventing future generations of children from starting to smoke, helping current adult smokers to quit remains critical to reducing the tobacco-attributable burden of disease and mortality over the next three decades. As such, the role of social and behavioral scientists in smoking cessation will likely be increasingly productive.

The effectiveness of efforts to encourage smokers to quit depends to a significant degree on the environment in which smoking occurs. If smoking is increasingly viewed as antisocial, quitting smoking will become easier, and more urgent, for current smokers. Policy making is society's best means of intentionally altering the environment; and better understanding of the effects of policy interventions, and of how they come to be adopted, will be crucial to shaping the environment with regard to smoking in the coming years.

The multidimensional problems associated with tobacco use vividly illustrate the need for scientists of all disciplinary persuasions to work together. The next great challenge confronting the diverse fields of social and behavioral science in tobacco control is how to combine the methods and insights of the various disciplines into an integrated whole (Chaloupka 1999).

Smoking Prevention and Smoking Cessation

Cigarettes became popular after 1915. Today, approximately 1.1 billion people aged 15 years and over smoke: about one-third of the global population (see *Smoking and Health*). This article provides an overview of health effects, and methods for smoking prevention and cessation.

1. *Health Effects*

In the late 1940s, epidemiologists noticed that annual death rates due to lung cancer had increased fifteenfold between 1922 and 1947 in several countries. Since the middle of the twentieth century, tobacco products contributed to more than 60 million deaths in developed countries. The estimated annual mortality is 540,000 in the European Union, 461,000 in the USA, and 457,000 in the former USSR (Peto et al. 1994). Tobacco is held responsible for three and a half million deaths worldwide yearly: about seven percent of all deaths per year. This figure will grow to ten million deaths per year by the 2020s; about 18 percent of all deaths in developed countries and 11 percent of all deaths in developing countries. Half a billion people now alive will then be killed by tobacco products; these products will have killed more people than any other single disease (WHO 1998).

More than 40 chemicals in tobacco smoke cause cancer. Tobacco is a known or probable cause of about 25 diseases. Tobacco is recognized as the most important cause of lung cancer, but it kills even more people through many other diseases, including cancers at other sites, heart disease, stroke, emphysema, and other chronic lung diseases. Smokeless tobacco and cigars also have deadly consequences, including lung, larynx, esophageal, and oral cancer (USDHHS 1994). Lifetime smokers have a 50 percent chance of dying from tobacco. Half of these will die in middle age, before age 70, losing 22 years of normal life expectancy.

Exposure to environmental tobacco smoke (ETS) has been found to be an established cause of lung cancer, ischemic heart disease, and chronic respiratory disease in adults. Reported effects for children are sudden infant death syndrome, bronchial hyperresponsiveness, atopy, asthma, respiratory diseases,

reduced lung function, and middle ear disease. Barnes and Bero (1998) demonstrated from 106 reviews that conclusions on ETS were associated with the affiliations of the researchers. Overall, 37 percent concluded that passive smoking was not harmful to health. However, 74 percent of these were written by researchers with tobacco industry affiliations. The only factor associated with concluding that passive smoking is not harmful was whether the author was affiliated with the tobacco industry.

Declining consumption in developed countries has been counterbalanced by increasing consumption in developing countries. Globally, 47 percent of men and 12 percent of women smoke. In developing countries 48 percent of men and 7 percent of women smoke, while in developed countries 42 percent of men smoke as do 24 percent of women. Tobacco use is regarded as the single most important public health issue in industrialized countries.

2. *Smoking Prevention*

The process of becoming a smoker can be divided into several stages: preparation (never smoking), initial smoking, experimental or occasional (monthly) smoking, and regular (weekly and daily) smoking. In the preparatory stage attitudes towards smoking are formed. While at least 90 percent of the population has ever smoked a cigarette, the likelihood of becoming a regular smoker increases if initial smoking is repeated several times. In the third stage, a child learns how to smoke and the perceived advantages of smoking start to outweigh the disadvantages. In the fourth stage smoking becomes a routine. Most onset of smoking takes place during adolescence between age 10 and 20. Smoking onset as well as cessation are influenced by a variety of cultural (e.g., availability, litigation, smoke free places), biological (addiction), demographic (e.g., socioeconomic status, parent education), social factors (e.g., parental and peer smoking, parental and peer pressure, social bonding), and psychological factors (e.g., self-esteem, attitudes, self-efficacy expectations).

Various efforts have been undertaken to prevent youngsters to start to smoke (see e.g., Hansen 1992, Reid et al. 1995, USDHHS 1994).

2.1 *School-based Prevention Programs*

Three types of school programs can be distinguished (see *Health Promotion in Schools*). Knowledge programs were not effective. The social influence approaches result in reduced onset ranging from 25 to 60 percent; effects may persist up to four years. Long term effects are found with programs embedded in more comprehensive community approaches. The method includes five to ten lessons, emphasizes short-term consequences of smoking, discusses social (mostly peer) pressures, and includes refusal skills training. Life skills approaches focus on the training of generic life skills. Their effects are less strong than those of the social influence approaches.

2.2 *Out-of-school Approaches*

Youngsters can also be reached out of school. Mass media approaches and nonsmoking clubs are popular methods. They attract attention to the subject and may influence attitudes. A review of 63 studies about the effectiveness of mass media found small effects on behavior (Sowden and Arblaster 1999). Targeting smoking parents is important as well; children are almost three times as likely to smoke if their parents do. Helping parents to quit smoking may prevent their children from starting to smoke and may encourage adolescent cessation.

2.3 *Policies*

A range of policy interventions can be used to stimulate the prevention of smoking.

(a) *Price policies* can have preventive effects. Higher prices encourage cessation among current smokers and discourage initiation among young smokers. A price elasticity of -0.05 implies that a ten percent increase in price reduces consumption or prevalence by five percent. Price elasticity ranges between -0.20 to -0.50.

(b) *School policies* can stimulate smoking prevention. When examining the impact of school smoking policies over 4,000 adolescents in 23 Californian schools, it was found that schools with many smoking prevention policies had significantly lower smoking rates than schools with fewer policies and less emphasis on smoking prevention.

(c) *Public smoking restrictions* can contribute to adolescents' beliefs that nonsmoking is normative and that smoking creates health problems. Smoking regulations are more effective in preventing teenagers from starting to smoke than in reducing their consumption. Restriction of sales to minors often results in noncompliance: between 60 to 90 percent of the adolescents succeeded to buy tobacco products in situations where this was not allowed.

3. *Smoking Cessation*

Physical addiction is caused by the pharmacological effects of nicotine. Psychological addiction occurs because smoking becomes linked with numerous daily circumstances and activities (e.g., eating, drinking) and emotional and stressful events. A person becomes motivated to quit if he has a positive attitude, encounters social support, and has high self-efficacy expectations towards quitting (De Vries and Mudde 1998).

Cessation is a process: a smoker in precontemplation is not considering to quit within six months; a smoker in contemplation is, but not within a month; a smoker in preparation is considering to quit within a month; a person in action has quit recently; a person in maintenance has quit for more than six months (Velicer and Prochaska 1999).

Three outcome measures can be used to assess smoking cessation: point prevalence (having smoked during the preceding seven days), prolonged abstinence (not smoked during six or twelve months), and continuous abstinence (not smoked at all since the time of intervention). In longitudinal experimental designs more smokers than quitters may drop out, thus resulting in too optimistic estimates of successes of treatments. To correct for this bias, dropouts are coded as smokers; this is referred to as the 'intention to treat procedure.' This procedure may, however, result in conservative effect estimates. The desirability of biochemical validation is still controversial. Misreporting seldom exceeds five percent. Detection of occasional smoking in youngsters is difficult and expensive. Biochemical validation of self-reports should be considered when high demand situations are involved. A random subsample can be used to estimate bias and correct reported cessation rates. Cotinine has emerged as the measure of choice, with carbon monoxide as a cheaper but less sensitive alternative (Velicer et al. 1992).

Comparing the results of cessation studies is hindered by differences in outcome measures, populations (e.g., the percentage of precontemplators), and follow-up periods. This overview includes methods that have evidence for success. The numerous studies assessing and reviewing the efficacy of smoking cessation interventions provide different success rates. Hence, the figures reported below are estimates derived from various studies that are reported below, as well as from inspection of other publications.

3.1 Pharmacotherapy

Pharmacotherapeutic interventions increase quit rates approximately 1.5- to 2-fold. The absolute probability of not smoking at 6–12 months is greater when additional high intensity support is provided (Hughes et al. 1999, Silagy et al. 1999).

Nicotine Replacement Therapy (NRT) products are available in a number of forms, including gum, transdermal patch, nasal spray, lozenge, and inhaler. NRT is recommended to be part of the core treatment package offered to all smokers. There are few instances in which the use of NRT is contraindicated. A meta analysis including 49 trials found significant effects when applying gum, patches, nasal spray, inhaled nicotine, and sublingual tablet. These effects were largely independent of the intensity of additional support provided or the setting in which the NRT was offered. The efficacy of NRT appears also to be largely independent of other elements of treatment although absolute success rates are higher with more intensive behavioral support. The NRT cessation effects range from 6 to 35 percent, mostly ranging between 15 and 25 percent.

Bupropion is an atypical antidepressant that has both dopaminergic and adrenergic actions. Unlike NRT, smokers begin bupropion treatment one week prior to cessation. The recent evidence shows that cessation rates are comparable to those by NRT, between 15 and 25 percent (Hurt et al. 1997, Jorenby et al. 1999). One study found that the nicotine patch was less effective than bupropion (Jorenby et al. 1999). The drug appears to work equally well in smokers with and without a past history of depression.

3.2 Motivational Strategies

Various studies report on the effectiveness of group courses, self-help materials, computer tailoring, and competitions (e.g., Eriksen and Gottlieb 1998, Fisher et al. 1993, Matson et al. 1993, Skaar et al. 1997, Strecher 1999, Velicer and Prochaska 1999).

Group courses can be effective. Studies suggest 10 to 30 percent abstinence rates. The disadvantage is that they attract mostly smokers who are highly motivated to quit, and that many smokers want to quit on their own.

Self-help cessation interventions use different formats such as brochures, cassettes, and self-help guides. Point prevalence quit rates at one-year follow-up range between 9 and 15 percent.

Competitions were effective in three out of five workplace studies. No study showed enhanced smoking cessation past six months. Net effects for cessation rate of competition plus group cessation program over group program alone in three studies varied between 1 to 25 percent.

Computer tailoring results in personalized materials for smokers which are based on the (cognitive) characteristics of a person that were measured by a questionnaire. Large segments of smokers can be reached (De Vries and Brug 1999). A review of ten randomized trials found significant effects up to 25–30 percent.

3.3 Policy Interventions

Policy interventions can effect cessation (Cummings et al. 1997, Eriksen and Gottlieb 1998, Glantz et al. 1997, Meier and Licari 1997, Zimring and Nelson 1995).

Price policies, as with adolescents, influence cessation rates. Price elasticity rates for adults range between -0.3 and -0.55. Increases in cigarette prices may place a greater burden on those with lower incomes who tend to have greater difficulty in stopping smoking.

Smoke-free areas can be effective as well, although evidence is not unequivocal. Smoking bans in workplaces resulted in reduced tobacco consumption or cessation at work, results ranging from 12 percent to 39 percent. The findings on reductions on prevalence were not consistent.

Advertising, including tobacco sponsorship of events, is believed to stimulate the uptake of smoking and to reinforce the habit. This finding was supported by results from the COMMIT trial. The use of health warnings, however, has been found to be able to reduce tobacco consumption. Litigation by states and other groups may change the way tobacco is advertised and sold.

3.4 Special Settings for Cessation

Multiple smoking cessation interventions can be applied in specific settings. The goal is to attract large segments of smokers, or particular segments of smokers.

Advice by health intermediaries (physicians, nurses, midwives) is effective. A review describing the efficacy of 188 randomized controlled trials reported a two percent cessation rate resulting from a single routine consultation by physicians. While modest, the results were cost-effective. The effects are most salient among special risk groups, such as pregnant women and patients with cardiac diseases, although the additional cessation rates range from approximately 5 to 30 percent (Law and Tang 1995). In workplace settings cessation rates were four percent for a simple warning, eight percent for short counseling. They were highest among high-risk groups: 24 percent among workers at high risk for cardiovascular problems and 29 percent among asbestos exposed workers (Eriksen and Gottlieb 1998).

Community interventions have the potential to reach all segments of a community. They combine different methods, such as mass media approaches, counseling, and self-help materials. Both the broader cardiovascular risk reduction interventions and those focusing solely on smoking had very small effects (1–3 percent cessation rates), although somewhat larger effects may be reached when combining them with mass media approaches (Fisher et al. 1993, Velicer and Prochaska 1999).

Workplace programs also often combine methods. They can reach large and diverse groups of smokers and may produce an average long-term quit rate of 13 percent (ranging from 1.5 percent to 37 percent) at an average of 12 month's follow-up regardless of the intervention methods (Eriksen and Gottlieb 1998). Group programs were more effective than minimal programs, although less intensive treatments when combined with high participation rates can influence the total population as well.

4. Conclusions

School-based smoking prevention can prevent or delay smoking onset. It is unrealistic to expect long-term effects with short programs when prosmoking norms are communicated through multiple channels. Consequently, at least ten lessons are needed during adolescence in several grades. Outside of school, programs are needed, since adolescents with the highest rates of tobacco use are least likely to be reached through school based programs (Stanton et al. 1995). Innovative cessation interventions are needed as well, because youth cessation programs show no long-term success. Since multiple interventions are found to be most effective, priority should be given to broad-based interventions aimed at both the youngsters, the schools, the parents, and the community as a whole, including mass campaigns for all age groups, fiscal policies, restrictions on smoking, and bans on advertising.

Pharmacotherapy, motivational strategies, and policies are effective tools to promote cessation. The potential of other antidepressants (e.g., nortriptyline) on smoking cessation need attention as well. Innovative media strategies, such as computer tailoring, may reach less motivated smokers. Specific attention for underprivileged populations (e.g., ethnic populations, low socioeconomic groups) is needed as well. The combination of multiple methods given by multiple health care providers on multiple occasions will result in the greatest impact. Future research should assess the effectiveness of programs in smokers differing in motivational stages, since the most effective methods mostly attract smokers who are motivated to quit.

Effective methods that only reach a small segment of motivated smokers have a low impact. Less effective methods that reach large segments of the population have a higher impact. Velicer and Prochaska (1999) suggest the greatest impact for computer-tailored programs. Finally, cost-effectiveness studies reveal that cessation methods are most cost-effective when aimed at a particular subgroup, multiple interventions, and at maintaining abstinence.

H. de Vries

Soap Opera/Telenovela

'Soap opera' is a pejorative term coined in the 1930s by the entertainment trade press of the United States to designate the daytime dramatic serials that were broadcast on radio and aimed primarily at women. The term 'soap' was due to the sponsorship of the programs, which usually were produced by the advertising agencies of the soap and toiletry industries (see *Advertising Agencies*). The term 'opera' refers ironically to the dramatic character of the genre and its 'low cultural quality.' Soap operas are daytime serials with a dramatic content aimed primarily at a female audience. The genre emerged in the early period of the radio industry and has been broadcast by television stations since the 1950s. 'Telenovela' is a term used throughout Latin America to designate the melodramatic serials that became the most popular programs of the television industries of the region. They have been exported to every continent in the world. Although telenovelas have a similar history and common features when compared to soap operas, they are two distinct genres (see *Television: Genres*).

1. Soap Opera

The soap opera emerged in the US radio industry of the early 1930s. The genre developed as a response to a fundamental problem for the commercial radio stations and the advertising agencies: how to achieve the largest audience of potential consumers of certain products. The advertising agencies of the soap, toiletry, and foodstuff industries took on the role of developing programs that could attract the members of the general audience that were the main potential consumers: women between the ages of 18 and 49. When searching for formulas that could do this job, the agencies found in serials a type of narrative that

proved to be suitable in creating a faithful audience. By the late 1920s, a program that relied upon narrative and fictional characters, *Amos 'n' Andy*, established a crucial precedent by demonstrating the appeal of the radio serial form. The program presented the adventures of two Southern black men living in the city of Chicago and achieved an estimated daily audience of 40 million listeners by 1929.

The first radio programs that can be classified as soap operas appeared in the early 1930s and were based on these early successful experiments. The serial *Painted Dreams*, first broadcast in October 1930 by the station WGN, told the story of an Irish woman, her household, and daughter. The program was written by a school teacher turned radio actress, Irna Phillips, who has been credited with 'inventing' the genre soap opera. Phillips wrote many successful plots, for example, *The Guiding Light*, the longest running soap ever. The serial was introduced in January 1937, and lasted for 19 years on radio. It is still broadcast on television by CBS. Frank Hummert and his wife, Anne, were other key figures in the birth of the soap opera. Their advertising agency created one of the first daytime serials ever produced, *Stolen Husband*, in 1931. Although the serial failed, it helped the Hummerts develop the formula that proved to be successful in attracting large audiences.

Between 1933 and 1937, soap operas consolidated their dominant position in radio daytime programming and became the primary advertising vehicle for the soap, toiletry, and foodstuff industries. Although the soap opera faced a decline in broadcasting time and in number after this period of expansion, it remained one of the most popular genres in the history of radio. By 1940, the 64 serials being broadcast each day constituted 92 percent of all sponsored daytime broadcast hours and the 10 highest-rated daytime programs were all soap operas (Allen 1985). It is estimated that in the same year, one of the best in the history of daytime serials, about 20 million female viewers, approximately half the women at home during the day, listened to two or more serials daily (Cantor and Pingree 1983) (see also *Radio as Medium*).

The radio era of the soap opera in the US was terminated by the advent of a new technology, television, which would soon become the most important advertising medium. By 1955, radio soap operas were practically eliminated and the last ones were discontinued in the 1960–61 season. When the last daytime serials left radio in the early 1960s, they were already an established form of television programming and advertisers continued to produce soap operas after the transition to television. Proctor and Gamble, for example, produced the first television network soap opera, *The First Hundred Years*, first broadcast by CBS in December 1950. The reason for the longevity of the daytime serials and their successful transition to television was the suitability of fulfilling one key demand of the commercial broadcasting system: the need to attract the audience of heavy consumers in a cost-effective manner.

The main feature of the narrative text offered by the soap operas is 'openness.' Soaps are characterized by the absence of ultimate closure, since the plots never begin or end, staying on the air for several years or decades. The central elements of the serials' content usually gravitate towards issues such as love, family, intimate relationships, and other domestic concerns, although the genre has been characterized by a process of diversification. As we have seen, the history of the soap opera can be traced to the US. Nevertheless, the dramatic serials have become a common programming form all over the world, with specific national peculiarities (e.g., Allen 1995). In Europe, for example, an analysis of the network of family and romantic relationships portrayed by soap operas has shown that European serials are not simply an American genre which was imported. Europe has developed distinctive subtypes of the genre, most notably the 'community model' in which loves and family conflicts are colored by more or less pedestrian hardships of sickness, unemployment, and teenage drug habits (Liebes and Livingstone 1998).

By definition, soap operas are daytime serials. Nevertheless, in the case of the US, some prime-time dramatic serials, such as *Dallas* and *Dynasty*, have been broadcast during prime-time hours and have achieved a huge success both on the national and the international level. These prime-time serials frequently have been defined as soap operas, but they differ from daytime serials in several aspects. Prime-time serials demand a more expensive production structure and have fewer episodes. They also have a faster pace that leads to more resolution of conflicts when compared to soap operas (Cantor and Pingree 1983).

Despite the fact that soap operas have been one of the most popular and central genres in the history of television (see *Television: History*), there were very few published works on television serials until the early 1970s. This 'invisibility' of the soap opera was due, to a great extent, to the low position it occupies in the hierarchy of taste in the cultural field (see *Taste and Taste Culture*) and to the unequal gender relations that constrain it. Media, academic, and public discourses about soap operas have been marked by the fact these serials are 'woman's forms.' It was feminism that has transformed soap opera into a field for academic inquiry, although some feminists have also responded in a hostile manner toward the genre. Initially, feminist scholars used textual analysis to compare 'real' women with their stereotypical and unrealistic images (the sex object and the housewife), criticizing soap operas' tendency to confirm female subordination. Later on, feminists used more varied methodological approaches, including qualitative audience research, to affirm and authenticate the pleasures offered by the genre to its female audiences. The feminist notion that 'the personal is political' helped turn media research in

the 1970s and 1980s away from news and current affairs toward 'softer' programs. Ensuing studies found soap operas' focus on the domestic sphere of women's everyday lives to provide meaningful, rather than escapist, entertainment; they tended to validate, rather than condemn, the role that soap opera viewing plays in women's lives (see Brunsdon 1997, Brunsdon et al. 1997).

2. *Telenovela*

Telenovelas are melodramatic serials produced in Latin America. They have become the most popular programs of the television industries of the region and a successful phenomenon in the international market. Although telenovelas have features in common with soap operas, they are two distinct genres. Soap operas are broadcast during the day, usually in the afternoon, while telenovelas dominate the prime-time slots of Latin American TV networks. As a result, soap operas are watched primarily by women while telenovelas attract a broader audience in terms of age and gender. If soaps are 'open' forms, broadcast for years or decades, telenovelas are 'closed,' having a clear beginning and an end, and lasting approximately 180–200 episodes or 6–8 months. Finally, if soaps are characterized by authorial anonymity, telenovela writers in Latin America, particularly in Brazil, have personal styles that get recognized by the public (see Vink 1988).

As with their American counterparts, telenovelas have their roots in the daytime serials that were broadcast by the commercial radio stations, the *radionovelas*. Early on, Cuba consolidated a commercial broadcasting system, which became an important production center of radio melodramatic serials. By 1930, the city of Havana had proportionally more radio stations than New York and in 1932 Cuba was the third country in the world in terms of the number of radio receivers (Ortiz et al. 1989). A key figure in the development of the radio serials in Latin America was the Cuban writer Felix Caignet. After the first *radionovelas* were broadcast in Cuba around 1935, Caignet started writing several melodramatic texts which became popular not only in Cuba, but all over Latin America. For example, the story *El Derecho de Nacer* (*The Right to Be Born*) has been broadcast by radio stations all over the region for several decades and was adapted with great success for television in the 1960s.

After the introduction of the first television stations in Mexico and Brazil in 1950, telenovelas gradually became the most popular programming form of the television industries of the continent. Since the late 1960s, telenovelas have dominated prime-time and commanded the highest advertising rates. Globo Network in Brazil and Televisa in Mexico became giant media corporations and their successful programming strategies have been based largely on the local production of telenovelas. In the late 1970s, after becoming virtual monopolies in their national markets, these companies began exporting telenovelas with great success. Globo pioneered the conquest of the international market in the early 1980s by exporting the telenovela *Escrava Izaura* (*Izaura, the Slave*) that became a national obsession in countries like Poland, China, and Cuba. On the other hand, Mexico concentrated first on Latin America and Hispanic audiences in the US. Later on, some of its telenovelas, as *Los Ricos También Lloran* (*The Rich also Weep*), were successful phenomena in countries like Italy and Russia. Latin American telenovelas have been viewed in more than 120 countries and besides Globo and Televisa, the telenovelas from Venevision Network of Venezuela have also been successful in the world market (see Mattelart and Mattelart 1990, Lopez 1995, Martin-Barbero 1995).

The Latin American telenovelas focus on melodramatic conflicts, passion, tragic suffering, and moral conflicts. There are, nevertheless, important national peculiarities in the development of the genre. Mexican telenovelas are known for their weepiness and lack of specific historical references, while Brazilian telenovelas are more 'realistic' in their depiction of specific historical and political events of the country (see Lopez 1995), although more recently Mexican telenovelas such as *Nada Personal* (*Nothing Personal*) and Colombian serials like *Por estas Calles* (*In These Streets*) have also dealt with political and social contexts in a more explicit way. Latin American telenovelas have, therefore, played a growing role in representing the cultural, social and political conflicts that have shaped the region.

Sociability in History

Sociability is a notion used by historians to apprehend different forms of social relationships, in particular interpersonal bonds that are initiated either consciously or unconsciously in a given context. General distinctions are made, according to their social character, between bourgeois sociability and popular sociability, and, according to the shape it assumes, between formal sociability and informal sociability.

1. *Sociological Background*

Before historians adopted the term sociability, sociologists had used it in various ways. The first to cite is Georg Simmel, who made the notion of *Geselligkeit* (sociability) a key concept of his formal sociology. In his *Grundfragen der Soziologie* (1917), Chapter III is entitled *Die Geselligkeit. Beispiel der Reinen oder formalen Soziologie*. According to Simmel, sociability is a form of socialization, engendered by interactions exercised among individuals on the basis of reciprocity and equality. This new sociological approach made it possible to shift the emphasis of the axis of a social analysis from the content to the form of the social games.

Another sociologist for whom the notion of sociability was fundamental was Georges Gurvitch. For him, sociability comes under what he calls microsociology. In *La vocation actuelle de la sociologie* (1950), a chapter is devoted to the microsociological scale where different forms of sociability are dealt with. One significant point is his distinction between organized sociability and spontaneous sociability. This corresponds by and large with the historians' distinction between formal sociability and informal sociability.

2. *Adoption by Historians of the Notion of Sociability*

Agulhon was the first to use this notion as a key concept in his historical analysis of Provençal society. Agulhon was not inspired directly by the sociological theories mentioned above; their interpenetration came about later little by little. The starting point was his dissertation of 1966, *La sociabilité méridionale: Confréries et associations en Provence orientale dans la deuxième moitié du XVIIIe siècle*. In this work, Agulhon threw into relief an extremely dense network of social bonds, given concrete expression at the popular level in the shape of confraternities of penitents, and at the higher level, masonic lodges. He recognized in these phenomena certain characteristics of Provençal society, and called them *sociabilité méridionale*, or *southern sociability*. He later extended his research beyond the French Revolution to the mid-nineteenth century, and discerned at the base of republican movements developing in the villages a strong tradition of southern sociability. In the first half of the nineteenth century it is to be seen at the popular level in the increasing number of associations known as *chambrées*, and at the higher level in the proliferation of *cercles* (Agulhon 1970).

These pioneering works by Agulhon reverberated widely among social historians and opened up a new direction in the field of social history. The two following points represent the especial novelty of the notion. (a) Until then, the fundamental categories that constituted the very basis of social history had been the notions of social class and nation. Agulhon introduced a new dimension by adopting an ethnological perspective aimed at penetrating the intimacy of everyday life and discerning there the original social bonds that govern the society in question. (b) Social history in France came into being through criticizing traditional political history—so much so that there was a certain tendency to separate politics from social history. That was also the case with the Annales school until the 1970s. Agulhon, on the other hand, succeeded in reintegrating politics and combining it closely with social studies. In this way, his work inaugurated a new political history, closely linked with political anthropology.

The role played by Agulhon is, therefore, very important, but that does not mean that previous or parallel research in the same field had been lacking, even though they did not make use of the notion of sociability. To begin with, the very early case of Georges Lefebvre must be cited. In his 1932 presentation on the revolutionary crowd to the *Semaine de*

Synthèse presided over by Henri Berr (*Foules révolutionnaires* in the Proceedings of the colloquium, 1932), he identified three levels of social grouping: (a) simple (involuntary) crowd; (b) semivoluntary gathering; and (c) (voluntary) assembly.

While the first level corresponds to an amorphous, involuntary crowd, and the third to a body that acts collectively with a common objective and a precise consciousness, like the Revolutionary *sans-culottes*, the second intermediate level represents people who form a certain community in their everyday lives through activities such as communal work in the fields, Sunday mass, evening meetings, markets or fairs, local festivals, or drinking in taverns, and who are thus imbued with their own collective mentality. By identifying these three levels, Georges Lefebre especially underlined the importance of this second level for correctly apprehending the popular movements of the Revolutionary period. It must be noted that what he here calls 'semi-voluntary gathering' is no other than informal sociability.

A similar preoccupation is also to be found among historians contemporary with Agulhon. Yves Castan, for example, succeeded in discerning the social bonds that affect ordinary people in southwest France, by discovering the systems of codes that determine their behavior (*Honnêteté et relations sociales en Languedoc au XVIIIe siècle*, 1974). Without actually using the word *sociability*, and without any prior contact with the work of Agulhon, this study by Castan was inspired by the same concerns and remains a classic of the history of popular sociability.

For sociability in the upper levels of society, one of the best examples is presented by Roche. In his doctoral dissertation, he studied some 2,500 provincial academics who constituted a cultural network of their own. Here is another instance of a classic study of sociability without actually using the term (Roche 1978).

3. *Acceptance of the Notion of Sociability in French Historiography*

The term sociability proposed by Agulhon in his first book was favorably accepted by historians such as Philippe Ariès, Emmanuel Le Roy Ladurie, and Daniel Roche, exceeding even the writer's expectations. Vovelle, who compiled in 1980 a survey of the previous ten years' research on southern sociability, concluded: 'Sociability, a notion contrived or rediscovered over ten years ago, has entered the ranks of those supporting concepts needed by the history of mentalities in any attempt to define the collective realities on which it faces' (Vovelle 1982). Agulhon himself revised and refined this theme on various occasions. Other historians also undertook parallel studies, first within the framework of the Mediterranean, and later crossing those frontiers that had initially been assumed. Witness is borne by Guitton, whose book extended the horizons of investigation to villages throughout France, and discovered in northern France, too, intensely real-life social bonds that would constitute a village sociability (Guitton 1979).

As fast as research proceeded, discussion arose around Agulhon's initial hypothesis. Above all, criticism concerned the following two points. (a) While Agulhon considered the density and vivacity of associative life as one of the special features of Provençal life or at most the regions of the south, other researchers such as Guitton, Michel Bozon, or Jean-Luc Marais demonstrated that the phenomenon exceeded the boundaries of Provence, and that the notion of sociability was also applicable to other regions. (b) While distinguishing between the two levels of sociability, namely informal (spontaneous) sociability and formal (organized) sociability, Agulhon attached importance to the evolution from the former to the latter, this latter being the very basis of associative life. Vovelle, however, believes that informal sociability retains a vague but persistent existence, without necessarily taking on any institutional form. Agulhon himself, in his later articles, revised his initial position. He admitted in part that the notion of sociability was operative on a general plan beyond regional temperament. He also acknowledged that informal sociability had a being of its own and played an important role, especially at the popular level (Agulhon 1976, 1986).

Thus, since the 1970s, sociability has been an honored bastion of social history, alongside the history of mentalities or the history of everyday life (see the excellent survey in François and Reichardt 1987). Increasing numbers of monographs have appeared on a wide variety of themes. At the level of informal sociability, different social activities have been studied, both for villages and for urban environments, for example, collective work in the fields, community's assembly, taverns, evening meetings (*veillées*), rough music (*charivari*), carnivals or feasts, youth groups, markets and fairs, pilgrimages, games, and divertissements. All of these activities are supposed to favor a spontaneous sociability, not organized but having organic life (J-P. Guitton, R. Muchembled, N. Pellegrin, M. Bozon). In the urban framework, neighborhoods and the social life in a street or a city quarter have been brought into relief, rather than the municipal institutions that used to be studied by classical urban historians (see Farge 1979). Confraternities and *chambrées*, which Agulhon showed to be so important, now constitute a major theme of research in popular sociability.

As far as formal sociability itself is concerned, what counts above all is the sociability of the bourgeois middle classes or of the intellectual elite. Apart from freemasonry and the provincial academies mentioned earlier, objects of study include local activities of literary or other erudite people, societies of all kinds,

as well as less closed locations frequented by less elevated social strata: cafés or reading clubs (Roche, Jean-Pierre Chaline, Eric Saunier, D. Goodman).

For research as a whole, the Association for Research in Sociability (ARS) at the University of Rouen has made a valuable contribution in its wide perspective of current research. The themes chosen for colloquia that have been organized there display a wide variety of work in progress (ARS 1987, 1989, 1992, 1997).

4. *Beyond French Historiography: Influence or Coincidence*

For Germany and Switzerland, it is a case more of coincidence than of influence. In 1983, François organized an important Franco–German colloquium on sociability. According to him, 'The study of the facts of sociability and of associative life has become one of the most fertile fields for study in the new history,' but 'this parallel discovery—or re-discovery—of sociability as an object of historical research and the resulting profusion of studies have come about in France, as in Germany, in almost complete ignorance of inquiries being carried out at the same instant by historians in the neighboring country' (François 1986). A stinging comment. He also points out that German historians were concentrating on institutionalized associations (*Vereinswesen*), while their French counterparts were interested rather in all forms of sociability (*Geselligkeit*), in particular the informal sociability. This contrast between two neighboring cultural zones is also confirmed by Otto Dann in his presentation to the Franco–German colloquium. He attributes the contrast not to national temperaments, but to the difference in historical conditions experienced by the two countries in the eighteenth and nineteenth centuries. In any case he insists that henceforth for both Germany and France there is a primordial necessity to carry out parallel and joint research on these two complementary dimensions of sociability (François 1986).

In Germany in the eighteenth century, a process of transition in upper-class sociability took place from the aristocracy or the court to the rising middle classes. There was a clear increase in numbers of associations such as academies, scientific societies, musical or literary societies, reading circles, masonic lodges, student associations. Also in the nineteenth century a transference is to be observed from *bourgeois* sociability to the working-class sociability. Workers' educational associations were set up on the initiative of middle-class leaders, and working-class movements for political mobilization came into being. The end of the nineteenth century, with the rise in the consciousness of Germany as a single nation, saw the formation on a national scale of new organizations for sport, for soldiers, and so on. One feature of these associations is that women were excluded. As a result, from 1848 onward, women began setting up their own associations to campaign for their rights to education, and indeed the right to vote.

Because of its importance in the country's cultural, social, and even political life, this kind of institutionalized sociability (*Vereinswesen*) has long been a focus of interest for German historians (Dann 1984, Siebert 1993). But recently they have begun to show interest in another kind of sociability, which is rather less formal and less rigidly organized, as in family or neighborhood ties. Family celebrations, dinner parties, balls, coffee house circles, and family concerts are in their turn being studied from the point of view of sociability. Historians are also examining the blurred boundaries between public and private, and including in their work the problems posed by gender history. It is in this direction that the current of the history of everyday life is flowing (see Lüdtke 1989). Here this new orientation in German historiography can be seen converging with the preoccupations of the French historical anthropology.

The contribution of Swiss historians is important, too. The work of Im Hof not only for Switzerland but also for Europe in the Enlightenment is well known (Im Hof 1982). In his presentation to the Franco-German colloquium mentioned previously, he stresses the liveliness and the density of associative life in Switzerland. During the first half of the nineteenth century there was a blossoming of associations of widely varied types: not only artists, musicians, historians, or students, but also gymnasts, marksmen, and singers banded together in associations. He points out, too, a boom in explicitly democratic sociability, but with a strong patriotic and national inclination—a predominant Swiss characteristic (François 1986).

In the Anglo-Saxon world, the term sociability as a historical notion is not very frequent, but there are certain currents in research which have clearly been inspired by the history of sociability. At the level of informal sociability, neighborhood has become an appealing theme for urban historians: the London suburbs of the seventeenth century and the local community in eighteenth-century Paris have been admirably well analyzed (Boulton 1987, Garrioch 1986). The bonds of sociability in taverns are also considered an essential element of popular culture (Brennan 1988). In this way the approaches of English social history concur with those of French historians of sociability. On the other hand, at the level of the history of ideas, a perceptive study by Gordon points up the correlations between egalitarian-minded associations and the formation of the public sphere (Gordon 1994). This important problem of the public sphere should be further examined in close connection with social practices.

In the Mediterranean world, the influence of French historiography is more strongly felt. In Italy, Gemelli

and Malatesta compiled a volume of extracts from 10 or so major articles in the history of sociability, with a substantial Introduction which succeeds in locating the 'adventures' of sociability in the current of contemporary French historiography (Gemelli and Malatesta 1982). It should be noted that Italian *microstoria* and the new French history share many of their concerns. The works of Levi (1985) or Cerutti (1990) are good examples of this. Moreover, for analyzing urban societies in the Middle Ages and the Renaissance, Italian historians propose the notions of *parenti* (family), *amici* (friends), and *vicini* (neighbors) as elements of the social network. These are very suggestive of the point of view of sociability.

Similarly, outside the Western world, new currents in historical research are to be seen. In Japan, for example, the immediate postwar years saw the birth of a powerful current of social science history which, strongly influenced by Marxism, tried to analyze Japanese society based almost exclusively on the notions of social class and nation-state. For criticizing the nationalistic historians, who had been dominant during the War, or the traditional pure positivists, these concepts worked well and made it possible to propose a structural vision of the history of Japan. Nevertheless, with the passage of time, this unidimensional viewpoint proved too categorical and not capable of explaining the sociocultural background of Japanese history. And the rapid, unexpected transformation of Japanese society after the War made it necessary to reconsider the framework of social analysis. Therefore, since the 1970s, a new current in historical research is to be observed which, endowed with a multidimensional viewpoint, tries first to define history as lived by the people in their everyday lives and from there to approach economic or political aspects in order to reformulate the mechanisms by which Japanese society functions. It is in these new circumstances that notions of mentalities and of sociability have been integrated into Japanese historical research. A colloquium organized in Tokyo in 1994 by Hiroyuki Ninomiya on 'Different forms of social ties, or to what extent can the notion of sociability operate' was one outcome of these efforts (see Ninomiya 1995). In this way the notion of sociability has become operative even in the fields of Japanese history. The same endeavors are being followed up for other Asian regions.

5. *Perspectives*

The notion of sociability remains ambiguous. But despite its ambiguity, or rather because of its vagueness, it has been able to play a heuristic role, just like the notion of mentalities (see Le Goff 1974). Thus, it has opened up a new perspective in social history. To be sure, there are some important gaps to be filled in actual research.

(a) In general, formal (organized) and informal (spontaneous) sociability are treated separately even now. The connection and the interference between these two aspects of sociability must be elucidated.

(b) There is a certain tendency to consider sociability in isolation. Originally, sociability was about openness, exchange, communication. It would be interesting to look at it from the point of view of network and strategy theory, and to exchange problems.

(c) The relations between sociability and the creation of public sphere should be reconsidered not only at the level of bourgeois sociability and its associations, but also at the level of popular sociability, without detaching the public sphere from everyday life.

Social Behavior (Emergent), Computer Models of

By the term 'emergent social behavior' we mean those patterns of social behavior that arise automatically without relevant specifications being in-built in the individual. Under what conditions such patterns may emerge, and of what kind they are, is unpredictable in itself, but can be learned from 'bottom-up' models. In such models, a so-called 'process-oriented' approach is used. An artificial system is constructed in which agents are equipped with behavioral rules and mechanisms. While these agents interact with their environment and other agents, their behavior is studied in the same way as in ethological studies. Results show that in this way simple agents generate complex social structures, and that the same set of rules may lead to different patterns depending on the past experiences of the individuals, the demography of their population or the distribution of their food.

Studies of such complex systems were, of course, made possible by the development of computers, which have led to new modeling techniques. Initially, these studies dealt with emergent phenomena in chemical and physical research (Gleick 1987). In this article, the major issues and characteristics of these models (called 'individual-oriented,' 'individual-based,' or artificial life models) are explained by examples. Their connection with views on evolution and their general usage is discussed.

1. Major Issues of Self-Organized Social Behavior

Computer models in question deal with the emergence of:

(a) the formation of groups;
(b) collective 'decisions' (e.g., as regards the choice of a food source);
(c) the distribution of tasks over individuals (such as brood care and foraging);
(d) a reproductive 'clock';
(e) spatial structure of groups; and
(f) social organization of groups.

1.1 Group Formation

Many animal species live in groups which vary in characteristics, such as composition, size, permanency, and cohesion. One of the most cohesive and largest societies is found in army ants (with populations of up to 20,000,000 ants). Remarkably, these ants are practically blind and rely on a pheromonal system with which they mark their paths and by which they follow paths taken by others. Preying upon insect colonies, they raid over the forest in phalanxes of about 200,000 workers. Different species display different swarming patterns. To explain the differences among species in swarming, it is usually assumed that there are corresponding differences in the underlying behavioral motivations. Deneubourg and co-authors (1989), however, have shown that such markedly different swarming patterns may arise from one and the same system of laying and following pheromone

trails, when ants are raiding in different environments with different distributions of food. To show this, the authors used a simulation in which 'artificial ants' moved in a discrete network of points, and marked their path with pheromones. Further, when choosing between left and right, they preferred the more strongly marked direction. By introducing different distributions of food, different swarming patterns arose from the interaction between the flow of ants heading away from the nest to collect food, and the different spatial distributions of the foragers returning with the food. These different swarm types were remarkably similar to those of certain army ants.

1.2 Collective 'Decisions'

Further, the use of trail pheromones is also a mechanism of collective 'decision' making. Experiments with real ants combined with modeling have shown that trail laying often causes ants to choose the food source that is nearest to the nest (Deneubourg and Goss 1989). This observation seems to suggest that individual ants possess considerable cognitive capacities, but Deneubourg and Goss show in a computer model that ants may accomplish this remarkable feat without comparing distances to various food sources. When ants mark their path by pheromones and follow the more strongly marked branch at crossroads, then, by returning to the nest more quickly when the road to and from the food source is shorter, they obviously imprint the shorter path more heavily with pheromones. Thus, positive feedback is the result: as the shorter path attracts more ants, it also receives stronger marking, etc.

In subsequent extensions of this model (Detrain et al. 1999), path marking and following are shown to imply automatically risk avoidance (which agrees with observations in some species of ants), as follows: a hostile confrontation delays the forager for a certain time before returning to the nest. Thus the path to the dangerous food source automatically is marked more slowly and less strongly. Consequently, the safest food source is usually 'preferred.'

1.3 Distribution of Tasks

Such a division of labor occurs in colonies of many species of social insects. Remarkably, such division is flexible, i.e., the ratios of workers performing different tasks may vary according to the changing needs of the colony. The earliest model on the emergence of task division is that designed for bumblebees (*Bombus terrestris*) by Hogeweg and Hesper (1983, 1985). In an earlier experimental study, it was discovered that, during the growth of the colony, workers developed into two types, 'common' and 'elite' workers. The activities carried out by the two types differ remarkably: whereas the 'common' workers mainly forage and take rests, the 'elite' workers are more active, feed the brood, interact often with each other and with the queen, and sometimes lay eggs. To study the conditions for the formation of the two types of workers, Hogeweg and Hesper (1983, 1985) set up a so-called 'Mirror' model. This kind of model is complex in the number of variables included, but simple as regards behavioral processes. It contains biological data concerning the time of the development of eggs, larvae, pupae, etc. Space in the model is divided into two parts, peripheral (where inactive common workers doze part of the time) and central (where the brood is, and where all interactions take place). The rules of the artificial adult bumblebees operate 'locally' in that their behavior is triggered by what they meet. What they meet is picked out in the model randomly from what is available in the space in which the bumblebee finds itself. For instance, if an adult bumblebee meets a larva, it feeds it, and if it meets a pupa of the proper age, it starts building a cell in which a new egg can be laid, etc. All workers start with the same dominance value after hatching, with only the queen starting with a much higher rank. When one adult meets another, a dominance interaction takes place, the outcome of which (victory or defeat) is self-reinforcing. The positive feedback is 'damped,' however, because expected outcomes reinforce or diminish the dominance values of both partners only slightly, whereas unexpected outcomes give rise to relatively large changes in dominance value. Dominance values of the artificial bumblebees influence almost all their behavioral activities; for instance, individuals of high rank are less likely to forage.

It appears that this model generates two stable classes automatically, the 'elites' and 'commons,' with their typical dominance and behavioral conduct. For this result, the nest has to be divided into a center and a periphery (as found in real nests).

The flexibility of the distribution of tasks becomes obvious upon halving the worker force in the model. In line with observations in similar experiments on real bumblebees, this increases markedly each individual's tendency to forage. This arises in the model as follows: the lowered numbers of workers reduces the number of encounters among them, and thus increases the frequency of encounters between bumblebees and brood. Encountering the brood more often induces workers to collect food more frequently.

A different approach to the effect of social interactions on task allocation was taken by Pacala et al. (1996). In their model, individuals will stick to a certain task as long as it can be executed successfully, but otherwise give up (e.g., stop foraging when food is depleted). Then, as soon as they encounter another individual that is performing a task successfully, they will switch to perform that task too.

Another approach to the emergence of task division in social insects is described by Bonabeau et al. (1996). Their basic assumption is that different types of workers have different, genetically determined response thresholds for behavioral tasks. This is particularly relevant for dimorphic species, such as the ant *Pheidole megacephala*, in which two physically different castes, the so-called majors and minors, exist. Majors generally have higher thresholds than minors.

This fixed threshold model has been extended to variable response-thresholds by Theraulaz et al. (1998). They added learning in the form of a reinforcement process. This implies that performing tasks lowers the threshold of task execution and not-performing them heightens it.

1.4 Behavioral 'Clock'

In real bumblebees, the queen switches at the end of the season from producing sterile offspring to fertile ones, after which she is either chased away or killed in spite of the fact that she is still as dominant as before. The time of departure/death of the queen is important for the 'fitness' (i.e., number of new queens) of the colony.

After the demise of the queen, new queens and males (so-called generative offspring) are reared. It is assumed that the switch should take place some weeks before the end of the season, because at that time the colony is at its largest and can take care of the largest number of offspring. But it is very difficult to think of a possible external signal that could trigger such a switch. However, Hogeweg and Hesper (1983) show in their Bumblebee model that no external signal is needed, and that the switch may occur as a socially regulated 'clock' involving a fixed threshold, as follows. During the development of the colony, the queen is able to inhibit worker ovipositions by producing a certain pheromone that delays their production of eggs. Just before she is killed, she can no longer suppress the 'elite' workers, because, due to the large size of the colony, individual workers are less subjected to the dominance of the queen. So they start to lay unfertilized (drone) eggs. Further, the stress on the queen increases each time she has to perform dominance interactions with workers during her egg laying. When the 'stress' of the queen is at a low fixed threshold value, she switches to producing male eggs (drones), and when it increases to a high fixed threshold, she is killed or chased away.

The notion of this switch, which functions as a kind of social clock, has been challenged, because generative offspring are sometimes also found in small nests. However, in response to this objection, Hogeweg and Hesper have shown that the switch in small nests created in the Bumblebee model by reducing the growth speed, appears to occur at the same time as in large nests (1985). This is due to a complicated feedback process.

1.5 Spatial Structure

In many animal groups, there is a spatial structure in which dominants are in the center and subordinates at the periphery. This spatial structure is usually explained by the well-known 'selfish herd' theory of Hamilton (1971). The basic assumption of this theory is that individuals in the center of a group are best protected against predators, and therefore have evolved a preference for positions in which group members are between them and the predators, the so-called 'centripetal instinct.' However, such a spatial structure with dominants in the center also emerges in a model designed by Hemelrijk (2000), called DomWorld, in which such a preference for the center is lacking. The model consists of a homogeneous virtual world inhabited by agents that are provided with only two tendencies: (a) to group, and (b) to perform dominance interactions. Dominance interactions reflect competition for resources (such as food and mates) and the agent's capacity to be victorious (i.e., its dominance) depends, in accordance with ample empirical evidence, on the self-reinforcing effects of winning (and losing).

In this model, the spatial configuration arises without any 'centripetal instinct,' but is the result of the mutually reinforcing effects of spatial structure and strong hierarchical differentiation. It can be explained as follows. Pronounced rank differentiation causes low-ranking agents to be chased away by many, and therefore to end up at the periphery. Automatically, this leaves dominants in the center. Besides, this spatial structure causes agents to interact mainly with partners close in rank; therefore, if a rank change occurs, it is only a minor one. Thus, the spatial structure stabilizes the hierarchy and maintains its differentiation.

Spatial structure in human organizations is, for instance, evident in ghetto formation and in the formation of same-sex groups at parties. The Harvard economist, Thomas Schelling (1971), has shown how a stronger segregation emerges than is wanted by the individuals—who have only a slight preference for their own type—due to a positive feedback. Once individuals obtain minority status in a subgroup, because they are surrounded by an insufficient number of individuals of their own type (race or sex), they leave the subgroup, and this induces others of the same type to leave their former subgroup too. Their arrival in another subgroup may in its turn induce individuals of the other type to leave. Accordingly, Schelling notes that, even if the preference to have some individuals of one's own type close by is slight, its behavioral consequences may increase at a group level, leading to unexpected 'macropatterns.'

1.6 Social Organization of Groups

Two types of society are generally distinguished in the study of animal behavior: egalitarian and despotic ones. In certain primate species, such as macaques, a steep dominance or power hierarchy characterizes a despotic society, and a weak hierarchy an egalitarian one. Furthermore, both societies differ in a number of other characteristics, such as bidirectionality of aggression and cohesion of grouping. For each of these (and other unmentioned) differences a separate, adaptive (i.e., evolutionary) explanation is usually given, but DomWorld provides us with a simpler explanation for many of them simultaneously (Hemelrijk 1999): by simply increasing the value of one parameter, namely, intensity of aggression (in which egalitarian and despotic macaques differ—see Thierry 1990), the artificial society switches from a typical egalitarian to a despotic society with a cascade of consequences that resemble characteristics observed in the corresponding society of macaques. Such resemblances imply that differences between egalitarian and despotic societies of macaques may be entirely due to one trait only, intensity of aggression. On an evolutionary timescale, one may imagine that species-specific differences in aggression intensity arose, for example, because in some populations of a common ancestor, individuals suffered more food shortages, and consequently only those with intense aggression could survive.

Apart from variation among individuals in power, human societies are also characterized by a distribution of wealth. Epstein and Axtell (1996) show how, under many circumstances, a very skewed distribution of wealth emerges among heterogeneous agents (for instance, differing in vision and metabolism) in a model called 'Sugarscape.' Such a skewed distribution of wealth appears to be a general outcome of many specifications of agents that are extracting resources from a landscape of fixed capacity.

2. Characteristics of Models for Emergent Social Patterns

Typical of models for self-organized social behavior are the following characteristics of some or all of the above examples: (a) nearby perception and activation, (b) positive (instead of the more commonly used negative) feedback processes, (c) spatial distribution, (d) the possibility of studying complex behavior, and (e) 'open-endedness'.

(a) *Nearby perception and activation*. Individual agents have exclusive information about what is happening nearby. Further, timing of acts of agents is not ruled by a central clock, but nearby agents activate each other. Otherwise, agents are activated randomly.

(b) *Positive feedback processes*. Examples of these are the trail marking (with pheromones) and tracking system of ants, winning and losing of dominance interactions and a mutual reinforcement between spatial structure and the development of the hierarchy among group-living agents.

(c) *Spatial distribution*. The inclusion of space in the model creates the possibility for spatial structures to emerge. Such a spatial structure may affect behavior of individuals.

(d) *The possibility of studying complex behavior*. In these models, behavior is recorded in behavioral units similar to those used by ethologists for studying the behavior of real animals. Data are analyzed to detect new behavioral activities and patterns.

(e) '*Open-endedness*'—that is, at the time when the model is designed, it is unknown what patterns may emerge.

3. Emergence and Evolution

Because in these models behavioral mechanisms are implemented without continuous reference to pay-off benefits, this procedure leads to a parsimonious or restrictive view of evolution in the sense that the behavioral patterns observed need not always be based on trait-specific genes, and are not willed expressly by the individuals. Besides, many of the behavioral patterns usually attributed to long-term evolution may instead be explained as direct, short-term effects of other mechanisms. In these respects, these models agree with the social genetic and evolutionary explanations of, for instance, Lewontin, Gould, and Eldredge (Depew and Weber 1995), and they contrast with the thermodynamic and gene-focused views of Fisher and of sociobiology. In sociobiology, it is not the 'processes' that are of interest, but questions regarding adaptivity of behavior, and regarding evolutionarily stability of strategies. These issues are studied in the sociobiologically-oriented game-theoretic models. In contrast to models for emergence, behavioral strategies (such as 'hawks and doves,' 'cooperators and defectors') are defined in terms of pay-off without taking into account the underlying mechanisms or behavioral and environmental features; entities with different strategies are pitted against each other in order to examine which maintain themselves and which disappear, or in what proportions they may continue to exist in combination; new strategies that are not included from the start cannot arise in these game-theoretic models.

4. The Benefits of Models for Emergent Social Behavior

Models of self-organization are never to be regarded as a proof of how behavior arose. They are, however, useful for several reasons. First, they may suggest explanations that cannot be reached by theorizing alone. Take, for instance, Camazine's model on the structuring of the comb of honey bees (Camazine

1991). The comb of honey bees is structured with brood in the center, and pollen and honey in layers around it. This organization is usually attributed to a cognitive blueprint in the honey bees. Camazine's model shows, however, that the structuring of the comb may also result as a side-effect from the feeding activities of the brood, and from the relative quantities of pollen and honey imported or removed.

Second, these models can be used as 'search indicators' for empirical studies. If models are firmly based on observed biological mechanisms (as in many of the above mentioned examples), and if the emerging patterns agree with the patterns observed in real groups of organisms, then additional patterns observed in the model, but not yet noted in the real world, may be looked for in the real world. In the same way, in a model that has been shown to be relevant for real animal behavior, consequences of certain parameters may also be studied, e.g., the effects of different degrees of cohesion of grouping. To carry out such experiments in computer simulation is very easy. Usually, similar experiments are much more difficult in the real world.

Third, the insight that certain patterns of social behavior may be emergent often leads to new, parsimonious hypotheses about their evolution.

Fourth, such models can also be used in teaching pupils how to think in terms of self-organization in general as is done, for instance, by Resnick (1994).

Fifth, certain kinds of insight obtained from models may be used to solve real-world-problems (e.g., Bonabeau and Theraulaz 2000). For instance, the ant models by Deneubourg have been extended by Dorigo to solve the famous 'traveling salesman problem.' In this problem, a person must find the shortest route by which to pay a single visit to a number of cities. This problem is very difficult to solve, because the possibilities easily run into the millions.

Social Capital

With roots in de Tocqueville, Durkheim, Weber, and others, current approaches to social capital were formulated most clearly by Coleman (1990), who distinguished the term from physical and human capital. Physical capital identifies investment in tools and other tangible productive equipment; human capital refers to less tangible investments in skill and knowledge by individuals (manifested specially by educational attainment). Social capital is even less tangible, and refers to relations among persons that facilitate action, embodied in the collective norms of

communities that extend beyond immediate family members and the trustworthiness of the social environment on which obligations and expectations depend.

Most ensuing discussions of social capital emphasize levels of trust and patterns of social networks within communities. Putnam takes social capital to reflect 'features of social organization, such as trust, norms, and networks, that can improve the efficiency of society by facilitating coordinated actions' (1993). For Fukuyama, social capital is 'a capability that arises from the prevalence of trust in a society or certain parts of it' (1995). More complete surveys of the term are available in Jackman and Miller (1998) and Portes (1998).

While it is an intangible that affects the behavior of individuals, social capital itself is cast as a collective or group-level phenomenon that identifies the informal social contexts that constrain and influence the behavior of individuals. Because it is relational and inheres in social networks, social capital minimally involves dyads and typically groups of larger size: communities, neighborhoods, ethnic and national groups. In high social capital environments, individuals are networked into a variety of larger informal groups that emphasize norms of trust and reciprocity from which those individuals benefit.

While the concept is intangible, the underlying variable is clearly consequential. There is broad agreement that effective social networks and pervasive interpersonal trust enhance efficiency in social relations and lower transaction costs, both of which have direct implications for social, economic, and political behavior. Some have further suggested that high levels of social capital foster cooperative and perhaps altruistic behavior, a theme with communitarian origins. The tendency to couple social capital and cooperative behavior is specially pronounced among scholars uncomfortable with the premise that human behavior is grounded in the egoistic optimization of individual utility. However, the line between cooperation and collusion is fine.

Much has been written about social capital recently. In a noted analysis, Putnam laments the political consequences of a decline of social capital in the US during the 1980s and 1990s, a trend he claims has led increasingly to a society of go-it-alone bowlers, isolated both from each other and from broader currents of community political life (Putnam 1995). Yet the evidence for any such pattern is mixed. Voter turnout in the US has declined since around 1960, and there has also been a decline in reported levels of political trust on some survey responses (Levi and Stoker 2000). These trends appear to be the exception rather than the rule, however, and their meaning is unclear. A broad review of the available evidence since the 1960s finds no reduction in social capital, indexed by general levels of trust or group membership (Ladd 1999). Shrinking membership rates in some organizations (e.g., labor unions) have been more than offset by increases in others (e.g., environmental groups). Further, there is no evidence of a decline in social activities associated with group membership. Associational membership in the US thus appears live and well. Data on trends in group membership in other countries are less complete, but do not suggest a decline.

A more fundamental issue hinges on the causal significance attached to social capital, and here there is considerable disagreement. The bowling alone thesis attracted attention because of the consequences it imputes to social capital. Reduced social capital becomes noteworthy because it heralds increasing problems of governability and other social pathologies. The idea that social capital affects other outcomes is, indeed, a recurring theme in recent studies. For example, Putnam (1993) concludes that the effectiveness of Italy's regional governments stems from durable regional differences in patterns of social networks (civic associations): his statistical analyses explain current performance as a function of social networks in place a century earlier, and at various points, regional differences are traced back almost 1,000 years. Similarly, Fukuyama (1995) argues that the key to economic growth is social capital in the form of a supporting culture of trust, or 'spontaneous sociability.' This theme is echoed in Harrison's (1992) conclusion that political and economic developments hinge critically on values involving trust, ethical codes, and orientations to work and risk-taking. Inglehart (1997) offers a minor variation by suggesting that membership in voluntary associations and levels of trust explain stable democracy and patterns of democratization in recent years. In such ways, social capital has been linked to a variety of political and social outcomes.

These claims are more than a simple statement that social capital is important. They instead imply that social capital reflects enduring cultural norms passed across generations by socialization, norms that cannot be explained in terms of reasonable responses to current circumstances. Further, these cultural norms are durable: allowing for slight short-term forces, they reflect the long haul. Finally, these norms are taken to be the key exogenous factors in generating economic and governmental performance. Social capital is, in this sense, more crucial than objective conditions embodied in institutions, and endures in the face of institutional change. Social capital is critical in a second sense. Different levels of social capital lead people to process the same information differently, even in face of the same institutional constraints and incentives.

Such claims parallel earlier arguments linking political culture to development and governmental performance. For example, Banfield (1958) argued that the poverty of a small southern Italian town stemmed from a dominant ethos of 'amoral familism.' Residents displayed no concern for collective issues facing the

community, operating instead according to the axiom, 'Maximize the material, short-run advantage of the nuclear family: assume that all others will do likewise.' In current terms, social and political pathologies in the town were attributed to low levels of social capital. Similarly, Almond and Verba (1963) claim that variations in democratic performance reflect national differences in civic orientations as a function of social capital.

An alternative approach identifies conditions that enhance levels of mutual trust. This is the strategy suggested by Coleman (1990) and others, one that parallels recent institutional approaches to politics that specify how institutions constrain behavior through the incentives they embody. Social capital (reflected in trust and group membership) then becomes a function of the political and economic performance induced by effective institutional arrangements, not the other way round. Consider the following examples.

The Mafia is often seen as a product of distinctive enduring Sicilian subcultural norms in which trust is at a premium. Since the norms are seen as both exogenous and durable, the Mafia should persist indefinitely. In contrast, Gambetta (1993) takes the Sicilian Mafia to be a loose cartel of families that produces and sells private protection. Gambetta treats this product as a surrogate for the enforcement of property rights by the state, so that protection is an imperfect substitute for mutual trust, and demand for protection is highest when the state does not enforce contracts. While state enforcement of property rights constitutes a public good, however, Gambetta shows that the distinctive feature of the Mafia's product is that the protection offered is private. Traders can distinguish insiders (other traders with Mafia protection) from outsiders (traders without it). The incentives for both insiders and the Mafia favor cheating outsiders, thereby increasing distrust. Distrust is thus endogenized, a product of the Mafia, not its source.

Recasting the argument this way makes a difference on at least two counts. First, by identifying the sources of low social capital in the form of distrust, it offers an analysis of ways in which levels of trust might be enhanced. In this case, one focuses on ways in which the state might enforce contracts even-handedly, as opposed to centering attention on a deep-seated subcultural ethos. Second, it offers a general approach that can be applied in different settings. For example, the rapid increase in Mafia activities in Russia after the collapse of the Soviet Union also appears to have origins in the state's inability or unwillingness to enforce contracts (Varese 1994). Clearly it involves a stretch to attribute such changes to entrenched and distinctive subcultural values, whether from Sicily or elsewhere.

Ethnically divided societies constitute another significant phenomenon, since ethnic markers have so often been taken to reflect the boundaries of 'primordial' groups (the quintessential form of exogenously-defined cultural groups) that pose particular threats to states. However, despite numerous ethnically divided societies, ethnic conflict itself is relatively unusual, which implies that such conflict is not an automatic fuction of the ethnic differences themselves. A principal source of ethnic conflict in divided societies is fear of victimization in the form of aggression from rivals (Weingast 1998). When a group fears victimization and can employ the state against another, it has an incentive to mount a preemptive strike against the other. Since being an aggressor is preferable to being a victim, and because promises not to aggress by individual groups are insufficient to deter conflict, ethnic conflict is likely.

It is, thus, crucial to construct political institutions that raise the costs for any group to use the state this way. Effective institutions modify incentives to make toleration self-enforcing, credibly committing each group to honor its promises and thereby minimizing the odds of victimization for any group. Such institutions provide incentives for groups and their leaders to conclude that neither they nor their rivals have an interest in striking first. They thereby help induce trust and co-operation. The advantage of this perspective is that it allows variations in conflict across divided societies to be specified. It also focuses more directly on the temporal ebbs and flows of ethnic conflict that occur with institutional collapse and rebuilding within divided societies.

Levels of trust and patterns of group membership within communities, however intangible, are clearly of intrinsic social and political consequence, and recent work on social capital has restored these issues to center stage. Fully understanding the sources and distribution of social capital is an important issue on the current research agenda.

Social Categorization, Psychology of

Humans experience the world through a filter of categorization. They distinguish among natural kind categories such as plants, animals, and minerals, and among artifact categories such as tools, machines, and works of art. Still other categories are abstract (e.g., peace, love, happiness) or *ad hoc* (e.g., things I need to pack for a trip). Social categorization is mainly concerned with the way people categorize themselves and others. Like any other kind of categorization, social categorization raises two fundamental questions. How do categories come to be coherent, and how do they affect human perception and action (Sternberg and Ben-Zeev 2001)

Before addressing these questions, one may wonder what would happen if there were no social categories. People would either be lumped together or considered individually. Though intuitively appealing, both options are impractical. Neither an all-inclusive human category nor all-exclusive person categories allow precise inferences about individuals. Such inferences are important because of their adaptive functions. People need to be able to predict—beyond chance levels—what others are like and what they are likely to do. Social categorization facilitates and constrains two kinds of inductive inferences. Downward induction occurs when the features of a category are attributed to individual members; upward induction occurs when the features of individuals are generalized to the category at large. Both inferences become more precise as categories become smaller and more homogeneous (Holland et al. 1986). Knowing that Jacques is French, for example, suggests more precise attributions than merely knowing that he is European. These attributions, in turn, may change when even more exclusive categories (e.g., Parisian) are used (Nelson and Miller 1995). Similarly, the discovery that Jacques is a connoisseur of fine wine is more readily generalized to the French than to Europeans, and it is even more readily generalized to other people from Jacques' region.

Precision and economy are two inversely related aspects of the quality of inductive inferences. The use of exclusive and homogeneous social categories benefits precision, but it is not economical. Any given inference, be it attribution or generalization, can reach only few individuals. Conversely, large (and heterogeneous) categories permit attributions and generalizations to many members, but these inferences lack precision. Like object categories, social categories form hierarchies in which large heterogeneous categories comprise smaller and more homogeneous ones (Sternberg and Ben-Zeev 2001). In a hierarchy of religious categories, for example, the distinction between Christians and Muslims lies at a highly inclusive level. Further distinctions between Catholics and Protestants, and between Sunnis and Shiites, lie at more exclusive levels.

Social categorization is extraordinarily flexible because any particular category falls within a web of overlapping and conflicting hierarchies (Wattenmaker 1995). When Jacques is considered Parisian, French, and Catholic, three hierarchies intersect. Most Parisians are French, and most French are Catholic, but no category is contained fully within another. Parisians can also be classed with other city-dwellers (e.g., Romans) as urbanites, and the French can also be classed with other nations (e.g., the Italians) as Europeans. The availability of alternative groupings permits strategic choices among equally valid depictions of the social world. Whether the choice of a social category is apt depends heavily on the context in which it is made. Natural kind categories are more resistant to changes in context. Most of the time, a furry companion is simply a dog.

1. *Coherence*

Categories are coherent if induction effectively differentiates among them. Downward induction is effective if the features of a category can be attributed to its own members at a higher rate than to the members of other categories. Upward induction is effective if the features observed in an individual can be generalized to other members of this category at a higher rate than they can be generalized to members of other categories.

Inspired by Aristotle's beliefs about the structure of nature, the classic theory postulated the existence of features that are individually necessary and jointly sufficient for categorization (Sternberg and Ben-Zeev 2001). When there are defining features, inferences are certain and deductive instead of probabilistic and inductive. Because, for example, all geometric shapes with three sides and angles summing to 180 degrees are known to be triangles, no generalization needs to occur. Incidental features, such as the color of the shapes, have little inductive interest. Most social categories lack defining features. To illustrate, Allport (1954) noted that the Jews 'cannot be classified as racial, ethnic, national, religious, or as any other single sociological type.' The lack of classic definitions in the social domain creates a psychological challenge. How can we perceive and judge people by categories that we are unable to define?

The idea of essences protects the faith in classic definitions of social categories. Essences are invisible—or at least so far undetected—defining features. No matter how much a person's surface features may change, the philosophy of essences assumes the existence of an immutable underlying nature (Rothbart and Taylor 1992). Essentialist beliefs thus obscure the social origin of many categories. Even during the nineteenth century, some scientists believed that differences observed between human races were actually differences between species (Gould 1996). Since essences, by definition, are postulated rather than discovered, they tend to follow rather than precede social categorization. Once a set of social categories—be it by cultural convention or political expediency—is established, people tend to accept it as natural. They tend to believe that there must be defining features even if they are unable to name them.

Wittgenstein (1958), who was more interested in language than in nature, refuted the classic theory when he asked what games are. Although they have little in common, chess and bingo can be grouped together because other games share features with either one or the other (e.g., poker requires both skill and luck). Family resemblance makes categories cohere without requiring that a single feature is shared by all members (Rosch and Mervis 1975). The term family resemblance aptly describes what many vintage portraits of extended families reveal. The patriarch seated in the center is obviously related to everyone, but the cousins on either side have no apparent similarities.

Categorization by family resemblance is effective because it captures the lumpiness of the social world. Family resemblance categories comprise members of varying typicality, they have unstable and fuzzy boundaries, and their features tend to be correlated with one another (Rosch and Mervis 1975). Consider the social category of 'actors.' Typical members, or prototypes (e.g., Humphrey Bogart), have more features in common with members of the same category than with members of other categories. Prototypes come to mind faster and are recognized more easily than less typical members. Atypical members (e.g., Ronald Reagan) are not categorized effectively. Minor changes in their feature sets, or even changes in the perceiver's attention to some features, can lead to categorization elsewhere. Crossing a fuzzy boundary, Ronald Reagan went from being a moderately typical actor to being a prototypical politician. His example illustrates how some features (e.g., the ability to portray sincerity) can contribute to separate family resemblance categories. Individual features tend to be correlated across categories. Feathered animals also tend to fly, and people who prefer Beaujolais over beer tend say *santé* instead of *prosit*. Correlations among features and across categories provide useful, though partly redundant, information. They increase the perceiver's confidence that categorization has been correct and they allow inductive inferences from one feature to another.

2. *Consequences*

Unless categorization is random (see discussion of 'thin categories' below), most individuals are more similar to other members of the same group than to members of other groups. Both attribution and generalization inferences benefit from this basic similarity relation. If there is no specific information about a group member, any trait can be attributed to him or her with a probability corresponding to the perceived prevalence of the trait in the group. To make such trait attributions is to stereotype. Stereotyping may be questioned on ethical grounds—especially when the expectations are incorrect (Banaji and Bhaskar 2000)—but as an inductive inference, stereotyping is necessary if beliefs about categories and their members are to be coherent (Krueger and Rothbart 1988). Conversely, traits observed in individuals may be generalized to the group. If there are many observations, the prevalence of a feature in a sample is the best estimate for its prevalence in the group at large. But is it possible to justify a generalization to the category if only a single category member has been observed?

Mill (1843/1974) noted that people sometimes generalize from single instances, whereas at other times they do not. He realized that this fundamental problem of induction can only be understood by taking into account *a priori* expectations about the homogeneity of the group. In the simple case of dichotomous features (i.e., a person either does or does not possess a given trait), the group becomes more homogeneous as the prevalence of the trait approaches either zero percent or 100 percent. If traits are thought to be either present in all group members or in none, a single observation of a particular trait can

be generalized to everyone. If the group is thought to be more heterogeneous, generalizations are 'regressive,' which means they shift further towards the 50 percent mark.

Suppose half of the traits are presumed common (with $p = 0.8$) and half are presumed rare ($p = 0.2$). Before there is relevant information about an individual, any particular trait may be expected with the average of these probabilities (i.e., $p = 0.5$). When the person turns out to be friendly, the trait of friendliness is more likely among the common ones than among the rare ones. The probability that friendliness is a common trait (0.8) may then be multiplied with the probability of encountering a friendly person if friendliness is indeed common (also 0.8). An analogous calculation is done for the possibility that the trait is rare (0.2×0.2), and the products are summed and multiplied by 100. The result is an estimate for the prevalence of friendliness (68 percent), which, although it does not match either of the assumed base rates, minimizes the expected error in the long run (Dawes 1990). Generalizations allow the formation and the change of stereotypes. Because generalizations, unlike attributions, are regressive, stereotypes are harder to change than to apply.

Categories are coherent inasmuch as similarities within categories are greater than similarities between categories. This simple rule suggests that similarity relationships are there to be detected, and that social categorization is free from errors if this detection task is mastered. Somewhat surprisingly, however, no theory of similarity can fully explain why people use certain categories and not others. Before similarity can be estimated, a finite number of features must be selected from the infinite pool of possible features (Sternberg and Ben-Zeev 2001). These selections partly depend on value judgments or other (social) intuitions that may have little to do with similarity itself. In other words, categorization depends heavily on the perceiver's theories of how to construe the world and what features to ignore. Some social categories are so 'thin' that they are held together by little more than the label itself. Thin categories are superimposed on social reality rather than extracted from it (Krueger and Clement 1994). Labels create quasi-Aristotelian categories because they do double duty as defining features. Labels create patterns of inclusion and exclusion that might as well be different. The US Census 2000, for example, distinguishes between Hispanics and non-Hispanic Blacks, not between Blacks and non-Black Hispanics. Despite meager underlying similarity relations, these categories organize perception and thought, and thus provide a platform for prejudice, stereotyping, and intergroup relations.

The perceiver's perspective on social categories depends critically on their own sense of identity (Oakes et al. 1994). Some categories include the self, whereas others exclude it. The egocentric distinction between ingroups and outgroups, which is peculiar to social categorization, has two major consequences: ingroup favoritism and perceptions of outgroup homogeneity. Both phenomena are related reciprocally to the thinness (or arbitrariness) of categorization and to inductive reasoning.

3. *Ingroup Favoritism*

Typically, a group is judged more favorably by people who are in it than by people who are not. In real social categories, ingroup favoritism has many causes, such as competition for scarce resources, a history of ideological or symbolic conflict, or unrepresentative interactions among group members. Therefore, it is important to note that the same bias emerges in the so-called minimal group situation. Minimal groups are very thin categories created in research laboratories. Group membership is completely arbitrary; often it depends merely on the luck of the draw in a lottery. There is no contact among members, no information about the attributes of others, and no dependence on their actions. Still, people discriminate (Tajfel et al. 1971). Compared with outgroup members, ingroup members give away more money or symbolic rewards, they are more interested in making friends, and they expect to see and are prepared to remember more positive personality traits.

These differences point to the crucial role of self. When people find themselves in an unfamiliar group, self-knowledge is the only information available to support judgments about others, and social categorization provides the only framework for the generalization of this knowledge. Indeed, people 'project' their own features to others with whom they know they have something salient in common, namely group membership (Krueger and Clement 1994). Because most people have favorable self-images, generalization creates a favorable description of the group. Outgroup members do not generalize, believing that their own features do not represent the group. This lack of induction results in a more neutral description of the group. Whose judgments are mistaken? The interplay of induction and categorization suggests that the judgments made by outgroup members are biased. When a population is arbitrarily broken up into different categories, these categories inherit the same features. Therefore, any individual is similar to both ingroup and outgroups. Ingroup favoritism primarily reflects a failure to generalize one's own favorable features to outgroups, rather than any excessive tendency to ascribe desirable features to the ingroup.

Although egocentric and asymmetric induction patterns go a long way to explain ingroup favoritism, other motives also come into play (Abrams and Hogg 1999). Being able to discriminate against an outgroup

can strengthen a sense of social identity and heighten self-esteem while reducing feelings of uncertainty. These motives can be so strong that people forfeit possible gains for the ingroup as long as the ingroup is better off than the outgroup.

4. Perceptions of Outgroup Homogeneity

The mere act of categorization suggests that the categorized instances can be treated as equivalents. In social categorization, the assimilation of instances (people) to the group average is asymmetric. People who do not belong to the group usually perceive it to be even less variable than group members do (Park and Rothbart 1982). Italians, for example, may appear to be more homogeneous to Americans than to Italians themselves. This homogeneity bias is expressed in several ways. Individual group members are easily confused with one another; individual traits appear to be either extremely common or extremely rare; and judgments about individual group members on a given trait dimension do not depart much from the average of these judgments.

The homogeneity bias is not a mere by-product of ingroup favoritism because it affects both positive and negative attributes, and because it is absent in minimal groups where ingroup favoritism is common. The psychological need to differentiate ingroups from outgroups—which contributes to ingroup favoritism—would lead people to perceive the ingroup as homogeneous. Moreover, the homogeneity bias does not simply reflect differences in induction. Although outgroup members may have less information than ingroup members do, differences in familiarity do not necessarily produce a bias. Statistically, sample size is unrelated to sample variance (unless the samples are very small). Finally, the selective induction from the self to ingroups works against the outgroup homogeneity bias. Induction reduces perceptions of variability and thus uncertainty. Not using self-related information to make inferences to outgroups thus supports perceptions of heterogeneity.

The main source of perceived outgroup homogeneity are processes of categorization themselves. People who belong to a group are more likely to perceive differentiated subgroups (Park and Rothbart 1982). Italians more than Americans, for example, further categorize Italians by geographic origin, distinguishing between Tuscans, Romans, Calabrians, and so forth. To ingroup members, the group is thereby located at a higher level in the hierarchy than it is to outgroup members. The homogeneity bias then results from the assumption that categories not divided any further are more homogeneous than divisible categories. The error is the failure to realize that members of other groups consider their own categories to be as divisible as we consider our own.

5. Conclusion

Frameworks of social categorization may change across time and place, but they are functional in that they enable people to reason inductively and to situate themselves within the social world. Making predictions about the self and others is potentially more adaptive than withholding judgment altogether (Krueger 1998). In the process, however, social categorization also enables the persistence of prejudicial beliefs and discriminatory behavior. The tension between the adaptive and the biasing effects of categorization highlights the importance of this topic.

Social Change: Types

Two sets of assumptions must be made explicit to identify different types of social change. The actor's attributes are needed to understand what they do and why. The social structure—options and payoffs—within which the actors choose and act are needed to explain what happens and why. The two sets of assumptions are needed to construct a logical narrative of systemic effects.

Changes can consist in either

(a) *the actors changing*: what they want, know, do, obtain, or are burdened with, i.e., actor change in cognition, attitudes, sentiments, attributes, actions; or

(b) *the structure changing*: i.e., change of states, their correlatives or distributional aspects. These face the actors as facts, options, or structured costs and benefits, such as property rights, vacancies, socially available marriage partners, health hazards, or language boundaries.

The structure may change the actors, their hearts and minds. The actors may change the structure, its positions and possibilities. And the actors may react to conditions they have brought forth—by an echo effect, so to speak, from an edifice of their own making.

From answering two questions: (a) do the actors change, and (b) does the structure change, we may identify four kinds of models of social change, as shown in Fig. 1. Examples from classical texts below illustrate these types.

		Does the structure change?	
		No	**Yes**
Do the actors change?	**No**	Aggregate effects	Structural effects
	Yes	Actor effects	Dialectical effects

Figure 1
Types of models of social change

1. *Models of Aggregate Effects*

An example of a model of 'aggregate effects' is found in microeconomic theory. Under 'pure barter,' each actor is assumed to prefer certain combinations of goods, to know who commands what goods, etc. Among the structural assumptions are that actors have rights to goods, that goods can be exchanged freely without transaction costs, etc. From such assumptions it follows that the actors will barter goods they like less for goods they want more. The driving force is the initial gap between what they have and what they want—between what they actually prefer and what they initially control. Hence, a new distribution of goods will arise among the actors from which nobody will want to move because none can get more satisfaction from another exchange. The actors themselves remain unchanged, as does the value of their goods. The model is one of change only in the sense than that the actors' bundles of goods at the end are different from the outset. Hence economists call this genre 'models of static equilibrium,' though a process runs until this equilibrium is reached. Distributional characteristics may be modified—e.g., the degree of concentration of goods. But they have no further motivational effects in these models—the actors' choices shape the final allotment of goods, but they do not react to it once equilibrium is reached. The distribution of final control is just an aggregate outcome, not input for further action. Economics has many variations on this theme. It is a separate, empirical question to what extent such a model agrees with a barter process in the real world.

There are even more stripped down models of aggregate effects. A stable population model assumes nothing about what the actors want or know—only that they have constant probabilities of offspring and death at specific ages. Initially the population pyramid may deviate from its final shape. Having arrived there, it will remain unchanged. The stable proportions in the different age/sex categories are equilibrium states which represent the 'latent structural propensities of the process characterized by the [parameters]' (Ryder 1964, p. 456)—the values that proportions move toward when parameter values remain constant. For some, even important, phenomena, cut down actor models (no intentions or knowledge) are powerful. Simple assumptions can take you a long way in making a logical narrative.

2. *Models of Actor Effects*

The second type of model is illustrated by 'learning by doing.' In *Capital*, Marx describes how a specialist (a 'detail laborer') acquires skills within manufacture

production. A 'collective laborer' is the organized combination of such specialists. Manufacture ripens the virtuosity of the 'detail laborer' in performing his specialized function by repetition:

> A labourer who all his life performs one and the same simple operation, converts his whole body into the automatic, specialized implement of that operation. Consequently, he takes less time doing it, than the artificer who performs a whole series of operations in succession. But the collective labourer, who constitutes the living mechanism of manufacture, is made up solely of such specialized detail labourers. Hence in comparison with the independent handicraft, more is produced in a given time, or the productive power of labour is increased. Moreover, when once this fractional work is established as the exclusive function of one person, the methods he employs become perfected. The workman's continued repetition of the same simple act, and the concentration of his attention on it, teach him by experience how to attain the desired effect with the minimum of exertion. (Marx [1864] 1967, p. 339)

The first logical element of this argument is actor assumptions:

(a) Actors are purposive—i.e., they seek desired effects. Indeed, Marx was no strict determinist, but assumed purposive action explicitly:

> A spider conducts operations that resemble those of a weaver, and a bee puts to shame many an architect in the construction of her cells. But what distinguishes the worst architect from the best of bees is this, that the architect raises his structure in imagination before he erects it in reality. And at the end of every labor-process, we get a result that already existed in the imagination of the labourer at its commencement. He not only effects a change of form in the material on which he works, but he also realizes a purpose of his own. (Marx [1864] 1967, p. 178)

(b) The actors are satisficing, i.e., they start pursuing their goals by procedures that may not be the best (which provides room for improvement).

(c) They recognize deviations from present satisfactory performance.

(d) They evaluate deviations as either positive or negative by a criterion such as the 'principle of least effort' (to attain the desired effect with the minimum of exertion).

(e) There are two sources of deviation from current routines. The actors may search for better solutions, i.e., purposively probing for improvements by 'trial and error.' Or actors make mistakes—a stochastic element producing random departures from current routines. Accidentally hitting better solutions could be called 'spot and snatch.' Hence the model has two sources of new alternatives—deliberate exploration and random variation—one sought *ex ante*, the other sighted *ex post*.

In short, behavior is result controlled: when the outcome of an action deviates from the intended result, actors may modify their conduct. Negative deviations in terms of an actor's purposes will be avoided and result in a return to the standard routine. Positive deviations will be retained.

The second logical element is the structure assumptions of Marx' selection model:

(a) The actors are set to repetitive tasks.

(b) There are alternative ways of carrying out the tasks.

(c) The choice of alternative has consequences for the actors, being rewarding or penalizing in terms of their goals. These consequences may be due to laws of nature (e.g., efforts required or difficulties encountered) or they can be socially organized (e.g., reducing costs or increasing payoffs).

Such are the assumptions of Marx' argument. He constructed a selection model which at the individual level works like this: the probability of mistakes is cut with every attempt, while methods giving better results are retained. Initially satisfactory but unwieldy procedures are abandoned—more effective ones are kept when captured, e.g., by the principle of least effort. Hence the laborer becomes a special tool for the task at hand—more adept and adroit. The best form found solidifies into a routine. And the collective worker as the sum of detail laborers can reach a perfection beyond any single individual carrying out all operations alone. Manufacture begets handicraft industries that push the skills required for carrying out a specific task in the same direction. The progression toward a best response pattern hence leads to homogenization of actions.

In short, on the assumptions of purposive action and selection of beneficial deviations, Marx explains individual adaptation as well as uniforming selection—i.e., increased dexterity in repetitive tasks until the form best fitted to the task is found. Note that in this model what changes is not actors' preferences but their skills—not what they want, but what they know. Their bias for less effort is stable.

There are other models where actors change without this being part of their intention or recognition—effects may occur behind their backs. For example, a contagious disease may immunize a group against further outbreaks even if neither the contagion nor its effects are understood. If insights are won, actors may change practice, as when humans started to infect themselves with cowpox as protection against smallpox.

3. *Models of Structural Effects*

The brilliant Norwegian sociologist Eilert Sundt (1817–75) provides an example of structural change inspired by the logic of mutations and selection found in *The Origin of Species*. 'Learning by doing' can modify not just behavior, but also material forms. Sundt had a keen eye for the logic of both error-based 'spot and snatch' and the more deliberate 'trial and error' mentioned above. In this quote, both the stochastic component in generating variation and the

purposive element in discovery and selection of slight beneficial deviations are exposed lucidly:

> A boat constructor may be skilled, and yet he will never get two boats exactly alike, even if he exerts himself to this end. The deviations occurring may be called *accidental*. But even a very small deviation usually is noticeable during navigation, but it is *not accidental* that the sailors come to *notice* that the boat that has become improved or more convenient for their purpose, and that they should recommend it to be *chosen* for *imitation* … One may think that each of these boats is perfected in its way, since it has reached perfection through one-sided development in one particular direction. Each kind of improvement has progressed to the point where further development would entail defects that would more than offset the advantage … Hence I conceive of the process in the following way: when the idea of new and improved forms had first been aroused, then a *long series of prudent experiments* each involving extremely small changes, could lead to the happy result that from the boat constructor's shed there emerged a boat whose like all would desire. (Sundt [1862] 1976)

In this case, then, the material structure of society is modified via learning by doing. Note also that Sundt argued that the recognition of accidental discoveries ('spot and snatch') itself leads to the discovery of the usefulness of experiments ('trial and error'), i.e., to second order learning. Marx used a similar line of argument to explain the differentiation of tools adapted to different tasks, and second order learning when science is used to improve industrial means of production.

Before turning to the fourth type, dialectical change, the analyses of Marx and Sundt may highlight how the same basic mechanism can be used to explain constancy as well as change, i.e., the evolution of social habits, tools, and organizational forms toward an optimal equilibrium pattern. Or, put differently, how continual trial and error leads to optimal responses which are then crystallized as customs, standard operating procedures, or best practices. The skills required are pushed in the same direction and the progression toward a best response pattern leads to homogenization of actions, i.e., to uniforming selection. Likewise, adaptation for divergent purposes generates differentiation. The essence of ordinary work is repetition—i.e., variations on the same theme. But by chance variations and serendipity, skills can be acquired, tools developed, and workgroups rearranged. This is how Marx explains changes in organizations and in aggregates at the macro level.

The first organizational consequence is that craftspeople, the best performers, may become locked into lifetime careers. The second organizational consequence is that, on the basis of skill and mastery, industry may sprout into different occupations—a structural change arising from the social organization of individual skills. That is, a particular task selects a best response that becomes fixed as a routine, different tasks select different types of best responses: 'On that groundwork, each separate branch of production acquires empirically the form that is technically suited to it, slowly perfects it, and as soon as a given degree of maturity has been reached, rapidly crystallizes that form' (Marx [1864] 1967, p. 485). Marx uses his selection model to explain structural differentiation. The resulting structure may be no part of any individual's or group's intentions, though it is a result of their choices.

By the same logic Marx explains change in the social structure of society as the gradual adaptation of different groups of workers. What is the best relative size of groups of specialized workers in different functions? Marx argues that there is a constant tendency toward an equilibrium distribution, forced by competition and the technical interdependence of the various stages of production:

> The result of the labour of one is the starting-point for the labour of the other. The one workman therefore gives occupation directly to the other. The labour-time necessary in each partial process, for attaining the desired effect, is learnt by experience; and the mechanism of Manufacture, as a whole, is based on the assumption that a given result will be obtained in a given time. It is only on this assumption that the various supplementary labour-processes can proceed uninterruptedly, simultaneously, and side by side. It is clear that this direct dependence of the operations, and therefore of the labourers, on each other, compels each one of them to spend on his work no more than the necessary time, and thus a continuity, uniformity, regularity, order, and even intensity or labour, of quite a different kind, is begotten than is to be found in an independent handicraft or even in simple cooperation. The rule, that the labour-time expended on a commodity should not exceed that which is socially necessary for its production, appears, in the production of commodities generally, to be established by the mere effect of competition; since, to express ourselves superficially, each single producer is obliged to sell his commodity at its market price. In Manufacture, on the contrary, the turning out of a given quantum of product in a given time is a technical law of the process of production itself. (Marx [1854] 1967, p. 345)

There are two types of selection pressures in this argument: *structural dependence*, or integration that compels each to spend on his or her work no more than the necessary time, and economic *competition*. In short, the argument is based not just on purposive actors but on their location in a particular social macrostructure (competition) resulting in modification of another part of the structure (occupational composition). This argument also uses a conception of bottlenecks—a condition or situation that retards a process and thwarts the purposes of actors involved. This mode of explanation is often used by social scientists, e.g., for the logic of the industrial revolution: the invention of the Spinning Jenny made weaving a bottleneck and hence led to improved shuttles and machine looms requiring greater power to drive them, favoring the use of the steam engine, etc.

Learning in this case consists in gradual adaptation of group sizes to obtain the most efficient production.

That definite numbers of workers are subjected to definite functions Marx calls 'the iron law of proportionality' (Marx [1854] 1967, p. 355). From firms, Marx moves on to the societal level: adjusting different work groups within the manufacture generates a division of labor at the aggregate or macro level.

Third, the basic selection model is used to explain not only change—i.e., the succession of steps towards the best suited response—but also *constancy*, i.e., the locking in of a structurally best response. 'History shows how the division of labour peculiar to manufacture, strictly so called, acquires the best adapted form at first by experience, as it were behind the backs of the actors, and then, like the guild handicrafts, strives to hold on to that form when once found, and here and there succeeds in keeping it for centuries' (Marx [1854] 1967, p. 363).

The fourth point made by both Sundt and Marx is a conceptual one: learning may take place not just by doing, but also through a second form of learning, namely, *imitation*. That is, those who have found the knack can be emulated, and, as Sundt argued, tools improved by accidents are chosen for imitation. Marx wrote: 'since there are always several generations of labourers living at one time, and working together at the manufacture of a given article, the technical skill, the tricks of the trade thus acquired, become established, and are accumulated and handed down' (Marx [1854] 1967, p. 339). In other words: socially organized purposive actors may learn vicariously. They recognize and copy the improved solutions others find to their own problems.

Basically then, Marx and Sundt argued that a constant technology advances the development of an equilibrium pattern of behavior, corresponding to the best possible practice, which also congeals social forms at the macro level. This takes place through the selection of the most adept methods by individuals, which, when aggregated, moves a group or even a mass of people from one distribution to another. They used selection mechanisms to explain a wide range of phenomena: development of individual dexterity, the evolution of lifetime careers, the homogenization of practices and the differentiation of tools, the evolution of occupations—indeed, the drift of large aggregates as well as equilibrium patterns and constancy.

The fifth point is that they considered new technology as a driving force which may require readaptation of behavioral responses (cf. Arrow 1962). From the notion of change moving toward an equilibrium or constancy Marx introduces the notion of the *constancy of change*. This happens when the random nature of learning by doing yields to the systematic search for new knowledge by applied science:

> The principle, carried out in the factory system, of analysing the process or production into its constituent phases, and of solving the problems thus proposed by the application of mechanics, of chemistry, and the whole range of the natural sciences, becomes the determining principle everywhere. Hence machinery squeezes itself into the manufacturing industries first for one detail process, then for another. Thus the solid crystal of their organisation, based on the old division of labor, becomes dissolved, and makes way for constant changes. (Marx [1854] 1967, p. 461)

Marx' explicit logic, therefore, was not just one of learning by doing and second order learning by out-and-out search and science. He went even further in analyzing how the introduction of new implements required new learning by the users of those implements, and indeed, led to a change in attitudes as well. In other words, learning made people change their own conditions—by adapting to those conditions people changed themselves by learning to learn. This is the double logic of dialectical models.

4. *Models of Dialectical Effects*

Dialectical models analyze structures which motivate actors, by accident or design, to bring forth structural changes which then change the actors' own attributes. In shorthand, such models look like this:

Structure → Actoral Change → Structural Change → Actoral Change

This is, of course, a very important category for social analysis—the more so the longer the time perspective. People have not shaped the society into which they are born—they are molded by a society before they can remake it. But humans can remake themselves indirectly by changing the structure or culture within which they act. A classical text, Max Weber's (1904–5) *The Protestant Ethic and the Spirit of Capitalism*, can serve to illustrate such models.

Weber first identified a specific tendency among Protestants to develop economic rationalism not observed to the same extent among Catholics (Hernes 1989). Weber's paradoxical thesis is that the supposed conflict between otherworldliness or asceticism on the one hand, and participation in capitalistic acquisition on the other, is in fact an intimate relationship.

Weber's model departs from what he calls traditionalism, populated by two types of actors: traditionalistic workers, and traditionalistic entrepreneurs. The key attribute of the former is that increasing their rewards does not lead to an increase in their output, but rather makes them decrease the amount of work they put in. People 'by nature' do not want to earn as much as possible: traditionalistic workers adjust their supply of labor to satisfy their traditional needs. This 'immense stubborn resistance' is the 'leading trait of pre-capitalist labor.' Likewise, traditional entrepreneurs adjust their efforts to maintain the traditional rate of profit, the traditional relations with labor, and the traditional circle of customers.

However, what these actors want is not hard-wired—their character can be changed. Weber wants to explain this change from the tranquil state of traditionalism to the bustling dynamism of capitalism. The first part of his argument is about how the actors' temperaments are changed: how a *homo novus*—or rather two—is brought forth. The second part of the argument is about how they trap themselves and everyone else in the new conditions or structure they create. The new entrepreneurs came to see money-making as an end in itself. The new workers came to see labor as an end in itself. The argument runs briefly as follows.

In the beginning there was logic. Conceptual activity worked on beliefs to turn doctrines of faith into maxims for behavior. At the outset traditionalists had faith in God. He was omniscient and omnipotent. By pure logic this led to predestination: an omniscient God had to know ahead of time who were among the chosen; an omnipotent God must have decided already and must know the outcome of his decisions. Humans could do nothing to bring about their salvation by their own actions. Fates were preordained by God. Those who had salvation could not lose it and those without it could not gain it. What is more, neither group could know who had it. So for every true believer one question must have forced all others into the background: 'Am I one of the elect?' At first there seemed to be no answer; however, all the faithful were to act *as if* they were among the chosen. Doubts were temptations of the Devil—a sign of failing faith, hence of imperfect grace. And the faithful should act in the world to serve God's glory to the best of their abilities. Those unwilling to work therefore had the symptoms of lack of grace. Hence there were *some* signs.

But the logic of this argument resulted in a peculiar psychology of signs—a mental reversal of conditional probability notions. The original argument ran: if you are among the elect, you work in a calling. The psychological reversal became: if you work in a calling, you have a sign that you are among the elect. Moreover, this sign— working—could be affected. By choosing to work hard, you attain a sign that you are among the chosen:

> In practice this means that God helps them who helps themselves. Thus the Calvinist, as it is sometimes put, himself creates his own salvation, or, as would be more correct, the conviction of it. But this creation cannot, as in Catholicism, consist in a gradual accumulation of individual good works to one's credit, but rather in a systematic self-control which at every moment stands before the inexorable alternative, chosen or damned. (Weber 1930, p. 115)

This is the first part of Weber's analysis of actor change: the moral construction of the new actors—new workers and new entrepreneurs working in a calling for the glory of God—driven to restless work by their fierce quest for peace of mind.

However, this actoral change is not a sufficient condition to explain the structural change, i.e., the establishment of a new economic system—capitalism. Hence the next part of Weber's logical chain is the following. Working in a calling was not enough. For even if many were called, few were believed chosen. Identifying who they were—and if one was among them—could only be done by comparisons. 'Success reveals the blessings of God' (Weber 1930, p. 271, n. 58). But success can only be measured in relative terms: 'But God requires *social achievement* of the Christian because He wills that social life shall be organized according to His commandments, in accordance with that purpose' (Weber 1930, p. 108, emphasis in original). Each Christian had, so to speak, to prove that he or she was 'holier than thou.' Moreover, each of them had to assess their success relative to others, and moreover, they had to do it in terms of economic achievement. The sign of salvation is not what you did unto others—it was whether you outdid the others.

Here is the nexus between actor change and structural change. From this mode of thinking, the individualistic Protestants were, so to speak, connected behind their backs. Religious attainment became measured by private profit. The market united those that theology separated. From being religious isolates the Christians became rivals—assessed by the relative fortunes they amassed. But then, to hold their own, they forced each other to work harder. In effect they set up a new social structure for themselves by their thinking and by their actions. Their religious mindset produced the new social setup. By taking not a good day's work, but the *relative* fruits of labor in a calling, as a measure of success, they in effect caught themselves in a prisoner's dilemma.

Since capital accumulated but not capital consumed was measured, the logic of asceticism 'turned with all its force against one thing: the spontaneous enjoyment of life and all it had to offer' (Weber 1930, p. 166). Hence assets could also serve as a relative measure of success. And this had the 'psychological effect of freeing the acquisition of goods from the inhibitions of traditionalistic ethic' (p. 174). The double-barreled effect of ascetic Protestantism, in short, was to join the compulsion to work with the obligation to reinvest its output.

But the prisoner's dilemma that the Protestants established by their particular comparative, even compulsive, work ethic not only captured their creators. By their logic of relative success they also dragged everybody else into the vortex of the market—they changed the social structure in a decisive way because it also entrapped all others:

> The Puritan wanted to work in a calling; we are forced to do so. For when asceticism was carried out of the monastic cells into everyday life, and began to dominate worldly morality, it did its part in building the tremendous cosmos of the modern

> economic order. This order is now bound to the technical and economic conditions of machine production which today determine the lives of all individuals who are born into this mechanism, not only those who are directly concerned with economic acquisition, with irresistible force. (Weber 1930, p. 181)

The structure that the actors created turned on themselves with a compelling might—their internal convictions transformed into external forces, so to speak. Moreover, not only are people compelled to react to conditions of their own making. The new structure of the competitive market in turn creates yet new types of actors without the religious motivation from which it sprang:

> The capitalistic economy of the present day is an immense cosmos into which the individual is born, and which presents itself to him, at least as an individual, as an unalterable order of things in which he must live. It forces the individual, in so far as he is involved in the system of market relationships, to conform to capitalistic rules of action. The manufacturer who in the long run acts counter to these norms, will just as inevitably be eliminated from the economic scene as the worker who cannot or will not adapt himself to them will be thrown into the street without a job. Thus the capitalism of today, which has come to dominate economic life, educates and selects the economic subjects which it needs through a process of economic survival of the fittest. (Weber 1930, p. 54 f.)

By measuring success in relative terms, the Puritans established a prisoner's dilemma in which they not only ambushed themselves and ensnared non-Puritans, but in addition, once it had been socially established, in turn liberated capitalism from its connection to their special *Weltanschauung*. It no longer needed the support of any religious forces: 'Whoever does not adapt his manner of life to the conditions of capitalistic success must go under. But these are phenomena of a time in which modern capitalism has become dominant and has become emancipated from its old supports' (Weber 1930, p. 72).

Hence, having explained the generation of the capitalist system, Weber takes competition to be source of its own reproduction, i.e., for the constancy of the new system. The paradox is that the religious belief that set people free from restraints on acquisitive activity, in turn liberated the resulting economic system from its creators and their beliefs. Once the new system is in place, it selects and shapes the actors needed to maintain it. The Protestant entrepreneurs who established the new system thereby in turn called forth yet another *homo novus*—industrialists and managers and workaholics infused not with Protestantism, but with the spirit of capitalism.

The short version of Weber's analysis is this: religious conversion led to economic comparison; and the importance of relative success as a religious sign led to competition. This was a systemic transformation that in turn led not only to accumulation and innovation, but also to selection and socialization of new actors. A system brought into being by actors who feared eternal damnation bred actors who maintained it from concern for their daily survival and without religious qualms.

Weber's analysis provides a very good example of dialectical change in that it explains how a new type of actor, with different beliefs and knowledge, modifies its own environment out of existence and in turn creates the conditions for yet another type of actor that is different from themselves. As Garrett Hardin (1969, p. 284) has written of ecological succession: 'It is not only true that environments select organisms; organisms make new selective environments' (cf. Hernes 1976, p. 533).

5. *Conclusion*

The analysis of change is at the heart of social theory because it attempts to answer this question: How do humans cope with the effects of their own creativity? To carry out such analysis one needs simple, yet potent, tools. They are embedded in the classical works of social science. When they are identified, we can emulate the best practitioners in the field.

Social Changes: Models

There is an amazing multiplicity of social forms: rites, tools, languages, and rules. How has this variety come about and why is it forever changing? Yet most of the

time humans behave like those around them. How has this conformity developed? And why is it maintained?

Models of social change address these questions: What generates change, and is it differentiating or uniforming? What maintains established structures, whether they are simple or complex?

Classics, such as Durkheim, Marx, Sundt and Weber, provided models of the transformation as well as the preservation of social forms, and analyzed diversification as well as homogenization. This they did not so much by general theoretical statements as by laying bare the social logic driving specific historical passages. They can be used to highlight models of social change and provide paragons that present-day studies can be appraised against.

1. *Individual Actions and Social Facts*

Durkheim, in *Suicide* ([1897] 1951) sought to explain both constancy and variety. He asked: why are suicide rates so stable—indeed, more stable than ordinary death rates—and yet vary systematically between groups? Why do they take on a new stubborn stability after marked shifts? Durkheim held stable, but differing suicide rates to be social facts. They exist relatively independent of the individuals who compose the group on which they are measured. Social facts—e.g., the language we speak, rites we share, or streets we walk—endure, Durkheim argued, *sui generis*.

Social facts have an existence of their own, like a swarm of moths which can change its shape or shift its position—yet, of course, there are no social phenomena without individuals being part of them: no swarm without the ephemeral movements of moths. Put paradoxically: social facts—both change and constancy—are relatively independent of those on whom they depend. Individuals are held in place by their fellows and take their cues from each other. This is important in study of social change: it is always mediated through individuals who are shaped by their physical and social environment before they can act on it, and who change it by reacting to circumstances they have brought forth or are transmitted from the past.

Social change is at the core of sociological analysis. Yet, few studies cover the whole cycle of analyzing 'how men react to conditions of their own making and in so doing change these conditions' (Hernes 1976, p. 513). Rather they present snapshots of a condition, such as a poll of opinions or their causal determinants. The reasons are many: collecting data as a process unfolds may be too costly or time-consuming. Data from other sources do not easily lend themselves to analysis over time. Survey techniques often result in a kind of aggregate social psychology rather than in studies of structural change, and when it restricts itself to 'enumerating individual characteristics, [it] treats the individual as if he were detached from his environment and hence as an abstraction' (Boudon 1971, p. 48). Indeed, the methodological successes of survey analysis can lead to conceptual failures. So most social scientists do not go into deep analysis of social change even if it is at the core of social analysis.

2. *Requirements of Theories of Social Change*

From the above observations, three logical requirements of theories of social change can be identified (Hernes 1976). First, it should be possible to use the same basic approach in studying both constancy and change. This implies that a stable structure should be seen as a process in (temporary) equilibrium and that the theory must include an explanation of why the forces or parameters governing a process themselves are regenerated. Structural change must be described in terms of the processes that generate the change. Structural stability must be explained in terms of the processes that not only maintain the stability, but also maintain the processes that maintain the stability.

Some accounts are static, e.g., 'percentage unemployed.' Yet, from a model point of view, it not only makes better sense, but also for more interesting analysis to conceptualize even 'static' phenomena in terms of processes. For example, if the number unemployed remains stable, this does not imply that the same individuals remain out of work—only that the flows of individuals in and out of employment cancel out. Hence stability can be viewed as a process in equilibrium (Coleman 1964).

Second, models of social change should incorporate intrinsic sources of change. Changes in social systems may be induced from the outside, but all changes cannot be thus induced (Elster 1971). Even when the impetus for change is imported, the mechanisms transmitting external impacts should be identified. Indeed, when an item is taken from the outside, it should be possible to employ the same kinds of explanations for its adoption as if it had been invented at home. Moreover, the sources of change should also be intrinsic to the theory in the sense that effects of previous actions provide or change premises for further choices of action.

Lauriston Sharp (1952) gives an example in 'Steel axes for Stone Age Australians.' He describes how the aboriginal Yir Yoront group as late as the 1930s lived an essentially isolated and independent economic existence based on Stone Age techniques. However, 'their polished stone axes were disappearing fast and being replaced by steel axes which came to them in considerable numbers, directly or indirectly, from various European sources to the south' (Sharp 1951, p. 17). Sharp then discusses what changes in the lives of the group resulted from the replacement of stone axes around which their culture was built. For example, stone axes were an item of trade hence important in intertribal relations, belief systems, celebrations, and totemic ceremonies. Men crafted the stone axes, which were a symbol of their masculinity, yet they were lent

to women who used them in their heavy chores. Furthermore, 'The shift from stone to steel provided no major technological difficulties' (Sharp 1952, p. 20). Sharp then analyzes how this change of tools changed trade relations, gender interactions, and authority structures.

> The most disturbing effects of the steel axe, operating in conjunction with other elements also being introduced from the white man's several sub-cultures, developed in the realms of traditional ideas, sentiments, and values. These were undermined at a rapidly mounting rate, with no new conceptions being defined to replace them. The result was the erection of a mental and moral void which foreshadowed the collapse and destruction of all Yir Yoront cultures, if not, indeed, the extinction of the biological group itself. (Sharp 1952, p. 21)

Here the new technology came from the outside—the impetus for change was exogenous. But its adoption is explained in terms of simple principles at the level of actors: steel axes were nearly free good tools, simple to use, and requiring less effort—the same types of explanation we would use if they had been invented locally. The effects of this *deus ex machina* changed premises for further choices of action—in this case with devastating aggregate effects: it reduced women's dependence on men, it undermined belief systems, it wrecked havoc with traditional trade relations and their social embellishments.

Finally, as just seen, social change is mediated through individual actors. Hence the third requirement of theories of social change: they must show how macrovariables or structural characteristics affect individual motives, capacities, and choices and how the choices of actors in turn change the macrovariables. For the Yir Yoront, adopting a new tool changed their social structure in ways that was no part of their intention.

3. *Elements of Models of Social Change*

Next we can identify the locuses of change. Basically they can be of two kinds: (a) the actors can change, and (b) the structure within which they operate can change. Models must be constructed from these two sets of abstract elements—actors and structures—to mirror what drives the changes in them (Hernes 1989, 1999).

Hence, the first element to specify in a model of social change is the types of actors assumed to operate. In the language of the theater, specifying the actors corresponds to the casting of a play. For example, in microeconomic theory two types of actors are distinguished: consumers maximizing utility by spending their resources to obtain goods, and producers maximizing profit by the quantities they market.

The second element to specify is the structure the actors are lodged in—the staging of a play. For example, in microeconomic theory three main market structures are distinguished: perfect competition where the actors are so many and small that none of them can affect the price; oligopoly, where the producers are so few that they react to each others' decisions; and monopoly, where a single producer can set the price.

One reason for combining actors and the structure within which they operate, is to construct a model so that one can logically work out the systemic effects of actors' choices within the structure—the plotting of the play. The point is to answer questions about what happens to the actors or to the structure as a consequence of the actors reacting to the initial conditions—i.e., the logical sequence of consequences that flow from the assumptions made. In other words, we construct models of actors within a structure in order to understand what the actors are doing and why, and to explain what results from their actions and why, whether the results are intended or not. In other words, a model of change is a logical narrative. A logical narrative may have logical flaws and hence be theoretically unsound. And one such logical narrative may exclude others: it simultaneously empowers our reasoning and limits our comprehension—both our understanding of the actors and the explanation of the results of their interaction.

A second purpose is to compare the logical outcomes of the model to a real life sequence of events. A compelling argument may be empirically false—the logical narrative may not match the historical record. Hence, if the model is to provide a valid understanding or a tenable explanation, there must be a rough goodness of fit between what the model logically leads us to expect about what will transpire and what actually takes place in the real world. The model cannot just be plausible in theory—it must at the end of the day be admissible by the facts: the observed must agree with the inferred. If the model is ruled out by the facts, it must be discarded and another constructed from different assumptions that provide a more realistic understanding and credible explanation.

For example, the simple model of perfect competition implies that profits will tend towards zero. If we observe that profits in fact are high, we may modify the model to better account for this fact by changing the assumptions, e.g., by allowing producers to change consumers' attitudes (advertising) or by allowing for monopolization—i.e., discarding the model of perfect competition.

4. *Specifying Actor Assumptions and Structure Assumptions*

To give a logical portrait of the types of actors involved in a social process, the following kinds of questions must be answered:

(a) What do they *want*—what are their preferences or purposes?

(b) What do they *know*—what are their beliefs, their potential for changing them or for learning?

(c) What can they *do*—what are their capacities or skills?

Sometimes answers are only rudimentarily specified, e.g., in models of contagion where contracting a disease clearly is not something sought but something caught.

Actor assumptions allow us to understand what actors can do, what they actually do and why, or how others react to them and why.

A similar set of questions must be answered to specify assumptions about the structure:

(a) What *alternatives* or *constraints* do the actors face? These may span from opportunity for migration to household budgets. They include collective properties such as laws and norms and physical barriers such as roads or rivers.

(b) What *social positions* can the actors hold—e.g., organizational roles? What are the *correlates of positions*—e.g., their status or the hierarchy of wages linked to a given division of labor? Rewards, rights, and burdens are structural correlates of positions—they also define, fix, or freeze the alternatives actors face.

(c) What are the *distributional characteristics* of actors, as distinct from their individual manifestations? For example, the number of other actors may affect options as in perfect competition, the age distribution may affect outlooks for marriage. The sex ratio and the population pyramid are structural characteristics.

Specifications of the actors' attributes are needed to understand what they do and why. Specifications of the structure—options and payoffs—within which they choose and act are needed to explain what happens and why. The two sets of assumptions are needed to construct the logical narrative of systemic effects.

5. *Intentions vs. Effects*

A key point in analyzing social change is the nexus between intentions and effects. Purposive action may have unanticipated consequences (Merton [1936] 1976). That is why understanding the actors is not sufficient—explaining the interworkings of their actions beyond their intentions is necessary. The net outcome of rational choices may be counterintuitive. The way to hell may be paved with good intentions and simultaneous choices based on the best of motives may be counterproductive by some hidden hex. Private vices may give public benefits (Mandeville [1714] 1989), self-serving interest may yield benefits as if guided by an invisible hand. Sometimes actors are caught by what they have wrought; sometimes they do not master the world they have made. Such unintended effects, counterproductive actions and counterintuitive results which flow from the actors' choices, not their intentions, often produce engaging logical narratives.

6. *Expected vs. Desired Consequences*

The distinction between actors and structure is useful also when what happens deviates from what was anticipated.

In 1936 Robert K. Merton wrote a famous article on 'The unanticipated consequences of purposive social action' (Merton [1936] 1976). A key point is that the effects of actors' choices may interact to produce effects that are no part of the intentions. This notion is very useful for describing models or mechanisms of social change.

The simplest models of change are of course when purposive actors produce intended results. What appears is what was planned, what materializes is what was sought. However, sometimes what turns up is not what the actors had in mind. Sometimes their best intentions interact to produce self-defeating results, as when a stampede to get out blocks the exit. Sometimes selfish motives produce positive overall effects over and beyond their expectations, with improved welfare coming as a by-product, as if an invisible hand guides self-interest to efficient use of resources. As the argument runs in Adam Smith's classic text:

> He [every individual] generally, indeed, neither intends to promote the public interest, nor knows how much he is promoting it. By preferring the support of domestic to that of foreign industry, he intends only his own security; and by directing that industry in such a manner as its produce may be of the greatest value, he intends only his own gain, and he is in this, as in many other cases, led by an invisible hand to promote an end which was no part of his intention. Nor is it always the worse for the society that it was no part of it. By pursuing his own interest he frequently promotes that of the society more effectually than when he really intends to promote it. I have never known much good done by those who affected to trade for the public good. It is an affectation, indeed, not very common among merchants, and very few words need be employed in dissuading them from it. (Smith [1776] 1937, Book 4, Chap. 2)

A key point for the analysis of social change is that what results, whether it appears as the compelling influence from a hidden hex or an invisible hand, flows from the actors' choices, not from their motives. That is why understanding the actors is not sufficient—explanation of interworkings of their actions beyond their intention, expectation, or belief is necessary. Simultaneous choices based on the best of motives may be counterproductive. The net outcome of rational choices may be counterintuitive. Silly choices

Are the consequences expected?	Are the consequences desired? Yes	Are the consequences desired? No
Yes	Intention = consequence	Suboptimality
No	Invisible hand	Counterfinality

Figure 1
Actions and consequences

may prove lucky strikes, bad motives may result in good fortunes. The way to hell may be paved with good intentions just as private vices may give public benefits (Mandeville [1714] 1989).

In fact, we can classify types of explanations from the answers to two questions: were the consequences expected or not, and were they desired or not? If the results coincide with what was desired, the actors have produced the intended results.

If the results were not expected, but when they appear are desired, we have what could be called 'invisible hand' explanations, since they are of the kind illustrated by the quote from Adam Smith above.

The case where the consequences are expected, but actors do not like them when they turn up, can be termed *suboptimality* (cf. Elster 1978): the actors know that when they act in their own interest, they nevertheless collectively end up in an undesired state—the joint outcome of their choices make them worse off. 'The Tragedy of the commons' illustrates the logic. A 'commons' is any resource that can be used as though it belongs to all. However, when rational agents use it, such a shared resource is doomed, though this is no part of the users' intent. Everyone gains from using it, none gains anything from not taking out what they can when others do. When utilized near carrying capacity, additional use will degrade its value to all. 'Ruin is the destination toward which all men rush, each pursuing his own best interest in a society that believes in the freedom of the commons' (Hardin 1968). The inexorable working out of the resource's ruin is Hardin's tragedy of the commons. Social change is the consequence of the sum of self-interested actions. And all could be better off by restraints on their own action. If such collective restraints are imposed by the actors themselves, this represents a change of political strutcture. This latter logic and model of structural change was first suggested by Thomas Hobbes ([1651] 1982) who called the commons 'the state of nature' and 'war of all against all,' whereas the joint establishment of an authority to keep all from self-defeating actions he called Leviathan (cf. Hernes 1999).

The fourth case is where the actors misjudge what others will do. Intentions that could be realized under constant conditions are rendered impossible when everyone seeks to realize them and change the conditions. Hog cycles is an economic example: producers act on the same assumptions and overinvest or underinvest in concert—the results of their decisions appear too late to become premises for their decisions. Erosion is another example—the irreversible destruction of alternatives. With a term Elster (1978) borrows from Sartre, this could be called *counterfinality*.

The four kinds of models are summarized in Fig. 1. Sometimes the actors get caught by what they have wrought; sometimes they do not master the world they have made. But independent actions can also turn out to be blessings in disguise.

7. *Models vs. Types of Social Changes*

Some key aspects of models of social change have been identified. A question of equal import is whether it is possible to identify basic types of social change. To answer this question requires a separate analysis.

Social Class and Gender

Both 'class' and 'gender' are contested concepts. Debates around gender and class have focused on employment-based approaches to 'class analysis.' It is argued that these have reached an *impasse*. It is, however, still of importance to retain a focus on the *processes* of gender and class structuring.

1. *Concepts and Definitions*

Three different meanings (or dimensions) of the class concept may be identified:

(a) 'Class' as prestige, status, culture, or 'lifestyles.'

(b) 'Class' as structured inequality (related to the possession of economic and power resources).

(c) 'Classes' as actual or potential social and political actors.

The use of 'class'—often as an adjective—to describe prestige or lifestyle is probably the most common use of the concept in everyday speech. Social scientists have also carried out descriptive investigations of social differentiation (e.g., Warner 1963), and market research companies have devised occupational classifications in order to give an indication of lifestyles and consumption patterns.

Following Weber, many sociologists would insist on the distinction between this use of 'class' to indicate prestige, or consumption patterns, and the use of 'class' in the second sense above, that is to describe groups with differential access to economic and power resources (these could be the ownership of capital or productive resources, skills and qualifications, networks of contacts, etc.) that generate structures of material inequality. Such unequally rewarded groups are often described as 'classes.' The identification of these groups summarizes the outcome, in material terms, of the competition for resources in capitalist market societies.

The term 'class,' however, has not just been used to describe levels of material inequalities or social prestige. 'Classes' have also been identified as actual or potential social forces, which have the capacity to transform society. Marx considered the struggle between classes to be the major motive force in human history. From the French Revolution and before, 'classes'—particularly the lower classes—have been regarded as a possible threat to the established order. Thus 'class' is also a term with significant *political* overtones.

The use of the single word 'class,' therefore, may describe hierarchical rankings of social prestige or lifestyles, patterns of material inequalities, as well as revolutionary or conservative social actors. It is a concept that is not the particular preserve of any individual branch of social science—unlike, for example, the concept of marginal utility in economics. It is not possible to identify a 'correct' sociological perspective, or an agreed use of the term.

In contrast to 'class,' the concept of gender might seem to be unproblematic, given its overt physical manifestations in all spheres of human life. However, its meaning has also been disputed. It is commonplace to draw a distinction between sex and gender, where sex denotes anatomical and physiological differences, and gender the social construction of masculinity and femininity. This is not universal (i.e., there is no 'essence' of masculinity or femininity), but created and interpreted differently by different cultures. However, recent theoretical developments within poststructuralist and postmodernist feminism have argued that sex itself is a social construct rather than biologically given, and the categories 'men' and 'women' *discursively* constructed through 'performance.' Thus, 'gender' has become overlaid with 'sexuality.' This has resulted in a focus on the sexual identity of the individual, and the discourses through which these identities are constructed, rather than on gender as a set of social relations.

However, an emphasis on the discursive construction of gender (or sex) effectively detracts from the investigation of the systematic structuring of inequality between men and women (through, for example, the gender division of labor). The question of sexuality has a focus on the *individual* and their associated identity—albeit an individual that is constructed, in process, undetermined, etc.—whereas gender is inevitably a *relational* concept. However, although gender, like class, is a social relationship of

power, there is a crucial difference between the two phenomena. Were private property to be abolished overnight, and class differentiation processes outlawed, there would be no 'classes.' However, were the differentiation processes of 'gender' as we know it to cease tomorrow, approximately half of the human population would nevertheless continue to have breasts and wombs. To recognize the biological roots of gender, however, is not to collapse into a biological determinism or essentialism. While gender differentiation is universal and persistent, what constitutes this concrete 'difference' will be variable in its nature and extent, and subject to constant construction and reconstruction.

2. Approaches to Class Analysis

The three different meanings of the class concept identified above are widely employed in a range of different approaches to the analysis of class and stratification. These approaches may be grouped within four areas (Crompton 1993, 1998):

(a) The study of the *processes* of the emergence and perpetuation of advantaged and disadvantaged groups or 'classes' within society. This may be described as 'class analysis' as a 'dependent variable' enterprise, in which the 'class' (or classes) itself is the object of study. All three meanings of 'class' may be employed in this approach, and indeed, these different dimensions are often seen as being intertwined with each other—as in, for example, E. P. Thompson's *The Making of the English Working Class* (1968).

(b) The study of the concrete consequences (or *outcomes*) of class location. This may be described as 'class' as an 'independent variable' specialty, in which 'class' is the constant factor and its contribution to other factors—e.g. voting behavior—is that which has to be explained (Wright 1997). Occupational 'class' may be related to consumption, inequalities, and political preferences, thus all three meanings of 'class' may be drawn upon in empirical investigations. However, the methodology of 'employment aggregate' class analysis means that these different dimensions of class have to be treated as discrete variables. Thus, for example, its practitioners argue that it is important to establish that occupational classifications do not correspond to a 'status' scale. In practice, however, economic and cultural dimensions are closely intertwined (particularly in the case of gender), and this separation is problematic.

(c) The discussion of the significance of 'class,' and class processes, for macro theories of societal change and development. These discussions mainly relate to the third meaning of class identified above. In Marx's work, 'classes' are seen as having the causal capacity to shape societies and generate social change (Sayer and Walker 1992; it should be noted that these claims are not only made by Marxists). Much of the debate with 'reflexive' or 'post' modernist critics of 'class analysis' has centered on this issue, i.e., whether, with increasing 'individuation,' 'classes' are still relevant social forces (Pakulski and Waters 1996, Clark and Lipset 1991). These preoccupations lead directly into a fourth approach to 'class' within sociology:

(d) The development of class and status cultures and identities. These discussions have tended to have a major focus on the first meaning of class identified above. However, Bourdieu's (1973) influential work combines an analysis of both class cultures and class inequalities, and focuses on both the processes of class formation as well as their outcomes.

3. Processes and Outcomes

The notion of class *processes*, therefore, may be used as a general term to identify the patterns of change, tensions, and struggle that generate the differentiated groupings that we call 'classes'—although, as we have stressed above, there would be no general agreement on the composition of these 'classes.' We have to distinguish between the processes of the formation and emergence of advantaged and disadvantaged, more powerful and less powerful, groups (or 'classes') in society, and the concrete consequences or outcomes of these processes. It has been suggested that this distinction broadly corresponds to two rather different approaches to 'class analysis' ((a) and (b) above). In a similar vein, it may be argued that it is important to distinguish between the processes of differentiation between men and women—that is, the construction of gender as a social relation—and the concrete consequences of this construction, that is, measurable differences between the sexes when taken in aggregate. Thus measurable 'sex differences' may be seen as outcomes of gender differentiation processes.

4. Measuring Social Class

The occupational structure is often used to generate 'class' groupings. This approach to the measurement of class may be described as the 'employment aggregate' approach, and is so widespread that the occupational structure and the class structure are frequently referred to as if they were synonymous.

From the 1970s leading practitioners of 'class analysis' argued that the classifications used by leading researchers of the time—(e.g., Blau and Duncan 1967)—did not measure 'class' in a truly sociological sense. Albeit from rather different theoretical perspectives, both Wright and Goldthorpe argued that the occupational measures previously used had in fact been hierarchical ('gradational') status scales rather than 'relational' class schemes. Thus throughout the

1980s, two major cross-national projects, both of which developed their own, employment-based class schemes, were established. The International Class Project, directed by Wright (1985, 1997), was explicitly Marxist in its inspiration and the scheme(s) he devised classified jobs according to a Marxist analysis of relations of domination and exploitation in production. The Comparative Analysis of Social Mobility in Industrial Societies (CASMIN) project used an occupational classification initially derived from Goldthorpe's study of social mobility.

Even in these improved versions, however, there are a number of problems with the assumption that the job or occupational structure may be divided so as to generate 'classes.' The occupational structure does not give any indication of wealth or property holdings. Not all adult persons have an occupation and there are therefore problems in allocating an individual 'class situation'—this has been particularly problematic in relation to the 'economically inactive,' such as housewives. The occupational structure also bears the imprint of other major stratifying factors—notably gender, race, and age—which are difficult to disentangle from those of 'class.'

We will expand our discussion of feminist criticisms of 'class analysis' in the next section, but for the moment, it is important to reiterate the point that occupational class schemes are only a proxy for 'classes.' Occupation gives a reasonable indication of 'life chances,' but no accurate measure of property or wealth. Employment aggregates do not correspond to politically conscious collectivities. Rather, sociological class schemes may be seen as an approximate measure (probably the best we have) of the outcomes of the *processes* of class differentiation. Wright and Goldthorpe take different positions regarding the identification of these processes. Wright's location of jobs into particular classes is guided by Marxist class theory. However, Goldthorpe emphasizes that no particular theory has contributed to his class scheme which must be judged by its empirical adequacy—'it is consequences, not antecedents, that matter.' Nevertheless, the schemes intercorrelate quite highly and indeed Wright suggests that his scheme can be interpreted 'in a Weberian or hybrid manner.'

5. *Feminist Criticisms of 'Class Analysis'*

In contrast to both Goldthorpe and Wright, feminists have argued that the processes of class formation and emergence—the divisions of capital and labor which led to the development of the bourgeoisie and mass proletariat—were intimately bound up with parallel processes of gender differentiation (e.g., Bradley 1989). They have described the processes whereby the sexual division of labor which culminated in that stage of modern capitalism we may loosely describe as 'Fordist' was characterized by the 'male breadwinner' model of the division of labor, around which 'masculine' and 'feminine' gender blocs were crystallized.

Thus feminist criticisms of employment aggregate class analysis derive from the observation that, because the primacy of women's family responsibilities has been explicitly or implicitly treated as 'natural' and men have been dominant in the employment sphere, this approach has effectively excluded women from any systematic consideration in 'class analysis.' It is argued:

(a) That the primary focus on paid employment does not take into account the unpaid domestic labor of women. Thus, women's contribution to production is not examined or analyzed (as in, for example, the debate around 'domestic labor,' see Molyneux 1979).

(b) The expansion of married women's paid employment has, apparently, rendered problematic the practice of taking the 'male breadwinner's' occupation as a proxy for the 'class situation' of the household.

(c) That gendered occupational segregation makes it difficult to construct universalistic 'class schemes' (that is, classifications equally applicable to men and women). The crowding of women into lower-level occupations, as well as the stereotypical or cultural 'gendering' of particular occupations (such as nursing, for example), gives very different 'class structures' for men and women when the same scheme is applied to both. Even more problematic is the fact that the same occupation (or 'class situation') may be associated with very different 'life chances' as far as men and women are concerned (for example, clerical work).

This third criticism emphasizes the *de facto* intertwining of class and gender within the employment structure (Crompton and Mann 1994). As noted above, the occupational structure emerging in many industrial societies in the nineteenth and early twentieth centuries was grounded in a division of labor in which women took the primary responsibility for domestic work, while male 'breadwinners' specialized in market work. Today this is changing in that married women have taken up market work, and this has had very important consequences for employment aggregate class analysis.

5.1 *Response of Leading Practitioners*

When Goldthorpe's major national investigation of the British class structure was published (1980/1987), it was subjected to extensive criticism on the grounds that it focused entirely on men, women only being included as wives. However, Goldthorpe argued that as the family is the unit of 'class analysis,' then the 'class position' of the family can be taken to be that of the head of the household, who will usually be a male. Thus were the assumptions of the male breadwinner model incorporated into sociological class analysis in

Britain. To incorporate women's employment into 'class analysis' on the same terms as men's, he argued, would lead to confusion. Many women work in lower-level white-collar jobs ('Intermediate' class locations in Goldthorpe's original class scheme), and to include their occupations would result in the generation of 'excessive' amounts of spurious social mobility.

However, he subsequently modified his original position in adopting, with Erikson, a 'dominance' strategy, in which the class position of the household is taken as that of the 'dominant' occupation in material terms—whether a man or a woman holds this occupation. Furthermore, although Erikson and Goldthorpe (1992) still insist that the unit of class analysis is the household, their class scheme has been modified in its application to women as individuals. Class IIIb (routine nonmanual) has been categorized as 'intermediate' for men, but 'labor contract' for women. Besides these modifications of his original approach, Goldthorpe has demonstrated that as measured by the Goldthorpe class scheme, the pattern of women's relative rates of social mobility closely parallels that of men. Thus although, because of the effects of occupational segregation, the distribution of men and women within occupational 'class' schemes is different, when considered separately, the impact of 'class' on mobility chances is similar for men and women.

Wright's analysis generally takes the individual, rather than the household, to be the unit of class analysis. However, in respect of economically inactive housewives, Wright (1997) employs a similar strategy to that of Goldthorpe. He introduces the notion of a 'derived' class location, which provides a 'mediated' linkage to the class structure via the class location of others. Wright is sensitive to the issue of gender, and the fact that gender is a major sorting mechanism within the occupational structure as well as reciprocally interacting with class. Nevertheless, he argues that while gender is indeed highly relevant for understanding and explaining the concrete lived experiences of people, it does not follow that gender should be *incorporated* into the abstract concept of 'class.' Thus in his empirical work, 'class' and 'gender' are maintained as separate factors.

We can see, therefore, that in responding to feminist criticisms, both Goldthorpe and Wright insist that class and gender should be considered as *distinct* causal processes. This analytical separation of class and gender may be seen as part of a more general strategy within the employment aggregate approach in which the continuing relevance of 'class' is demonstrated by the empirical evidence of 'class effects' (Goldthorpe and Marshall 1992). Although, therefore, Goldthorpe and Wright have apparently developed very different approaches to 'class analysis,' their underlying approach to the articulation of gender with class is in fact the same. It may be suggested that this stems from the similarity of the empirical techniques used by the CASMIN and International Class Projects: that is, the large-scale, cross-nationally comparative, sample survey. This kind of research proceeds by isolating a particular variable—in this case, employment class—and measuring its effects.

Feminist criticisms, therefore, were important in making explicit the fact that the 'employment-aggregate' approach within 'class analysis' is largely concerned with the *outcomes* of employment structuring (via its analysis of occupational aggregates or 'classes'), rather than the *processes* of this structuring. To paraphrase Goldthorpe and Marshall, employment aggregate 'class analysis' now appears as a rather less ambitious project than it once appeared to be. In a parallel fashion, it may be suggested that a major weakness of Wright's class project (not specific to the gender question) is that the linkage between Marxist theory and his 'class' categories has not been successfully achieved.

Although important issues have been clarified, therefore, this debate can go no further, and Wright argues that it is necessary to get on with '… the messy business of empirically examining the way class and gender intersect.' While one may be in broad agreement with this sentiment, it may be noted that Wright's preferred methodology focuses only on the association between job categories and biological sex. However, developments within the employment structures of the advanced service economies suggest the need for an approach that recognizes the complex processes of the structuring of both class and gender.

6. *The Restructuring of Gender and Class: the Shift to Services*

In today's advanced service economies, employment is still a significant, although not the only, determinant of 'life chances' and access to them. The last 20 years, however, have seen two major, and related, developments. These are, first, the shift to service work, and second, the growth and development of women's employment.

The growth of male-dominated industrial employment was paralleled by the increasing development of social protections associated with the welfare state. Welfare state institutions, such as occupational pensions and other social benefits, were in many countries explicitly created on the assumption that the male breadwinner model was the norm, and women received social benefits via their 'breadwinner.' In countries without extensive state welfare protections, such as the US, there has been an extensive development of marketized personal services. The expansion of the welfare state (as well as the expansion of other services such as education and health) was a major source of employment growth for women. Similarly, marketized personal services are also female dominated. Thus the basis of the male breadwinner model was being eroded even as its principles were

being consolidated in national institutions and policies.

Other factors were also leading to the growth of women's employment, including 'push' factors such as rising levels of education, effective fertility controls, and the growth of 'second wave' feminism, as well as 'pull' factors including the buoyant labor markets of the 1950s and 1960s. Service expansion was fueled not only by state expenditure and job creation, but also the growth of financial, leisure, and business services.

In the West, much of the growth of women's employment in the decades after World War II was in low-level and subordinate jobs. This reflected not only the directly discriminatory employment practices that were a major target of feminist action and protest in the 1960s and 1970s, but also the relatively low level of formal employment experience among women entering the labor force at this time. However, over the last 10 years, women have been steadily increasing their representation in managerial and professional occupations.

7. *The Growth of Women in Management and the Professions*

In all Western countries, the proportion of women in professional and managerial occupations is increasing at a faster rate than the proportion of women in the labor force as a whole. The level of increase of women's representation in some heavily feminized professions, such as teaching, is relatively low, suggesting that these professions might be nearing female saturation. In other professions such as engineering, the increase of female representation is again only modest, but in these instances, from a low base. Well above average rates of increase in the numbers and proportions of women are to be found in public service, financial and legal professions, in 'people centered' management such as personnel, marketing, and advertising, and above average rates in previously male dominated medical professions such as medicine. These trends support Esping-Andersen's (1993) assertion that the postindustrial (or service) job hierarchy is becoming increasingly feminized.

The feminization of the middle classes would appear to be a universal trend. This means that growing numbers of women are earning sufficient amounts to enable them to support a household. There has been an increase in the proportion of 'dual breadwinner' households. One outcome of this trend has been growing social polarization at the level of the household, as the gap between two income and one income households widens. Occupational polarization is also occurring with the growth of a new servant class. Another major outcome of the increase of women in managerial and professional occupations has been a decline in fertility levels, particularly among well-educated women. These demographic trends serve to illustrate, in a rather dramatic fashion, the *de facto* intertwining of employment and domestic life, which was one of the major points emphasized by 'second-wave' feminism.

8. *Discussion*

Changes in the gender division of labor are leading to increasing tensions between the demands of employment and caring responsibilities (Hochschild 1997), and some have argued that gender conflicts are replacing class conflicts (Beck and Beck-Gernsheim 1995). We have suggested, however, that rather than viewing 'gender' and 'class' as *alternative* causal processes, we should rather focus on their interaction. With the mass entry of women into the labor force, it is increasingly problematic to regard paid and unpaid labor as residing in 'separate spheres,' as class analysis conventionally has done. Demands originating from the domestic realm—for example, for time to carry out caring responsibilities or unpaid labor (both men and women may make these demands)—might potentially have a substantial impact on the structuring of paid employment and thus on a significant aspect of class relations. Thus although debates between feminist critics and 'employment aggregate' practitioners may have ended in stalemate, the actual need for a refocus on the interaction of gender and class *processes* is, arguably, greater than ever.

Social Cognition and Affect, Psychology of

The role of affect in social cognition has fascinated writers and philosophers since the dawn of antiquity. Starting with Plato, many theorists saw affect as a potentially dangerous, invasive force that subverts rational thinking. However, recent advances in social cognition, neuroanatomy, and psychophysiology suggest that affect is often a useful and even essential component of adaptive responding to social situations. The 1980s and 1990s produced something like an 'affective revolution' in psychology. Indeed, most of what we know about the role of affect in social thinking has been discovered since the early 1980s. As a result, we are now in a better position than ever before to pursue the age-old quest to understand the relationship between the rational and the emotional aspects of human nature. This article will consider early research on affect and social thinking, followed by a survey of contemporary theories and substantive research areas. The behavioral consequences of affect, and integrative theories of affect and social cognition, will also be discussed.

1. *Background*

Although affect has long been recognized as having a critical influence on thinking and judgments, empirical research on this link is quite recent. Psychologists traditionally studied the three fundamental faculties of the human mind—affect, cognition, and conation—as independent, isolated entities. Radical behaviorism consigned affect into the 'black box' of irrelevant mental phenomena, and the objective of most cognitive research was the study of cold, affectless ideation. The idea that affect is an integral and often adaptive part of how information about the social world is processed was not seriously entertained until the early 1980s. In a radical departure, Robert Zajonc argued that affective reactions often constitute the primary response to social stimuli and may influence subsequent attitudes and behaviors even in the absence of any cognitive memory trace (e.g., Zajonc 2000). Affective reactions such as feelings of anxiety, intimacy, or pleasure are also critical to cognitive representations of social experiences. More importantly, affect has a dynamic influence on memory, thinking, and judgments. Such 'affect infusion' was explained initially in terms of either psychodynamic or associationist principles.

Psychoanalytic theories suggested that affect has an invasive quality and can 'take over' thinking and judgments unless adequate psychological control is exerted. Attempts to suppress affect may increase the 'pressure' and could cause affect infusion into unrelated thoughts and judgments. In contrast, conditioning theories maintained that reactions to previously neutral social objects can be conditioned by simultaneous exposure to emotion-arousing stimuli. Consistent with this idea, investigators found that people who feel good or bad report significantly more negative or positive attitudes towards social stimuli. Byrne and Clore (1970) relied on this principle to explain the influence of affect on interpersonal attitudes and attraction.

2. *Contemporary Cognitive Theories of Affect and Social Cognition*

In contrast to psychoanalytic and conditioning accounts, contemporary cognitive theories focus on the information-processing mechanisms that link affect and cognition. Two kinds of mechanisms have been proposed: memory-based accounts (e.g., the affect-priming model; see Bower 1981, Forgas 1995), and inferential models (e.g., the affect-as-information model; see Clore et al. 1994). In addition, several theories highlight the influence of affect on information-processing strategies (Bless 2000, Fiedler 2000).

2.1 *Memory Models*

Affect may influence access to positively or negatively valenced ideas, producing more affect-congruent thoughts and judgments by happy or sad people. The associative network model proposed by Bower (1981) suggested that affect and cognition are integrally linked within an associative network of mental repre-

sentations. Affect will prime associated thoughts and ideas that are more likely to be used in constructive cognitive tasks. However, affect priming is subject to important boundary conditions. Mood-state dependence in memory is more likely when the affective state is strong, salient, and self-relevant, and the task involves the active generation and elaboration of information (Eich and Macauley 2000).

2.2 Inferential Models

Alternatively, rather than computing a judgment on the basis of recalled features of a target, individuals may simply ask themselves, 'How do I feel about it?' and in doing so, may use their mood to infer a reaction to the target. The 'how-do-I-feel-about-it' heuristic thus involves an inferential error: People misattribute their prevailing affect to an incorrect source. This theory is similar to conditioning approaches (Byrne and Clore 1970), as well as more recent work on misattribution, and research on judgmental heuristics. Accumulating evidence suggests that affect is most likely to be used as a heuristic cue when people are unfamiliar with the task, have no prior responses to fall back on, involvement is low, and cognitive resources are limited (Clore et al. 1994, Forgas 1995). Calling attention to the source of affect can reduce or even eliminate this effect. The affect-as-information model assumes that affect has invariant informational properties. Critics argue, however, that the informational value of affective states is not given but depends on the situation. The affect-as-information model has little to say about how affect and the stimulus information, and internal knowledge structures, are combined in producing a response. In that sense, this is more a theory of nonjudgment or aborted judgment rather than a theory of social judgment. Social cognitive tasks that require some degree of processing are more likely to be influenced by affect-priming rather than affect-as-information mechanisms.

2.3 Affect and Information Processing

In addition to informational effects (influencing *what* people think), affect can also influence the process of cognition, that is, *how* people think. It has been suggested that positive affect promotes less effortful and more superficial processing strategies, while negative affect triggers a more systematic and vigilant processing style. However, recent studies show that positive affect can also produce processing advantages. Happy people seem to adopt more creative and constructive thinking styles, use broader categories, show greater mental flexibility and perform better on secondary tasks (Bless 2000, Fiedler 2000). Explanations of mood effects on processing style at first emphasized the influence of affect on processing capacity. However, evidence for such accounts remains inconsistent. Alternative, motivational accounts suggest that people experiencing positive mood may try to maintain this pleasant state by refraining from any effortful activity. In contrast, negative affect may motivate people to engage in vigilant, effortful processing. Such a 'cognitive tuning' account seems consistent with evolutionary ideas about the adaptive functions of affect.

More recently, Bless (2000) and Fiedler (2000) argued that positive and negative affective states trigger equally effortful, but qualitatively different processing styles. Thus, positive affect promotes a more assimilative, schema-based, top-down processing style, where pre-existing ideas, attitudes and representations dominate information processing. In contrast, negative affect produces a more accommodative, bottom-up and externally focused processing strategy where attention to situational information drives thinking.

3. The Empirical Evidence

A growing number of empirical studies illustrate the role of affect in thinking and judgments in such areas as the perception of self and other people, the use of stereotypes, intergroup attitudes, attitude change, and persuasion.

3.1 Affect and Social Perception

Affect has a significant influence on how people respond to others (Forgas 2001). According to memory-based theories, affect infusion into social judgments is due to greater availability of affectively primed information when interpreting ambiguous social behaviors. Thus, a smile that may be seen as 'friendly' in a good mood could be judged as 'awkward' or 'condescending' by an observer experiencing negative affect. Surprisingly, these mood effects seem to be greater when people need to think more extensively about a more complex or unusual person, as confirmed by studies measuring reaction times and processing latencies. The more ambiguous the target, the more people will need to rely on their stored knowledge about the world to make sense of these stimuli. Such affect infusion effects also occur in realistic interpersonal judgments when people evaluate their real-life interpersonal relationships (Forgas 1995, 2001).

3.2 Affect and the Self

Affect has a particularly strong influence on self-related attitudes and judgments (Sedikides 1995): Positive affect improves, and negative affect impairs, the valence of self-conceptions. Thus, students in a negative mood tend to blame themselves more for failing, and those in a positive mood claim more credit for success in an exam (Forgas 1995). More recent

studies indicate that affect congruence in self-related thinking is subject to a number of boundary conditions. Affect infusion into self-judgments is more likely when the task requires open, constructive thinking. Compared with peripheral self-conceptions, central and familiar self-conceptions that require less elaboration also show reduced affect sensitivity (Sedikides 1995). Low self-esteem persons generally also have less certain and stable self-conceptions, and affect appears to have less of an influence on their self-judgments. Affect intensity and motivational factors also moderate mood congruency effects. Overall, affect seems to have a strong mood-congruent influence on many self-related attitudes and judgments, but only when some degree of open and constructive processing is required, and there are no motivational forces to override affect congruence.

Positive affect may also serve as a resource that allows people to overcome defensiveness and deal with potentially threatening information about themselves. People in a positive mood appear to be more willing to expose themselves voluntarily to threatening but diagnostic information. It seems that positive mood functions as a buffer, enabling people to handle the affective costs of receiving negative information, as long as the negative feedback is seen as useful (Trope et al. 2001).

3.3 *Affect and Stereotyping*

Early theories based on the frustration–aggression hypothesis and psychoanalytic notions of projection implied that negative affect may directly produce negative responses to disliked groups. Conditioning theories offered an alternative explanation of such effects, and also suggested that increased contact with outgroup members in positive situations should reduce aversive feelings and improve intergroup relations, a prediction that received considerable support (the so-called 'contact hypothesis'). Positive affect may also promote more inclusive cognitive categorizations of social groups, thus reducing intergroup distinctions (Bodenhausen and Moreno 2001). Individual differences such as trait anxiety can also significantly moderate the influence of negative affect on intergroup judgments; paradoxically, highly anxious people seem to show reduced intergroup discrimination when in an aversive mood. Affect is thus likely to influence intergroup judgments both by influencing the information processing strategies adopted, and the way positive and negative information about outgroups is selected and used.

3.4 *Affect in Persuasion and Attitude Change*

Writers on rhetoric have long assumed that producing an emotional response in an audience is an important prerequisite for effective persuasion. Recent dual-process theories of persuasion suggest that response to a persuasive message depends on the particular information-processing strategy people use, partly influenced by mood (Petty et al. 2001). For example, college students are significantly more likely to agree with persuasive messages advocating comprehensive exams when they are interviewed on a pleasant, sunny day rather than an unpleasant, rainy day. In general, affect should selectively prime mood-congruent thoughts and should influence responses to persuasion when a systematic, central-route strategy is adopted. However, people in a positive mood often process persuasive messages more superficially, and respond to both low-quality and high-quality messages the same way (Petty et al. 2001). Sad persons, in contrast, seem to be more persuaded by high-quality messages, consistent with their more externally focused and bottom-up information-processing style (Bless 2000).

3.5 *Affect and Cognitive Dissonance*

The experience of dissonance between attitudes and behaviors is a potent mechanism that produces attitude change. Cognitive dissonance involves negative affect because discrepancy among cognitions undermines our clear and certain knowledge about the world, and thus our ability to engage in effective action (Harmon-Jones 2001). Studies suggest that positive affect decreases, and negative affect increases, dissonance reduction and attitude change. Once consonance is restored, affective state also tends to improve. However, much work remains to be done in discovering the precise cognitive mechanisms responsible for these effects.

3.6 *Affect, Cognition and Social Behavior*

Affect can influence not only social cognition but also subsequent social behaviors. People need to evaluate and plan their behaviors in inherently complex and uncertain social situations. Positive affect may thus prime positive information and produce more confident, friendly, and cooperative 'approach' attitudes and behaviors, whereas negative affect should prime negative memories and produce avoidant, defensive, or unfriendly attitudes and behaviors. Research shows that people in a happy mood respond more positively when approached with an impromptu request, and produce more confident and more direct requests themselves in a variety of social situations. These effects also influence real-life interpersonal behaviors. Further, affect infusion into attitudes and behaviors is greater when more elaborate, substantive processing is required to produce a strategic response in more complex social situations. Affective states also play an important role in elaborately planned interpersonal encounters such as the planning and performance of complex negotiating encounters (Forgas 2001). Why do these effects occur? When people face an

uncertain and unpredictable social encounter, such as a negotiating task, they need to rely on open, constructive processing in order to formulate new plans to guide their interpersonal behaviors. Affect can selectively prime more affect-congruent thoughts and associations, and these ideas will ultimately influence people's plans and behaviors. However, affective influences on social behaviors are highly process-dependent: affect infusion is increased or reduced depending on just how much open, constructive processing is required to deal with a more or less demanding interpersonal task.

3.7 Integrative Theories: The Affect Infusion Model

Affective states thus have powerful informational and processing effects on the way people perceive, interpret, and represent social information. It is also clear, however, that affective influences on social cognition are highly context-sensitive. A recent integrative theory, the Affect Infusion Model (AIM; Forgas 1995) argued that affect infusion should only occur in circumstances that promote an open, constructive processing style. Constructive or generative processing may be defined here as genuinely open-ended, generative thinking that involves the selective search for, and on-line elaboration of, external information, and the constructive combination of stimulus details with internal knowledge structures that results in the creation of a new response. In contrast, merely reconstructive processing involves the retrieval and use of a previously computed response, with no on-line elaboration or stimulus details (Fiedler 2000).

The AIM identifies four alternative processing strategies: direct access, motivated, heuristic, and substantive processing. These four strategies differ in terms of two basic dimensions: the degree of effort exerted, and the degree of openness or constructiveness of the information search strategy. The combination of these two processing features, quantity (effort), and quality (openness), produces four distinct processing styles: substantive processing (high effort/open, constructive), motivated processing (high effort/closed), heuristic processing (low effort/open, constructive), and direct access processing (low effort/closed).

Direct access processing occurs when a pre-existing, stored response is directly accessed and used without any on-line elaboration. Motivated processing is driven by a strong pre-existing motivational objective that determines information search strategies and thus limits the likelihood that incidentally primed, affective information will be incorporated into the response. Heuristic processing, although a constructive process, is based on the limited consideration of information, and the use of mental shortcuts and heuristics (such as the affect-as-information heuristics) whenever possible. It is only substantive processing that involves the full and elaborate processing of stimulus information and the constructive integration of stimulus details with primed memories and associations. According to the AIM, mood congruence and affect infusion is most likely when constructive processing is used, such as substantive or heuristic processing. In contrast, affect is unlikely to affect the outcome of closed, merely reconstructive tasks involving motivated or direct access processing (see also Fiedler 2000).

4. Conclusion

The evidence shows that mild everyday affective states can have a highly significant influence on the way people perceive and interpret social situations. Further, several of the experiments discussed here show that different information-processing strategies play a key role in moderating these effects. Affect infusion influences not only attitudes and judgments but also interpersonal behaviors, such as the monitoring and interpretation of observed encounters; the formulation of, and responses to, requests; and the planning and execution of strategic negotiations. In contrast, affect infusion is absent whenever a social cognitive task could be performed using a simple, well-rehearsed direct access strategy, or a highly motivated strategy. Obviously a great deal more research is needed before we can fully understand the multiple influences that affect has on attitudes, judgments, and interpersonal behavior.

Social Cognition and Aging

There is a rich and abundant history of research in cognitive aging. However, studies typically have ignored the influence of social factors on cognition with one exception, metacognition. More specifically, there has been considerable research on self and other beliefs about memory such as personal control and memory self-efficacy. In the 1990s social cognition and aging research has grown considerably in both breadth and scope. This movement reflects a broader interface between mainstream social cognition and cognitive aging to better understand how cognition in the aging adult operates in a social context.

There are pervasive findings in the cognitive aging research that demonstrate age-related decline in cognitive performance such as working memory, abstract reasoning, and speed of processing. However, taking into consideration the pragmatics of cognition and social-contextual factors may help broaden our understanding of cognitive functioning in older adults beyond linear decline. Accordingly, a recent wave of studies has begun to examine social cognitive functioning in an effort to better understand the effects of cognitive aging and associated adaptive developmental processes. These studies raise important issues in relation to cognitive functioning such as age-related increases in experience, pragmatic knowledge, social expertise, beliefs about aging and social values, and social contextual variation. In addition, they highlight the importance of considering both the basic cognitive architecture of the aging adult and the functional architecture of everyday cognition in a social context. In the latter case, even if certain basic cognitive mechanisms have declined, older adults may possess appropriate knowledge and skills in a given context to function adequately through adaptation and compensation. Before we entertain these issues and findings in the extant literature, let us first consider a definition of the social cognitive perspective as it is applied to aging research.

1. *Definition of Social Cognition*

The basic goal of a social cognitive perspective is to understand how individuals make sense of themselves, others, and events in everyday life. These goals are reflected in the study of (a) cognitive mechanisms that may explain social cognitive processes (as illustrated above); (b) the content and structure of social knowledge; and (c) the influence of social situational and individual demands on social information processes and social knowledge.

To illustrate these points within an adult development and aging perspective, first consider the well-documented finding that age-related decline in processing capacity correlates with age-related decline in cognitive performance. The question is whether age-related changes in working memory, attentional capacity, and speed of processing also relate to and/or explain age changes in social cognitive processes (Hess 1999, Schwarz et al. 1999). Researchers have suggested that age-related decline in processing capacity could explain the finding that older adults rely more on easily accessible trait-based information when making social judgments as opposed to more elaborative processing (Hess 1999).

However, from the second goal perspective listed above, age-related change in content and structure of social knowledge, accessibility of this knowledge held in memory, and related motivation and goals of the individual in the context of concurrent processing resources may offer competing explanations of age differences in social reasoning. Finally, personal and situational factors associated with aging could also explain a reliance on easily accessible social knowledge and beliefs. For example, older adulthood has been associated with a decrease in personal characteristics such as tolerance for ambiguity and attitudinal flexibility (Blanchard-Fields 1999). It may be the case that such decreases in cognitive flexibility may lead to social processing biases (Hess 1999). Alternatively, older adulthood is associated with changing situational factors, which influence social goals such as an increase in the importance of emotional considerations. In this case such an increase in emotional

salience influences how information is processed (see Turk-Charles and Carstensen 1999 for a review). Let us now turn to each of these goal perspectives in more detail.

2. Cognitive Mechanisms and Social Cognition

There is a history of social cognition research that posits information-processing models for making social judgments (e.g., Gilbert and Malone 1995). For example, Gilbert and Malone have shown that the ability to make nonbiased attributional judgments depends upon the cognitive demand accompanying those judgments. In this case individuals are more likely to rely on their initial dispositional attribution (attributing the cause of an outcome to personal characteristics of the main character involved in producing the outcome), ignoring compelling situational causes. Accordingly, in a number of studies, Blanchard-Fields and co-workers (see Blanchard-Fields 1999 for a review) have found that older adults consistently attributed the cause of problem dilemmas to dispositions about the primary protagonist more than younger age groups. However, this was only demonstrated when events reflected negative interpersonal content. It may be the case that older adults relied more heavily on easily accessible dispositional attributions given the demands on cognitive resources to deliberate about situational factors. However, keep in mind that these findings were content-specific (i.e., only found when situations were negative and interpersonally oriented).

Hess and co-workers (see Hess 1999 for a review) have demonstrated that the use of diagnostic trait information (such as immoral behavior) in making initial impressions of an individual varied with age. They find age differences in the use of negative information in modifying impressions. When first presented with a positive portrayal of an individual (e.g., honest) followed by negative information (e.g., dishonest behavior) older adults were more willing to modify their impression from an initially positive to a more negative one. However, older adults did not modify their first impression when it was an initially negative portrayal followed by positive information. Younger adults did not exhibit this pattern of impression change. Instead, they engaged in effortful processing of the text in their concern with the situational consistency of the new information presented. Hess suggests that older adults may rely more on life experiences and social rules of behavior in interpreting these types of situations, whereas young adults were more concerned with situational consistency of the new information presented. Again, it is suggested that older adults do not correct their initial impressions because they were affected by the availability of negative information or a negativity bias. Such influences of processing biases suggest that decline in cognitive functioning limits the ability of older adults to override the impact of more easily accessible information such as the negativity bias. However, Hess also suggests that the use of such information appears to be related to age differences in social experience and changes in the salience of specific behavioral realms.

Finally, another example of a processing resource approach to social cognition and aging is illustrated in the work of Schwarz et al. (1999). They found that manipulating the salience of the information given, and thus its accessibility, can modify social judgments in young and older adults. However, in some circumstances, older adults' judgments show smaller context effects than young adults. One explanation of such findings is that reduced processing resources constrain the processing of contextual information by older adults.

Based on the above research, it appears that both processing resource limitations as well as the social content of memory play an important role in understanding how older adults process social information. However, it is also the case that the extent to which social information is accessible may operate independently of a processing resource limitation to influence social judgments. Next we will explore the issue of knowledge-based views of social cognitive processing.

3. Social Knowledge and Social Cognition

There is a history of social cognition research that suggests that strongly held and easily accessible social beliefs and knowledge are activated automatically and can influence social judgments in general, and promote social judgment biases in particular (e.g., Gilbert and Malone 1995). The prepotent influence of such beliefs and knowledge on social judgments may operate even when individuals are not constrained by high cognitive demands and possess ample resources to engage in elaborative processing. This brings into play alternative explanations for older adults' tendencies to rely on easily accessible information in making social judgments. First, as alluded to earlier, older adults may exhibit a cognitive style that forecloses further consideration of information such as intolerance for ambiguity or a need for structure. As indicated above, age-related decreases in attitudinal flexibility may lead to biases in social judgment. Second, strong attitudinal beliefs and values may be evoked by the presenting situation. For example, Blanchard-Fields (1999) suggests that particular types of situations such as negative interpersonal relationship situations trigger relatively automatic trait- and rule-based social rules or schemas pertinent to the actor in the problem. In this case the individual may not engage in intentional, effortful processing of detailed information. Instead, the older adults may have relied more on activated social beliefs resulting in dispositional biases. Thus, it is not a matter of insufficient processing capacity to

engage in elaborative social inference, but overriding considerations (e.g., irrepressible beliefs or values).

Accordingly, Chen and Blanchard-Fields (reviewed in Blanchard-Fields 1999) explored both a processing explanation and a belief content hypothesis to explain dispositional biases in older adults' attributions about negative relationship situations. They manipulated the timing of when dispositional ratings were collected and obtained belief statements regarding appropriate behaviors in the social situations presented. They found that older adults produced more dispositional biases only when time was constrained. However, they also found that older adults made more evaluative rule statements about the main character than younger adults and this rendered all age differences in dispositional biases nonsignificant.

Such findings suggest that a knowledge-based explanation of social judgments is a viable alternative to resource limitations. This approach is also evidenced in the research examining the influence of social situational factors and cognitive functioning in older adults. In this case, the research focus is on one's changing life context and adaptation or social competence. We turn to this approach next.

4. *Social Situational Factors, Social Competency, and Social Cognition and Aging*

The social cognition paradigm has offered an enriched understanding of competency in older adulthood. From this perspective, social competence is seen as an important and valid dimension of cognition and intelligence. Social cognitive performance, from this perspective, incorporates principles derived from the lifespan contextual perspective and can be explained in terms of adaptation to particular life contexts. For example, research exploring such social cognitive constructs as possible selves (one's hopes and fears for the future) indicates that they change throughout the latter half of the lifespan (Hooker 1999). For example, health-related selves achieve greater importance in older adulthood and relate to adaptive self-regulatory health behaviors.

This is most evident in areas such as wisdom, practical and social problem-solving, and postformal reasoning. For example, Staudinger et al. (1992) argue that wisdom involves an expert body of knowledge and strategies related to life composition and life insight. These strategies are used to produce adaptive outcomes in managing and composing one's life. Examples of such knowledge and strategies include the ability to select appropriate abilities and strategies, compensate for declining abilities, and optimize one's performance, e.g., as in increased flexibility in coping behavior. Similarly, Turk-Charles and Carstensen's (1999) work suggests that changes in the relative importance of social cognitive goals across the lifespan profoundly influence the interpretation of social information and the selection and maintenance of intimate relationships. In this latter case, important new variables affecting social information processing emerge. Carstensen and co-workers argue that perception of time is responsible for this change in social motivation. By considering such changes, age-related decreases in social interaction can be recast in terms of its adaptive significance.

In another domain, Dixon (1999) examines cognition in social collaborative contexts. The primary thrust of this work examines age differences in the benefits or costs of collaboration in cognitive performance (e.g., memory, problem solving). He argues that collaborative cognitive functioning characterizes another aspect of social competence. Finally, we cannot ignore the negative role that social situational factors can play in the social cognitive functioning of older adults. This is reflected in the work on social stereotypes and aging. A number of researchers have examined adult developmental changes in the content and structure of stereotypes (e.g., Hummert 1999). For example, Hummert finds that older and young adults hold quite similar age stereotypes. However, she and other researchers find that older persons have more complex representations of the category 'older adult' as opposed to young adults who, in addition, hold more negative representations. However, unlike the social cognitive research reviewed above, these studies primarily look at age differences in the content of stereotypes. The explicit social cognitive mechanisms that account for these differences are not revealed clearly.

Relative to the knowledge-based framework discussed above, the content of social knowledge, attitudes, and beliefs such as stereotypes is important. However, the content must be accessed or activated in order to influence behavior. An important question is how does stereotype activation encourage or discourage the individual to be a more effective information processor? With respect to older adults, how do the stereotypes of aging provide expectations of mental deficiencies? In her research Levy (1996) suggests that such automatically activated (that is subliminally primed) stereotypes about aging and memory adversely affect the cognitive performance of older adults. This is, of course, a provocative finding and in need of replication. However, the point here is that it provokes issues for further research. The issue of directly manipulating threatening and/or facilitative and nonfacilitative social contexts is only beginning to undergo examination.

5. *Future Directions*

In conclusion, the social cognition and aging research highlights the importance of considering social factors in explanations of social cognitive functioning. Such factors as the communicative context, social beliefs

and values, cognitive style, stereotypes, motivational goals, among others influence social information processing in important ways. Thus, it is important not to limit explanations of social cognitive change to cognitive processing variables. There are important social factors influencing how and when older adults will attend to specific information and when this information will influence social cognitive functioning.

However, current research in social cognition and aging has only begun to address important questions regarding older adults' social cognitive functioning. In order to understand more fully the role and interplay of social cognitive structures and mechanisms in social cognition and aging, more research is needed. For example, are there qualitative changes in underlying mechanisms influencing social cognitive functioning? Age differences in the nature of social beliefs, values, and goals activated in social reasoning need to be explored. How and under what conditions do age differences in the content and activation of social knowledge and social belief systems account for social information processing? Can factors that influence variability as to when social judgment biases occur in young adults account for age-related variability? Under what conditions does working memory load compromise social information processing and under what conditions is it irrelevant? We can be optimistic in the growth of the social cognitive approach in research on aging. Although many of the cognitive and socio-emotional aspects of behavior and aging have been addressed, we have only begun to scratch the surface.

Social Cognition in Childhood

'Social cognition' refers in very general terms to thinking about people, knowledge of people, and the social world, as well as to social processes in cognitive development. That is, it is a term that is used to refer both to the nature or content of children's understanding of others and themselves, and to theories and explanations of how social experiences are involved in the development of understanding more broadly considered—the role of social factors in cognitive growth. The study of social cognition then is at the border of cognitive and social developmental psychology (Butterworth 1982). It brings together very different theories of the growth of knowledge, and is a growing point for new ideas on the nature of children's understanding of mind and emotion, and on the relation of this understanding to children's prosocial and moral development, and their social relationships.

1. Changes in Ideas on Social Cognition

Five themes in the changing ideas on the development of social cognition over recent decades are evident. One concerns the question of how social experiences are implicated in sociocognitive development, in terms of the processes by which cognitive change takes place. The second concerns ideas and evidence on the nature of children's understanding of emotion, mind, intention, and the connections between these inner states and people's actions—a domain which has come to dominate cognitive developmental research since the early 1990s. The third theme is the rapidly growing interest in individual differences in social understand-

ing, and the implications of these differences for a wide range of children's outcomes. The fourth is the role of social experiences in contributing to these individual differences in children's social understanding. The fifth is the recent interest in bridging the gap between the study of cognitive and of social development through a focus on how cognitive development is implicated in social relationships, moral and prosocial development. These themes will be considered in turn.

1.1 Individual and Social Approaches to Cognitive Development

Piaget's ideas on cognitive development centered on both the process of understanding, and on the nature of knowledge, and a key notion was that the individual child actively constructs knowledge by selecting and interpreting information in the environment. The processes he proposed for the growth of intelligence were seen as applying to both the inanimate and the social world. His investigations of children's understanding of the mind began in the 1920s (e.g., Piaget 1926); after these first books he focused chiefly upon children's growing knowledge of the physical world, and the development of logicomathematical thought. The emergence of social knowledge was not seen as essentially different from other forms of knowledge, though social interactions (especially those with peers) were seen as contributing to children's growing understanding (see Sect. 1.4 below).

In contrast to Piaget's focus on the individual actively constructing knowledge as an individual, there is a strong tradition within psychology that emphasizes the social nature of cognitive processes, beginning as early as the 1890s with Baldwin's seminal writings (e.g., Baldwin 1895). In Russia, Vygotsky argued that cognitive growth was socially determined—that cognitive development proceeded from the social plane to the individual (see Wertsch 1985). He famously proposed that new cognitive abilities were first seen when a child was interacting with another person, and only later became internalized. Individual development was, he argued, embedded in a social context. Vygotsky emphasized the difference between a child's level of potential ability, and his or her actual ability.

The difference between these two levels he termed the 'zone of proximal development'—abilities that were just beyond what a child could achieve alone, but was able to achieve when interacting with a cooperative, supportive other person (adult or peer). Thus to Vygotsky, the scaffolding or facilitation provided in social interaction (especially interaction between adult and child, or expert and novice) was key for the development of new abilities. Within this broad theoretical framework, researchers have examined the significance of 'scaffolding' and facilitation in cognitive performance, and the 'expert–novice' interaction (Rogoff 1990). A whole new view of cognitive growth in infancy has flourished, in which the context in which new abilities are fostered is seen as essentially social (Hala 1997). So for example, recent research on the development of understanding of emotion takes off from Darwin's observations of the development of emotions (which highlight the biological foundation and function of emotional expression) to emphasize the sociocultural contributions to the development of both expression and understanding of emotions.

The idea that cognitive growth takes place through social interaction has also been experimentally investigated within a different research tradition, that of Doise and his colleagues in Geneva, with a series of studies that began in the 1970s (e.g., Doise and Mugny 1984). Rather than emphasizing scaffolding and supportive cooperation, they argued that cognitive conflict between individuals who may view a problem differently, or have different levels of ability can stimulate cognitive development.

These theoretical positions have all been concerned with the normative processes by which cognitive changes take place, rather than with the role of social experiences as contributors to individual differences in social cognition; this is considered in Sect. 1.4 below.

1.2 The Nature of Children's Developing Social Understanding

After Piaget's seminal work in the 1920s, it was not until the mid-1980s that interest in children's understanding of mental life, and their perspective on why people behave the way they do, began to revive; since the early 1990s there has been a great increase in developmental research on children's understanding of emotion, mind, and intention. The focus has been chiefly on normative developmental changes in children's understanding of emotional and mental life and their relation to people's behavior, beginning with the work on infancy that highlights the extent to which babies are 'prepared to learn about people' from very early in infancy. For example, babies discriminate different emotional expressions very early (a key first step for understanding emotions); by the time they are nine months old they already act in ways that indicate they have considerable grasp of affective communication, and are able to communicate their desires—clearly, these are efforts at symbolic communication. At the end of the first year, the emergence of 'social referencing' is a key development: in situations of ambiguity for the baby (such as when a strange person or object appears), the baby looks at a familiar adult (in most experimental settings, the mother), and apparently is guided by her emotional expression, showing different behavior if she is expressing happiness or fear, for instance. Such differential behavior is taken as evidence that the baby 'understands' that

the mother's emotional expression provides important information about the ambiguous situation.

During the second year, babies begin to show pride, shame, and embarrassment—the 'social emotions,' emotions that highlight how closely tuned the children are to other people's reaction to them. They also clearly show their understanding of others' feelings in their attempts to comfort, tease, and joke, and, with the acquisition of language, in their talk about feelings (Bartsch and Wellman 1995).

The marked changes between two and five years old in children's ability to distinguish thoughts and things; their increasing interest in talking about feeling, thinking, and knowing; their curiosity about why people behave the way they do; their ability to play with hypothetical social events, to share narratives in pretend play, and to deliberately deceive others, have been documented in a burst of research since the early 1990s (Astington 1993). There has been considerable controversy about the details of the timing of these normative changes (conclusions about children's abilities depend very much on the methods used and the setting in which children are studied; see Sect. 2), and competing theoretical accounts of these cognitive changes have been articulated. However the broad outline of development in what has been termed children's 'theory of mind' has been mapped, as follows.

Children's understanding of people's feelings and mental states, and their use of this understanding to explain and predict people's behavior begins in infancy, as the evidence of their intention to communicate shows. It develops in the toddler years with their growing ability to talk first about what they and other people see, want, and feel, then later in their talk about what they think and know. The critical understanding that people behave in the world as they see it or believe it to be, even when those beliefs or perceptions may be inaccurate, is reached by most children around four years. Note that much of the most recent research emphasizes the substantial competence of children as young as three, and the gradual nature of developmental change. A key tool in this research has been the demonstration that children understand how a 'false belief' can influence how someone will behave.

Other key developments in children's social understanding include children's growing understanding that people are different, their grasp of understanding the self, and their moral understanding. On the first of these, children's understanding and attribution of traits, a clear developmental pattern was described from work in the 1970s and 1980s, with marked change around six to eight years in children's appreciation of trait terms; it is usually presumed that this reflects age-related cognitive changes. Recently the 'theory of mind' research has been integrated with this 'traditional' approach, and there is increasing empirical support for the idea that both cognitive development and sociocultural influence play a role in the development of trait attribution (Hala 1997).

On the development of moral understanding, there has been a parallel shift from a focus primarily on the cognitive underpinnings of moral development (e.g., Kohlberg 1984) to a recognition that cognition, emotion, and moral action are closely interrelated (Eisenberg et al. 1997). Thus while we now know that developmental changes in prosocial behavior are complex, and influenced by the methodology employed (Eisenberg and Fabes 1998), it is recognized that the relations between perspective-taking abilities and prosocial behavior are moderated by affective factors, by the particular emotional relationship between the child and the other person involved, and by the child's interpretation of the situation, and attributions about the individuals involved.

1.3 Individual Differences in Social Cognition

Individual differences in sociocognitive abilities have been shown to be importantly linked to children's adjustment and 'social competence' (skills, deficits) in middle childhood; the wealth of research on social cognition and children's peer relations—and specifically to problems in those relations—illustrates these associations. One line of research has focused on information-processing models (as in Dodge's 1986 social information-processing model), which highlight children's attributions about their peers, their goals, and strategies in peer relations. These models conceptualize an ordered series of steps in social information processing that includes encoding and representational processes, search and decision-making strategies. Differences in processing patterns may underlie the form of aggressive behavior that children show towards their peers. Experimental studies with aggressive children show, for instance, that they did not attend to all relevant cues, they attributed hostile intent to a protagonist in an ambiguous setting, and failed to generate enough viable alternative strategies. The original social information-processing models were criticized on the grounds that the linear model was too constrained, and that no role of emotion was included. Revised models now include emotional states as influences on what is perceived, how it is processed, and what attributions are made.

A second line of evidence links children's thoughts about themselves, such as their perceptions of their own competence, to individual differences in peer relations (Ladd 1999). Thus children who are both aggressive and rejected by their peers, compared to other children, overestimate their own social skills and competence, and underestimate the degree to which their peers dislike them. Other research links individual differences in early social understanding to later differences in moral sensibility, and to the ways in which children adjust to school. Such findings high-

light the importance of clarifying what are the key processes implicated in the development of such individual differences in social understanding.

1.4 Social Experience as Contributor to Individual Differences in Social Understanding

To understand these individual differences in children's social understanding, it is increasingly clear that their social experiences must be examined. Research that includes a focus on social experiences not only reveals children's abilities vividly, but also suggests some key processes implicated in their development (Dunn 1996). The interactive events that have been highlighted include sharing a pretend world with another person (especially a peer or sibling), participation in conversations about inner states (Bartsch and Wellman 1995), joint narratives and causal discourse about the social world, engagement in certain kinds of 'constructive' conflict with others. For example, several studies have shown that children who grew up in families in which they participated in discourse about feelings, and causal talk about why people behave the way they do, were, in later assessment of social understanding, more successful than those who had not engaged in such talk; other research has shown that those who had experienced much shared, cooperative pretend play with a sibling were also in later assessments particularly mature in their social understanding.

Three general principles that emerge from this empirical research are the following. First, the emotional context in which such interactions take place may be key to what is learned; it is not simply the child's exposure to new information or another's point of view that matters, but the emotions and pragmatics of the relationship between the interactants that are important. Second, how children use their social understanding in real-life interactions differs in different social relationships, depending on the quality of that relationship. Relationship quality depends on both partners, and is unlikely to be linked simply to the sociocognitive skills of either partner. Third, different kinds of social relationship appear to play different roles in influencing the development of social understanding.

Two recent lines of evidence illustrate this point. First, studies of child–child relationships show these peer interactions to be of special significance in the development of understanding feelings and other minds, and of moral sensibility (as originally proposed by Piaget [1932] 1965). Second, recent work on attachment quality links the security of children's attachments to their later mind-reading abilities—and it is inferred that the key process implicated here is mothers' sensitivity to their children's current levels of understanding and their use of mental state terms in interactions with them, a propensity that Meins (1997) refers to as 'mind-mindedness.' The role of family processes, more broadly conceived, in influencing children's social cognitive abilities during early and middle childhood—both directly and indirectly—continues to be a focus of much research interest. It should be noted that inferences about the direction of effects in such research present particular problems.

1.5 The Significance of Cognitive Processes in Social Development

The advances in our understanding of children's cognitive development have important implications for how we view and study children's social development and their social relationships—both the nature of social development and the processes implicated in it. First, what has been learned from cognitive research about the development of understanding of emotion and mind in childhood, means not only that dimensions of empathy and understanding are part of their early close relationships, but that aspects of intimacy (previously thought only relevant to the relations between much older children) may also be present in the relationships between preschoolers. Thus observational research shows that three year olds who are close friends engage in shared imaginative play in which their cooperation, the smooth co-construction of narratives, reflect an impressive 'meeting of minds'—a mutual understanding of how the other thinks the play might develop, and what are the exciting next moves in the narrative. Second, the cognitive research alerts us to the importance of looking beyond the 'security' aspects that have dominated conceptions of parent–child relationships. Manipulation of control and power within a dyadic relationship, deception, teasing, and shared humor all depend on a grasp of the other's motivation, beliefs, desires, and capacities. These dimensions may well be relevant for a full account of young children's relationships. Third, to understand developmental changes in children's social relationships, the evidence for developments in metacognitive skills is clearly relevant. Perhaps most important of all are the implications of cognitive research for children with difficulties in social relations, for example children with problems such as autism or hyperactivity. Whether these children's social problems are antecedent to or sequels of their cognitive problems remains a question of central social and clinical importance, as well as one of theoretical interest.

Two other lessons from cognitive research have major implications for the study of children's sociocognitive development. The first concerns the developmental impact of relationships between other people. Cognitive research has shown us that children are interested in, and reflect on, others' intentions,

thoughts, and feelings, reminding us to pay attention to the developmental impact of what is happening between the other people in children's social worlds. Three lines of evidence illustrate this significance: the evidence for the negative impact of marital conflict on children's adjustment; the research on co-parenting, which shows the poor outcome of children whose parents disagree and fail to support one another over parenting; and third, the accumulating evidence that differential treatment of siblings within the family is associated with later problems in children's development.

The second lesson is that the evidence for children's interest in the inner states of others suggests that children may be sensitive to the responses, opinions, and relationships between other members of their peer groups to an extent that is only recently being appreciated. Recognizing that children's problems in peer group relations are a key marker for later adjustment problems suggests that further attention to this sensitivity to the group is important.

2. *Methodological Issues and Problems*

In research on social cognition there is a new concern with the contextual validity of experimental tasks used, particularly in terms of the social situation in which children are placed in such tasks; their relationship with the experimenter plays a role in their task performance (Dunn 1996). More generally there is a concern to expand the social context of such studies to more 'real-life settings': research within a Vygotskean framework, for example, has chiefly been limited to adult–child encounters of a didactic nature, which are affectively neutral—unlike the interactional settings within the family in which children are likely to make advances in sociocognitive ability (Goodnow 1990).

Research on children in real-life social settings—as opposed to controlled experimental settings—highlights the capacities that even young children can show in the domain of understanding other people's feelings, beliefs, and intentions. Studies of natural discourse have been centrally important here (Bartsch and Wellman 1995). There is a tension here in current developmental research, as the naturalistic data suggest children's capacities for social understanding are evident at considerably younger ages than would be expected on the basis of the standard experimental assessments of sociocognitive development; the various studies of deception provide a good example (Dunn 1996). Such studies not only show that children's abilities may be misrepresented by their limited abilities in more formal settings; they have also contributed importantly to ideas on the social processes that may influence the development of individual differences in social cognition.

Different methodologies can importantly affect the inferences we make about children's prosocial behavior (Eisenberg and Fabes 1998), as well as about their mind-reading and emotion understanding. Moreover, children use their sociocognitive abilities differently within their various relationships: one lesson from research that focuses on children in different relationships is that we should move away from the conception of sociocognitive capacity as a characteristic of a child that will be evident in all social situations (Dunn 1996).

3. *Future Directions*

Among the many challenges posed by the research to date, four stand out as key. First, to make progress in understanding the development of social understanding, we need to address the difficult issue of how affect is linked to cognitive change, and to bridge the divide between research on social and cognitive development. The developmental work that documents children's explanations of people's actions first in terms of emotions and desires, and then later incorporating the notion of belief, has led for instance to the provocative argument that an understanding of cognitive states arises from an earlier understanding of emotional states (Bartsch and Estes 1996).

Second, we need to investigate the differentiation of different aspects of social understanding—too often combined into global categories at present—and to further explore the relation of language and general intelligence to the various aspects of understanding the social world.

Third, the challenging question of how developmental accounts based on children within the normal range of individual differences relate to the development of children at the extremes remains both theoretically and clinically important. Fourth, more research on implications of cultural and class differences, and more diversity in the children studied is needed. Finally at a methodological level, researchers need to include both experimental and naturalistic strategies, and to study children in different social settings, to use as informants both children and others in their social worlds.

Social Cognitive Theory and Clinical Psychology

1. Social Cognitive Theory

Human behavior has often been explained in terms of one-sided causation. In these unidirectional models, behavior is depicted as being predominantly shaped and controlled by environmental influences, or impelled by inner drives and dispositions. Social cognitive theory explains human functioning in terms of triadic reciprocal causation (Bandura 1986). In this model of reciprocal determinism personal determinants in the form of cognitive, biological, and emotional factors, behavior patterns, and environmental events all operate as interacting determinants that influence each other bidirectionally.

2. Agentic Perspective

Social cognitive theory is rooted in an agentic perspective. People are self-organizing, proactive, self-reflecting, and self-regulating, not just reactive organisms shaped and shepherded by external events. Human adaptation and change are rooted in social systems. Therefore, personal agency operates within a broad network of sociostructural influences. In these agentic transactions, people are producers as well as products of social systems. Sociostructural and personal determinants are treated as co-factors within a unified causal structure rather than as rival conceptions of human behavior.

3. Fundamental Human Capabilities

In social cognitive theory, people are characterized in terms of a number of fundamental capabilities. These are enlisted in effecting personal and social change.

3.1 Symbolizing Capability

The extraordinary capacity to represent events and their conditional relations in symbolic form provides humans with a powerful tool for comprehending their environment and for creating and managing environmental conditions that touch virtually every aspect of their lives. Most environmental events exert their effects indirectly, through cognitive processing, rather than directly. Cognitive factors partly determine which environmental events are observed, what meaning is conferred on them, what emotional impact and motivating power they have, and how the information they convey is organized and preserved for future use. Through the medium of symbols, people transform transient experiences into cognitive models that serve as guides for reasoning and action. By symbolizing their experiences, people give structure, meaning, and continuity to their lives. The sociocognitive methods for promoting personal and social change draw heavily on this symbolizing capability.

If put to faulty use, the capacity for symbolization can cause distress. Indeed, many human dysfunctions and torments stem from problems of thought. People live in a psychic environment largely of their own making. In their thoughts, they often dwell on painful

pasts and on perturbing futures of their own invention. They burden themselves with stressful arousal through apprehensive rumination, debilitate their efforts by self-impeding ideation, drive themselves to despondency by harsh self-evaluation and dejecting modes of thinking, and often act on misconceptions that get them into trouble. Thought can thus be a source of human failings and distress as well as a source of human accomplishments. Faulty styles of thinking can be changed to some extent by verbal analysis of faulty inferences from personal experiences. However, corrective and enabling mastery experiences are more persuasive than talk alone in altering faulty beliefs and dysfunctional styles of thinking (Bandura 1986, 1997, Rehm 1988, Williams 1990).

3.2 *Vicarious Capability*

There are two basic modes of learning. People learn by experiencing the effects of their actions, and through the power of social modeling. Trial and error learning is a tedious and hazardous process. Fortunately, this process can be short cut by social modeling. Humans have evolved an advanced capacity for observational learning that enables them to expand their knowledge and competencies rapidly through the information conveyed by the rich variety of models (Bandura 1986, Rosenthal and Zimmerman 1978).

Modeling is not simply a process of response mimicry as commonly believed. Modeled activities convey rules for generative behavior. Once observers extract the rules underlying the modeled activities they can generate new patterns of behavior that go beyond what they have seen or heard. Self-regulatory and other cognitive skills can also be developed by using models to verbalize plans, action strategies, and self-guidance to counteract self-debilitating thought patterns, as solutions to problems are worked through (Meichenbaum 1984). Deficient and faulty habits of thought are corrected as participants adopt and enact the verbal self-guidance.

In addition to cultivating new competencies, modeling influences can alter incentive motivation, emotional proclivities, and value systems (Bandura 1986). Seeing others achieve desired outcomes by their efforts can instill motivating outcome expectations in observers that they can secure similar benefits for comparable performances; seeing others punished for engaging in certain activities can instill negative outcome expectations that serve as disincentives. Observers can also acquire lasting attitudes and emotional and behavioral proclivities toward persons, places, or things that have been associated with modeled emotional experiences. Observers learn to fear the things that frightened models, to dislike what repulsed them, and to like what gratified them.

During the course of their daily lives, people have direct contact with only a small sector of the physical and social environment. As a result, their conceptions of social reality are greatly influenced by modeled representations of society, mainly by the mass media (Gerbner 1972). Video and computer systems feeding off telecommunications satellites are now rapidly diffusing new ideas, values, and styles of conduct worldwide. At the societal level, symbolic modeling is transforming how social systems operate and serving as a major vehicle for sociopolitical change (Bandura 1997). As Braithwaite (1994) has shown, the speed with which Eastern European rulers and regimes were toppled was greatly accelerated by televised modeling of successful mass action.

The vast body of knowledge on modeling processes is being widely applied for personal development, therapeutic purposes, and social change (Bandura 1997, Bandura and Rosenthal 1978, Rosenthal and Steffek 1991). For human problems that stem from sociocognitive deficits, the guided mastery approach that is highly effective in cultivating personal efficacy and psychosocial competencies combines three components. First, the appropriate competencies are modeled in a stepwise fashion to convey the basic rules and strategies. Second, the learners receive guided practice under simulated conditions to develop proficiency in the skills. Third, they are provided with a graduated transfer program that helps them to apply their newly learned skills in their everyday lives in ways that will bring them success. In ameliorating anxiety and phobic dysfunction, the modeling provides coping strategies for managing threats. One can eventually overcome fears without the aid of modeling through repeated unscathed contact with threats, although it takes longer and is more stressful. However, modeling of cognitive and behavioral skills is a key ingredient in the development of complex competencies.

Sociocognitive approaches rely on mastery experiences as the principal vehicle of change. The enabling power of social modeling is enhanced by guided mastery enactments. When people avoid what they dread, they lose touch with the reality they shun. Guided mastery treatment quickly restores reality testing in two ways. It provides disconfirming tests of phobic beliefs by persuasive demonstrations that what phobics dread is safe. Even more importantly, it provides confirmatory tests that phobics can exercise control over what they fear. Intractable phobics, of course, are not about to do what they dread. Therapists must, therefore, create environmental conditions that enable phobics to succeed despite themselves. This is achieved by enlisting a variety of performance-mastery aids. Threatening activities are repeatedly modeled to demonstrate coping strategies and to disconfirm people's worst fears. Intimidating tasks are reduced to graduated subtasks of easily mastered steps. Joint performance with the therapist enables frightened people to do things they would refuse to do on their own. Another method for overcoming re-

sistance is for phobics to perform the feared activity for only a short time. As they become bolder the length of involvement is extended. Protective conditions can be introduced to weaken resistance that retards change. After effective functioning is fully restored, increasingly challenging self-directed mastery experiences are then arranged to strengthen and generalize the sense of coping efficacy. Varied mastery experiences build resiliency by reducing vulnerability to the negative effects of adverse experiences. This is a powerful treatment that eliminates phobias, anxiety arousal, biochemical stress reactions, and wipes out recurrent nightmares and intrusive rumination (Bandura 1997, Williams 1990).

Symbolic modeling lends itself readily for society-wide applications through creative use of the electronic media. For example, the soaring population growth and the environmental devastation it produces is the most urgent global problem. Worldwide use of enabling and motivating dramatic serials is raising people's efficacy to exercise control over their family lives, enhancing the status of women to have some say in how they live their lives, and lowering the rates of childbearing (Singhal and Rogers 1999, Vaughan et al. 1995).

3.3 Self-regulatory Capability

People are self-reactors with a capacity to motivate, guide, and regulate their activities through the anticipative mechanism of forethought. People set goals for themselves, anticipate the likely consequences of prospective actions, and plan courses of action that are likely to produce desired outcomes and avoid detrimental ones. The projected future is brought into the present through forethought. A forethoughtful perspective provides direction, coherence, and meaning to one's life.

Much human motivation and behavior is regulated anticipatorily by the material and social outcomes expected for given courses of action. Social cognitive theory broadens this functionalism to include self-evaluative outcomes. People do things that give them satisfaction and a sense of self-worth, and refrain from actions that evoke self-devaluative reactions. Incentive systems are enlisted, if needed, to promote and help sustain personal and social change (Bandura 1986, 1998, O'Leary and Wilson 1987).

In keeping with the agentic perspective of social cognitive theory, the greatest benefits that psychological treatments can bestow are not specific remedies for particular problems, but the self-regulatory capabilities needed to deal effectively with whatever situations might arise. To the extent that treatment equips people to exercise influence over events in their lives, it initiates an ongoing process of self-regulative change.

Personal standards for judging and guiding one's actions play a major role in self-motivation and in the exercise of self-directedness (Bandura 1991, Locke and Latham 1990). Self-regulatory control is achieved by creating incentives for one's own actions and by anticipative reactions to one's own behavior depending on how it measures up to personal standards. Sociocognitive principles of self-regulation provide explicit guidelines for self-motivation, personal development, and modification of detrimental styles of behavior.

A favorable self-regulatory system provides a continuing source of motivation, self-directedness, and personal satisfaction, but a dysfunctional self-system can breed much human misery. For people who adopt stringent personal standards, most of their accomplishments bring them a sense of failure and self-disparagement (Bandura 1997, Rehm 1988). In its more extreme forms, harsh standards of self-evaluation give rise to despondency, chronic discouragement, and feelings of worthlessness and lack of purposefulness. For example, Hemingway, who took his own life, imposed upon himself demands that were unattainable throughout his life, pushed himself to extraordinary feats, and constantly demeaned his accomplishments.

Effective treatments for despondency arising from stringent self-imposed standards remedy each of the dysfunctional aspects of the self-system (Rehm 1981). They correct self-belittling interpretative biases that minimize one's successes and accentuate one's failures. To increase self-satisfaction and a sense of personal accomplishment, participants are taught how to set themselves attainable subgoals in activities of personal significance and to focus their efforts and self-evaluation on progress toward their aspirations. Through proximal structuring, goals become motivating rather than demoralizing. Depressed individuals tend to be less self-rewarding for successes and more denying and self-punishing for failures than the nondepressed for similar performances. They are taught how to be more self-rewarding for their progressive personal attainments.

Deficient or deviant standards also create problems, although the distress is inflicted on others rather than on oneself. Unprincipled individuals who pursue an ethic of expediency, and those who pride themselves in antisocial activities readily engage in conduct that is socially injurious (Bandura 1991). Antisocial and transgressive styles of conduct have diverse sources requiring multifaceted approaches to personal change. Successful treatments promote the development of competencies and prosocial self-regulatory standards and styles of behavior sufficiently attractive to supplant antisocial ones (Bandura 1973, Reid and Patterson 1991, Silbert 1984). Education provides the best escape from crime and poverty. Promoting educational development is, therefore, a key factor in reducing crime and delinquency.

3.4 Self-reflective Capability

Among the mechanisms of personal agency none is more central or pervasive than people's beliefs in their capability to exercise control over their own functioning and over environmental events (Bandura 1997). Efficacy beliefs are the foundation of human agency. Unless people believe that they can produce desired results by their actions, they have little incentive to act or to persevere in the face of difficulties. Meta-analyses, which combine the findings of numerous studies, attest to the influential role played by efficacy beliefs in human adaptation (Holden 1991, Holden et al. 1990, Multon et al. 1991, Stajkovic and Luthans 1998).

Self-efficacy beliefs regulate human functioning through their impact on cognitive, motivational, emotional, and choice processes. They determine whether people think pessimistically or optimistically, and in self-enhancing or self-debilitating ways. Efficacy beliefs play a central role in the self-regulation of motivation through goal challenges and outcome-expectations. Whether people act on the outcomes they expect prospective performances to produce depends on their beliefs about whether or not they can produce those performances. It is partly on the basis of efficacy beliefs that people choose what challenges to undertake, how much effort to expend in the endeavor, how long to persevere in the face of obstacles and failures, and whether failures are motivating or demoralizing. Efficacy beliefs play a key role in shaping the courses lives take by influencing the types of activities and environments people choose to enter. By choosing their environments, people can have a hand in what they become.

People's beliefs in their coping capabilities also play a pivotal role in the self-regulation of affective states (Bandura 1997). Efficacy beliefs influence how potential threats are perceived and cognitively processed. If people believe they can manage threats they are not distressed by them. But if they believe they cannot control potential threats they experience high anxiety. Through inefficacious thinking they distress themselves and constrain and impair their functioning.

Many human distresses result from failures of thought control. It is not the sheer frequency of disturbing cognitions, but the perceived inability to turn them off that is the major source of distress. Similarly, in obsessional disorders, it is not the ruminations, *per se*, but the perceived inefficacy to stop them that is perturbing.

Phobics display high anxiety and physiological stress to threats they believe they cannot control. After their perceived efficacy is raised to the maximal level by guided mastery experiences, they manage the same threats with equanimity.

It was widely assumed that phobic behavior was controlled by anxiety. Many therapeutic procedures were, therefore, keyed to extinguishing anxiety arousal. The anxiety control theory has not withstood experimental scrutiny, however. A low sense of coping efficacy produces both anxiety and phobic behavior. People often perform activities even though highly anxious, as long as they believe they can master them. Intense stage fright, for example, does not stop actors from going on stage. Conversely, people avoid situations they believe exceed their coping capabilities without waiting for visceral arousal to tell them to do so. Williams (1992) has shown that people base their actions on efficacy beliefs in situations they regard as risky not on anxiety arousal.

A low sense of efficacy to exercise control over things one values can give rise to feelings of futility and despondency through several pathways. In one pathway, a low sense of efficacy to fulfill personal standards of worth gives rise to self-devaluation and depression. A second pathway occurs through a low sense of social efficacy to develop social relationships that bring satisfaction to people's lives and enable them to manage chronic stressors. Another is through the exercise of control over depressing thoughts themselves. Low efficacy to regulate ruminative thought contributes to the occurrence of depressive episodes, how long they last, and how often they recur.

People's beliefs about their efficacy are constructed from four principal sources of information. The most effective way of instilling a strong sense of efficacy is through mastery experiences. Successes build a robust belief in one's personal efficacy. Failures undermine it. Development of resilient self-efficacy requires experiences in overcoming obstacles through perseverant effort. The second method is by social modeling. Models serve as sources of competencies and motivation. Seeing people similar to oneself succeed by perseverant effort raises observers' beliefs in their own capabilities. Social persuasion is the third mode of influence. The fourth way of altering self-efficacy beliefs is to enhance physical strength and stamina and alter mood states on which people partly judge their capabilities.

These different modes of influence create and strengthen beliefs of personal efficacy across diverse spheres of functioning. Such beliefs predict the level, scope, and durability of behavioral changes (Bandura 1997). Microanalyses of how given treatments work, reveal that the efficacy belief system is a common pathway through which different types of treatment produce their effects. Knowledge of the determinants and processes governing the formation of efficacy beliefs provides explicit guidelines on how best to structure programs to achieve desired change.

4. Sociostructural Change

Many human problems are sociostructural, not simply individual. Common problems require social solutions through collective action. Social cognitive theory

extends the conception of human agency to collective agency (Bandura 1997). People's shared belief in their collective power to produce desired results is a key ingredient of collective agency. The stronger the people's perceived collective efficacy the higher their aspirations and motivational investment in their undertakings, the stronger their staying power in the face of impediments and setbacks, the higher their morale and resilience to adversity, and the greater their accomplishments.

Efforts to improve the human condition must, therefore, be directed not only at treating the casualties of adverse social practices, but also at altering the social practices producing the causalities. The models of social change derived from social cognitive theory (Bandura 1986, 1997), draw heavily on knowledge of modeling, motivational, regulatory, and efficacy mechanisms operating at the collective level.

Social Comparison, Psychology of

Social comparison occurs when an individual compares himself or herself to another person. The dimension on which the comparison is made can be almost anything—attractiveness, tennis skill, wealth, etc. The comparison might be deliberately sought, or it might occur by chance. It is not social comparison when one compares one person to another, as in comparing one neighbor to another; the individual making the comparison must be included in the comparison for it to fit the commonly accepted definition.

1. The Original Theory

Leon Festinger's (1954) paper, *A Theory of Social Comparison Processes*, still serves as the basic formulation, although there have been many additions

and revisions. Festinger argued that it is necessary for people to know what they are capable of doing and to hold correct opinions about the world. Sometimes people can perform a physical reality test on their abilities and opinions, but that could be dangerous, inconvenient, or impossible. For example, if individuals want to know whether they can swim across a swift river, they could simply try it, but that could be dangerous. If it is a person's opinion that the Russian Revolution would not have occurred without V. I. Lenin, there is simply no physical reality test of the truth of that opinion. Consequently, people often seek *social reality* rather than physical reality for their abilities and opinions, and that social reality is obtained through social comparison.

1.1 Similarity

A cornerstone of Festinger's theory is that comparison with others who are similar provides better information than comparison with dissimilar others. The theory was ambiguous, however, about the concept of similarity, and critics argued that if an individual already knows that someone is similar, that implies that a comparison has already been made and that further comparison with that person would be redundant. Goethals and Darley (1977) combined *attribution theory* with social comparison theory and suggested that similarity should refer to similarity on 'related attributes,' attributes correlated with and predictive of the particular ability or opinion to be evaluated. To answer the question, 'How good a tennis player am I?' a person should compare with someone of the same age, gender, physical condition, and tennis experience. The person should logically expect to perform equally to that comparison target and, if this turns out to be so, would probably feel that he or she is a fairly good player ('as good as I ought to be'). If the comparison is with someone advantaged (or disadvantaged) on related attributes, the person would expect to lose (or to win) and, if this turns out to be so, wouldn't be able to draw any clear conclusion about his or her ability level. The person wouldn't know whether the loss or win was due to ability or to the related attributes. 'Did I win because I am a good tennis player, or because I am in better physical condition?'

1.2 The Unidirectional Drive Upward

An important difference between opinions and abilities in Festinger's theory is a *unidirectional drive upward* for abilities but not for opinions. Regardless of the ability, people would generally like to have more of it than other people have. With opinions, however, people feel confident when they have the same opinions as others. Thus, all the members of a group can be satisfied when they have the same opinion, but not when they have exactly the same level of ability.

2. Methods for Studying Social Comparison

The three major methods for studying social comparison are 'selection' approaches, which examine characteristics of the people with whom individuals choose to compare; 'reaction' approaches, which examine individuals' emotional or cognitive reactions to comparison information; and 'narration' approaches, which examine individuals' self-reports of comparisons made (Wood 1996). Each of these will be examined below.

2.1 The Selection Approach

Individuals are given the choice of two or more comparison targets that differ in theoretically important ways. The choices they make (and related data) provide clues concerning social comparison motives. The first notable example, known as the 'rank order paradigm,' was introduced to study the unidirectional drive upward. Experimental participants were tested on a (fictitious) desirable or undesirable personality trait such as 'intellectual flexibility' or 'intellectual rigidity' and were told that they occupied the middle rank in a group of several other participants tested at the same time. Participants were given their own (fictitious) score on the test, as well as the rank of each of the other participants, and were told that they could be shown the score of one other person in the group. The rank of the person participants chose to see could be of someone better off than themselves (known as an 'upward comparison') or worse off than themselves (a 'downward comparison'). In most of the experiments using this method, participants made upward comparisons. That is, they wanted to compare their scores to better scores, either more flexible or less rigid (Wheeler et al. 1969). They believed that they were similar to and almost as good as those better off than themselves and chose to compare with these others in order to confirm that similarity.

2.2 The Reaction Approach

Individuals are presented with social comparison information, and their responses to that information are measured. In what is known as the Mr. Clean/Mr. Dirty study, job applicants casually encountered another applicant whose appearance was either socially desirable (dark suit, well-groomed, and confident)

or socially undesirable (torn and smelly clothes, poorly-groomed, confused). Those participants who encountered Mr. Clean showed a decrease in self-esteem measured a few minutes later, whereas those who encountered Mr. Dirty increased in self-esteem (Morse and Gergen 1970). In this research, participants contrasted themselves against the other job applicant, but this is not always what happens. For example, Van der Zee et al. (1998) exposed cancer patients to a bogus interview with another patient who was doing better than participants (upward comparison) or worse (downward comparison). Patients responded with more positive affect to upward than to downward comparisons, particularly those patients who scored high on a measure of identification with the upward comparison patient. Collins (1996) called this 'upward assimilation,' the perception that one is similar to superior others. This is opposed to 'upward contrast,' in which comparing with someone who is better off (like Mr. Clean) makes people feel worse about themselves.

2.3 The Narrative Approach

This approach attempts to measure the comparisons that people make or have made in their everyday lives. At the most basic level, participants are sometimes asked who they have compared themselves with in the past. This places too great a burden on memory, however, and a better method is the *Social Comparison Record*, a diary recording of all comparisons as they occur over a period of two weeks, including the dimension of comparison (e.g., appearance, happiness), the direction (e.g., upward, downward), relationship to the target (e.g., friend, stranger), and mood before and after the comparison (Wheeler and Miyake 1992).

Free response measures are also narrative in approach. These are spontaneous statements, usually made during the course of an interview or conversation, implying comparisons. Wood et al. (1985) reported that breast cancer patients made many free response comparison statements, most of which seemed to indicate downward comparison, such as 'I think I am coping a little better than these other women.'

3. Downward Comparison Theory

The rank-order experiments drew attention to the difference between upward and downward comparisons, and one of the experiments (Hakmiller 1966) demonstrated downward comparison. Participants who were threatened with having a very high score on the undesirable personality trait 'hostility toward one's parents' chose to compare with others who had even more of the trait. This was a downward comparison because it was with someone worse off than themselves. By verifying that someone had even more of the negative trait than themselves, participants could defend their self-esteem. Influenced by this research, Wills (1981) proposed a *theory of downward comparison*—that persons experiencing threat or negative affect will enhance their subjective well-being through comparison with someone worse off than themselves, thereby reducing distress. This prediction received support from studies of cancer and other medical patients, particularly those studies using free response measures (see Buunk and Gibbons 1997).

3.1 Challenges to Downward Comparison Theory

There is substantial controversy about the empirical support for downward comparison theory. The theory makes the intuitively appealing prediction that when people are experiencing distress they will make a downward comparison to reduce the distress. Others have questioned whether people experiencing distress are psychologically capable of making a downward comparison; their attention may be so focused on their distress that they are unable to see others as being worse off than themselves. In research using the Social Comparison Record (see above), Wheeler and Miyake (1992) found that when participants were experiencing negative affect, they made upward comparisons rather than the downward comparisons predicted by downward comparison theory. In contrast, when the same participants were experiencing positive affect, they made downward comparisons. Such a result is not consistent with downward comparison theory but is consistent with *affect-cognition priming* models in which affect primes (makes ready and available) cognitions about the self that are congruent with the affect. Experiencing negative affect primes a person to have negative thoughts about the self and thus to see others as superior to the self, leading to a contrastive upward comparison and further feelings of inferiority and negative affect.

4. A Return to the Concerns of the Original Theory

4.1 Abilities

It should be apparent that Festinger's (1954) original theory is very different from most of the subsequent research and theory. Festinger was concerned with social comparison providing accurate evaluation of one's opinions and abilities, whereas much of the later work was concerned with how social comparison relates to how people feel about themselves. Some recent work has returned to Festinger's original con-

cerns. For example, one of the questions addressed by Festinger's theory was 'Can I do X?' Can I swim across the river? Can I complete a college degree? Can I have both a family and a career? One way to answer such questions is to compare oneself to someone—called a proxy—who has already succeeded at the task (Martin 2000). If people seem to have the same amount or more of the ability or abilities required as the proxy does, they could conclude with some confidence that they could also perform the task. There are two ways that people can be confident that they have as much of the underlying ability as the proxy: (a) they have competed directly against the proxy and have performed as well as the proxy when the proxy was performing to maximum, or (b) they have observed the proxy performing, are unsure whether the proxy was performing to maximum, but are similar to the proxy on attributes related to the ability. In both cases they have established with some degree of certainty that they are similar in ability to the proxy and thus have the same action possibilities.

4.2 Opinions and Attitudes

Suls (2000) proposed that the social comparison of opinions is best considered in terms of three different evaluative situations: preference assessment (i.e., 'Do I like X?'), belief assessment (i.e., 'Is X correct?'), and preference prediction (i.e., 'Will I like X?'). Each evaluative question is associated with a different comparison dynamic. (a) If the question is 'Do I like X?,' persons similar in related attributes have special importance. Thus, in deciding whether one likes a new political candidate, a person should prefer comparison with someone with similar political values and goals. Such a comparison target should share one's assessment of the candidate, and if not, something is amiss, and the situation should be re-examined. (b) If the question is 'Is X correct?,' comparisons with persons of more advantaged status (or 'expert') are most meaningful, although they also should hold certain basic values in common (the 'similar expert'). Thus, to determine the truth of the belief that guns should not be in private hands, comparison with the opinion of an expert on the relevant statistics would be useful, but only if the expert shared one's values about human life, freedom, etc. (c) If the question is 'Will I like X?,' the most meaningful comparisons are with persons who have already experienced 'X' and who share a consistent history of preferences. Thus, in deciding whether a movie would be enjoyable, a person would consult with someone who has seen the movie and who has in the past usually agreed or usually disagreed with the person. If the other has usually agreed, the person would expect to have the same reaction to the movie; if the other has usually disagreed, the person would expect to have an opposed reaction to the movie.

5. Prospects

There is more interest in social comparison theory now than any time in its almost half-century history because it has become clearer that comparison with other people is central to the human experience. The theory is being applied to new problems and is increasingly influencing and being influenced by other areas within psychology.

Social Competence: Childhood and Adolescence

1. Definitions

Social competence refers to the effectiveness of a person's functioning as an *individual*, in *dyadic relationships* and in *groups*. Like other general constructs used by psychologists (e.g., *risk*, *stress* and *vulnerability*), competence refers to a general class or category of phenomena. In this respect, *competence* brings together a set of ideas or concepts regarding individuals' capacities to function in their environments. Insofar as competence refers to a property of the relationship between the individual and the environment, one cannot think of individuals as being competent without knowing the contexts in which they are engaged. Competence is also a metatheoretical construct in the sense that it is not linked to a single theoretical perspective. Instead, it serves as an organizing principle for research programs and it allows scientists from diverse areas of study to see the links and commonalities among them.

1.1 Initial Conceptualizations

An etymological analysis of the word *competence* shows that it refers to the engagement of an individual in activity oriented toward the achievement of a state or goal (Bukowski et al. 1998). Therefore, a competent person is not a person who possesses a particular skill or ability but is a person who is able to engage in the activities needed to achieve particular goals or outcomes. This exact view—that competence is a process—serves as the centerpiece of White's (1959) seminal conceptualization of competence as an organism's orientation toward an efficient interaction with the environment. For White (1959), this orientation was a profound and basic form of motivation, as critical as any fundamental drive. According to his view, competence is not a form of motivated behavior that serves other drives, but is a fundamental form of motivation in and of itself. To support this argument, he referred to the high rates of exploratory behavior seen in many animals and the infant's instinctual curiosity in novelty. Both of these phenomena show that organisms are inherently oriented toward interaction with the environment. He found evidence of this 'instinct to master' in the observations and interpretations provided by neo-analysts (e.g., Fenichel 1945, Hendrick 1942). Hendrick, for example, went so far as to write that individuals have an 'inborn drive to do and to learn to do.' Again, White was careful to point out that according to these neo-analysts, such activity is not in the service of another goal (e.g., anxiety reduction), but is instead a basic human motivation by itself. White noted that this proposal was central also to the ideas of Erik Erikson. In Erikson's (1953) description of the latency years, he emphasized that this developmental period is a time in which competence is the main developmental struggle that children confront. Erikson wrote that 'children need a sense of being able to make things and to make them well and even perfectly: this is what I call a sense of industry.'

1.2 Current Definitions

The impact of White's views is, in part, apparent in the definitions of competence that subsequent writers have offered. These include the following: 'the effectiveness or adequacy with which an individual is capable of responding to various problematic situations which confront him' (Goldfried and D'Zurilla 1969 p. 161); 'an individual's everyday effectiveness in dealing with his environment' (Zigler 1973); 'a judgment by another that an individual has behaved effectively' (McFall 1982 p. 1); 'attainment of relevant social goals in specified social contexts, using appropriate means and resulting in positive developmental outcomes' (Ford 1982 p. 324); the ability 'to make use of environmental and personal resources to achieve a good developmental outcome' (Waters and Sroufe 1983 p. 81); and 'the ability to engage effectively in complex interpersonal interaction and to use and understand people effectively' (Oppenheimer 1989 p. 45). In a review of these definitions, Rubin et al. (1998), pointed out that they share at least two points: (a) an emphasis on effectiveness, and (b) an understanding of the environment so as to achieve one's own needs or goals. One has to presume that the dynamism that stood at the center of White is implicit in these definitions even if it is not stated explicitly.

Using definitions noted above, as well as from others found in the work of Attili (1989), Dodge (1986), Gresham (1981), Strayer (1989) as a point of departure, Rubin and Rose-Krasnor (1992, 1986) have defined social competence as *the ability to achieve personal goals in social interaction while simultaneously maintaining positive relationships with others over time and across situations*. A significant feature of this definition is its implicit recognition of the importance of individual and social goals. This emphasis reflects essential duality of self and other, placing the individual within a social and personal context. The conceptualization of self and other as indistinguishable is an important feature of theory from several domains including personality theory (Bakan 1966, Sullivan 1953), gender role theory (Leaper 1994), feminist psychology (Jordan et al. 1991), and philosophy (Harré 1979, 1984). Accordingly, this definition is valuable as it points to the complex goals that persons confront as individuals and as members of

groups. It is in this regard that individuals, as well as social scientists, have struggled with the tension between agentic and communal orientations.

2. The Socially Competent Child and Adolescent

Children's competence within social contexts depends upon their social skills. These skills are both behavioral and cognitive. The cognitive skills include the ability to understand and predict the internal states (i.e., the thoughts, feelings, and intentions) of other children and to understand the meaning of these states within the present context. Using this information, a competent child is able to develop plans for interacting with others to achieve desired outcomes and to evaluate the flow of the interaction as it unfolds. Part of this evaluation concerns the consequences of one's actions as well as those of the partner, on both instrumental and moral grounds, so as to maintain positive interaction, and either repair or terminate negative interactions. In the behavioral domain, a competent child is able to act prosocially and is capable of displaying appropriate positive affect while avoiding or inhibiting negative affect and is able to communicate verbally and nonverbally so as to facilitate the partner's understanding of the interaction. (These issues are discussed further in chapters found in Asher and Coie (1990) and Schneider et al. (1989).)

2.1 Competence as Process

Recent approaches to social competence have gone beyond the emphasis on skills *per se* and have argued that social competence needs to be understood as a hierarchical process. Two models of this sort have been proposed by Rubin and Rose-Krasnor (1992) and Crick and Dodge (1994). In parallel to previous process-oriented approaches to social cognition and behavior (e.g., Miller et al. 1960) these models include a series of steps that are presumed to underlie social interaction. Rubin and Rose-Krasnor adopt an interpersonal problem solving model of social competence which is largely predicated on the view that most social interactions appear to be routine, reflecting an automaticity in thinking and a scriptedness in social interchanges (Abelson 1981, Nelson 1981, Schank and Abelson 1977). They note, for instance, that children quickly learn many rudimentary scripted forms of social behavior, such as greeting and leave-taking sequences, as well as acquiring an understanding that many social relationships 'slot' members into particular roles that are played out in highly predictable ways (e.g., Strayer 1989). Such scripts and role understandings allow children easy access to sequences of actions corresponding to highly familiar social situations thus facilitating social competence. Indeed, for both competent and less-than-competent children, familiar social situations easily elicit routine, script-driven behavior. In the absence of such familiarity, when appropriate and routine eliciting conditions are not present, this sort of script driven enactment of social behavior is precluded.

2.2 Rubin and Rose-Krasnor Model

Rubin and Rose-Krasnor propose that in such novel conditions, social competence derives from the following sequentially organized steps. First, a goal needs to be chosen. Often several goals are apparent, and they can often conflict with each other. For this reason Dodge et al. (1989) argued that the successful *coordination* of goals is more likely to be a challenge to an individual's competence than is the achievement of a particular goal. Second, the chosen goals need to be understood according to contextual factors, such as whom they are interacting with (e.g., stranger, acquaintance, friend) and this person's characteristics, and the features of the context (e.g., school, home, or playground), population density, and visibility (public versus private encounters). Next, strategies for achieving that goal need to be chosen. To do this, a child may retrieve one or more strategies from long-term memory or new strategies may be constructed from those already available. Once selected, the child must produce the strategy in its relevant context and the results need to be evaluated. If the strategy is judged to be *successful*, the problem-solving process ends and relevant information concerning the social interchange is retained in long-term memory. If a strategy has been judged as *partially successful*, the actor may accept the outcome as 'successful enough' and proceed as if the outcome was a success; alternately, the individual may decide to judge the outcome as a failure.

If this case, the child may stop the sequence and leave the goal unattained or may choose to either repeat the original strategy or choose to alter the previous strategy in some way while maintaining the same goal.

2.3 Crick and Dodge Model

Another approach to understanding the process of social competence is seen in a model proposed by Crick and Dodge (1994). They also emphasize the importance of information processing as the basis of social competence. Their model involves six stages, each of which involves a form of information processing that draws upon currently available information as well as a data base of rules, schemas, and social knowledge. The six steps in their model are as follows.

First the child *encodes* social cues by attending to relevant social information such as who is in the social milieu (a friend, a stranger, a popular child, an unpopular child), how it is that this person is expressing him or herself (affectively happy, angry, or sad), and so on. Second, the child must *interpret* the encoded cues. This requires that the child search his or her memory store in an effort to understand the meaning of the encoded information. For example, one of the social cues encoded at Step 1 might be a facial expression denoting anger. Interpreting the facial expression correctly may lead to the assumption that the social situation involves hostility and anger. Third, the child *develops a goal or set of goals* based on his/her interpretation of the encoded cues.

Fourth, the child *accesses or constructs potential responses* to achieve the selected goals. The fundamental question asked here is 'What are all the things I can do in this situation?' Next, she or he must *decide on a particular response* to be enacted. This selection depends on various considerations including the expected outcomes of particular responses, his/her confidence that the selected strategy can be enacted, and their evaluation of the response itself. For example, the individual might consider the potential interpersonal consequences ('Will she still like me?'), the instrumental consequences ('Will I get what I want?'), and the moral value of the strategy. Finally, the child *enacts* the chosen response.

The models of Rubin and Rose-Krasnor (1986) and Crick and Dodge (1994) are similar in that they both emphasize (a) that the processing underlying social competence occurs rapidly in real time, (b) that the steps of information processing follow a particular sequence, (c) that they are dynamically interrelated, yet separable, and (d) that processing can proceed automatically at the unconscious level. Most importantly they regard social competence as a plan of action by which social goals are achieved.

3. Competence at Different Levels of Social Complexity

Thoreau, in his description of his cabin near Walden Pond said 'I have three chairs—one for solitude, two for friendship, and three for society.' This multilevel scheme applies equally well to *social competence*. As we state above, competence is not a feature of a single domain of functioning but instead can be seen at multiple levels of social complexity, specifically, the *individual*, the *dyad* and the *group*. This recognition that competence needs to be assessed at multiple levels of experience is a central theme in the writings of Bronfenbrenner and Crouter (1983) and Hinde (1979, 1987, 1995). Our point is that these different levels of complexity provide different contexts for competence. One goal of research on peer relations has been to identify competence at different levels and to understand how these levels are related to each other. In the following sections we describe briefly the ways that competence is manifested at these three levels of analysis.

3.1 The Individual

The level of the individual refers to the behavioral, affective, and cognitive characteristics and dispositions that a child brings to social interaction. These characteristics include behavioral tendencies, either derived from experience or temperament, cognitions about self and other, motivations and goals, relationship history, and affective states and traits. The level of the individual is the most basic level of social complexity. While it might appear that the level of the individual has no social complexity, such complexity can exist in a child's representations of self and other (e.g., in internal working models) as well as in their planning for social interactions and relationships. Certainly, characteristics from the level of the individual can be interpreted as indicating social competence. The two features from the level of individual that have been studied most broadly concern individuals' general social behaviors and their social cognitions. In parallel to psychology's general concern with the processes of (a) moving against others, (b) moving toward others, and (c) moving away from others, research on social behavior and competence has been largely organized around the constructs of aggression, sociability and helpfulness, and withdrawal. This interest in how the child's individual behaviors influence experiences with peers has comprised a large portion of research on the peer system during the past 15 years. In fact, the very large literature on children's popularity has been typically focused on behaviors at the level of the individual. Information about the correlates of popularity is important as it reveals which characteristics from the level of the individual are related to effectiveness in establishing a general place within the peer group.

3.1.1 Individuals and behavior. In a meta-analysis of this large body of literature regarding individual behaviors and popularity, Newcomb et al. (1993) were able to reach conclusions about differences between individuals from different popularity groups, especially, the popular, rejected, and neglected groups. They were able to interpret these differences as a function of what they reveal about competence. Specifically, they reported that popular children (i.e., those who were liked by many children and disliked by very few) are more likely to be helpful, to interact actively with other children, to show leadership skills, and to engage in constructive play (see Newcomb et

al. 1993). These findings show that popular children are capable of pursuing and achieving their own goals while simultaneously allowing others to do the same. In other words, they not only engage in 'competent' action themselves, but they are able to promote it in others. One critical finding in regard to the behavior of popular children is that there are no differences between them and other children on all aspects of aggression. Newcomb et al. differentiated assertive behaviors and disruptiveness. Popular children did not differ from others on the dimension of aggression but they were significantly less disruptive. These findings show that although popular children engage in assertive and agonistic behavior, these assertive actions are unlikely to interfere with the actions and goals of others. Consistent with other reports (Olweus 1977, Pepler and Rubin 1991), it would appear as if some forms of aggression may be compatible with being popular and with the concept of social competence. As Hawley (1999) has argued, children's strategies for controlling resources do not necessarily involve coercive or agonistic actions. In this way children can be dominant and competent. In contrast with the popular children, Newcomb et al. reported that rejected children not only showed high levels of disruptive behavior but also showed little evidence of engagement in activities with peers. In other words, their activities disrupted their peers' effective engagement with the environment, and showed little effective engagement themselves. This latter point is true of the neglected group also.

3.1.2 Individuals and social cognition. A second phenomenon from the level of the individual is that of social cognition. Social cognition includes a broad array of processes, including the way that an individual interprets and understands the behaviors of one's self and of others. Akin to research on the link between behavior and experiences with peers, much of the research on social cognition has focused on how an individual's use of social information is linked to the person's experiences with peers at the group level. Indeed, research on social cognition has also examined how an individual's understanding and interpretation of experience may partially determine the impact that experiences with peers have on development. This sort of social understanding is likely to be a prerequisite for competence. Without knowing how others will act, and without having a means of understanding the motives of others, individuals do not have a 'ground' on which to base their action (Harré 1974). Moreover, in order to effectively interact with the environment, one needs to possess the 'local knowledge' about how this environment functions (Geertz 1983). Considering this, it is not surprising that most models of social competence place a strong emphasis on social understanding as a powerful antecedent to competent social action (Crick and Dodge 1994, Rubin and Rose-Krasnor 1986).

3.2 The Dyad

Peer experiences at the level of the dyad can be conceptualized as reflecting either interactions or relationships. According to Hinde (e.g., 1979, 1987, 1995) interactions are the series of interchanges that occur between individuals over a limited time span. Interactions are defined as interdependencies in behavior (Hinde 1979). That is, two persons are interacting when their behaviors are mutually responsive. If a person addresses someone (e.g., says 'Have a nice day') and the other person responds ('Don't tell me what to do') they have had an interaction, albeit a rather primitive one. Relationships are based on these patterns of interaction. The relationship consists of the cognitions, emotions, internalized expectations, and qualifications that the relationship partners construct as a result of their interactions with each other.

3.2.1 Basic aspects of friendship. Researchers can examine dyadic relationships, such as friendship, according to (a) what the partners do together (i.e., the content of the relationship); (b) the number of different activities in which the partners engage (i.e., the breadth of their interactions); and (c) the quality of the interactions within the relationship (e.g., reciprocal, complementary, positive, negative). As in the research on popularity in which associations between behavior and popularity were used as the basis of conclusions regarding competence, research on friendship, a primary form of relationship experience for children, informs us of the processes that are central to engagement at the dyadic level. In research on friendship, different characteristics of relationships can be contrasted empirically, for example, between friends and acquaintances or disliked others.

3.2.2 Conflict. One domain of interaction, which nicely illustrates the nature of competence in friendships, is that of conflict. Conflict is one of the few dimensions of interaction in which there are no differences between friends and non-friends. Researchers have shown repeatedly that during childhood and adolescence, pairs of friends engage in the same amount of conflict as pairs of non-friends (Hartup 1992, Laursen et al. 1996, Newcomb and Bagwell 1995). There is, however, a major difference in the conflict resolution strategies that friends and non-friends adopt. In a large meta-analysis of research on friendship, Newcomb and Bagwell showed that

friends were more concerned about achieving an equitable resolution to conflicts than achieving outcomes that would favor one partner. More specifically, Laursen et al. and Hartup reported that friends are more likely than nonfriends to resolve conflicts in a way that will preserve or promote the continuity of their relationship. In this respect, competence in friendship appears to require the ability of the two partners to find a balance between individual and communal goals.

3.2.3 Self and other. A significant feature of this interpretation of these findings is its implicit recognition that competence in friendship is based on achieving a balance between personal desires against social consequences. This emphasis reflects an essential duality of self and other, placing the individual within a social and personal context. The conceptualization of self and other as interdependent is an important feature of theory from several domains including personality theory (Bakan 1966, Sullivan 1953), gender role theory (Leaper 1994), feminist psychology (Jordan et al. 1991) and philosophy (Harré 1979, 1984). This view of the self as inseparable from the other underscores the complex goals that persons confront as individuals and as members of dyads. In this way competence in friendship involves resolving the tension between agentic/individual and communal orientations.

3.3 The Group

Group experiences refer to experiences among a set of individuals who have been organized by either formal or informal means. Group phenomena do not refer to individuals but instead refer to (a) the links that exist among the persons in the group, and (b) the features that characterize the group. Groups can be measured according to (a) their structure and size (see Benenson 1990), and (b) the themes or the content around which groups are organized (see Brown 1989). Many of the best known studies of children and their peers were concerned with the group *per se*, including Lewin et al. (1938) study of group climate, and Sherif et al. (1961) study of intragroup loyalty and intergroup conflict.

3.3.1 Studying the group. In spite of the apparent importance of phenomena at the level of the group, group measures have received far less attention than measures conceptualized at the level of the dyad and the individual. This is surprising because persons generally refer to the peer system as a group phenomenon. Indeed references to experiences with peers invariably refer to the 'peer group.' Moreover, as Hartup (1983) noted, early theory and research on the peer system was organized around the idea that group experiences were powerful determinants of behavior. Nevertheless, research on the factors related to the peer group *per se* has been relatively sparse. In spite of a relative lack of research, the studies regarding peer group behavior generally converge on the same conclusion. This conclusion is that groups that show the most effective engagement with the environment (e.g., those that can complete a task most efficiently) are those that have the strongest sense of cohesion and shared purpose (e.g., Sherif et al. 1961) or that have the most engaged leadership (Lewin et al. 1938). These studies show that a factor that may be critical for an individual to be competent within a group is the shared knowledge or understanding of a task or ritual necessary for a group to function toward a common goal.

4. Conclusion and Future Directions

Social competence refers to an individual's capacity to achieve goals at the individual, dyadic, and group levels. Being competent means that one can balance one's own goals with those of one's partners and group members. Competent behavior is predicated on social cognitive processes underlying the encoding and interpretation of social problems and the development, execution and evaluation of plans to solve problems. The socially competent child and adolescent achieves his/her own goals while promoting the goal-oriented actions of their friends and companions. In this regard they have enduring positive relationships with others. Research on the development of competence needs to be focused on how children resolve the demands required for functioning at the individual, dyadic, and group levels of social complexity. Consistent with definitions of competence, researchers need to treat competence as a process, rather than as a static individual entity. An emphasis on action and process is necessary to reveal the integrative mechanisms that underlie a child's 'competence' in social and personal domains.

Social Constructivism

In its original version, social constructivism is a view about the social nature of science. It rests on the methodological assumption that a sociological analysis of science and scientific knowledge can be empirically fruitful and epistemologically illuminating. This approach has generated detailed empirical studies of scientific practices (for instance, of what is going on in laboratories on a day-to-day basis). According to social constructivism, these studies show that it does not depend exclusively on the objective external world which scientific beliefs are held to be true or false, and thus, what are the scientific facts, but rather also (or even mainly or exclusively) on social arrangements resulting from negotiations between scientists taking place in the course of scientific practices. It is in this sense that scientific knowledge and scientific facts are supposed to be socially constructed. Social constructivism is not a unique specified doctrine, however, but rather a bunch of related studies representing different versions of the general approach.

1. *Historical Background*

One of the guiding ideas of social constructivism is that science, scientific knowledge, and scientific practices are *socially determined*. Historically, this idea is rooted in the historical materialism developed by Marx. Historical materialism is best understood as a research program, roughly in the sense of the methodology of research programs proposed by Lakatos; the core of historical materialism consists of the claim that the economic base of a society determines its superstructure. This core is supposed to generate testable historical theories or hypotheses about what are, in various societies, the base and the superstructure, and about the specific ways in which they are related. The strongest, but not the only possible, interpretation is that the superstructure is causally determined by the base. This approach was taken up by sociologies of science worked out during the twentieth century. Thus, for instance, Karl Mannheim wanted to show how humanities and theories of society are socially determined; and one of the leading American sociologists of science, Robert Merton, suggested that it is primarily the rise and success of science that is determined by social forces (Merton 1973).

Another important intellectual source of social constructivism is the historical turn of twentieth century philosophy of science (Kuhn 1962, Bachelard 1937, Canguilhem 1966, Foucault 1969, Hacking 1990). This movement is vigorously opposed to scientific realism and rejects the claim, so crucial for the traditional philosophy of science, that there are universal rational scientific methods and rules such that the history of science can be rationally reconstructed as an continuous intellectual enterprise constantly improving our scientific knowledge by applying these methods. Instead, proponents of the movement see the history of science and scientific beliefs shattered by contingent breaks and dependent on normative attitudes and hidden non-scientific assumptions that an adequate philosophy of science must aspire to reveal.

A third theoretical background of social constructivism is the program of naturalizing epistemology initiated by Quine (Quine 1969). The crucial idea of this programme is that traditional epistemology, centering around the question of the justification of claims to (scientific) knowledge, should be replaced by a scientific study of causal processes of belief formation and information. In this way, epistemology is supposed to be transformed into a natural science.

In sum, social constructivism puts together three ideas, borrowed from a broadly Marxist sociology of science, from the historical turn of twentieth century philosophy of science, and from the program of naturalizing epistemology, that the development of scientific knowledge is (a) determined by social forces, (b) essentially contingent and independent of rational methods, and should (c) be analyzed in terms of causal processes of belief formation.

2. *The Edinburgh School of the Sociology of Science*

The first prominent version of social constructivism is the Edinburgh school of the sociology of science. The proponents of this school start out by criticizing the Marxist sociology of science for the exclusion of mathematics and natural sciences as a proper subject of the sociology of science. The extended claim is that mathematics and natural sciences are socially determined too, and it is this extension that is fun-

damental to the further claim of many social constructivists that, in a sense, the world as such is socially constructed (Bloor 1991; Knorr-Cetina 1981; Latour and Woolgar 1986). Specifically, it is, according to the Edinburgh sociologists of science, not only the historical development of science, its rise and success, that is influenced by social forces; rather, it is the content of accepted scientific beliefs that is determined by social factors or by the social interests involved in scientific practices.

Edinburgh sociologists of science conclude that there is no definite unique set of rational methods that guide scientific practices which can be referred to in order to explain how scientific results and beliefs are established. Another result is that it is not helpful to make a sharp distinction between the context of discovery and the context of justification in sociological investigations of scientific practices. In this way the Edinburgh school rejects fundamental assumptions held by the traditional philosophy of science.

If scientific practices and the development of science cannot be rationally reconstructed, then the sociological analysis of scientific practice must basically be a causal explanation of belief *formation* and belief *validation*; it is supposed to show in detail how specific scientific beliefs are established as a result of a causal process proceeding from social conditions, social interests, and negotiations between scientists guiding the specific scientific practice under consideration. Therefore, social constructivism is, in the view of the Edinburgh school, itself a kind of natural science. The domain of this sort of science is the set of all scientific beliefs that get accepted for the time being, independently of whether they are true or false and whether they ultimately prove to be successful or not.

Some constructivists focus not on belief formation, but rather on scientific facts: they want to know in which way such facts are hardened, i.e., get accepted as facts by all researchers in the field (Latour and Woolgar 1986). However, focusing in this way on scientific facts instead of scientific beliefs does not make much difference if scientific facts are supposed to be what accepted scientific beliefs are about—roughly the content of statements showing up in established scientific textbooks on the field (Quine 1969). Nevertheless, it is precisely by shifting the focus from beliefs to facts that some social constructivists are inclined to entertain an *ontological* version of social constructivism that sees scientists as essentially contributing to the existence of scientific facts. Obviously, this claim has idealistic implications only if scientific facts are understood in a strictly realistic fashion—roughly as the way things are independently of the way we take them to be.

Social constructivism, as proposed by the Edinburgh sociologists, can also be formulated as a methodological claim mandating a naturalistic approach to scientific practices; as such, social constructivism is best understood as being part of a naturalized epistemology concentrating on the investigation of the social causes of belief formation. In the methodological version, social constructivism does not seem to be committed to ontological claims; however, it remains committed at least to the epistemological claim that scientific knowledge cannot simply be seen as a good representation of the external objective world, but must rather be taken as a result of an extremely complex process involving mainly, and most importantly, social causes. In this way, social constructivism is not only a form of anti-rationalism, but also a form of anti-realism and in this twofold sense, a form of relativism.

3. *The Actor-network Theory*

The actor-network theory (Latour and Woolgar 1986, Latour 1987) is a form of constructivism that rejects the idea of a social determination of scientific knowledge, prominent in the Edinburgh school, mainly for the reason that the social is barely better understood than the natural. The leading thought is that scientific knowledge is an effect of established relations between objects, animals, and humans engaged in scientific practices. An *actor* is, according to this theory, everything that in some causal way affects the production of scientific statements and theories: not only scientists, but also, for instance, background assumptions, methodologies, techniques, social rules and institutions, routines, experiments, measurements and the appropriate instruments, scientific texts and, last but not least, external objects. For an entity to be an actor in this sense it is obviously not required to have contentful mental states, but to be able to perform actions as a kind of behavior describable under some intention. Thus, there can be many sorts of relations and interactions between actors; in particular, some actors can transform other actors (these transformations are sometimes called translations). A *network* is a set of actors such that there are relations and translations between the actors that are stable, in this way determining the place and functions of the actors within the network. Once a network has been established it implies a sort of closure that prevents other actors or relations from entering the network, thereby opening the possibility of the accumulation of scientific knowledge that is taken to be the result of translations within the network. Establishing a scientific belief, theory, or facts comes down, from the point of view of the actor-network theory, to placing these actors in a stable network. In this sense, scientific beliefs, knowledge, theories, and facts are taken to be constructed by translations taking place in established networks.

The actor-network theory shares a number of basic assumptions with social constructivism as conceived in the Edinburgh school. Thus, both approaches entertain a naturalistic account of scientific practices,

do not presuppose a distinction between true or successful and false or unsuccessful scientific beliefs, and reject the possibility of a rational reconstruction of scientific practices and their outcomes. But constructivism in the sense of the actor-network theory is social not in the strong sense that social forces that are presupposed to exist largely independently of scientific practices have a causal impact on these practices; but rather in the extremely weak sense that as a *result* of processes taking place in networks, a scientific claim can eventually be developed about a distinction between the natural and the social, and consequently also about the function of the social for scientific practices (Pickering 1992).

Social constructivism usually does not hold that, in the course of scientific practices, scientific facts of the external world are literally constructed of some other entities. The crucial idea of a (social) construction of scientific knowledge and scientific facts is, rather that an analysis of the process and history of scientific belief formation will not be able to show that the methods of science continuously increase the probability that scientific beliefs will be good representations of an independent external world, and should not even try. Instead, scientific belief formation should be modeled in terms of very different factors, mainly social ones like rules, techniques, institutions, power relations, and negotiations, which affect scientific belief formation in a causal way that can be studied empirically and sociologically

One of the most debated applications of social constructivism is the claim held by many feminists that gender is socially constructed (see *Comparable Worth in Gender Studies*, *Feminist Political Theory and Political Science*). Originally, the most prominent feminist theories introduced a distinction between a naturalistic notion of sex and a social notion of gender to denounce all attempts of deriving properties of gender from properties of sex as mere constructions of gender that do not refer to reality. More recently, in some postmodern feminist accounts of sex and gender, it is also the very distinction between sex and gender, and thus, sex itself, that are supposed to be socially constructed.

4. Social Constructivism About the Social

In one of the most recent developments of social constructivism, leading proponents of the Edinburgh school try to exploit the thought that scientific knowledge is, after all, something like an institution and that institutions are constructed by humans (Bloor 1996). It seems to follow that scientific knowledge is, because constructed by humans, socially constructed. This idea is part of what is often called the intentionalist program of social ontology, the aim of which is to clarify the ontological status of social entities, i.e., groups and of institutions. The fundamental claim is that it is on the basis of intentional mental states and associated actions that social entities come into existence. That is to say that human beings construct social entities by having specific contentful thoughts and by performing intentional actions.

It is obvious that this approach is a sort of social constructivism in the sense that it is a theory about the construction of the social; this is held to be so insofar as it consists largely of normative interactions between humans. It must be emphasized that this sort of constructivism is restricted to the realm of the social, that it presupposes a sharp distinction between the natural and the social, and that it has nothing to say about the construction of natural facts or physical entities. Most importantly, though, the intentionalist program relies on an intentional vocabulary. In all these respects the program differs fundamentally from traditional versions of social constructivism.

Basically the intentionalist program of social ontology is an individualistic account of the social; at the same time, however, one of the crucial theoretical moves is to introduce notions of collective intentionality and of collective actions. The first step is to assume that for some persons to be socially related in a specific way is to be treated by most of the other members of their society as being related in this way. Social relations are taken to imply rules as well as certain rights. In general, therefore, to treat some persons as socially related in way S is to treat them as being entitled or committed to perform actions according to the rules and rights derivable from S.

One of the next important moves is to introduce the notion of a collective attitude (or, as it is sometimes called, a we-attitude and, in particular, the notion of a collective intention to perform a specific action. Roughly speaking a person P as member of a set S of persons has a contentful collective attitude of the sort A iff (a) P has the A-attitude herself, (b) P believes that every other member has the A-attitude, and (c) P believes that every other member M of S believes that every member of S other than M has the A-attitude. In particular, if a number of persons P_i intend to perform action A together or collectively, then it must be the case, in addition to (a)–(c), that every P_i intends to perform A by performing a specific action A_i as her specific contribution to the performance of A such that P_i thinks that A_i is necessary for A and results, together with the other specific actions A_j intended to be performed by the other P_j, in performing A, and that P_i believes that the other P_j intend to do the same thing and believe themselves that every other person intends to do the same thing.

On the basis of these notions it can be asserted that a number of persons P_i have the collective intention to perform action A iff each P_i has the collective intention to do A by performing a specific A_i, in the sense just explained; and P_i perform a collective action A iff A can be described under some collective intention of the P_i. It might be suggested that a number of

persons P_i represent a social group iff they share a collective attitude. Finally, let MR be a set of sematically consistent rules R_i such that a number of persons collectively treat an X as a Y by following R_i, then MR is, in the most basic sense, an institution. In particular, if MR is the set of rules according to which scientific results and scientific knowledge are established, and if the persons in question are trained scientists, then MR is an institution of epistemic or scientific practices, and in this sense, scientific knowledge might be called an institution that is constructed by intentional acts of human beings (Searle 1995, Tuomela 1995).

This line of argument is a rough sketch that by no means exhausts the theoretical complexity of the intentionalist program. For instance, something has to be said about the mechanisms of the formation of collective attitudes which account for the stability of social groups and institutions; at this point, a theory of consensus and a theory of power has to be incorporated into the general account. In any case, even a rough sketch of this sort of social ontology shows how, to put it very generally, the mind can be thought of as bringing into existence, and keeping in existence (and thus to construct) social entities in a fairly literal manner. It also becomes clear how and why traditional social constructivists might be inclined to render their position more precise by exploiting the intentionalist program of social ontology.

This program is a philosophically sound approach; it makes evident, however, that human beings do not construct social facts as they construct natural facts. Traditional versions of social constructivism tend to downplay this distinction, which might be thought of as a fundamental flaw. Another problem with these versions is that they seem to commit themselves to relying exclusively on a causal, physicalist vocabulary. While it certainly makes sense to examine whether a purely naturalistic account of epistemic practices might be fruitful, it does not follow from this strategy, even if it proves fruitful, that intentionalist strategies must be excluded. On the contrary, it is doubtful whether epistemic practices can be adequately described without also using intentionalistic and normative vocabulary. Finally, it is hard to see how traditional social constructivists can overcome Davidson's point that, according to interpretation theory a basic form of rationality is constitutive for mastering a natural language and must therefore be the same in all epistemic practices (Davidson 1973); obviously, this insight is inconsistent with the unqualified contingency claim about the development of scientific knowledge which is so central to traditional social constructivism.

Social Democracy

The term 'social democracy' can refer either to a form of societal organization, an ideology, a set of public policies, a political party or group of parties, or a broad social and political movement centered on such parties and their allies within different sectors of society. The meaning of 'social democracy' has varied enormously since its original adoption by a small, vaguely-socialist group within the left wing of the French democratic-republican opposition prior to the Revolutions of 1848. At various times and places, the social-democratic label has been adopted by revolutionary Marxist, democratic-socialist, liberal/center-left, and even conservative-authoritarian political parties and tendencies, usually but not always with closer or more distant ties to blue-collar labor unions. Most commonly, the term 'social democracy' is used either in connection with political parties that have belonged to the contemporary Socialist Inter-

national or its predecessor, the Second International of 1889–1914, or with reference to policies and ideologies close to such parties.

As parties calling themselves social-democratic have grown steadily more moderate over time, gradually becoming less and less anticapitalist and antiliberal, usage of the term 'social democracy' has evolved in a similar fashion. At the turn of the twenty-first century, 'social democracy' generally refers either to the programs and policies of the largely center-left political parties that belong to the Socialist International, or to a vague set of essentially liberal, center-left ideological and policy orientations that are often associated with these parties. While specific policies may vary, such center-left 'social-democratic' approaches share a commitment to a relatively free-market-based capitalist economy, a fairly developed welfare-state, a liberal-democratic ('polyarchic') political system, and a relatively internationalist approach to questions of foreign policy, security, and globalization. All over the world, parties and ideologies of this type are currently among the most important in the vast majority of countries with relatively competitive elections. The term 'social democracy' is rarely any longer used as a self-description by Marxist or other anticapitalist and antiliberal tendencies.

1. *The History and Significance of Social Democracy*

Ever since the Revolutions of 1848, which are generally considered to mark the birth of the social-democratic movement, the history of social democracy has been characterized by a profound ideological and tactical struggle between relatively radical, anticapitalist tendencies and relatively moderate, reformist orientations. In this dialectical contest, the radicals have generally adhered to some form of State socialism, usually of a Marxist (but anti-Leninist) variety, and/or some version of decentralized and radical-democratic cooperative socialism ('self-management,' 'economic democracy'); the comparatively moderate reformists, by contrast, have increasingly made their peace with multiclass ('catch-all') parliamentary politics, liberal ideology, and the capitalist system. Over the decades, this internal struggle has interacted with the often complex relationships of social-democratic movements with other political, social, and economic forces within particular societies to give rise to a wide variety of more or less 'socialist' ideological visions and public policies, often very effective and/or highly original, which have directly or indirectly exerted a tremendous influence on virtually all aspects of political, social, economic, and intellectual life in the modern world, particularly in countries with relatively capitalist economic systems and relatively liberal-democratic political systems. Although social-democratic movements and governments have frequently been frustrated in their reformist efforts by powerful domestic or international pressures, the resulting compromises and modifications have often marked significant new developments in the history of their respective countries, and of the world as a whole. Indeed, even when confined to the ranks of the political opposition in a particular country, social democrats have sometimes played a major role in bringing about political, social, or economic reforms, by means of political pressure, foreign example, or intellectual influence.

Among the most important of these social-democratic contributions to the development of the 'welfare-capitalist' synthesis that has gradually come to dominate an increasing portion of the world since the 1880s, have been the following: (a) the striking (albeit gradual) democratization and humanization of political, social, and economic life; (b) the enormous growth and modernization of both the state and the economy, particularly in the realms of social policy, industrial policy, macroeconomic policy, industrial and labor relations (the much-celebrated 'democratic corporatism' of various Northern European countries, now largely defunct in a more market-oriented age), and recently also environmental policy; (c) the more or less successful promotion of social harmony and ideological consensus within previously much more polarized societies; and (d) strong support for international integration and world peace (although the temptation to join in nationalistic ventures, on the one hand, or in pacifistic crusades, on the other hand, has been a frequent source of tension within the social-democratic movement ever since its inception, most notably during the First World War).

Although self-styled 'social-democratic' parties and ideas have played a leading role in the history of an increasing number of countries around the world since 1880s, the concept of 'social democracy' is generally couched in terms based on the experience of Northern European Social Democratic, Socialist, and Labor parties (particularly those of Sweden and the other Scandinavian countries, as well as Germany, Austria, Great Britain, the Netherlands, and Belgium), because they have usually been the leading forces associated with the 'social-democratic' label, whether in terms of ideological and tactical development, policy-innovation, electoral support, governmental influence, or international prestige.

To the extent that world history since 1848 has been the story of the grand struggle between capitalism and socialism, social-democratic movements and ideas have often played a decisive role in finding a more or less successful middle-ground between the two (frequently under the slogan of some sort of 'Third Way' between unbridled capitalism and state-socialism), particularly in Sweden, Norway, and the other countries of Northern Europe. And to the extent that world history during the same period has been the story of the grand struggle between democracy and

dictatorship, social-democratic movements and ideas have contributed greatly to both sides: on the one hand, social democracy spawned radical, antiliberal offshoots that quickly evolved into the rival totalitarian movements of communism and fascism during and after the First World War; on the other hand, social democrats have often played a decisive role in resisting and defeating these totalitarian movements, as well as other antidemocratic political, social, economic, and intellectual forces.

From the 1945 onwards social-democratic parties all over the world have grown steadily more dependent on the success of the welfare-capitalist social-market economy and the support of middle-class voters and relatively privileged elites in both the public and private sectors. This has been the result of two major interrelated processes: first, the continuation of these parties' aforementioned gradual movement toward the liberal center of the ideological spectrum; and second, the search for new bases of support and new reasons for existence under the impact of the gradual economic and cultural disappearance and disaffection of these parties' traditional blue-collar industrial ('proletarian') base. The first of these processes, that of increasing ideological moderation, has largely been due to the combination of mass prosperity, the rise of the welfare-state, profound political and social democratization, the failure of Marxist ideas and State socialist regimes ('real-existing socialism'), the spread of international peace and integration, American political and cultural hegemony, and the all-but-inevitable habituation of social-democratic elites to existing power-structures. The second process, namely the disappearance and disaffection of social democracy's old blue-collar base, has stemmed primarily from the combination of four interrelated developments that are associated with relentless economic and social modernization: first, much greater levels of social and economic mobility and opportunity, partly as a result of successful social-democratic policies; second, the accelerated disintegration and dissolution of inherited social and cultural solidarities and cleavages, including class-consciousness ('individualization,' 'desegregation,' 'depillarization'); third, the drastic weakening of inherited attitudes, beliefs, and values ('postmodernization,' the rise of 'postmaterialist' or 'left-libertarian' values), particularly among highly-educated elites; and fourth, the transition from a predominantly 'Fordist' socioeconomic system based on mass production in 'smokestack' industries, to an increasingly 'postindustrial' economy based on much more sophisticated technology, a much older, more highly-skilled, and more highly-educated labor-force, a burgeoning service sector, much more widespread share-ownership, much higher levels of flexibility in all areas of economic and social life, much greater concern for environmental protection, and much higher levels of international interdependence, integration, and homogenization ('globalization').

2. *The Challenges Facing Social Democracy Today*

In the twentieth century, social-democratic parties and elites increasingly staked their claim to rule less on utopian visions of 'socialism' than on their ability to manage and modernize the welfare-capitalist social-market economy more fairly, more humanely, more democratically, and, above all, more competently and more efficiently, than their rivals on right and left. Yet, although egalitarian and statist alternatives to free markets and a fairly rapacious capitalism were in the year 2000 weaker and more uncertain than ever before, challenges from the populist and often vehemently antiliberal and antimodern right, which since the 1980s has increasingly drawn the support of traditionally social-democratic (or communist or Christian Democratic) working-class voters, are often close at hand. Thus social democracy is faced with the difficult task of reconciling the interests and aspirations of an economically and culturally ever-more diverse potential constituency, a task which may prove extremely difficult once the worldwide economic boom at the turn of the twenty-first century dissipates. The danger, then, is that social democracy may become caught between the conflicting demands of relatively successful or privileged and relatively unsuccessful or underprivileged sectors within increasingly unequal and *anomic* postindustrial societies, with the attendant risk that important groups within either or both sectors may gravitate toward antiliberal and antimodern movements on the left or, more likely, the right.

Social Demography: Role of Inequality and Social Differentiation

The description and analysis of inequality and social differentiation are fundamental components of social demography. In this context, a socially differentiated population is one characterized by a variety of subgroups that are distinct according to generally persistent social criteria such as race, ethnicity, religion, language, and so on. Inequality, on the other hand, is a hierarchical concept and is used here to refer to differences in the actual possession of resources of various types or in access to such resources. Resources are in the form of political power or influence, income, schooling, health care services, etc. Differentiated groups may also be extremely unequal but the idea of socially different need not imply inequality. This article briefly reviews several of the reasons why demographers study differentiation and inequality and then goes on to discuss how four different theoretical perspectives have been applied to the problem. The first emphasizes cultural explanations; competing somewhat with it are resource-based explanations which focus particularly on differences in opportunities and constraints. Cutting across both of these are reference group theory and life-course analysis.

1. *Introduction*

A perennial demographic question is the extent to which diverse or unequal groups exhibit marked differences in demographic behavior. Are there substantial race, ethnic, or religious differences in marital or fertility behavior, in mortality, or in patterns of migration? One reason it is important to study such differentials is that they indicate the extent to which the overall demographic performance of a population is a function of subgroup diversity. How big an impact a subgroup's behavior can have on overall population measures depends on the distinctiveness of that group's behavior weighted by its relative size. Although size counts for much, if the group's behavior is unusual enough, it can still have a substantial impact on overall measures. For example, using never married women, aged 30–34, as a rough indicator of marriage delays in the US, 22 percent of all women of that age were never married in 1998. However, the proportion was much higher for African American than white women—47 as opposed to 17 percent. The differences were so large that even though African American women were only 14 percent of all women in this age group while whites were 80 percent, the proportion never married was pulled up by five points—or almost 30 percent—for all women as compared to whites (US Bureau of the Census 1998).

Documenting subgroup differences in demographic behavior also provides important insights into the demographic concomitants of inequality and a socially differentiated population. It also poses analytical questions about the underlying determinants of these differences since group membership is usually an indicator of a variety of more proximate causes of an observed demographic pattern—e.g., the role of unequal access to medical care in ethnic group differences in mortality. A classic example in social demography is the influence of marriage timing on fertility in early industrializing populations. Given women's circumscribed reproductive period, delayed marriage in a noncontracepting population typically leads to smaller completed family size, while an earlier marriage promotes higher fertility. Thus, in rural areas in many parts of Western Europe, where inheritance of the farm was a precondition for marriage, marriages were often greatly delayed. On the other hand, factory workers in the cities usually married much earlier as their economic fortunes were tied to the developing wage economy rather than the traditional inheritance system (Anderson 1971).

2. *Varying Theoretical Perspectives*

The remainder of this article will focus on the impact of inequality and social differentiation on demographic behavior by examining four theoretical approaches to the problem. Together these underlie most research in social demography; hence the discussion will begin by a brief introduction to the general thrust of each perspective before applying them to issues of social differentiation and inequality. Two distinct and often competing theoretical approaches

have been particularly influential in social demography; these are cultural compared to resource explanations of demographic behavior. Cross-cutting them are two additional perspectives—reference group theory and life-course analysis.

2.1 Socioeconomic Constraints and Opportunities

Resource based explanations focus on how differences in resources affect demographic behavior—e.g., differences in social or economic constraints and opportunities. Thus, a major feature of the Theory of the Demographic Transition is the argument that economic development raises the cost of children and reduces their economic value to families, thereby promoting the transition from the relatively high fertility characteristic of most preindustrial societies to the typically low fertility of industrialized societies (see *Fertility Transition*: *Economic Explanations*). By focusing on differences in resources, this approach also lends itself well to analysis of the determinants and consequences of inequality.

In the resource-based approach, differences or changes in goals or preferences among individuals or groups are frequently not examined in any great detail. In fact, neoclassical economists have typically argued that preferences are fixed across time and do not systematically vary among individuals, thereby permitting changes in demographic behavior to be unambiguously attributed to changes in constraints. However, for most social demographers, such an assumption is generally too strong and variations in preferences are usually considered an important, if often understudied, source of differences in people's behavior.

2.2 Cultural Factors

A second approach views 'culture' as the most important factor influencing demographic behavior. The nature of cultural factors being considered are highly variable, ranging from the narrowly to the broadly conceived—from norms regarding the permissibility of divorce or the number of children a couple should raise all the way to more complex and sometimes highly abstract constructs such as religious or basic value systems. For example, it has been argued that both earlier and more recent European fertility transitions are largely the result of a major change in the 'ideational' system marked by the growth of secular individualism among other value changes. While some recognition is given to the influence of economic factors, their importance is often minimized by scholars operating in this tradition (see *Fertility Transition: Cultural Explanations*; *Demographic Transition, Second*; *Family Theory: Role of Changing Values*). The cultural approach tends to emphasize *differences* in goals and values and hence seems more oriented towards explaining socially differentiated behavior rather than behavioral differences based on an inequality of resources. However, it is often recognized that certain cultural patterns arise out of conditions of inequality and may even contribute to its persistence (Parsons and Goldin 1989).

2.3 Reference Group Models

Cutting across these general perspectives are two additional approaches that have been influential in explanations of demographic behavior. The first is the use of reference group models. The idea here is that people use selected others whose behavior or characteristics provide positive—or sometimes negative—models for themselves. How this approach is implemented partly depends on whether the researcher's primary orientation is cultural or resource based. If cultural, the emphasis is more likely to be on reference groups as normative models to emulate. If the investigator is more resource oriented, the emphasis is likely to be on relative economic status concerns (see *Social Networks and Fertility*; *Human Ecology: Insights on Demographic Behavior*).

2.4 Life Course Approach

A second influential cross-cutting perspective has been the lifecycle/life course approach. Lifecycle analysis is the pioneering version of this approach and focuses particularly on age-related characteristics and behavior. It can be applied either to an individual—an individual's career or family cycle, for example—or to a group—the family's developmental cycle. Because of the scarcity of life history data, lifecycle analysis has often had to restrict itself to age patterns measured at one or more points in time (using cross-sectional data on the behavior of different age groups, i.e., 'synthetic' cohorts) rather than being able to follow individual life histories over real time. The later developing life course perspective adds a particular emphasis on such life histories, although it too has sometimes had to settle for cross-sectional data. The availability of longitudinal data has increased in recent years, permitting more extensive analyses of life histories. Some life course researchers have also placed great emphasis on normative issues as well, a major one being that there are norms governing the sequencing of life course transitions—for example, that there is a norm against marrying before completing school (Elder 1977, Hogan 1978).

While all these perspectives, singly and in combination, have been generally important in demography, the discussion below will focus on their use in analyses of the role of socioeconomic inequality and differentiation in demographic behavior. Although often viewed as competing, neither the resource nor cultural perspective alone can do an entirely satisfactory job of explaining patterns or changes in demographic behavior. Both approaches profit by incorporating elements from the other.

3. *Cultural Differences and Demographic Behavior*

Probably the most extensive research project which came to espouse a cultural explanation of demographic behavior was the Princeton European Fertility Project which examined the transition from high to low fertility occurring over much of late nineteenth and early twentieth century Europe. By using provincial-level data, the project set out to test several propositions of Demographic Transition Theory, one of which was that fertility declines were a consequence of economic development. A major conclusion of this body of research was that the observed fertility declines appeared to be only weakly related to conventional measures of socioeconomic development, such as the proportions in a province who were literate, employed in agriculture, lived in large cities, etc. In fact, in most European countries the fertility transition appeared to have begun at nearly the same time, despite considerable geographical variability in economic and social conditions. Hence, this too seemed to be a strong indication that the fertility transition was not an adaptive response to the changing conditions brought about by economic development. However, areas which shared similar *cultural* characteristics, such as language and religion, exhibited different rates of fertility change compared to areas at a similar economic level but with different cultural characteristics (Coale and Watkins 1986).

To explain these findings, an innovation and diffusion hypothesis was invoked, involving elements of reference group as well as cultural theories. The argument is that the deliberate control of completed marital fertility was generally unknown in Europe throughout most of its history although large families were not highly desired. However, late in the nineteenth century certain influential opinion leaders in local areas not only became innovators in the use of contraception but also in promoting the view that family size could and should be legitimately controlled. Their views and practices provided a behavioral model and were, accordingly, rapidly adopted by others. Such changes were more likely to occur within cultural groups, defined, for example, by language and religion, partly because of the ease of within-group communication. In addition, shared norms and values increased the influence innovators were likely to have within the group, thereby fostering a rapid diffusion of innovations. Moreover, some cultural groups were more open to change than others. In Belgium, for example, traditional Catholic doctrines were much more powerful in the Flemish-speaking areas than in the French which were more secularized. Throughout much of Europe, France being a notable exception, fertility changes were more rapid in Protestant than Catholic areas (see *Fertility Transition: Cultural Explanations*).

The Princeton Project's contention that the European fertility transition was only weakly related to economic development has been subject to a variety of criticisms. The argument heavily depends on two empirical generalizations—first, that the adoption of fertility control was an innovative behavior and, second, that the fertility transition began at roughly the same time over most of Europe despite considerable regional variations in the pace of industrialization. However, because the kind of data collected during this historical period were severely limited, indirect statistical measures had to be developed as indicators of these behavioral patterns. Recent work on the validity of these measures, some by an original contributor to one of the measures (Trussell), indicates that they will not reliably detect the start of the transition until it is well underway and hence arguments about the simultaneity of transitions all over Europe, regardless of the level of economic development, are not reliable. Moreover, the statistical measure of the proportion of couples who were fertility controllers requires a fairly large number of them in order to be detected by the measure, casting doubt on the ability to determine whether fertility control was actually an innovation at the times indicated (Guinnane et al. 1994). In addition, recent analyses of German data, employing more sophisticated multivariate statistical methods than typically used in the Princeton project, have found that indicators of economic development were strongly related to declines in fertility during this period; however, although a cultural factor, such as religion, was important in predicting fertility *levels*, it did not have an effect on *changes* in fertility (Galloway et al. 1998).

While there is increasing doubt that cultural factors alone can explain the European fertility transition, the continuing social policy goal of reducing fertility in currently developing societies has kept alive a strong interest in more rigorously developing an innovation and diffusion model. However, recent work in this area has placed a greater emphasis on the value of the process as a mechanism for explaining changing fertility patterns in *conjunction* with changing socioeconomic constraints rather than *instead* of them (Montgomery and Casterline 1996). Moreover, in contrast to the provincial-level data the Princeton project was necessarily limited to, detailed microlevel research involving network analysis is being carried

out in several less developed countries to determine the particular social interaction and networking mechanisms involved in promoting the diffusion of contraceptive use and declines in fertility (see *Social Networks and Fertility*; *Human Ecology: Insights on Demographic Behavior*).

In general, although there is little doubt regarding the importance of investigating the effect of cultural differences on demographic behavior, in practice it is not always so easy to pin down the causal role of cultural factors. The easiest but probably also the least sophisticated approach is to assume that if there is a simple correlation observed this constitutes reliable evidence of a causal relationship between demographic behavior and membership in socially differentiated groups such as those defined by religion, ethnicity, social class, metropolitan residence, etc. Sometimes, the existence of cultural determinants is deduced as the residual explanation when other variables, such as socioeconomic ones, do not explain much of the between-group differences. However, to do so makes the unrealistic assumption that all other relevant variables are included in the analysis and are also properly measured. Moreover, given the preliminary nature of some of the theories under investigation as well as the uneven quality of demographic data and weaknesses in current measurement capabilities, attaching specific meanings to unexplained variance is always a risky procedure.

Another problem involved in opting too quickly for purely cultural explanations is that cultural identities are usually related to economic characteristics. Hence multivariate analyses are essential for separating out the role of economic constraints from cultural characteristics. Even then, the nature of the causal process is not always clear. For example, education is more highly stressed among Chinese than Latin American immigrant populations in the United States, suggesting a causal sequence between ethnicity, educational attainment, and socioeconomic status rather than one of these factors alone dominating the process. This may indicate a culturally related higher value placed on education among the Chinese—because of a Confucian tradition, for example—but it may also partly reflect differences in the socioeconomic origins of the two immigrant groups—one having a greater representation of professionals while the other coming from a much poorer socioeconomic background. Hence, sorting out the nature of the causal process is often complex and the data available to accomplish this are not always readily available.

The magnitude of the effect of cultural differentiation on demographic behavior can also be quite different depending on whether one is discussing *levels* or *changes* in behavior. For example, religion usually has historically had a consistently sizable impact on fertility in the cross-section but if the religious composition of an area does not change markedly over time, and the effect of any given religious identification remains constant, religion's role in *changes* in demographic behavior may be minimal. However, if different cultural groups vary in their openness to change introduced from the outside, as is sometimes argued, then cultural differences could indeed have a substantial impact on change.

4. *Socioeconomic Constraints and Opportunities*

Social scientists who primarily focus on the role of resources and constraints in demographic behavior have often ignored how institutional and normative commitments may constrain individual choices, both in terms of affecting preferences and also by limiting what are considered the legitimate means for realizing these preferences. In this respect, neoclassical economists have often chastised sociologists for their apparent willingness to posit a plethora of attitudes and norms to explain every observed behavior, thereby trivializing the analytical process. Nevertheless, it is possible to accept the idea of systematic variations and changes in preferences as a reasonable analytical tool and to apply it in a disciplined fashion in conjunction with resource constraints—that is, without positing a different or changing norm or value to explain every observed variation in demographic behavior. Hence the view that one must choose either a cultural approach *or* a resource constraint approach is unnecessarily confining intellectually.

4.1 *Relative Economic Status Models*

A major example of the integration of the idea of using varying lifestyle aspirations in conjunction with varying resource constraints to explain demographic behavior is found in Richard Easterlin's work on relative cohort size in the US. Easterlin hypothesized that intergenerational shifts in relative cohort size produce intergenerational inequalities in people's economic position which, in turn, affect age at marriage, fertility, and a number of other demographic responses. In addition, he maintained that lifestyle aspirations were learned in the parental household so that children raised in affluent households would develop higher-level consumption goals than those raised in poorer households. He combined these two views by arguing that cohorts who were entering young adulthood in the early postwar period were small due to low fertility during the Great Depression and were also raised in less affluent households, resulting in relatively modest consumption aspirations. However, because of this depression cohort's small size, they were in a very favorable labor market position as adults which encouraged early marriage and childbearing, as well as larger families—in short, they produced the postwar baby boom. The baby boomers, in turn, were raised in these affluent house-

holds and acquired high consumption aspirations; however, because of their large size, their labor-market position was not as good as that of their parents and this led to delayed marriage and lower fertility, resulting in the baby bust. In short, the Easterlin hypothesis posited that a feedback effect was produced by this process and created self-generating demographic cycles. Due to intergenerational shifts in relative economic status and consumption aspirations, small cohorts begat large ones which, in turn, produced small cohorts (Easterlin 1987).

Empirically, the status of Easterlin's theory has been criticized on a number of counts (see *Baby Booms and Baby Busts in the Twentieth Century*). A major one is that the postwar demographic changes were primarily driven by 'period' rather than 'cohort' factors. For example, annual birth, marriage, and divorce rates have tended to fluctuate together among larger and smaller cohorts alike, suggesting that there was something about particular historical periods that influenced behavior rather than cohort size. Nevertheless, the relative economic status aspect of the model remains interesting because the existence of inequality can provide a motivation for adaptive behavioral changes to occur; thus it is an intrinsically dynamic type of model.

Easterlin's hypothesis focused only on *inter*-generational inequalities; however, reference group and relative economic status models can also be applied with*in* generations. One example comes from the rapid postwar rise in US married women's paid employment so that by 1990 around 70 percent of wives, aged 25–54, were in the labor force compared to less then 25 percent in 1950. There is little evidence that this transformation was precipitated by major changes in norms or values. While opinion poles and other attitudinal studies indicate that approval of married women's employment became increasingly positive with time, attitudinal changes did not precede the changes in employment behavior but rather lagged behind them. A far more influential factor appears to have been the postwar economic expansion which greatly increased job opportunities for married women because the demand for women workers in female dominated occupations far exceeded the size of the population group that had traditionally been the backbone of the female labor force—young single women (see Oppenheimer 1970).

In addition to substantial changes in labor-market conditions, a type of innovation and diffusion model combined with a relative economic status approach might further clarify why the employment shift has taken place so rapidly. The rationale is that the rise in married women's employment changes how families are stratified by reducing some previous socioeconomic inequalities and creating others. When married women's employment outside the home was relatively rare, a family's socioeconomic position was primarily dependent on the husband's economic status, although earlier in the twentieth century the work of the family's adolescent and young adult children was also important at certain periods in the family's developmental cycle. As wives' employment became more common in the postwar period, however, many families within the same socioeconomic group, but without working wives, could increasingly be put at a relative economic disadvantage, thereby generating inequalities within groups which had previously been at roughly the same socioeconomic level, based on husbands' economic position alone. On the other hand, wives' employment can *reduce* the relative economic advantage of some families who might previously have been at a somewhat higher socioeconomic level. Hence, wives' employment in some families but not others creates both an objective and subjective instability in how people experience the stratification system. But it also creates a model of how to deal with these instabilities—the entry of other wives into the labor force. Wives already working also provide a source of information on the nature of the job market for others contemplating entering the labor force, as well as providing models of strategies for how wives and mothers could cope with work and family responsibilities.

The impact of this process should, if anything, have increased over time. As long as there were few wives employed, their work would have relatively little impact on both intra- and intergroup reference comparisons and the easier it would be to dismiss their behavior as 'deviant' or the 'exception that proves the rule.' However, as the proportion of wives working rose and became increasingly full-time, then their example would become more salient, thereby increasing its destabilizing effect on reference group comparisons. Moreover, the more wives who worked, the fewer nonworking women there would be around to socialize with, share childcare responsibilities with, etc., hence, the lifestyles as well as the relative socioeconomic position of families with nonworking wives would be increasingly affected. All this should have contributed to the continued rapid expansion of married women's employment in the postwar era in addition to any changes in labor market conditions (Oppenheimer 1982).

Although not easy to operationalize, due to data limitations, relative economic status models have attractive theoretical features for analyzing change. They posit changes in lifestyle aspirations which affect behavior but which nevertheless remain embedded in a stable preference structure—maintaining one's socioeconomic position in the community. They also involve feedback effects that foster a continuation of the diffusion process whose momentum may even increase rather than peter out over time. Furthermore, the existence of feedback effects means that not all those changing their behavior need experience the same initial motivating factors that the earlier innovators were exposed to; whatever its original cause,

the behavior of innovators itself creates an additional set of pressures that influences others, in turn, to shift their behavior and attitudes as well. Nor need such an amalgam of a relative economic status model with an innovation and diffusion model operate independently of social norms. For example, in the American case, although there continued to be a *general* disapproval of married women's employment long after it had already substantially increased, even early on in the process there was evidence of a considerable flexibility in attitudes, depending on the circumstances. Thus attitudes were very negative in the 1940s if it was specified there was only a limited number of jobs but much more permissive if a wife worked in order to facilitate a marriage (Oppenheimer 1970). Hence, the conditionality of many norms permits a certain amount of innovative behavior which may ultimately modify the normative structure more generally. In this case, changing socioeconomic conditions encouraged an increase in wives' employment which was facilitated by norms viewing working to achieve family goals as a legitimate exception to the general disapproval of married women's employment. The ultimate result, however, was not only a permanent change in employment behavior but a radical reduction in the *general* disapproval of wives' working as well.

4.2 Socioeconomic Inequalities and the Life Course

While cross-sectional analyses are major sources of information on socioeconomic inequality and its demographic concomitants, they often miss an important dimension of inequality: the variation in socioeconomic well-being over the life course and how this may systematically differ among socioeconomic groups as well as change over time. However, there is a substantial body of work—primarily in historical demography—that directly addresses these problems within a life course context.

An inescapable fact of human biology is that individuals' economic productivity varies over the lifecycle. For example, very young children and the very old have few productive capabilities. The nature of the economic system also influences these variations and, along with it, the individual's earnings position. If work involves considerable physical effort or health risks, a reduction in productivity may happen at a relatively young age so that the most economically productive part of the career cycle occurs fairly early in adulthood. On the other hand, if skill is the major job characteristic required, relatively high productivity may last well into old age; however, in this case, lengthy training requirements during an individual's youth are likely to reduce productivity then. Research on middle-class English, European, and American families and on the working classes around the turn of the nineteenth century not only reveals the substantial general economic inequality between these groups but the considerable differences in how relative affluence or deprivation was experienced over the life course, along with the resulting differences in demographic responses. In the case of the middle classes, while earnings might ultimately be substantial, early in the career cycle they were usually inadequate to permit a young man to marry and set up a household in the style considered appropriate to his social station in life. The common pattern was therefore for men to delay marriage until they were economically established and had proved themselves capable of 'properly' supporting a wife and family (Banks 1954, Alter 1988).

In contrast to the middle classes, the career-cycle pattern of earnings was far different for industrial workers, both in Britain and many other nineteenth century industrializing populations. In addition to their generally much lower earnings, the lifecycle period where earnings were greatest and most assured was in young adulthood rather than middle age; hard physical labor, the risk of debilitating disease or accidental maiming or death in the far more dangerous work settings of that era all raised the risk that the middle and older years would be ones of declining or lost productivity. Several adaptive strategies seemed to have been extremely common in such populations. One was a major reliance on the earnings of children to help maintain or improve the family's economic stability over its developmental cycle. Another was an early timing to the start of both marriage and childbearing, thus placing these transitions during the period when working class men's earnings were at their greatest; in addition, this increased the likelihood that at least some children would be old enough to go out to work and contribute to the family's income as the father aged and entered into a higher risk period. However, the downside to this strategy was a frequent pattern of life-cycle poverty or, at the very least, of relative deprivation—for example, when there were several children in the household but none old enough yet to go out and work: this problem was particularly acute if the earnings of the father were lost or much reduced. A different kind of life-cycle poverty typically occurred after all the children had left home and the parents were too old to engage in extensive employment. As a consequence of this life-cycle poverty pattern, the economic situation of individuals at any single point in time was a poor indicator of the frequency with which poverty or relative economic deprivation might be experienced over their entire life course (Anderson 1971, Haines 1979, Rowntree 1922).

While such strategies might well be characterized as rational adaptations to the life course circumstances faced by many working class families, they were also cultural in nature. Historical research indicates that they had a major normative component; children were placed under a strong obligation to work and help improve the family's economic well-being and they

were often allowed to keep very little of their earnings (Parsons and Goldin 1989). Although their work might also improve their own well-being while in the household, such a pattern could nevertheless work against children's long-term self-interest because it tended to reduce the amount of schooling they received and hence their adult socioeconomic status. Moreover, delaying or even foregoing marriage was not entirely uncommon because of the obligations adult children had to help support the family and/or help care for younger siblings, especially if one or both parents were lost (Hareven 1982).

Work on contemporary populations shows that different socioeconomic groups have also been experiencing quite contrasting career development patterns and that this can have significant demographic consequences. For example, consistent with their traditionally important and normatively prescribed economic role in the family, it was still true in the 1980s that American men were much less likely to marry while in an unstable labor market position with low earnings. How large a cumulative impact this had on their marriage timing, however, depended on the length of time a young man remained in such an 'immature' career state and this varied considerably among racial and schooling groups. Compared to men with one or more years of college, a much higher proportion of high school graduates, as well as dropouts, were experiencing a far more difficult and prolonged transition to a relatively stable career position, leading to substantial educational differences in marriage timing. African American males were having particular difficulties and their marriages were much more delayed than that of whites, as indicated by the never married figures cited earlier. These findings also suggest that, given the considerable rise in economic inequality in the US starting in the mid-1970s, increasing career-entry difficulties may have played a significant role in the overall rise in the age at marriage, not only for those reaching adulthood during the 1980s but for earlier and later cohorts as well (Oppenheimer et al. 1997; see *Family Theory: Competing Perspectives in Social Demography*).

Social Dilemmas, Psychology of

The functioning of societies, groups, and relationships is strongly challenged by social dilemmas, situations in which private interests are at odds with collective interests. Social dilemmas are potentially disruptive for functioning of collectives because the well-being of these larger units is threatened when most or all individuals act in a self-serving manner. For example, during periods of water shortage, it is tempting not to worry too much about how much water to use; but if most people exercise no restraint, this may create severe societal problems. Also, meetings at work would be considerably more productive if all people invest sufficient time and effort in preparing for these meetings. And close partners too, face social dilemmas, such as whether or not one should spend less time with one's independent friends. In a sense, social dilemmas are so pervasive in everyday life that one can go so far as to claim that the most challenging task governments, organizations, and even partners in

a relationship face is to successfully solve social dilemmas. After a brief discussion of the history of social dilemmas, as well as their methodological underpinnings, the basic question of how cooperation between people can be promoted will be addressed.

1. Social Dilemmas: An Historical and Methodological Perspective

The intellectual parents of social dilemmas can be found in early formulations of game theory concerned with the strategic analysis of conflicts of interests (e.g., Luce and Raiffa 1957). Game theory captures decisions in terms of experimental games, that is, situations in which each of the participants has to choose one of two (or more) alternatives, which affect one's own outcomes as well as the other's outcomes. The most famous game following from this work is the Prisoner's Dilemma Game, which represents a true conflict of private interests and collective interests. The prisoner's dilemma derives its name from an anecdote about two prisoners who were accused of robbing a bank. The district attorney, unable to prove that they were guilty, confronted the prisoners with two options: either confess to the crime (option D), or not confess to it (option C). Paradoxically, option D stands for the Defecting option and option C for the Cooperative option, for reasons which will be apparent by the consequences these choices had for both prisoners. If both confess, each will receive a five-year sentence, whereas if neither confesses each of them receives a one-month sentence. Thus, each prisoner would be better off when neither confesses than when both confess. However, the decision is complicated by the fact that each prisoner has a clear temptation to confess. If one confesses and the other does not, then the prisoner who does not confess will receive a 10-year sentence, while the other will be set free. Thus, in a prisoner's dilemma, two individuals are interdependent in that each person is better off by behaving noncooperatively, regardless of the other's behavior (individual rationality). At the same time, both individuals are better of when both behave cooperatively, rather than when both behave noncooperatively (collective rationality).

The interdependence structure underlying prisoner's dilemmas is characteristic of many dyadic interactions. For example, two neighbors living in apartments with thin walls may wish to play their favorite music at high volume, but they together would probably be better off by playing it at a somewhat lower volume. The conflict between individual and collective rationality apparent in the prisoner's dilemma can be extended to situations involving many individuals, which are often referred to as N-person prisoner's dilemmas. For example, trade unions can function considerably better to the extent that a greater number of individuals become members; however, membership requires fees and time and thus is a costly option from an individual perspective. Social dilemmas is a generic concept, embodying both two-person and N-person prisoner's dilemmas, as well as some situations that are quite similar to prisoner's dilemmas, and that do represent a conflict between self-interest and collective interest. It is also noteworthy that in everyday life social dilemmas tend to take the form of either a resource dilemma or a public good dilemma. A resource dilemma calls for a decision whether or not to take (or how much to take) from a public resource. An example is the degree to which one uses water during a period of water shortage. A public good dilemma calls for a decision whether or not contribute (or how much to contribute) to a public good. An example is the degree to which one contributes to the maintenance or improvement of public television. Public good dilemmas pose the problem of free-riding, not contributing but still enjoying the benefits of the public good.

In actual research on social dilemmas, researchers often use experimental games, a technique is that closely linked to study of conflict, cooperation and competition, as well as intergroup relations (e.g., conflict and conflict resolution; cooperation and competition, intergroup relations). The experimental game approach has a number of advantages, in that allows researchers to confront participants with a real dilemma, especially when the 'outcomes' represent real outcomes (e.g., money). Thus, this approach focuses on actual behavior in a context characterized by high levels of experimental realism—it is an involving experimental task. At the same time, to enhance mundane realism researchers have become increasingly interested in examining simulations of social dilemmas as they appear in the real world. Examples are well-designed simulations of the resource dilemma or the public good dilemma. And there is increasing research which examines social dilemmas directly in the real world, which involves correlational survey research, observational research, and experimental field research (see Komorita and Parks 1995). These multitudes of techniques and procedures are used by not only psychologists, but also by anthropologists, economists, sociologists, political scientists, and even biologists. Many or most of the findings reviewed below are observed in various research paradigms.

2. What Factors Promote Cooperation in Social Dilemmas?

How can one promote cooperation in social dilemmas? One important factor derives from the structure itself; that is, the degree to which self-interest and collective interest are conflicting. Cooperation can be enhanced by both decreasing the incentive associated with

noncooperative behavior and increasing the incentive associated with cooperative behavior (Kelley and Grzelak 1972). Generally, the influence of the structure itself has been shown to be strong not only in experimental work on social dilemmas, but also in field studies. For example, it has been found that monetary reward for electricity conservation was one of the most effective means to attaining electricity conservation.

A second factor concerns the possibility of communication. Indeed, one interesting and potentially important way to escape from massive noncooperation is to coordinate the social dilemma in a manner such that people feel committed, or actually promise to contribute to the collective welfare (Orbell et al. 1988). However, opportunities for verbal communication tend to be effective only when individuals indeed discuss their actions relevant to the dilemma at hand. One of the explanations for the fruitful effects of communication is that it enhances trust in others' cooperative choices, and that it is difficult for people to break a promise.

A third factor derives from the personalities involved, in particular differences among three types of social value orientation: prosocial orientation (enhancement of collective outcomes as well as equality in outcomes), individualistic orientation (enhancement of own outcomes with no or very little regard for others' outcomes), and competitive orientation (enhancement of relative advantage over others; Messick and McClintock 1968; Van Lange 1999). People with a prosocial orientation exhibit greater cooperation, expect others to behave more cooperatively, are more trusting of others' intentions and motivations, and interpret the dilemma more strongly as a moral issue and less of an intelligence task than do individualists and competitors. Also, such personality differences tend to be a function of social interaction experiences, in that, for example, prosocials were raised in larger families, having more sisters in particular than individualists and competitors, and people over time tend to become more prosocial and less individualistic and competitive (Van Lange et al. 1997; see also *Personality Development in Childhood*; *Personality Development in Adulthood*).

3. *From Two-person Social Dilemmas to N-person Social Dilemmas*

In two-person social dilemmas, individuals may to some degree be able to promote cooperation in the other. In this regard, one of the most effective strategies is the tit-for-tat strategy (Pruitt and Kimmel 1977), a strategy which starts with a cooperative choice, and subsequently mimics the other's prior choice. Thus, tit-for-tat's willingness to behave cooperatively is conditional upon the other's cooperative behavior. Several studies have revealed that tit-for-tat is more effective in eliciting cooperation in the other than a strategy which always makes cooperative choices irrespective of other's choices (perfect cooperation), which is more effective than a strategy which always makes noncooperative choices irrespective of other's choices (perfect noncooperation). Tit-for-tat is assumed to be effective because it is nice, retaliatory, forgiving, and clear (Axelrod 1984).

One potential limitation of tit-for-tat is that it can only be effectively used in the context of dyadic relationships or small groups. How is one to pursue tit-for-tat in large groups? Apart from the strategies that people use, there is typically a decline in cooperation as groups become larger in size. More specifically, cooperation typically declines as groups become larger up to about seven or eight persons. However, if groups become larger than seven or eight persons then the level of cooperation is not strongly influenced by a further increase in group size. How can one account for the group-size effect? It has been suggested that, with increasing group size, anonymity is greater, individuals become more pessimistic about the efficacy of their efforts to promote collective outcomes (Kerr 1996), people tend to feel less personally responsible for good collective outcomes. An effective solution might be a structural solution, by which one effectively changes the underlying structure, by implementing a system that rewards cooperation or sanctions noncooperation (Yamagishi 1986). The benefits need not necessarily be financial or even material. For example, reduction of car use (so as to reduce smog or congestion) might be promoted to some degree by establishing carpool priority lanes. Other solutions might derive from strengthening social norms,facilitating effective communication, or enhancing feelings of identity with the group or a sense of 'we-ness.' (see also *Social Categorization, Psychology of*)

4. *From Interpersonal to Intergroup Relations*

Interestingly, interactions between groups are characterized by lower levels of cooperation and higher levels of competition than are interactions between individuals (Insko et al. 1998). This individual-group discontinuity effect is accounted for by, first, lower levels of trust in intergroup relations, eliciting fear of being exploited by the other group. Second, individuals within a group are able to support each other in their pursuit of the interest of their own group (and each member's self-interest) at the expense of the other group. Third, responsibility for self-centered behavior is often shared in intergroup settings but interpersonal settings one is individually responsible for his or her actions. One way to enhance cooperation between groups is when one of both groups follows the tit-for-

tat strategy, which yields a level of cooperation comparable to that found among interactions between individuals when one of them follows the tit-for-tat strategy (Insko et al. 1998).

5. *Issues for Future Research*

Recent approaches to social dilemmas examine the ways in which social-cognitive mechanisms (e.g., construal of social dilemmas) might be associated with behavior in social dilemmas, examine how individuals themselves seek to change features of the social dilemma to enhance cooperation (e.g., excluding members from the group) or to escape from the dilemma (e.g., seeking greater independence), and examine the functionality and evolutionary stability of various strategies in large-scale social dilemmas through computer simulation techniques. These issues are examined by various social and behavioral scientists, and these interdisciplinary efforts should make important contributions to theory regarding cooperation and competition, social dilemmas, and interdependence as well as to providing effective solutions to various complex social dilemmas we face in the real world.

Social Evolution: Overview

1. *Concepts and their Definitions*

Social evolution: a process or set of processes of directional social change.

Unilinear evolution: the movement of societies along a single path of change.

Universal evolution: Steward's name for the revival of unilinear evolutionism by Childe and White.

Multilinear evolution: Steward's name for the movement of societies along many different paths of change.

General evolution: Sahlins's name for the overall movement of society and culture along a major path.

Specific evolution: Sahlins's name for the divergent evolutionary paths taken by different societies and cultures.

Progress: an improvement in the overall functional efficiency of society and the quality of life of the members of a society.

Evolutionary theory: any theory that attempts to describe and explain a sequence or sequences of directional social change.

Evolutionary transformations: see social evolution.

Survivals: structures or processes that have been carried by the force of custom or habit beyond the stage of society in which they originated.

Neolithic Revolution: the first great social transformation in human history associated with the domestication of plants and animals and the emergence of settled village life.

Urban Revolution: the name given by Childe to the second great social transformation in human history. It was characterized by the emergence of cities and states.

Environmental circumscription: blockage of the movement of peoples out of a geographic region by such natural barriers as mountain ranges or large bodies of water.

Social stratification: the existence within a society of distinct social strata, or groups distinguished by unequal levels of power, privilege, and prestige.

Economic surplus: a quantity of goods above and beyond what is needed by individuals for survival.

Adaptation: the process whereby individuals adjust themselves to their physical and social environments and solve the basic problems of human living.

Environmental depletion: the diminution of resources within an environment to a point whereby the standard of living is lowered.

Evolutionary materialism: the name given by Sanderson to the general theoretical framework developed by him on the basis of Harris's evolutionary theory.

Evolutionary universal: the name given by Parsons to any new social structure or process that allows a society to achieve a higher level of adaptation or functional efficiency.

Evolutionary typology: a set of stages through which a society or one of its sectors is said to pass.

Differentiation: the emergence of increasing complexity within a society or one of its subsystems.

Militant society: Spencer's name for a society that is highly specialized for warfare.

Industrial society: (a) a type of society characterized by urban life, the factory system, and the mass production of goods; (b) Spencer's name for a type of society specialized for economic activity rather than warfare.

Savagery: Morgan's name for the earliest and most primitive type of human society, one based on hunting and gathering, and a rudimentary technology.

Barbarism: Morgan's name for an intermediate type of society organized around simple forms of agriculture.

Civilization: (a) a type of society characterized by elaborate social stratification, urbanism and city life, occupational differentiation and craft specialization, trade and markets, monumental architecture, writing and record keeping, and the presence of a state; (b) Morgan's name for the highest stage of social evolution, one characterized by the phonetic alphabet and writing.

Societas: a stage of social evolution identified by Morgan that is organized on the basis of kinship and that is normally highly egalitarian and democratic.

Civitas: a stage of social evolution identified by Morgan that is organized along the lines of property and territory rather than kinship.

Mode of production: in Marxian theory, the economic base of society consisting of the level of technological development and the social relationships through which people carry on economic activity.

Primitive communism: in Marxian theory, the first stage of human society characterized by a rudimentary technology and common ownership of the resources of nature.

Slavery: in Marxian theory, the second stage of human society characterized by social and economic relations between a large class of slaves and a small class of slave owners.

Ancient mode of production: see *slavery* (above).

Feudalism: in Marxian theory, the third stage of human society characterized by social and economic relations between a large class of peasants or serfs and a small class of landlords.

Capitalism: in Marxian theory, the fourth stage of human society characterized by social and economic relations between a large working class and a small class of capitalists. Capitalism is based on the production of goods for sale in a market for profit and the accumulation of capital over time.

Hunting and gathering: the simplest stage of social evolution characterized by an economy based on the hunting of wild animals and the collection of fruits, nuts, vegetables, and other plant materials.

Simple horticulture: a stage of social evolution characterized by societies in which people cultivate gardens through the use of digging sticks.

Advanced horticulture: a stage of social evolution characterized by societies in which people cultivate gardens through the use of metal hoes.

Agrarianism: a stage of social evolution characterized by societies in which people cultivate the land with plows and draft animals.

Simple agrarian society: a society that cultivates the land with plows and draft animals but that lacks iron tools and weapons.

Advanced agrarian society: a society that cultivates the land with plows and draft animals and that possesses iron tools and weapons.

Industrialism: see *Industrial Society/Post-industrial Society: History of the Concept*.

Industrial Revolution: a technological and economic transformation, beginning in England in the second half of the eighteenth century, characterized by the development of the factory system and the substitution of machinery for hand power.

Band: a residential association of nuclear families, usually numbering less than 100 individuals, who govern themselves by purely informal mechanisms.

Tribe: a population, numbering in the thousands or tens of thousands, sharing a common culture and language and living in politically autonomous and economically self-sufficient villages of a hundred to several hundred people.

Chiefdom: a hierarchical sociopolitical structure consisting of a chief and various subchiefs who administer an integrated set of villages.

State: a form of political organization characterized by a monopoly over the use of force within a society.

Capitalist world-economy: the name given by Wallerstein to the large-scale intersocietal system that began to develop in Europe in the sixteenth century.

The capitalist world-economy was associated with production of goods for the market and high levels of economic and geographical specialization.

Social evolution is a term that has been used in a number of different ways, but most often it refers to a form of social change that exhibits some sort of directional sequence, a passage from less of something to more of something, or from one type of social arrangement to another type. Usually the term connotes slow and gradual change, and most often it carries with it the notion that the change in question is progressive, i.e., that it leads to some sort of improvement or enhancement. However, social evolution can be fast and even sudden, and it need not lead to improvement or enhancement.

Erik Olin Wright (1983) has offered a precise set of criteria for identifying an evolutionary theory of human society. According to him, a theory is evolutionary if it has four characteristics: (a) it proposes a typology of social forms with potential directionality; (b) the order or arrangement of the social forms is based on the assumption that the probability of remaining at the same stage exceeds the probability of regressing; (c) it asserts a probability of transition, even if only weak, from one stage to another; and (d) it proposes a mechanism or set of mechanisms that will explain movement from one stage to another. One of the benefits of Wright's characterization is that it makes no assumption that social evolution is some sort of automatic or inevitable process. Regression is permitted (although unlikely), and much of the time societies may be undergoing little or no change. Nor need it be assumed that social evolution always proceeds through some sort of rigid sequence.

2. *Historical Development of Theories of Social Evolution*

Theories of social evolution go back to the very beginnings of the social sciences and even earlier. The second half of the nineteenth century was a sort of 'golden age' of evolutionary thinking in sociology and anthropology, the fields that have contributed by far the most to the study of social evolution. There were many well-known evolutionary theorists during this time, but the three greatest were Herbert Spencer (1972, Peel 1971), Lewis Henry Morgan (1974), and Edmund Burnett Tylor (1871). Spencer was a British social theorist who contributed to philosophy, psychology, biology, and sociology. He saw evolution as a process that occurred in the entirety of the natural and social world. All phenomena, he said, had an inherent tendency to change from a state of 'incoherent homogeneity' to a state of 'coherent heterogeneity.' In simpler terms and with respect to human societies, they grew and expanded over time, their structures and functions became increasingly differentiated, and these increasingly differentiated wholes achieved higher levels of unification or integration. Morgan, an American anthropologist, saw social evolution as rooted in technological change, and in his great work *Ancient Society* (1974) he focused mainly on the evolution of government, property, and the family. In terms of the institutions of property and government, Morgan traced out a process whereby highly democratic and egalitarian societies were gradually replaced by societies marked by differential property ownership, social inequality, and the domination of the many by the few. Tylor was a British anthropologist who was much less concerned with the evolution of technology, economy, and political life and much more interested in what anthropologists regard as ideational and symbolic culture, i.e., with myth, language, customs, rituals, and, in particular, religion. Tylor is famous for his use of the concept of survivals, which are features of culture that have been carried by the force of custom or habit into types of societies beyond the one in which they initially appeared. For Tylor, survivals were excellent evidence of a process of social evolution. Completely outside of the disciplines of sociology and anthropology, Karl Marx and Friedrich Engels (1964) developed their own evolutionary model of society. This model focused on the economic evolution of societies over thousands of years and made use of a revised version of the Hegelian dialectic as the mechanism of evolution. Within the economic infrastructures of societies, contradictions or tensions built up that eventually led to explosive situations and the transition to a new stage of society. Engels developed his own highly abstract theory of social evolution in his book *Anti-Duhring* (1939). He also formulated a much less abstract theory in *The Origin of the Family, Private Property, and the State* (1970), a book that depended heavily on the ideas of Morgan.

After about 1890 the golden age of social evolutionary thought came to an end and was succeeded by what has been called 'the antievolutionary reaction' (Harris 1968, Sanderson 1990). Under the leadership of Franz Boas (1940), anthropologists in large numbers turned against the evolutionary theories of Spencer, Tylor, and Morgan. Evolutionary thought was kept alive to some extent through the work of such thinkers as L. T. Hobhouse (Hobhouse et al. 1965) and the celebrated sociologist William Graham Sumner (Sumner and Keller 1927). However, the intellectual atmosphere was for the most part unfriendly to it. But by the 1930s this atmosphere began to change and evolutionism revived. Three thinkers were most responsible for the revival. In 1936 V. Gordon Childe, an Australian archaeologist who taught in Scotland, wrote a famous book entitled *Man Makes Himself*. In this book Childe identified two great evolutionary transformations in human history. The first he called the Neolithic Revolution, which was associated with the domestication of plants and animals and led to larger and more settled societies. The second evolutionary transformation Childe called the Urban

Revolution, which was made possible by the invention of the plow. The Urban Revolution was marked by the emergence of the city, the development of sharp class divisions, and of the form of political organization known as the state.

Following closely on the heels of Childe was the American anthropologist Leslie White. Throughout the 1940s White wrote a series of articles in which he attacked Boas and other antievolutionists for what he saw as their distortions of the claims of the nineteenth-century evolutionists. White (1943, 1959) also developed his own conception of the evolution of culture, which he expressed in terms of a law of evolution. This law stated that culture developed in direct proportion to the amount of energy per capita that societies had harnessed. Societies harnessed energy as they moved from one technological stage to another or as they made their existing technology more efficient, and thus for White technological change was what was driving the evolutionary process. The third major figure in the evolutionary revival was Julian Steward (1955). Steward introduced the concept of multilinear evolution, which he opposed to unilinear and universal evolution. According to him, the nineteenth-century evolutionists had all been guilty of seeing societies as moving through a fixed series of stages (unilinear evolution), and thus greatly oversimplified and distorted the process of evolutionary change. The resurrection of this idea by Childe and White Steward called universal evolution, and it was even more problematic than unilinear evolution. For Steward, evolution was largely multilinear, i.e., it moved along a series of paths rather than one grand path.

By 1960 the evolutionary revival had proceeded to the point of putting evolutionary thinking back into a dominant position, at least in anthropology. After 1960 a new generation of anthropologists (and at least one sociologist) built on this revival and solidified it (Sanderson 1990). Marshall Sahlins (1960) developed an important distinction between general and specific evolution. This paralleled the distinction Steward had made between unilinear or universal evolution and multilinear evolution, except that Sahlins saw both general (unilinear, universal) and specific (multilinear) evolution as real social processes that anthropologists should be studying. Despite being unique, specific evolutionary changes also involved an overall movement of social and cultural life from one stage of evolutionary development to another.
