These reports by the governments are often incorporated in the reports of international and other donor organizations; very few of them collect independent data. However, in 1993 the World Bank departed from this tradition by publishing a report, *World Development Report: Investing in Health*, based largely on independently collected data. Now this initiative has been carried forward by WHO in its *The World Health Report* 2000, in which countries are rated for their various achievements. According to this report, the South Asia region fares poorly both on the health status of its population (see Table 1) as well as on the overall performance of health systems (see Table 2).

3.3 Factors Hindering Progress

Increasing efforts are being made to understand the reasons for the poor performance of health systems in South Asia. The donors, mainly the WHO, the World Bank, UNICEF, and USAID, lead these efforts. The WHO has asserted that 'health is fundamentally different from other things that people want' (WHO 2000, p. 4) and, citing Jonathan Miller (Miller 1978) about its importance, has argued that health requires priority not only in funding decisions but also in ensuring effective access to the services. However, its analysis indicates that this argument seems to have had little effect on resource allocation decisions in South Asia. Countries in this region rank among the lowest for average per capita total expenditure on health as well as for public expenditure (Table 3). It is argued that the low priority given to health in this region is typical for developing countries. Generally, there is a strong positive correlation between the wealth of countries and the amount spent on health. The poorer the country, the lower the proportion of its wealth devoted to health (World Bank 1993, WHO 2000). It may be because the poor, after spending their income on food and shelter, are left with little for other things. But it may also be because the governments in the developing countries, even after the end of colonial rule, continue to perceive spending on health as 'expenditure,' not as 'investment.'

Table 3
Health expenditure in South Asian countries, 1997

Country	Total per capita expenditure in international dollars (1)	Total expenditure as % of GDP (2)	Public expenditure as % of total expenditure on health (3)	Public expenditure on health as % of total public expenditure (4)	Ranking for per capita total expenditure on health (184 countries) (5)
Bangladesh	70	4.9	46.0	9.1	144
Bhutan	82	7.0	46.2	10.1	135
India	84	5.2	13.0	3.9	133
Maldives	284	8.2	63.9	11.0	76
Nepal	41	3.2	26.0	5.3	170
Pakistan	71	4.0	22.9	2.9	142
Sri Lanka	77	3.0	45.4	5.2	138

Table 4
Ranking of South Asian countries for equality of access to health services and fairness of financial contributions (191 countries)

Country	Equality of access	Fairness of financial contributions
Bangladesh	125	51
Bhutan	158	89
India	153	42
Maldives	134	51
Nepal	161	186
Pakistan	183	62
Sri Lanka	80	76

Source: WHO *The World Health Report* 2000, Annex Table 5 for equality of access; Annex Table 7 for fairness of financial contributions

Several studies have focused on the issues of access to health services and financial burden (see Table 4), and have argued that the prevalent inequality is caused by uneven distribution of services between urban and rural areas, poor means of transportation and communication, gender bias and a high prevalence of for-profit health services (reliance on the private sector is 87% in India, 79% in Pakistan to 54% in Bangladesh). Further, it is observed that the poor carry a disproportionately heavy financial burden for obtaining health services, because of their lack of political power: not having effective access to state-supported health services, they are forced to purchase them. Even after paying for them, the services they get tend to be of poor quality. According to one estimate, more than 75 percent of all healthcare in India was delivered by 'private' physicians, most of whom lacked proper training in either allopathic or other healing traditions (Garrett 2000). The situation is not very different in most of the other countries in the region.

Other factors for the poor performance that have been identified include the scholarly tradition, the role of donors, prevalent work ethics and the unreliability of government-generated data.

It is argued (Jain et al. 1999) that the dominance of scholarship based on deductive reasoning generates interesting debates, but little action. Most of the energy in such debates is dissipated in derecognizing those from other groups—a notable characteristic of highly populated societies in which people face acute competition for survival and advancement. This not only makes decision-making difficult but, more importantly, it frustrates implementation. The countries in this region are known for the loftiness of their goals, progressive policies and legislation, and noticeably poor implementation due to the absence of what is described variously as 3Cs—concern with the issues, commitment to resolve them, and competence needed to resolve them—and also as 'organizational capital' (Brynjolfsson et al. 2000).

The scholarly tradition is only partly to be blamed for poor implementation. The prevalent work culture and work ethics have been found to be equally powerful factors. The dominant work culture is feudal and colonial, which denigrates 'work' and has a high tolerance for avoidance of accountability. As a result, 'delinquent' (absentee) and 'ghost' (fictitious) employees, toothless mandatory program evaluation, and noticeable non-performance, have become important features of the health systems in these countries (Jain et al. 1995). In combination with pervasive corruption (Chadda 2000, World Bank 1998, Jain et al. 1996, Jain and Nath 1996, Jain et al. 1997), the work culture saps the energy of the health system in many different ways.

3.4 The Role of Foreign Assistance

Foreign donors, including international organizations, bilateral bodies, foundations, non-governmental organizations (NGOs), churches, and charities, make significant financial contributions to the health

Table 5
Foreign assistance for health, 1990

Country	Total aid (million $)	Aid per capita ($)	Aid as a percentage of total health expenditure
Bangladesh	128	1.2	17.9
Bhutan	NA	NA	NA
India	286	0.3	1.6
Maldives	NA	NA	NA
Nepal	33	1.8	23.6
Pakistan	76	0.7	5.4
Sri Lanka	26	1.5	7.4

Source: World Bank *World Development Report* 1993, Table A-9

budgets of the countries in the region (Table 5). But this contribution is perceived increasingly as a mixed blessing, and as a result, a new body of literature is emerging which identifies the pros and cons of foreign assistance and proposes new models for making this assistance more effective.

Most of this literature is not health-specific, but the findings are generally applicable to this field. Following publication of the very popular book *The Ugly American* (Lederer and Burdick 1958), *The Ugly Indian*—a column written by the well-known Indian journalist, Kuldip Nayar (May 2000)—highlighted the excesses of Indian aid to Nepal. Dennis Merrill in his book *Bread and Ballot* (1990) reviewed US assistance for economic development during 1947–63. Choudhary (1991) produced a similar study on Canadian aid to countries in South Asia. Ghai (1991) examined the role of the International Monetary Fund in developing countries; and Rao (1999) and Priya and Qadeer (1998) examined the impact of the World Bank's conditional assistance for healthcare programs in South Asia. A number of other treatises also appeared (Ghosh 1984, Kanbur et al. 1999) examining prevalent models of developmental assistance and proposing new ones. In essence, these studies observed that while the countries received much-needed resources, the process of foreign assistance compromised their freedom of action, especially in those countries in which the foreign assistance accounts for large proportions of the health budgets.

This happened in several different ways. Each donor is led by its values, priorities, style, needs and power position. Consequently donors, whether individually or as a group, are rarely interested in the overall improvement in the health system of the country, but only in those parts that interest them. For instance, the WHO has been promoting primary healthcare under the flag of 'Health for All by Year 2000' (Wysocki et al. 1990); the US Agency for International Development (USAID) is interested mainly in the provision of family planning services through NGOs (Misra 2000); The World Bank is focused on 'structural adjustments,' privatization, and cost recovery (World Bank 1993, Rao 1999); and UNICEF on immunization of children. Each donor has different rules for project development, implementation and monitoring; and therefore makes different demands on the governments. More importantly, using their power position, the larger donors have tended to usurp the primary initiative for the stewardship of their health systems from the countries. As a result, governments have tended to spend a significant amount of their energy in addressing the interests and concerns of the donors, instead of providing the needed leadership to their health systems.

This incapacity for effective leadership is further compounded by the fact that the top health leadership in the governments tends to suffer from a high rate of turnover. One study found that the average tenure of health ministers and health secretaries was less than two years, while the senior staff of the donor organizations stayed in their posts an average of four years (Jain et al. 1995).

While the operating style of the donor organizations and their representatives has hurt the morale of the health leadership in the region, it has also contributed to the spread of corruption. However, this issue has not received focal attention in the studies on foreign assistance in South Asia, because until recently 'corruption' was a taboo term. Although everybody talked about it in informal settings, nobody wrote about it. Recourse was taken to euphemisms such as 'work ethics' and 'unhealthy conduct' when referring to corruption. This inhibition has prevented serious study of this grave problem. In this connection, special attention needs to be given to the staff evaluation policies of donor organizations. Most donor organizations, in the evaluation of the performance of their staff, place heavy emphasis to their ability to disburse aid funds. This policy places some pressure on their staff to make them resort to an 'end-justifies-means' approach (Jain et al. 1996, Jain and Nath 1996, Chadda 2000).

3.5 Health Statistics

South Asia is known for the superiority of its know-how in mathematics, statistics, demography, and computer sciences. Several world-class institutions such as the Indian Statistical Institute and International Institute of Population Sciences are located here. It has a long history of good quality census. Despite all these positives, the overall quality of health statistics in the region is fair to poor. This phenomenon has attracted the attention of major donors who have a large appetite for good data. Therefore, they have been probing this issue to find out the causes so that they could facilitate the needed correction. Most of these studies are in the form of consultancy reports, and they have identified a diverse group of factors

responsible for the poor quality of health statistics in the region. These include: health systems in these countries are dominated by physicians with little training in data management (Jain 2000), health data are generated primarily for the donors, health managers in these countries are more inclined to base their decisions on intuition and situational expediency than on data (Jain et al. 1999), the overall system of health data management is so out of date and inefficient that the data needed for decision-making are often not readily available, most program managers do not know how to use data in their work, target-oriented program planning generates pressure for falsification, and corruption needs the darkness of non-working information systems.

To compensate for the poor reliability of official health statistics, USAID supports an independent sample survey to monitor progress in health and population programs, the National Family Health Survey (NFHS), which is conducted periodically and covers several countries in this region as well as many other developing countries. In India, the autonomous National Sample Survey Organization (NSSO) was established in 1950. This organization, which has a reputation for producing high-quality data, was originally intended to collect data on the state of the economy but now also gives attention to health and other social sectors. However, the health statistics produced by NSSO and NFHS are fairly limited in scope. Improving health requires improved stewardship of the health system, and this, in turn, requires a sound information system. There is a strong need for active research to improve the quality of health statistics in the region.

3.6 Emerging Issues

To improve the health of their people, the countries in South Asia need to surmount the problems of high rate of population growth, infant mortality, maternal mortality, work injuries, and road accidents; contain malaria, TB and other old diseases as well as the new threat of HIV/AIDS; address the problems of a rapidly growing elderly population, rampant urbanization, and deteriorating environment; improve access to and quality of health services; deal with new pressures caused by new international forces such as the World Trade Organization (WTO) and Intellectual Property Rights (IPR), and get ready for new battles over linking trade to child labor and the environment, and foreign aid to privatization, structural adjustments, and corruption (Priya and Qadeer 1998). This poses a huge agenda of research for the social scientists interested in South Asian health.

South Asian Studies: Politics

The countries of South Asia that matter most have a colonial legacy in common. The British gradually established universities teaching social sciences all over the Indian subcontinent. This policy prepared the ground for the development of political science in most South Asian countries. The pattern is different in Nepal, which had eluded the British Raj. In this Himalayan kingdom social sciences remained centered on the sole department of political science, at Tribhuvan University, that was founded in 1961. It gained momentum gradually, not only because of the democratization process but also because Katmandu became the center for South Asian associations—including NGOs (nongovernmental organizations) and journals—dealing with education or human rights issues, like Himal and the South Asia Forum for Human Rights.

The most common, pattern, however, based on British-built institutions is found in India, Pakistan, and Sri Lanka. In the latter country, Colombo is the most active place, not only because of the university but also because of research centers such as the Regional Centre for Strategic Studies. Like Nepal, Sri Lanka can use its relatively neutral position vis-à-vis the Indo-Pakistani conflict for developing South Asian studies. However, political science remains rather underdeveloped. Interestingly, at the University of Colombo, political scientists are affiliated to the Department of History and Political Science (which was created in 1963). Besides, scholars tend to focus on one political issue, that is ethnic conflicts. (In 1982, an International Centre for Ethnic Studies was launched in Colombo). Often, the scholars who approached the national question either were not political scientists (Tambiah 1986, an anthropologist by training) or did not stay in Sri Lanka (Wilson 1974, 1988, occupied first the Chair of Political Science at the University of Ceylon but was appointed Professor of Political Science at the University of New Brunswick in 1972). This 'extraversion' is one of the specific features of the political science of India and Pakistan, the two countries on which we shall focus in this article.

1. *The Institutional Bases: Building Upon the British Legacy*

1.1 *The Indian Efflorescence*

Political science has flourished in India whether in the examination of the political system *per se* and its links to society or in the study of international relations. The British contributed to these postcolonial developments from two points of view. First, they enabled Indian students to study politics in England, notably at the London School of Economics. Second, they introduced courses of political science in Indian university, more especially in Calcutta (where U. Goshal became lecturer in Comparative Politics in the 1920s) and in Allahabad, where Beni Prasad (who was to found the Indian Association for Political Science and the *Indian Journal for Political Science*) was Reader in Civics and Politics in the 1920s too. However, these two cities receded in the background gradually as political institutions were transferred to Delhi.

With its twin educational and research institutions, the Jawaharlal Nehru University (JNU) and the Delhi University, India's State capital has quite logically been at the heart of the whole process. The School of Social Sciences and the School of International Relations at the JNU and the Faculty of Political Sciences at the University of Delhi were both founded in 1955. Partly, because of the influence of Marxist thought, until the late 1980s, the historiographical tradition was strong, particularly in the JNU, where the study of politics was above all seen in interlinked terms of class and political economy.

In spite of the domineering presence of these two rival institutions, some other research centers based in Delhi such as the Centre for the Study of Developing Societies (CSDS) founded in 1963 and the Institute for Defense Studies and Analyses (IDSA), founded in 1965, have managed to grow outside their fold and have been able to contribute new approaches in their own, very specialized, domains. The Centre for Policy Research (CPR), initially established in 1973 as an informal think-tank has also grown into a major center for studying public policies as well as foreign affairs and the political sociology of India.

In the same manner, political science departments have blossomed throughout India and can be found in most, if not all, the state universities. To name but a few, Calcutta, Chandigarh, Hyderabad, Jaipur but also Banaras and even smaller places like Meerut are endowed with universities that have their own departments of political science and in some cases also of

international relations, where research and teaching are being conducted with a focus on regional and local issues. This has in its times led to the development of journals and associations that are as many proofs to the vitality of the subject. The Indian Association for Political Science—which brings together large contingents of political scientists to the conferences of the International Political Science Association—edits the *Indian Journal of Political Science*. The *Indian Political Science Review* is another such journal based in Meerut University.

1.2 Outward-looking Pakistan

Political science is not as well established in Pakistan as in India but international relations tend to be studied by a comparatively larger number of institutions. The gap may be explained from three points of view. First, the political context was not very conducive to the development of this discipline: the prolonged phases of authoritarianism under Ayub Khan (1959–70), Zia ul Haq (1977–88), and Pervez Musharraf (1999–) did not allow much freedom of investigation and the instability of the regime did not help the conceptualization of what is the Pakistani political system. The phases of civil rule were not conducive to research work either. For instance, G. W. Chaudhury, who had published two reference books in the 1950s–1960s, was forced to exile under Zulfikar Ali Bhutto because of his account of the war of Bangladesh. Second, political scientists were dominated by history, the most influential social science because they took refuge in history for the reasons mentioned above, and, like in India, the historiographical tradition overpowered other disciplines. Third, political science—like many other social sciences suffered much from the weaknesses of the university system: the textbooks are substandard and the teaching of the discipline is especially bad because in most universities and colleges it is taught in Urdu—a language in which there are no quality standard textbooks (Shafqat 1989).

In stark contrast to the situation prevailing in India, there is no association of political scientists and no 'Journal of Political Science' in Pakistan. Certainly there are departments of political science in many Pakistani Universities—including Karachi and Lahore—but not in some of the largest ones. On the other hand, international relations are taught in many places including the departments of international relations of the Qaïd-i-Azam University (Islamabad), founded in 1973, the University of Karachi (1958), and the University of Sindh (1972). Besides these departments, there are many more specific bodies dealing with international affairs—such as the Institute of Regional Studies (1982) and the Institute of Strategic Studies (1973)—or with area studies, such as the Centre for South Asian Studies of the University of the Punjab (1973) and the Central Asia Centre of the University of Peshawar (1976). This list reflects the traditional outward looking tendency of Pakistan, a country at the crossroad of South Asia, Central Asia, and the Middle East and affiliated to associations of regional cooperation and defense since the 1950s. However, India and Pakistan have more in common as far as the relationship of their political scientists with the outside intellectual world is concerned.

1.3 The Study of South Asian Politics Abroad

The command of English by South Asian political scientists partly explains their sometimes-strong affinities with Anglo-Saxon specialists in the field. First, many of them studied abroad and settled down there. Among the founding fathers of 'Pakistani political science,' one finds several expatriates including Anwar Hussain Syed, Khalin Bin Sayyed, and S. M. M. Qureshi. On the Indian side, the list is much longer, especially in the United States where—possibly because of political correctness—the universities have recruited an ever-larger number of Indian scholars who found the American environment increasingly attractive in terms of its intellectual climate as well as its working conditions.

Second, American and British universities have well established traditions of South Asian studies in political science. In England, while Oxford and Cambridge tended to specialize in history, the School of Oriental and African Studies, the London School of Economics, and the University of Sussex have developed an early interest in South Asian politics. They were joined subsequently by the Institute of Development Studies (Brighton), Hull University, and Bristol University. While the other European countries have been less active, with the possible exception of Sciences-Po (Paris), the Südasien Institut (Heidelberg), and the Amsterdam School of Social Science Research, American universities have played a major role in this field.

The University of Pennsylvania's Department of South Asia Regional Studies (Philadelphia) was founded in 1948 by W. Norman Brown. Brown was not a political scientist. He had became professor of Sanskrit at Pennsylvania in 1926 (and retired in 1966 in this capacity) but he was interested in Indian current affairs and trained political scientists, such as Richard Park who, in 1951 became the first director of the Berkeley South Asia Program and then of the Center for Southern Asian Studies in Michigan (Crane 1985). Nicholas Dirks points out that Norman Brown's life 'helps to explain why area studies at the University of Pennsylvania, and elsewhere, privileged a combination of classical Indological scholarship and

modern political and economic concern in the early history of the field' (Dirks in press). Pennsylvania University, where Francine Frankel developed the Center for the Advanced Studies of Asia in the 1990s, continued to play a leading role in addition to Berkeley and Michigan. In Chicago, the study of South Asia was dominated by anthropology—Milton Singer played a major part there in the 1950s—but political science asserted itself in the 1960s with Susan Hoeber Rudolph and Lloyd Rudolph. The Massachusetts Institute of Technology, where Myron Weiner was the moving spirit of South Asian Studies between 1961 and his death in 1999, was one of the other key institutions. Every year, American social scientists—including political scientists—meet at the University of Wisconsin (Madison) for the Annual Conference on South Asia, an event which is incomparably more important for political scientists than the biyearly meeting of the European Association for the Study of Modern South Asia, which is still in its infancy.

The American institutional base, the presence of many South Asian political scientists in the United States, and the strong influence of this country over political science—a young discipline in which there was no well-established European tradition—largely explain that the field was initially dominated by American-born methodologies and theories (Brass 1995).

2. *Approaches in the Study of South Asian Politics*

2.1 *From Developmentalism to Political Sociology*

The first researches into the politics of South Asia were developed after World War II within the then most influential framework of the theories of development and modernization. Myron Weiner, whose pioneering work, *Party Politics in India* was published in 1957, played a leading role in this enterprise. He 'represented' India, for instance, in 'classics' of this Princeton University-dominated school of thought, such as Almond and Coleman (1960) and Binder et al. (1971). His books—more especially *The Indian National Congress* (1967)—however, did not suffer from the limitations of this developmentalist paradigm because they relied on intensive fieldwork and an empiricist methodology.

Contemporaries of Weiner, including the Rudolphs and Morris-Jones, however, initiated a different approach. They rejected the theories that postulated the replication in South Asia of the political trajectories that had occurred in the West. W. H. Morris-Jones underlined the specificities of the Indian political cultures in his *The Government and Politics of India* (1964) and the Rudolphs made a similar argument by focusing on the case of Gandhi in *The Modernity of Tradition* (1967).

Both trends—Weiner's empiricism cum developmentalism and the school emphasizing the indigenous dimension of the modernization process—had an echo in India thanks to the towering figure of Rajni Kothari, the real founder of political science in India. In the 1960s, Kothari developed the notion of 'the Congress system' in an often quoted article to describe the political domination of the Congress party along lines that were very similar to Morris-Jones' analysis (Kothari 1964b, 1970a). Secondly, he took up the issue of modernization in a famous article (that was also published in an Anglo-Saxon journal, Kothari 1964a) that criticized the approach of the Rudolphs but pointed towards the same direction. Thirdly, Kothari worked with M. Weiner (Kothari and Weiner 1965). He drew some of his inspiration from the developmentalist approach—as evident from the name of the research institution he founded—The Centre for the Study of Developing Societies (CSDS), and was favorably inclined towards empiricism. As a result, the CSDS played a pioneering role in electoral studies; its Data Unit organized the first opinion polls in 1967 and 1971 under the guidance of Bashiruddin Ahmed who published with Samuel Eldersveld a book entitled *Citizens and Politics. Mass Political Behavior in India* (1978).

Right from the beginning, R. Kothari and his center introduced a *modus operandi* combining two major features: openness to the Anglo-Saxon approaches (stemming in collaborative works) and, at the same time, an attempt at Indianizing the concepts of analysis (this is most obvious in Kothari's 1970b study of the functional role of caste in the Indian democracy). While these two characteristics virtually contradicted each other, the contradiction disappeared when the American brand of developmentalist receded in the background and let the empiricist approach result in research works paying more attention to Indian political cultures and practices. M. Weiner himself challenged 'modernization' theory that predicted erosion of religious, caste, linguistic, and tribal identities, as developing countries modernized in *Sons of the Soil* (1978), a book he wrote with Mary Katzenstein.

Paul Brass' initial work exemplifies this approach. Brass' initial interest in the politics of Uttar Pradesh had led him to question the relevance of parties as the basic unit of the state Indian politics; he magisterially demonstrated that factions—partly related to castes—played a more important role in his book, *Factional Politics in an Indian State. The Congress Party in Uttar Pradesh* (1965). His approach prepared the ground for a political anthropology, which materialized gradually with the growing interest of anthropologists as Harold Gould in politics. However, Brass is best known for his study of ethnic politics. In his seminal work, *Language, Religion and Politics* (1974), he analyzed

'communal' movements in Punjab, Uttar Pradesh, and Bihar in an instrumentalist perspective, explaining that such identity politics results from the conflicts of interest of ethnic groups. This anti-primordialist paradigm was well in tune with the approach of a large number of Indian scholars.

2.2 Political Economy and the Marxist School

Besides the initial—and sustained—interaction as well as cross-fertilization relationship between Indian and Western—mostly American—political scientists, another characteristic of the study of South Asia politics lay in the strong emphasis on political economy. The main object of study here is the State and the issue at stake is: why did the State fail in its efforts at implementing its socialist agenda during the Nehru years and after? F. Frankel argues that the dependence of the Congress Party on privileged classes, landlords, capitalists, and other notables delivering votes or funds, prevented the government from pursuing its intended policies (1978). Marxist scholars, like C. P. Bhambri, offer a similar analysis but emphasize the weaknesses of class-consciousness among the poor, especially the peasantry. However, the Rudolphs (1978) and Atul Kohli (1990) suggest that the State has gained some autonomy.

Indian Marxists have often drawn their inspiration from Gramsci and his theories about social hegemony and passive revolution. Pranab Bardhan has used this approach to analyze Indian society's economic as well as political relations. In *The Political Economy of Development in India* (1984) he shows how three 'proprietary classes,' the political establishment, the landlords, and the capitalists share power in India, the first group making concessions to the others in order to remain in power: the Congress party gave up substantial land reform in order to get the support of rural notables at the time of elections and did not implement its socialist agenda fully, so much so that the business community gave financial support to the party.

Parallel to this class-oriented approach of social tensions, political scientists have more and more emphasized the role of caste. Eleanor Zelliot (1992) and Owen Lynch (1969) focused on the mobilization of the Untouchables (and more especially on the movement of B. R. Ambedkar). In the wake of these pioneering works, Marc Galanter (1984) analyzed the impact of the affirmative action programs on the lower castes, Gail Omvedt, the rise of Dalit politics (1994), and F. Frankel and M. S. A. Rao the 'decline of a social order' that was based on the traditional caste system (1989). The issue of caste, class, and power, originating from the 1960s works of the Marxist scholars, has remained central to the study of Indian politics not only because the State has failed in its endeavor to bring the benefits of development to the masses but also because of the interaction between economic, social, and political power in India.

2.3 New Developments in 'Domestic Political Science'

In the 1990s, the development of communalism and the increased political use of religion India was witnessing, led many authors to scrutinize a subject that had become a non-issue: secularism. In an attempt to understand the polarization of communities along religious lines, the real impact of secularism on Indian society was reexamined by sociologists as well as political scientists (Nandy 1985, Bhargava 1996, 1998). The State was also a central focus of the research undertaken, the question being why it had failed to anchor the secularist agenda in Indian society (Basu and Kohli 1998). The historical and the Marxist traditions again played an important encompassing part in delimiting the approach. This can be seen in the works of Ashgar Ali Engineer, for instance, whose interpretation of communalism as the result of economic rivalry (1984) had a large scientific impact. It is also evident as prominent historians like Gyanendra Pandey had a large share of the study of communalism from the late 1980s onwards (1993).

Running parallel to the study of communalism was the new examination of the political system to account for the rise of the parties relying on religious identities for support. Bruce Graham's work on the Bharatiya Jana Sangh, covered both the fields of the study of opposition politics (organization, support bases, etc.) and that of the political use of religion (1990). Generally speaking, however, the study of the political parties has been one of the declining themes. While the Congress, when it was a ruling party, had been the central focus of works by Kothari, Morris-Jones, Weiner, Brass, and Stanley Kochanek (1968), its decline has not been studied very closely. Similarly, the communist parties, the socialist movement, and the peasant-based parties such as the Lok Dal have remained largely ignored. The State institutions, which were scrutinized when they were set up after independence Austin 1966, did not generate the same amount of work in the 1990s. Scholars like James Manor (who edited a book on the Indian Prime Minister), however, argue that institutional decay is not an irreversible trend and that the resurgence of the judiciary and the Election Commission, for instance, are a good reflection of this tendency (1994).

Similarly, State politics has not continued to attract the same interest. In the 1960s–70s Myron Weiner and Iqbal Narain edited volumes studying State politics, almost state by state (1974–7). Paradoxically, such comparative studies have become less and less numerous (a notable exception being Zoya Hasan's 1998

book on Uttar Pradesh), precisely at the moment when the dismantlement of the one-party system favors the emergence of an even larger number of regional parties. In the 1990s, the regionalization of politics resulted in the multiplication of political parties in Parliament. There were about 40 in the late 1990s.

On the other hand, election studies gained momentum. They have always been a very active sector of political science in, or about, India. Myron Weiner, once again, published several volumes untitled *India at the Polls*. Before him, R. Park and S. Kogekar had covered the first general elections (1956) and Iqbal Narain had coordinated similar surveys (Varma and Narain 1968). In a manner very different from the early years of Indian political science, the political assertion of new actors—including low castes, communal forces, and regional parties—and the tremendous transformations of the party system it triggered is now also being assessed through empirical studies of the voting pattern including exit polls. The Centre for the Study of Developing Societies again plays an essential part. Its Data Unit under the direction of Yogendra Yadav conceives and conducts nationwide polls before and after most elections since 1993. Focusing on socioeconomic criteria, they provide an exceptional corpus of material for the understanding of Indian political behavior. Yogendra Yadav's articles on the 1993–5 elections have cleared the ground for the analysis of post-Congress politics.

The current revival of Indian political science is driven by the analysis of the major and somewhat brutal changes undergone by Indian society since the late 1980s. One of the consequences is the relative decline of the historical tradition and the assertion of a more 'political' school of analysis. The main English-medium scientific press, the Oxford University Press, had launched a new series in 1997 that could be seen as an indication of the change taking place. This 'Themes in Politics' series co-edited by Rajiv Bhargava and Partha Chatterjee explored three subjects: the State, secularism, and gender, the three having been at the core of the then evolution of Indian society. The series shifted in 2000 to a new publishing house, Permanent Black, founded by Rukund Advani, a former senior commissioning editor with OUP.

2.4 International Relations: Nonalignment and Indian Neighbors

In the early 1960s, the study of international relations ran parallel with the setting of independent India's foreign policy and focused chiefly on the expectations rising from the Nonaligned Movement and the part India played in it. From the 1970s onwards, the development of strong links with the USSR provided a new focus of research. Soviet foreign policy became one of the main themes of research, in particular in relation to the USA and Eastern European countries. It therefore had a strong regional taste to it while conceptual issues were less prominent.

While it focused on countries with which India was having close interactions, Indian political science hardly covered countries with which there were few links. The case of the Chinese school of study provides an interesting example of the close relationship between research and India's foreign policy. With the 1962 war between India and China, the good relationship the two countries had enjoyed until the mid-1950s collapsed completely. With diplomatic relations down to the minimum, too little scientific research was encouraged either on China's foreign policy or later on the Chinese way to economic development. The Institute of Chinese Studies started publishing *China Report* in 1964, but it is rather later that China's evolution into a major player on the international scene helped to realize India's lack of knowledge of its chief neighbor.

Western Europe and the USA were not central to the study of international relations in India, and were chiefly investigated through their links to the USSR. Central Asia, in spite of its proximity to India, was also hardly studied at all. The same goes also for East and Southeast Asia. The new dynamism of research on the region owes a lot to India's 'Look East policy' since the early 1990s and the growing economic links between India and the various Southeast Asian countries.

Apart from the interest in regional studies, Indian schools of international relations also developed strategic analysis. Partly due to the country's size and its tendency to look inward, strategic culture had eluded India. With India's growth on the South Asian regional scene and its claims to being a major international player, a school of strategic thinking started to emerge.

The Institute for Defence Studies and Analysis (IDSA) played an essential part in this new school of thought. The center was founded in 1965 and has since focused on India's national security and orientations to defense. Through its long established influence on the Indian government, the IDSA has been instrumental in establishing India's naval and regional policy. The Centre's main publications are the journals *Strategic Analysis* and *Strategic Digest*, and the yearly *Asian Strategic Review*. The latter has been conceived as a reply to the Stockholm Institute for Peace Research's *Yearbook* and London's International Institute for Strategic Studies' *Military Balance*. Arguing against the Western perception that India's military policy was a risk to regional stability, the IDSA has argued in favor of the nuclear deterrence and of the necessity of developing a security establishment of adequate size. Its former director, K. Subrahmanyam, and director in 1999 Jasjit Singh, wield considerable influence over the Indian government as far as security issues are concerned.

Indicating the change of scale in the Indian current foreign policy, the relation to China, the nuclear doctrine, and the question of 'multipolarity' are nowadays central issues in international relation studies. The IDSA and the Delhi-based Centre for Policy Research concentrate on those subjects which can be seen as a major shift in Indian strategic thinking.

2.5 How to Study the Politics of Pakistan?

The study of Pakistan's politics, which is much less developed than its Indian counterpart has been dominated by two themes, the question of the regime and the issue of national unity. Historically, the latter came first: Pakistan was created to give a nation-state to the Muslims of British India but Islam did not turn out to be a sufficiently strong cementing force with East Pakistan fighting—successfully—for the establishment of a separate country (Bangladesh), the Pathans showing signs of irredentism vis-à-vis Afghanistan, the Baluchis displaying centrifugal forces too, and Sindh being gradually the framework for a major conflict between Mohajirs and Sindhis. Hence there are a large number of studies dealing with ethnic issues. Some authors focus on language as the main line of cleavage (Rahman 1998), while others (Amin 1988) look at ethnic groups (with their other characteristics such as religious affiliations). But most of the authors reject the primordial paradigm. They rather interpret ethnic conflicts as the outcome of socio-economic tensions or political rivalries. However, emphasizing that cultural features are instrumentalized for promoting collective interests does not mean that culture is ignored. This reading applies to studies of religious groups too. For instance, Vali Nasr underlines that the Jama'at-i-Islami had some affinities with Sufi orders (1994).

The question of the regime has been looked at very closely after the first military coup terminating Pakistan's first attempt at establishing democratic institutions. In his 'classic,' *The Political System of Pakistan*, Khalid B. Sayeed coined the expression 'constitutional autocracy' (1967) to describe Ayub Khan's regime. Pakistan's incapacity to escape the cyclical alternation of civil rule and praetorian politics is also central to another classic by Mohammad Waseem, *Politics and the State in Pakistan* (1994). Unsurprisingly, the periods of military rule have been studied in greater details. Ayesha Jalal and Mohammad Waseem have scrutinized respectively the reigns of Ayub Khan and that of Zia-ul-Haq in two complementary perspectives. While the former emphasized the political economy of defense (1990), the latter put a stress on the authoritarian overtone of the political culture of Pakistan—the viceregal legacy of colonial rule—and its affinities with the ethos of the army (1987).

Pakistani political scientists however often point out that the army's domination over society and politics—even after 1988 when the military personnel continued to exert a strong influence directly or via the President—is not in tune with the country's political culture. Saeed Shafqat refers to 'a case of disharmony between democratic creed and autocratic reality' (1998).

Political science in and about South Asia shares some features irrespective of the country one looks at. On the one hand, in most cases it is derived from the British tradition and this starting point generated rather strong affinities with the Anglo-Saxon academic world. On the other hand, India was especially studied by political scientists (either in India or abroad) from the point of view of its domestic scene whereas scholars working on Pakistan tended to pay more attention to its relations with neighbors and other countries. This differentiation is evident from a clear unevenness in terms of institutional developments. This contrast can be explained by the size of India–a world in itself—and its unique, democratic trajectory, on the one hand, and by the extraversion of Pakistan, a country where political surveys have never been easy, especially when it was under military rule, on the other hand. The alternation of civil governments and military coups probably explains the rather limited development of political science in Bangladesh, the only country of this area we have not mentioned yet. However, the universities of Dhaka, Chittagong, and Jahangirnagar have departments of political science and the resumption of the democratization process may contribute to their consolidation.

Southeast Asia, Archaeology of

Southeast Asia, a term which entered into common use and academic discourse during and after World War II, refers to the region covered by the modern nation-states of Burma, Thailand, Laos, Cambodia, Vietnam, Malaysia, Singapore, Indonesia, East Timor, Brunei, and the Philippines (although archaeologists also include southern China and Taiwan in studying aspects of the region's prehistory). Divided into mainland and island areas, this region extends across tropical latitudes for approximately 5,000 km southeastwards from Burma to eastern Indonesia.

Scholarly traditions of archaeological research in Southeast Asia are generally divided according to their focus on either prehistoric or historic periods. Prehistory begins with the Pleistocene artifactual record of early hominids and ends with the appearance of written records, the timing of which varies by area (e.g., in Indonesia stone inscriptions in Sanskrit appear in the fourth century AD whereas extant written

accounts of the Philippines date from the tenth century AD onward). Historical archaeology is subdivided into, for example, early, classical, Islamic, and protohistoric, depending upon the area. While the archaeology of European colonialism and the spread of capitalism are often used to define historical archaeology elsewhere in the world, in Southeast Asia these constitute more recent topics of research. European colonialism of Southeast Asia, however, was the context within which archaeology developed, and its legacy continues to affect contemporary archaeological practice. This history and the current understanding of Southeast Asia's prehistoric sequence (as based on English-language sources and primarily the better known archaeological records, at least for certain periods, of Thailand, Vietnam, Malaysia, Indonesia, and the Philippines) are summarized here, followed by a discussion of some of the problems and future directions in the archaeology of this region.

1. *Development of Southeast Asian Archaeology*

The study of archaeological remains in Southeast Asia has a long history, predating even that conducted by Europeans who are credited with introducing archaeology. Thai and Burmese rulers, for example, had previously initiated studies of stone inscriptions to reconstruct political-economic aspects of earlier states. The practice of archaeology as a Western scientific discipline began with European colonial expansion into Southeast Asia. Following an initial period of antiquarian interest, which in places such as Indonesia lasted for more than a century, during which Dutch and British recorded monumental sites such as Prambanan, collected artifacts (including specifically for museums), and published descriptions, the first archaeological institutions were established. In Burma, a research officer in archaeology was appointed in 1881 under the Indian Archaeology Department established by the British; in Indonesia, the Dutch established an archaeological society in 1885 to coordinate scientific exploration of ancient monuments in Java; in Indo-China (Cambodia, Laos, Vietnam), the French established the École Française d'Extrême Orient in 1898, which directed excavations, recorded and restored sites, and published reports; in Thailand, the Siam Society was founded in 1904 as a forum for those interested in the country's past, followed by the establishment of the Archaeological Service of Siam in 1924; in the Philippines, systematic explorations and collections were initiated in 1881, with archaeology established during the US colonial period; and in Malaysia, archaeological excavations began in the early 1930s conducted by the Raffles Museum in Singapore. Early investigations tended to focus on monumental sites, often in association with the study of the growing body of stone inscriptions, where these existed; however, excavations of prehistoric sites were also undertaken. Unlike Thailand, where from the beginning archaeological and art historical research was conducted by Thais, in the colonies this was not the case; thus, for example, Vietnamese, Khmer, and Laotians were neither trained in archaeology nor participated as professionals until after independence.

Beginning in the 1960s, there was a significant rise in archaeological research focused on prehistoric sites (although this did not happen everywhere; for example, no archaeological research was conducted in Laos between 1945 and 1975). Some were joint projects between foreign and local institutions, which included training of local students (a first in some countries such as Thailand). One outcome of the various research projects, some of which claimed early developments of agriculture and metallurgy, was that by the 1970s Southeast Asian archaeology was no longer viewed as a branch of Indian, Chinese, or Far Eastern studies, nor as a marginal zone in prehistory that was a backward appendage of the more advanced cultures of India and China. At the same time, diffusion and migration explanations of culture change began to be replaced by frameworks emphasizing local processes of innovation and adaptation. Also since the 1970s, the majority of archaeological research in the region has been conducted by Southeast Asian archaeologists (Miksic 1995) employing a range of perspectives from culture-historical to Marxist.

2. *From* Homo erectus *to Early States*

2.1 *Early Hominid Occupation of Southeast Asia*

The earliest known hominid occupation of Southeast Asia was by *Homo erectus*. It occurred by at least one million years ago, although redating of fossil-bearing deposits in Java suggests it may have been as early as 1.8 million years ago (Swisher et al. 1994). The majority of evidence is paleontological and primarily from sites on Java, although *Homo erectus* fossils are also known from Burma and Vietnam. Stone tool assemblages, composed of large pebble and flake tools (which differ from the contemporary Acheulian hand ax industries of Africa, Europe, and India: see *Sub-Saharan Africa, Archaeology of*), and generally not from primary contexts, have not yet been found in association with hominid fossils. The interpretation of much of the archaeological record assigned Middle Pleistocene dates thus continues to be the subject of debate. *Homo erectus*'s technical achievements may have included maritime technology, as suggested by the recovery of lithic artifacts from excavated sites on Flores dated to the Early Pleistocene (c. 800,000 year ago). Occupation of this island would have entailed crossing deep sea channels since it was not part of Sundaland (the land mass connecting the mainland with Sumatra, Java, Bali, Borneo, and Palawan, exposed at various times during the Pleistocene) and suggests *Homo erectus* possessed voyaging skills and watercraft (Morwood et al. 1999).

2.2 Late Pleistocene–Early Holocene Hunter-gatherers

The oldest evidence for occupation by anatomically modern humans dates to approximately 40,000 years ago. Only a few archaeological sites provide evidence of Late Pleistocene occupation: Lang Rongrien rock shelter, Lang Kamnan cave, Son Vi sites, Niah Cave, Tabon Cave, and Leang Burung 2 (see, for example, Anderson 1990, Ha Van Tan 1997, Shoocongdej 2000). The hunter-gatherer groups who occupied these caves and rock shelters are known primarily from their flake and pebble/cobble tool assemblages, although hearths and remains of hunted and collected animals (e.g., land tortoises, rodents, wild pig, monkeys, orangutan, shells) are also found. The majority of their material culture was probably made of bamboo and wood, as suggested by the generalized nature of the stone tools and their probable use in manufacturing activities.

By the early Holocene, hunter-gatherers appear to have occupied much of Southeast Asia, with some areas, such as the Malay Peninsula, reoccupied following the expansion of the postglacial equatorial rainforest. Occupation of the upland areas of the mainland is better known in contrast to the lowlands, where rising sea levels and subsequent landscape changes after the last glacial maximum destroyed or buried most sites. Holocene hunter-gatherers are known primarily from their stone tool assemblages, which are dominated by pebble tools. Other types of tool included grinding stones, bone points, and antler wedges, although the majority of their material culture was presumably made of perishable materials. Caves and rock shelters were used for occupation as well as for burial; individuals were buried in either flexed or extended positions and accompanied by stone artifacts, animal bones, and red ochre. Coastal areas were also occupied/exploited, as indicated by shell midden sites. Mobility strategies may have varied with the wet and dry seasons, entailing different types of settlement (including in open areas) and exploitation of different food resources (Shoocongdej 2000). Diet varied by location and included a wide variety of terrestrial (e.g., pig, deer, macaque, rhinoceros), riverine and marine shell species. Holocene hunter-gatherers also exploited a wide range of plants; their role in plant domestication, a topic of long-standing interest in Southeast Asia, remains little known. In part, this reflects current emphasis on rice—the subsistence base of later complex societies—especially the timing of its domestication, adoption and spread. (See *Hunter–Gatherer Societies, Archaeology of*.)

2.3 Early Rice-cultivating Communities

The earliest known domesticated rice comes from middle Yangtzi valley sites and dates to c. 6000 BC (see *Food Production, Origins of*); Southeast Asian sites have not yet yielded direct evidence of rice this early. Consequently, this evidence in conjunction with linguistic data, underlies modern models (e.g., Bellwood 1997, Higham 1996) which propose that in the third millennium BC early rice agriculture was introduced into mainland Southeast Asia by expanding Austroasiatic-speaking rice-farming communities that originated in the Yangtzi river area, and into island Southeast Asia by expanding Austronesian-speaking communities from Taiwan or southern China (see *Pacific Islands, Archaeology of*).

Archaeologically, early mainland rice-farming communities appear in northern Vietnam in the third millennium BC. Village settlements with associated cemeteries (of extended burials and infant-jar burials) were established in inland areas, and were engaged in rice cultivation, the raising of domesticated animals (dogs, cattle, pigs), the manufacture of decorated pottery, and the use of stone ornaments. In northeastern and central Thailand, farming villages are known from habitation remains and primarily from cemeteries of extended burials; some mortuary evidence suggests social status differences based on achievements in fine pottery crafting and exchange activities (Higham 1996). These contexts have yielded decorated pottery (some tempered with rice chaff), polished stone adzes, marine shell beads and bracelets, stone reaping knives, bone tools, spindle whorls, and remains of domesticated cattle, pigs, chickens, and dogs. These mainland communities also continued to hunt and collect wild resources, and they engaged in regional systems of exchange involving stone and marine shell. Interestingly, in northern coastal Vietnam, shell middens and other sites dated from the fifth millennium BC have yielded pottery and polished stone adzes, material culture often associated elsewhere with 'Neolithic' communities. Similarly, in Thailand, pottery (appearing as early as 6000 BC) and stone adzes, often from cave burials, predate evidence considered indicative of rice-farming villages. Whether such evidence indicates 'affluent foragers' or early farming activities of rice or other plants remains unknown.

Within the islands and the Malay Peninsula, early rice-farming communities are known almost entirely from occupation and burial remains in caves and rock shelters, along with a few shell midden sites (Bellwood 1997). In the Philippines, by the early third millennium BC, such sites contain various items including pottery, stone and shell adzes, spindle whorls, stone and shell jewelry, and tattooing chisels. Within the Indonesian archipelago, pollen evidence suggests minor forest clearance on Sumatra around 4500 BC and permanent clearance after 1000 BC, presumably for agriculture; other islands (again primarily from cave and rock shelter sites) provide evidence of pottery and rice around 2500 BC, and the human introduction (via watercraft) of pigs and nondomesticated animals

between 2500 and 2000 BC. During the second millennium BC, caves along the Malay Peninsula were used for burial rather than habitation, and contain graves of extended individuals accompanied by items such as stone adzes, bone points, shell beads and bracelets, and pottery.

2.4 Early Metal Crafting

By the early to mid-second millennium BC, autonomous village communities on the mainland (known primarily from mortuary deposits) became involved in the production and consumption of copper/bronze craft goods, with stone and pottery crafting also continuing (see *Intensification and Specialization, Archaeology of*). This technological change may not have been accompanied by changes in sociopolitical complexity, unlike Bronze Age periods elsewhere in the world. Bronze objects appear in sites in northern Vietnam prior to 1500 BC, in association with exotic jades from China. Sites in central and northeast Thailand, with initial use in the early mid-second millennium BC, provide the earliest evidence for the mining, crushing, smelting, and casting of copper into ingots (e.g., Pigott and Natapintu 1988), activities which appear not to have required full-time specialists (White and Pigott 1996). After 1500 BC, bronze-casting technology, which involved the use of ceramic crucibles and stone or ceramic molds, appears to have spread quickly along riverine and coastal exchange routes (Higham 1996). Copper ingots entered into existing exchange networks, thus enabling communities situated far from ore sources to engage in bronze casting. Prior to production of iron craft goods (c. 500 BC), bronzes were cast into ornaments (bracelets, ear ornaments) and utilitarian objects (e.g., socketed ax heads and other implements, chisels, arrow and spear points, fishhooks, sickles). Bronze objects and copper ingots (along with other items such as pottery vessels, animal remains, stone tools, and shell ornaments) served as grave accompaniments, although whether their value in mortuary contexts related to distinguishing status differences and/or other social identities remains unknown.

2.5 The Development of Chiefly Polities and Early States

Around the mid-first millennium BC, significant social changes entailing systems of hereditary ranking and hierarchical organization appear to have been under way, which archaeologists interpret as indicative of complex societies such as chiefdoms (see *Chiefdoms, Archaeology of*). In mainland Southeast Asia, larger settlements (some with moats, particularly in northeastern Thailand) integrated into regional hierarchies appeared, as well as urban settlements (Co Loa in northern Vietnam and Beikthano in Burma). Other changes, occurring variably within the region, included the development of iron production (of, for example, ornaments and tools in localized forms), with smelting and forging first appearing in the Chao Phraya and middle to lower Mekong river valleys; increased scale of production and variety of bronzes crafted (e.g., various vessel shapes, bells, large drums, axes, spearheads, jewelry), as exemplified by Dong Son bronzes; greater use of bronzes in mortuary ritual; glass working (in southern Vietnam); intensification of wet rice cultivation using water buffalo and iron plows; participation in maritime and long-distance exchange relations between the mainland and island areas (Bellwood 1997) and India (the earliest evidence dating to the fourth century BC; see, for example, Glover 1996), with exotic goods appearing in mortuary contexts; and the incorporation of the Dong Son polity (northern Vietnam) into the Han empire in 111 BC.

The complex societies that were developing during the last few centuries BC in areas of island Southeast Asia acquired bronze prestige/status items (such as Dong Son drums) and iron goods via exchange with the mainland, which was soon followed by the establishment of local metalworking centers. Island polities also engaged in exchange networks involving China and India, with Bali yielding the earliest dated Indian materials at around two thousand years ago (Ardika and Bellwood 1991). As with the mainland, the majority of information on island societies assigned to an 'early metal phase' (Bellwood 1997) derives from burials, in open sites and caves, including the distinctive jar burial, slab grave (Sumatra, Java and Peninsular Malaysia), and carved stone sarcophagi (Java and Bali) forms of interment. While these sites have yielded a wealth of material culture (e.g., decorated pottery; bronze socketed tools, bowls, drums; glass and carnelian beads; iron tools) and information on mortuary rituals, much remains to be learned of the social, political, economic, and ideological aspects of this period, which preceded the formation of state polities in various areas of the Indo-Malaysian archipelago.

States in Southeast Asia are traditionally thought to have appeared on the mainland during the early centuries AD. This dating reflects, in part, the privileging of written sources in the identification of state-level polities, and is exemplified by the case of 'Funan,' which is generally viewed as the earliest state. Written accounts, the earliest dating to the third century AD by visiting Chinese emissaries, describe Funan's origin story, dynastic lineage, raiding activities, vassal polities, the walled settlements which contained a palace, the taxation system (paid in gold, silver, perfumes, and pearls), and the presence of a representative of the Indian Murunda king, among other things. Oc Eo, a 450-hectare rectangular site (enclosed by several ramparts and moats) of approximately the second to sixth

century, is located in the lower Mekong valley, the area in which 'Funan' is thought to have been situated. It has yielded evidence of participation in extensive exchange networks involving Iranian, Roman, Indian (some engraved in Indian script), and Chinese goods from the second century AD onwards; and of glass, stone (precious and semiprecious), and metalcraft production (Higham 1996). An extensive system of canals (not yet dated) connects Oc Eo with several other large sites including Ta Keo (the probable port) and Angkor Borei. The latter was continuously occupied from the late centuries BC onwards, and was contemporary with and shared similarities in material culture to Oc Eo, which suggests the two were part of the same polity (Stark et al. 1999). The lower Mekong delta state, however, was not an isolated polity in its early years, as other contemporary maritime-oriented states appear to have existed on the west coast of the Malay Peninsula and in west Java (Wisseman 1995).

From the mid-first millennium AD, more historic Southeast Asian states are known (e.g., Chenla, Dvaravati, Champa, Kedah, Srivijaya), and these exhibit a shared incorporation of Indian legal, political, and religious ideas and institutions, including the use of Sanskrit names by rulers, as seen in stone inscriptions (first in south Indian and then indigenous scripts), and in the layout and styles of religious architecture and carvings. While 'Indianization' (the view that statecraft was brought to Southeast Asia by Indians) is no longer accepted, relatively little is known about indigenous sociopolitical processes in polities which immediately preceded the early historical states, including whether they already represented emerging states.

State polities may have existed earlier in northern Vietnam, prior to Han expansion, and this is an issue which requires further consideration and investigation. Several research projects aimed at understanding state development on the mainland have been initiated in central coastal Vietnam, the area of the Cham state (Glover and Yamagata 1995); the lower Mekong delta, an area associated with 'Funan' (Stark et al. 1999); and northeastern Thailand (Higham and Thosarat 2000). Throughout Southeast Asia, fundamental theoretical and empirical issues related to state formation remain, including the definition of a 'state,' the relevance of Western theoretical conceptualizations of states and of indigenous political theory, the dating of the earliest states, and the interplay of ideological, social, economic, and other factors in the transformation to states (see *States and Civilizations, Archaeology of*).

3. *Issues of Culture and Chronology*

'Diversity' is often used to characterize Southeast Asia (e.g., linguistically, ethnically, religiously), and this certainly applies to the premodern and prehistoric periods, in which, for example, at any point in time during the last two thousand plus years there existed various social formations from small, mobile hunter-gatherer groups to large, regional state polities. Consequently, the application of cultural frameworks derived from elsewhere in the world has been criticized, and attempts have been made to develop locally specific ones (e.g., Bayard 1984). Nevertheless, the challenge remains to develop cultural-chronological frameworks that do not rely on assumptions of simultaneous 'progressive' regional transformations. Related to this problem is the paucity of well-dated regional archaeological sequences, and the continued reliance on a few 'key' sites or artifact 'types' for dating, interpreting, and explaining Southeast Asia's pre- and early history; both reflect a need for more institutional and economic resources for archaeology in this region.

4. *Future Research Directions of Southeast Asian and Western Archaeologists*

The establishment of chronometrically anchored local sequences will continue to be an aim of much of the archaeological research conducted in the near future. Within the community of Southeast Asian archaeologists, future directions (as expressed at the first International Colloquium on Archaeology in Southeast Asia in the 3rd Millennium, 1998) include more collaborative projects and comparative research; development of theoretical- and problem-oriented research; theoretical contributions to world archaeology; the application of anthropological (also in combination with historical) approaches to archaeological investigation and interpretation; regional as opposed to single-site investigations; and analysis of entire assemblages (particularly in the case of stone tool studies). In addition, Southeast Asian and Western archaeologists will continue research on issues now beginning to be raised, such as local processes of domestication and plant cultivation; the impact and contesting of European colonialism by various social groups; pre- and early historic gender systems and ethnicity; the role of foreign religions (Hinduism, Buddhism) in indigenous social processes; and how nationalism and colonialism have impacted archaeological practice in Southeast Asia.

Southeast Asia: Sociocultural Aspects

Southeast Asia includes the ASEAN states of Brunei, Indonesia, Malaysia, the Philippines, Singapore, Myanmar, Thailand, Cambodia, Laos, Vietnam, and the territory of East Timor. Despite its extreme diversity in terms of population density, ethnic groupings, religion, politics, and economic development the area has common characteristics, many of them constructed by social scientists and politicians, that are increasingly recognized. In addition to the nation-building efforts of individual governments a common Southeast Asian identity has emerged, at least in the urban middle classes.

1. The Sociocultural Construction of Southeast Asia

1.1 Conceptualizing Southeast Asia

Southeast Asia has undergone a multitude of crises, economic, political, cultural, and social. Most of these have resulted in a fresh look at what course Southeast Asian societies have taken, and what concepts and theories can be used to analyze new developments. As a matter of fact, some of the new concepts and paradigms have been exported to other world regions, utilized and generalized and entered into the realm of general theory, while their procreators and their region of origin have often been forgotten. Dualism, plural societies, involution, strategic groups, or loosely structured social systems are by now standard terms in social science research, though originally they were empirically-based concepts used to describe Southeast Asian social conditions.

What we now call Southeast Asia has gone through a cycle of the social and political construction of itself. As Said (1978, p. 5) has rightly asserted 'geographical and cultural entities … are man-made.' Localities are not given, but socially constructed. To mention just a few terms that over time have signified the different external and internal efforts to construct a more or less unified image of the area: the 'Golden Chersonese' of Ptolemaeus, Further-India, Hinterindien, Extrême

Table 1
Conceptualizing Southeast Asia

Early concepts	Contemporary concepts	Future directed concepts
Social structure	Deconstruction	Transformation
Indianization, islamization, dualism	Moral economy of the peasant and of trade	Transnational business networks
Plural societies, loosely structured social systems, and involution	Deconstructing village society and ethnicity	Social transformation
Big men and theater states	Deconstructing class and the state: strategic group formation	Democratization and civil society
Modernization	Modernization of modernity	Globalization
Religious revivalism	Postmodernism, life styling, consumerism, and the new middle classes	Epistemic culture
Urbanization	Globalization and locality	Cultural construction of space

Orient, Nusantara, the Greater co-prosperity sphere, Pacific Asia, Southeast Asia, and, more recently, ASEAN.

Though empirical social science research has been carried out on many divergent topics, a limited number of theoretical concepts have emerged that show a certain consistency over time. The following table (Table 1) proposes a rough guide to the flow of sociocultural research on Southeast Asian societies. It also provides a framework in which to locate major concepts used in anthropological and sociological research on Southeast Asia. Some of these concepts will be explained below.

1.2 Indianization and Islamization

The term Southeast Asia became common use only during and after World War II. Before the area was seen as culturally colonized by its large neighbors India and China. Coedès (1968, pp. 15–16) described the classical states as *États Hindouisés* or in its translation as 'indianized states.' 'Indianization must be understood as the expansion of an organized culture that was founded upon the Indian conception of royalty, was characterized by Hinduist or Buddhist cults, the mythology of the *Purānas*, the observance of the *Dharmaśāstras*, and expressed itself in the Sanskrit language. Far from being destroyed by the conquerors, the native peoples of Southeast Asia found in Indian society, transplanted and modified, a framework within which their society could be integrated and developed.' This marriage of Austronesian and other local cultures with Indian patterns of sociocultural organization has remained a common background, on which later Chinese, Muslim, and European influences have been grafted. The Balinese and several smaller societies, such as the Tengger, maintain the Hindu tradition.

Islam came to Southeast Asia probably as early as the eighth century AD, but became a major force of social and political change only from the fourteenth century onwards. The creation first of a trading and religious, then of a political elite through conversion introduced a new element into the coastal states of Southeast Asia along the straits of Malacca, the Northern coast of Java, Sulawesi, and the Moluccas. The process of Islamization is a still ongoing process. Islamic revivalism is strong in Malaysia and is gaining strength in Indonesia, which has become the largest Muslim country worldwide.

1.3 Religious Diversity and Religious Revivalism

In addition to animistic beliefs and related belief systems, most major world religions are found in Southeast Asia. Indonesia, Brunei, and Malaysia together have the largest Muslim population worldwide. The majority of the population of Myanmar, Thailand, Cambodia, and Laos adheres to Theravada Buddhism, the Philippines has a majority of Christians, and Singapore and Vietnam are characterized by a multitude of religious beliefs often cutting across family and kinship lines, though Confucian ideas are also widespread. The Buddhist monkhood in Thailand (Tambiah 1976), Islam in Indonesia (Geertz 1960), and in Malaysia have been studied mainly in relation to local religious forms.

During the second half of the twentieth century, religious revivalist movements have swept through most of Southeast Asia. In Malaysia a missionary movement (*dakwah*) has led to a resurgence of Islamic practices, especially in the Eastcoast states of Kelantan and Trengganu. In Thailand, middle-class-based religious organizations have preached a return to Buddhist values. The Javanese mystical tradition has influenced Muslim brotherhoods or led to the foun-

dation of mystical sects: aliran kebatinan, Subud, and others (Geels 1997). The Singapore government has propagated Confucian values, while Christian sects have proliferated and found new adherents among students and young upwardly mobile employees.

1.4 Ethnic Diversity

Boundaries between ethnic groups are blurred, and there are differences between self-interpretation and ethnic classifications imposed by others. In Singapore, the population officially is classified into Chinese, Indians, Malays, and others (usually identified as Eurasians and Caucasians), though there are many more self-ascribed categories. The Malaysian government distinguishes between *bumiputra* (sons of the soil) and immigrants, but there are also *Orang Asli* (aborigines), Indians, and Chinese. People of Arab descent no longer are seen officially as a separate group, but in Indonesia the culture, legal system, and language of larger ethnic groups as Javanese, Balinese, Batak, Minangkabau, and many others are recognized and expressed in cultural, though not political terms. In Thailand, Laos, Myanmar, and Vietnam the lowland population is distinguished from 'hill tribes,' an ethnically and linguistically diverse population (Kunstadter 1967). The difference between a lowland, rice-growing peasant society and nonsedentary 'tribal groups' practicing shifting agriculture has been emphasized but is disappearing slowly due to assimilation or replacement.

The peoples of Southeast Asia have also been classified along linguistic lines. Despite recent criticism, the classification into Sino-Tibetan, Austro-Asiatic, Tai-Kadai, and Malayo-Polynesian is still widely used (LeBar et al. 1964, 1972).

In most countries or regions we can distinguish one dominant lowland and several upland satellite societies. Anthropological and sociological research has enriched our knowledge of the major societies that have been politically dominant in the formation of pre- and postcolonial states, but also the large number of smaller societies from hunter and gatherer societies, like the Orang Asli groups in Malaysia, to larger groups, like the Shan and Kachin in Myanmar (Leach 1954), the various 'hill tribes' of Thailand, Laos, and Vietnam (Kunstadter 1967), or the matrilineal Minangkabau of West Sumatra (Kahn 1993).

1.5 Plural Societies

The in-migration of Arab, Chinese, and South Asian migrants in the wake of the expansion of a colonial economy has created what Furnivall termed a plural society, 'with different sections of the community living side by side, but separately, within the same political unit' (Furnivall 1948, p. 304). This ethnic pluralism was transcribed into colonial and postcolonial administrative practice, giving rise to a classification of the population into Chinese, Malay, Indian, and others in colonial and contemporarary Singapore or into indigenous Malays as 'sons of the soil' (*bumiputra*) and migrant communities in Malaysia. Thailand, in contrast, has followed a policy of assimilation, in which all minorities were classified as Thai, whereas in Indonesia the Javanese dominance was balanced precariously by allowing the construction of ethnic, but not political, pluralism in the form of a cultural symbolism of local art forms and dances. Except for Singapore, one common national language has been introduced and enforced with varying degree of acceptance and use in all Southeast Asian states.

1.6 Moral Economy

Geertz and others have underestimated the dynamics of Southeast Asian peasant societies. Rebellions and peasant uprisings have continued well into the twenty-first century (East Timor, Aceh). The 'moral economy of the peasant,' illustrated by Scott (1976) with reference to Vietnamese and Burmese societies, indicates that a subsistence ethic governs peasant behavior. Only if the self-defined subsistence level is threatened have peasants rebelled.

The moral economy also governs petty trade in the informal sector of most of Southeast Asia. The moral obligation of sharing work (*gotong royong* in Indonesia) and profits puts a burden on small traders, mostly women, who find it difficult to accumulate profits to sustain and expand their trading enterprises. There are, however, solutions to this 'trader's dilemma' (Evers and Shrader 1994): where indigenous traders fail, immigrant-trading minorities like the Chinese take over the business. Otherwise, the indigenous traders themselves improve their moral status by forming or joining religious fundamentalist movements, like the Santri traders of Indonesia (Geertz 1965), to escape the pressure of moral obligations. Often trade is carried out on a subsistence level like by female petty traders where the obligation to share meagre profits does not arise because no cash is accumulated.

The informal sector of small handicraft production, petty trade, and other services is widespread in Southeast Asia, has increased in Vietnam during the transformation from a planned socialist economy to a more market-oriented economy, but has declined in Singapore and Malaysia. This sector is playing an important role in cushioning the effects of land shortage in the rice growing areas of Southeast Asia, of rural–urban migration and a general lack of social security provisions.

1.7 Big Men and Theater States

The Austronesian/Melanesian/Polynesian content of Southeast Asian culture becomes evident, the more one proceeds Southeast through Indonesia and the

Philippines. Wolters (1982) has drawn attention to the 'big man' phenomenon, which he locates in Polynesia. The current emphasis on personal prowess, on the power of the oratory and the admiration for superiors and leaders is put into this context. The state and its aristocratic bureaucracy is admired as much in Thailand as in Malaysia or Indonesia.

The state in these countries is highly ritualized and has been named 'theatre state,' following Geertz's analysis of the precolonial Balinese states (Geertz 1980). The state was largely a performance with little administrative or military power. It is debatable whether this analysis withstands the test of historical data, but at least the theme of vagueness, looseness, involution, and theatricality in some Southeast Asian societies pervades the anthropological literature.

1.8 Loosely Structured Social Systems and Involution

John Embree once classified Thai society as 'loosely structured,' thus producing a long-drawn controversy among social scientists (Evers 1980, pp. 163–98). Thai society has a cognatic kinship system, a shallow recognition of descent, and a high degree of individualism, but a highly regulated 'bureaucratic polity' and a tendency to form cliques and patronage. Another, equally unconvincing attempt at using single cultural traits or selected ethnographic details has stressed dualism as a common characteristic of Southeast Asian societies. There was a greater acceptance of the work of Geertz, who classified Javanese society as 'involuted,' by 'overdriving of an established form in such a way that it becomes rigid through inward over elaboration of detail' (Geertz 1963, p. 82). This process applied mainly to wet rice agriculture and its tenancy system, but was seen at work by other scholars also in other regions like the Philippines or Thailand, or in the relatively slow process of Southeast Asian urbanization up to the middle of the twentieth century (Evers and Korff 2000).

2. Contemporary Southeast Asian Studies

2.1 Diasporas and Business Networks

Migrant communities, like the Overseas Chinese originating from Southern China, the South Indian Chettiar, or the Hadramaut Arabs, have been classified as trading minorities in view of their economic position in Southeast Asian societies. Others have migrated to Southeast Asia in large numbers at the beginning of the twentieth century to work in plantations, mines, and the construction sector. Chinese business has been studied in great detail. Singapore has become the centre of the Chinese business community (Chan and Chiang 1994, Menkhoff and Gerke 2001). Confucian ethics, patrilineal kinship-based networks, and the patriarchal organization of family firms have been held responsible for economic success and the predominance of the Nanyang Chinese. Prosecution, discrimination, or conflict have strained interethnic relations in Malaysia, Indonesia, and Vietnam.

2.2 Social Class and Strategic Group Formation

Colonial Southeast Asian societies were 'moulded on racial principles: belonging to the dominant white upper caste provided one with prestige and power largely independent of one's personal capabilities. A strict ritual was introduced and maintained, by force when necessary, to preserve the white caste from contacts with Asiatics on a basis of equality and to maintain the former's prestige as the dominant group' (Wertheim 1968, p. 432).

In the course of decolonization and modernization Southeast Asian societies have undergone a process of class formation (Evers 1973, pp. 108–31). The colonial upper classes were replaced by ethnically differentiated elites, in which indigenous aristocrats, Chinese and European business people, and the upper ranks of a fast-growing bureaucracy and military officers played a major role. The concept of strategic group can be used to analyze this new situation more adequately. The pattern of strategic group formation differed from country to country. In Thailand, which had escaped the fate of colonialism, the growing bureaucracy, backed by sections of the military, revolted against the aristocracy and replaced the absolute monarchy in 1932 with a new regime, in which the strategic group of the military gained the upper hand, until a growing group of professionals, university lecturers, and students managed to establish a democratic government. Strategic group conflict continued, mediated by the electoral process, and put big business into power in 2001. Similar strategic group conflicts, rather than class struggle, signified the situation in most countries, except perhaps in the socialist states of Vietnam and Laos, were party cadres, another strategic group, maintained power after the communist victory in the Vietnam War. The partial reprivatisation of land and the deregulation of the economy introduced, however, new social processes from rural–urban migration to corruption of government officials and the formation of a group of newly rich businessmen.

Class formation moved ahead and the growth of a middle class became a much researched topic in Southeast Asia (Robison and Goodman 1996, Chua 2000). The growth of a new middle class was seen as a basic requirement for democratization and the building of a civil society. Whereas in Thailand, the Philippines, and in Indonesia a civil society with a proliferation of nongovernment organizations (NGOs) developed and pressed for reformation and

the introduction of democracy, the prodemocracy movement was crushed in Myanmar, while the strategic group of military officers stayed in power.

Middle classes have developed a special life-style of their own that blends Western consumerism with elements of Asian modes of living. Hawker centers, food courts, and markets exist alongside big department stores, pizza parlors, and hamburger outlets. The anthropology of Southeast Asian food has to be concerned with syncretism and life-styling as much as religious symbolism.

Along with the demand for consumer goods, the demand for knowledge also increased. In fact, the ASEAN region has undergone a tremendous expansion of higher education. In the core states Thailand, Malaysia, Singapore, the Philippines, and Indonesia the number of students and teachers, and of secondary schools, colleges, and universities, has risen dramatically. Malaysia and Singapore, in particular, are on the way to become knowledge societies, where economic and social development is increasingly knowledge driven. Most ASEAN leaders and governments have developed visions of the future that are targeting a knowledge society as a way to achieve parity with the Western world. This vision is but one in a long line of ideas on how Southeast Asia should be seen, interpreted, and eventually constructed.

2.3 Family and Gender Relations

The small nuclear family is widespread, or has become the norm more recently as in Vietnam (Pham Van Bich 1999) or among Singapore Chinese. The position of women has been regarded as strong throughout Southeast Asia; in particular in matrilineal societies like the Minangkabau (Kahn 1993). Demographic changes and the decline of fertility due to family planning has strengthened the position of women in Thailand, Vietnam, and Indonesia, giving them greater control over their own lives (Gerke 1992). Industrialization and the employment of female factory workers, especially in the garment and electronics industry has led to migration and chances for educational attainment but also to exploitation and harassment of women (Heyzer 1985, Sen and Stivens 1998).

2.4 Globalization, Urbanization, and Locality

Right into the 1980s Southeast Asia, except the city state of Singapore, showed only relatively low rates of urbanization. Since then urbanization has taken off, creating large urban conglomerates like the Greater Bangkok area, Jabotabek (Jakarta, Bogor, Tanggerang, Bekasi), the Manila Metropolitan Area, and the Klang Valley in Malaysia including the federal territory of Kuala Lumpur, the new administrative city of Putrajaya, and the high-technology center Cyberjaya. Southeast Asian urbanism has its roots in the Chinese-influenced walled city form, like Bangkok or Mandalay, the Malay or Muslim ports like Malacca, Banten, or Makassar, the court cities like Yogyakarta, and the colonial cities like Yangoon, Singapore, or Manila (Evers and Korff 2000). Next to the city centers with their culturally globalized population, we find localities of migrant groups, still maintaining a sociocultural flavor of their own. The various China towns, 'Little India' in Singapore (Siddique and Shotam 1982), or localities in Greater Manila (Berner 1997) should not be seen as remnants of traditional culture, but newly constructed forms of urban society.

2.5 Cultural Analysis

Southeast Asian cultures as systems of beliefs, values, symbols, and presentations are as diverse as the ethnic plurality of the local and migrant population. This diversity was analyzed in detail in earlier anthropological studies (Koentjaraningrat 1985, Boon 1977, Lombard 1990, and many others). There are, however, some underlying trends that have been used to construct national cultures or an ASEAN identity. The family and its values, reaching decisions through consensus rather the majority vote and a religiously grounded work ethic have been stressed in a debate on Asian values. Social scientists have taken up the cultural analysis of modernity (Hooker 1995). In his study of Thai, Indonesian, and Philippine middle-class culture, Mulder (1992) has stressed the reinterpretation of classical concepts for the construction of modernity.

The knowledge on Southeast Asian societies is increasing fast (Halib and Huxley 1996). Most of the relevant books and articles are still produced by foreign scholars, affiliated to universities or research institutions around the globe, but an increasing proportion of works are written by Southeast Asian nationals or by scholars, attached to Southeast Asian universities. An epistemic culture of local Southeast Asianists is emerging, contributing to a further construction of Southeast Asia as a sociocultural unit.

Southeast Asian Studies: Culture

1. *Southeast Asia as a Cultural Region*

The study of culture in Southeast Asia was from the beginning influenced by debates among Western scholars as to just what comprised the region. Before and after World War II, there was a tendency to merge the study of Southeast Asian culture with that of India, as evident in references to the region as 'greater India.' This approach highlighted the extensive borrowing that had taken place between parts of the region and India in the pre-modern era. But the characterization was not helpful for understanding the many local populations less affected by these exchanges, including Muslims, Southeast Asian Chinese, and nonstate peoples living in the region's vast hinterlands. The characterization also failed to do justice to the selective ways in which pre-modern Indian influences have been integrated into the mosaic of modern Southeast Asia.

In the 1950s and 1960s, the institutionalization of Southeast Asian studies in Western universities led some scholars to attempt to devise a less derivative list of cultural traits that might allow researchers to visualize Southeast Asia as a culture area in its own right. Early iterations of this approach identified a number of traits as prototypically Southeast Asian:

(a) the high status of women, especially by contrast with China and India;

(b) court ceremony and high arts, both with strong Indian influences;

(c) the resilience of ancestral and spirit cult traditions alongside world religions;

(d) the prevalence of nuclear families and cognatic (or bilateral) kinship as opposed to extended families and unilineal descent systems; and

(e) a marked contrast between the egalitarian cultures of upland dry farmers and the hierarchical ways of the wet-rice lowlands.

Although this effort to bundle traits into a convincing cultural typology helped to distinguish the region from India and China, it also suffered from conceptual blind spots. Some Southeast Asian societies display few of these traits. Equally serious, typological approaches of this sort provide few clues as to how the elements that comprise any specific culture are integrated into a meaningful whole. In the 1970s, then, bundled typologies gave way to two new approaches to the study of Southeast Asian cultures: historical-dynamic approaches that examine the diffusion and integration of diverse elements into local cultures over time, and the 'thick description' of individual cultures in specific social settings.

1.1 Historical-dynamic Approaches to Cultural Variation

Dynamic approaches to Southeast Asian culture recognized that Southeast Asia lacked the cultural integration characteristic of China and India, but attempted to demonstrate that there was a unity to Southeast Asia in the way in which different populations integrated incoming elements into a unique cultural whole. In religion, for example, Southeast Asia today is home to large numbers of Muslims, Buddhists, and Christians, as well as small populations of Hindus (immigrant and indigenous). Alongside each of these religious communities, there are also strong traditions of shamanism, ancestral veneration, monistic mysticism, and guardian-spirit veneration. Rather than seeing this religious diversity as evidence of cultural incoherence, historical-dynamic approaches to Southeast Asian culture emphasize that local populations have selectively appropriated external cultural influences in a manner that reflects their own exigencies and constraints.

This selective appropriation of cultural elements appears to go far back in time. Recent studies have demonstrated, for example, that from the first centuries of the Common Era to the thirteenth and fourteenth centuries, Saivite Hinduism was the predominant cultic tradition at courts across Southeast Asia. Just as Greco-Roman civilization provided a model of cultural excellence for courts and high-status people in the pre-Christian Mediterranean, Hindu civilization provided the symbols of distinction in law, literature, the performing arts, state ceremony, and religion. Even today, the aesthetic traditions and ceremonial customs of many Southeast Asian societies show strong 'Indic' (Indian-influenced) inflections. Vietnam, the Philippines, and Southeast Asia's non-state hinterlands were not much involved in this cultural exchange. However, even in regions exposed to the full force of Hindu influence, there was clear selectivity in the appropriation of foreign elements. As with Hinduism in contemporary Bali (Warren 1993), bits and pieces of India's caste traditions were incorporated into religious ceremony and the social hierarchy, but no population in Southeast Asia ever implemented the full range of regulations operative among Indian Hindus in matters of diet, marriage, and everyday commensality. Similarly, the restrictions on women's autonomy seen among Indian Hindus (or, when making the comparison for Islam, Middle Eastern Muslims) exercised less influence in Southeast Asia, where women's public roles remained relatively high. Rather than 'failed' Hinduization, this resistance to caste and restrictive women's roles showed the continuing influence of Southeast Asian notions of commensality and female autonomy.

The dynamic approach to the study of Southeast Asian culture has also been used to examine key aspects of political and economic culture in Southeast Asia. In the 1960s and 1970s, political scientists and anthropologists used their understandings of local culture to assess the impact of nationalism and nation building on Southeast Asian societies. As with Clifford Geertz's (1973) reflections on the 'integrative revolution' in postcolonial Indonesia, this research was initially concerned with the prospects for peace and integration in an unstable region. The nationalist project in Southeast Asia was seen as particularly daunting owing to the deep ethnic and religious divides in most countries. The concern for nation building has remained a key theme in analysis of Southeast Asian politics to this day. Rather than linking their research to questions of national stability, however, recent studies have examined the cultural terms through which the nation is 'imagined,' and highlighted the role of elites in manipulating the 'invention' of national tradition for their own ends (Keyes et al. 1994, Tonneson and Antlov 1996, Winichakul 1994).

As these examples illustrate, one of the distinctive features of cultural analysis in Southeast Asia has long been that it is applied, not just to the usual domains of religion and the arts, but also to politics and economics. In Thailand, the political scientist Fred W. Riggs (1966) drew on anthropological studies of Thai society in assessing the prospects for sustained economic growth. Riggs characterized the Thai state as a 'bureaucratic polity,' suggesting that it was so thoroughly preoccupied with parasitic patronage that any sustained economic initiative was unlikely. Bureaucrats regarded Sino-Thai businesspeople as 'pariah entrepreneurs,' and restricted their operations accordingly. As Ruth McVey (1992) has observed, Riggs was right to emphasize the tensions between

political and economic culture in Thai society, and to imply that corruption might remain a brake on economic progress. However, Riggs failed to anticipate the speed with which capitalist culture took hold in Thai society in the 1970s and 1980s. Popular society and bureaucratic culture both proved more open to new styles of production and new modes of conspicuous consumption than cultural analysts had earlier predicted.

In a related study of indigenous enterprise in Java and Bali, the anthropologist Clifford Geertz (1963) reached a different conclusion than Riggs. Geertz argued that there were extensive cultural resources for market development in both of these Indonesian societies. In Java, Geertz observed, a culture of enterprise was taking shape among Muslim entrepreneurs marginal to the local (court-based) status hierarchy. In Bali, by contrast, the carriers of the market revolution were aristocrats intent on displaying their distinction in market enterprise to neutralize challenges from upstart rivals.

Although both applied cultural analysis to the study of economic change, Riggs and Geertz's conclusions were, curiously, inverse images of each other. Riggs attributed too great a hold to culture, and thus failed to anticipate the flexibility Thai society would show in the face of new economic initiatives. By the 1980s, capitalist culture in Thailand showed an 'increasing intimacy and equality between business and political leadership' (McVey 1992, p. 22). If Riggs' preoccupation with politics led him to exaggerate the conservatism of Thai culture, Geertz was too optimistic precisely because insufficiently attentive to the political. His gaze focused on local entrepreneurs, Geertz failed to notice the looming structural impediments to indigenous enterprise. Already in the late 1950s, the Indonesian military had become a major player in the national economy. Concerned that an independent business class might challenge their power, after 1965 military and civilian elites channeled contracts and concessions away from indigenous entrepreneurs toward wealthy Chinese and cronies reluctant to protest against mandatory kick-backs and sweetheart deals. The native entrepreneurial class that Geertz had lionized declined precipitously.

The Thai and Indonesian examples remind us of the dangers of seeing culture in too-static terms, or isolating it from the social and political worlds that constrain its development. Recent studies of the culture of capitalism in Southeast Asia have adopted just such an interactive approach to culture and sociopolitical structure in their efforts to understand the economic boom of the 1980s and early 1990s. Although attentive to the legacy of ethnic and religious culture, these studies also emphasize that culture is not a finished script or program, but an open body of knowledge continually reconstructed in the face of changing social and political realities (Hefner 1997, Li 1989).

Historical-dynamic approaches remain a key instrument in the study of Southeast Asian culture; they also serve to counteract the tendency to think of culture in purely local terms. Two historians, Denys Lombard (1990) and Anthony Reid (1988 and 1993), have both made especially significant contributions to the study of Southeast Asian culture on such a grand scale. Tracing cultural developments in the arts, economy, politics, and religion since the early modern era, both authors show that Southeast Asian culture has long been affected by globalizing forces and transnational flows. Historical linguists (Collins 1996) have recently used a similar methodology to examine the diffusion of Malay language across vast stretches of island Southeast Asia in the early modern era. Malay's spread, these studies demonstrate, was intertwined with the expansion of Islam and Malay-based commerce. In these and other examples, historical studies reveal that the cultural variation seen in Southeast Asia is the result, not of slumbering societies lost in time, but of vibrant regional networks and globalizations with deep historical precedents. Southeast Asian culture was 'globalized' well before the late twentieth century.

1.2 Thick Descriptive Culture

Dynamic approaches to the study of culture arose through the efforts of historians and others to explain Southeast Asia's diversity and to illuminate the creativity of Southeast Asians in appropriating external influences. Locally oriented, 'thick' descriptions of culture, by contrast, had less to do with Southeast Asian studies as such than they did a methodological shift in the human sciences in the 1970s and 1980s. The shift was premised on a new skepticism toward general theory, especially the modernization variant, and a heightened interest in local lifeworlds and meanings.

The single most influential writer on Southeast Asian culture, Clifford Geertz's intellectual biography illustrates this subtle shift in the terms of cultural analysis. In his early years, Geertz had been a student of modernization theory, especially that version promoted by his two mentors, Talcott Parsons and Edward Shils. As in his *Religion of Java* (1960) and his, *The Interpretation of Cultures* (1973), Geertz's concept of culture at first owed much to the Parsonian model of culture as a system of meanings in ongoing interaction with institutions and patterned action (the 'social system'). According to this model, rapid social change causes serious instability when it runs so far ahead of the cultural system as to make difficult the development of new systems of meaning capable of orienting collective behavior. In his analysis of religion in Java, Geertz identified three subtraditions (an Islamic, a syncretic, and an elite-aristocratic) and speculated that Indonesian social structure was changing more rapidly than these cultural traditions could accommodate. The resulting discontinuity between

structure and meaning, Geertz argued, was likely to give rise to serious religious conflict and political instability.

Even in his early works, however, Geertz used other methodologies that showed great sensitivity to the nuances of local context and meaning. In the late 1960s and early 1970s, as interest in modernization theory waned, Geertz shifted his attention away from general theory and broad analyses of modernization toward the 'thick description' of local lifeworlds, performances, and meanings. If commented on at all, regional movements and transcultural flows were distant concerns at best. This was to be a hallmark of cultural research in Southeast Asia for the next 20 years.

One salutary effect of this heightened skepticism toward general models and macrohistorical generalizations was that students of Southeast Asia were able to explore a range of topics neglected in earlier theories. There was, for example, an efflorescence of research on the interaction between local culture and great religious traditions. With its split gaze on Buddhism and indigenous religion, S. J. Tambiah's (1970) study of Buddhism and spirit cults in northeast Thailand represents an early and paradigmatic example of this new approach. Rather than portraying local religion as a 'little' tradition playing catch up to modernized forms, the ever-unfinished interaction of the two traditions was seen as the key to religion's vitality. Students of religion in Muslim Southeast Asia were slower to apply a similarly bifocal approach to Islam. As John Bowen (1993) has observed, they often neglected to examine the textual and normative bases of Islam, concentrating instead on syncretisms and exotic local customs. This neglect of the normative reflected the lack of training in Arabic and Islamic textual traditions among Southeast Asian specialists of Islam. Some argue that it also reflected the conviction among certain scholars that, unlike Buddhism, Islam was only a nominal influence on Southeast Asian culture as a whole. In the 1990s, however, as thick description began to be complemented by cross-cultural comparison, researchers made the balanced examination of transregional Islam and local tradition a hallmark of revitalized Islamic studies (Bowen 1993).

Another area of cultural research that showed new vitality in the aftermath of modernization theory's demise was the study of women and gender. Because of the unusually public status of women even in traditional societies, gender had from early on been a focus of attention in Southeast Asian cultural studies, as illustrated in the pioneering works of Hildred Geertz (1961) and Rosemary Firth (1966). Influenced by feminist studies and social constructionist understandings of gender in anthropology, however, in the 1980s and 1990s gender issues moved into a far more central position in Southeast Asian studies as a whole. Whereas earlier studies had examined gender from the perspective of the household and family, the new generation used gender as a point of entry to a broader and often more political array of concerns. Aihwa Ong (1987) looked at female factory workers to examine the dynamics of gender, capitalism, and Islamic resurgence in Malaysia. Pham Van Bich (1999) used changes in family and gender roles to provide a unique perspective on the achievements and shortcomings of the Vietnamese revolution. More generally, the study of gender in Southeast Asia has been used to challenge Western-derived understandings of the public and private spheres (Peletz 1996).

With this heightened sensitivity to gender, and with the growing influence of subaltern studies in the new field of cultural studies, there was growing interest in the early 1990s in the study of marginal groups and in the cultural construction of 'marginality' itself (Tsing 1993). Some proponents of this research opposed all forms of comparative and translocal research, arguing that broad comparisons only did violence to local life worlds. As this research moved forward, however, it inevitably gave rise to its own comparative questions. Gender inequalities in one society raise questions concerning the conditions that facilitate gender equity in others. Marginality raises questions concerning citizenship and the processes by which local actors might control the terms of their participation in the public sphere. As these examples hint, the fine-grained thick description of the 1980s had, by the late 1990s, given rise to a renewed interest in cultural comparison, translocal communication, and globalization.

2. *The Return of the Translocal*

The effort to apply in-depth local cultural research to translocal and comparative issues is not a new one in Southeast Asian studies. As noted above, it was always a feature of cultural history in the region. Similarly, literary research has long shown a lively interest in the changing uses and meanings of texts as they move across time and social space (Sweeney 1987). In the late 1970s, one anthropologist attempted to carry out comparative ethnography, examining reformist Muslim psychology in Malaysia, Singapore, and Indonesia (Peacock 1978). It would be years, however, before other anthropologists would follow his model. Finally, and very important, the study of Chinese culture in Southeast Asia has always been a great exception to the tendency to ignore comparison or focus simply on the local. In both anthropology and history, studies of Southeast Asian Chinese have always examined the movement of people and ideas across national borders and sought to understand the way in which local environments inflect Chinese culture. Recent research shows that this concern remains as vibrant as ever (Dobbin 1996, Reid 1996).

Another important precedent for comparative and translocal research in Southeast Asian studies has

been the study of the specifically cultural dimensions of nationalism. With its attention to the impact of vernacular education, colonial culture, religious reform, and new forms of public association on Malay political identity, William R. Roff's (1967) study of the origins of Malay nationalism was an early and exemplary example of just such a line of research. Anthony Milner's (1994) more recent study begins from a similar historical base, but shows an even more deliberate concern with the question of whether Southeast Asian modernity is unique or reflects political challenges general to the modern world. With its comparisons to Western debates on liberalism and communitarianism, Beng-Huat Chua's (1995) study of culture and politics in Singapore shows a similarly refined balance between the study of local cultures and comparative reflection on the modern condition as a whole.

As researchers look to the future, it seems inevitable that efforts like these to balance local research with regional and cross-cultural comparison will become more common. Because many Southeast Asian societies have always been deeply multicultural, it has been difficult here to ignore comparisons or, conversely, dissolve specific cultures into a general analytic brew. At the same time, Southeast Asia's position as a locus of civilizational interaction has helped to sensitize scholars to the fact that cultural 'globalization' is by no means a new phenomenon. Whether in the study of politics, gender, or economic culture, Southeast Asia also shows that trans-regional flows and globalization are not necessarily part of a long march toward a drearily homogeneous modernity. In this crossroads of civilizations, the most enduring cultural globalizations have always been those able to take root and 'localize.'

R. W. Hefner

Southeast Asian Studies: Economics

The ten countries of Southeast Asia—Brunei, Cambodia, Indonesia, Laos, Malaysia, Myanmar (also still known as Burma), the Philippines, Singapore, Thailand, and Vietnam—soon to become eleven when East Timor obtains its independence, have a population of approximately 503 million persons, and an aggregate gross domestic product (GDP) of some $578 billion.

Their population is similar to that of the entire Latin American and Caribbean (LAC) region, about 80 percent of that of Sub-Saharan Africa (SSA), and 80 percent larger than that of the Middle East and North Africa (MENA). Their combined economies are similar to totals for South Asia and MENA, about 90 percent larger than SSA, about 60 percent of that of China, and about 30 percent of the LAC total.

With an average per capita GDP of $1,150 in 1998, the region is quite poor—about 50 percent above that of China, and almost treble that of India, but only about one-quarter of that of the large Latin American countries, Brazil and Mexico. The average, of course, conceals enormous intraregional differences. Indeed, apart from geographic proximity and membership of a regional association (ASEAN—the Association of Southeast Asian Nations), the countries share very few common characteristics. For example:

(a) They include countries both very rich (Singapore, with a per capita income of more than $30,000) and extremely poor (the four mainland Southeast Asian states, other than Thailand, have per capita incomes of less than $400, as does East Timor).

(b) They include economies which have been consistently among the most open in the world (Singapore, and to a lesser extent, Malaysia and Thailand) and those which, until quite recently, have been among the most closed in the world (the four mainland states again).

(c) There are mineral-rich economies, most notably the oil sultanate of Brunei, and also Indonesia and Malaysia, alongside the city state of Singapore, whose only real natural resource is its strategic location.

(d) Four of the ten countries have achieved rapid rates of economic growth since the 1960s, for at least three decades—Indonesia, Malaysia, Singapore, and Thailand. Three have generally performed very poorly—Cambodia, Laos, and Myanmar. The Philippines and Vietnam have an indifferent record over this period, taken as a whole, though for certain subperiods their performance has been quite good.

(e) The impact of the East Asian economic crisis, 1997–8, has been very uneven: Indonesia was very badly affected, as were Malaysia and Thailand, whereas the others, although affected to varying degrees, avoided economic contraction.

(f) One country is very large—Indonesia has a population of about 210 million people, the fourth largest in the world; three are sizable—the Philippines, Thailand and Vietnam each have 60–80 million people; while two (Brunei and East Timor) have fewer than one million inhabitants.

(g) There are pronounced subnational differences in all the larger countries: Java and the 'Outer Islands', north and south Vietnam, and East and West Malaysia. Indonesia and the Philippines are the world's largest archipelagic states. Bangkok is often mentioned as one of the most significant examples of a primate city.

This article draws attention to some of the stylized facts of the Southeast Asian economies, the lessons learned from past experiences, and some major ongoing analytical and policy debates.

1. *The Record, Lessons Learnt*

Economic performance and policy regimes in these countries have been episodic in varying degrees. Even high-growth Singapore experienced a mild recession in the mid-1980s, and a slowdown in 1998. The Philippines performed quite well until the late 1970s and during the mid-1990s but, like much of Latin America (with which it is often compared), it experienced a 'lost decade' during the 1980s. In the late 1980s Vietnam instituted significant liberalizing economic reforms under its 'Doi Moi' (renovation) banner, and in consequence its economic performance improved markedly. Indonesia swung from Sukarno's dirigisme, nationalizations and hyperinflation in the first half of the 1960s to economic orthodoxy for most of the Suharto rule (1966–98). Even Myanmar effectively renounced its one-time 'Burmese Road to Socialism' and isolation in the late 1980s, although, owing to its poor human rights record, it remains an international pariah state.

In such a heterogeneous region, generalizations are risky. Nevertheless, the following observations apply to many of the countries most of the time. First, rapid economic growth has been associated with profound structural change. As incomes have risen, the share of agriculture in output and employment has declined, at first as a proportion of the aggregate and at higher incomes in absolute terms. In Malaysia and Thailand, agriculture now contributes only about one-tenth of GDP, whereas in Cambodia and Laos its share is still about one-half. The slower the growth, the slower the rate of structural change. In the Philippines, for example, the share of manufacturing in GDP has not risen appreciably since the late 1960s.

Second, sustained economic growth is associated almost invariably with improved living standards and reduced poverty. In all the high-growth economies, there have been pronounced social improvements: education enrolments and life expectancy have risen, infant mortality and poverty incidence have fallen. Nevertheless, the key to poverty alleviation has been 'growth plus'. While there is less agreement over just what constitutes the 'plus,' the core elements almost certainly include the provision of basic public goods (e.g., primary education and health), an 'inclusive' labor-intensive growth path (especially one which combines outward orientation), and a reasonably equitable distribution of wealth and social opportunity.

There are, of course, marked differences. The Philippines had a head start in educational standards,

but over time the gap has narrowed. Regional differences also persist: Indonesia's eastern provinces are mostly poorer and have grown more slowly; Thailand has been concerned about its lagging northeast region; the northeastern states of West Malaysia are poorer than the more prosperous west and south; the southern regions have been more dynamic than the north in Vietnam. Particularly in Indonesia and Malaysia, much of the focus on distribution has an ethnic dimension, an issue to which we return below.

Third, we have at least a proximate understanding of the causes of economic growth, in Southeast Asia and elsewhere. Economic growth has been associated positively with—and by implication caused by—at least the following factors:

(a) macroeconomic orthodoxy, resulting from an appropriate mix of monetary, fiscal and exchange rate policies, has achieved a predictable and low inflation environment;

(b) openness to foreign trade, investment, and technology (and in some cases, labor);

(c) financial development, including effective prudential supervision;

(d) reasonable distribution outcomes, and a community perception that the benefits of growth have been 'fair';

(e) a set of political and legal institutions which, while not necessarily enshrining well-developed democratic principles, has at least ensured some measure of responsiveness to community concerns, including judicial redress and protection of property rights; and

(f) the public provision, or the coordinated private provision of, physical infrastructure at world competitive prices.

The particular 'fit' of these propositions to each country has, of course, varied considerably. But the higher a country has 'scored' according to these criteria, the better its long-term performance has been. Naturally, these factors do not take account of major insurrections (which plagued much of Indo-China until the late 1970s), serious political disturbances (a factor in Indonesia in 1965–6 and 1997–8 and the Philippines in the decade 1982–92), major seismological events (the Philippines again), or the systematic destruction of physical infrastructure (East Timor in late 1999).

Fourth, to varying degrees, these have been flexible economies, both in their policy regimes and their factor markets. Adverse exogenous shocks, such as a deterioration in the terms of trade, have resulted in compensating exchange rate and/or labor market adjustments. Indonesia in the early and mid-1980s is a good example of this proposition. When a strategy has not worked, or has been overdone—e.g., Singapore's high-wage policy in the early 1980s, Malaysia's high-tech ambitions in the 1980s—governments have introduced remedial measures. The presence of large numbers of migrant workers, often illegal, has facilitated labor market adjustment in Malaysia, Singapore, and Thailand. However, it is possible that some of these economies are becoming less flexible over time, as was evident in the crisis of 1997–8. Long-lived regimes in Indonesia and Malaysia were either unable or unwilling to introduce some of the bold reforms required by the international donor community. A similar problem afflicted the late Marcos period in the Philippines. Labor market regulations in Indonesia and the Philippines in the 1990s resulted in less flexibility. Vietnam's reforms seemed to have run out of steam by the mid–late 1990s. However, these economies generally remain more open and flexible than those of Latin America and South Asia.

Fifth, globalization, regional integration, and national economic integration have all proceeded more or less hand-in-hand throughout the region, to varying degrees, since at least the late 1980s, and a good deal earlier in some countries. Each has been propelled by different sets of factors. More open policy regimes have been introduced as suspicion towards markets and fear of Western commercial domination have waned. Initial reform successes have spawned coalitions favoring continued reforms. International institutions such as the IMF and the WTO have to some degree underpinned the process. Differences within the region remain very significant, however. Singapore has removed practically all obstacles to merchandise trade, but not services. Malaysia too has a very open goods sector, though in 1998 it introduced controversial controls on short-term capital movements. By contrast, the four poor economies of mainland Southeast Asia have barely established formal tariff codification provisions, nontariff barriers are often ill-defined (and are sometimes applied arbitrarily), and foreign investors have limited judicial protection.

Regional economic cooperation has been consistent with this general thrust toward increasing openness. ASEAN has wisely avoided EU-style bureaucratic concentration in its headquarters, and discriminatory trade policy liberalization. The Association was, however, unable to play an effective role during the region's recent economic crisis (or, for that matter, East Timor's political crisis of 1999).

Finally, there are numerous caveats which might be attached to the growth record, but none invalidates fundamentally the propositions that growth is good for a country's citizens, and that people are generally better off in richer than in poorer countries. Admittedly, the quality of urban amenities in Southeast Asia generally has deteriorated over the past three decades. But, through careful planning, ample resources, and strict controls over private automobile use, rich Singapore has one of the world's highest-quality urban environments. (Although, as illustrated dramatically during Indonesia's forest fires of 1997, it cannot control imported pollution.) Moreover, the most serious urban amenity problems seem to be

evident where rapid population growth and slow economic growth intersect, as in the case of Manila.

It is also probably the case that the quality of rural environments has deteriorated, as topsoils have been eroded, forests poorly (and corruptly) managed, mine wastes disposed of recklessly, and waterways polluted. Here also, economic growth may initially be a negative influence, but ultimately a positive factor, as incomes rise, and with them the resources to improve environmental standards. In addition, some exercises in 'green accounting' suggest that the economic growth in Indonesia and Malaysia may have been overstated by a percentage point or two once account is taken of the exploitation of nonrenewable natural resources, particularly oil and gas. Putting aside the heroic assumptions underpinning such calculations, here too it needs to be emphasized that economic growth in these countries was not explained primarily by resource depletion. Indeed, from the mid-1980s, growth accelerated in both Indonesia and Malaysia even as the share of the natural resource sector in the economy declined sharply.

2. *Some Debates and Puzzles*

While the general picture of economic development and its policy underpinnings may be clear enough, major analytical and policy debates abound, and there remain significant lacunae in our knowledge of the development process. The following are illustrative examples, by no means complete, of some of these gaps and intellectual challenges.

2.1 *The Crisis of 1997–8: Origins and Implications*

This crisis led to an unprecedented decline in output, of about 14 percent in Indonesia, 10 percent in Thailand, and 7 percent in Malaysia in 1998. It caused much social dislocation and hardship, it was instrumental in toppling a seemingly impregnable regime (Suharto's Indonesia), and it shook the region's self-confidence. It also caught governments, international development agencies, investors, and scholars off guard. Just when these groups were variously trumpeting the virtues of 'Asian style' development, making personal fortunes, or attempting to develop an intellectual framework for understanding the unprecedented high levels of growth, there was a sudden collapse. The crisis was not foreseen by anybody, notwithstanding much debate concerning the need for reform and the ills of corruption. There were some early warning indicators in Thailand, manifested in flight out of the capital market and the currency. Perhaps the biggest analytical conundrum was Indonesia: its economy remained buoyant right through to the general onset of the crisis in July 1997, and yet it suffered the most dramatic reversal of fortune in the region, from a precrisis growth rate of about 8 percent to a contraction of 14 percent.

There is still no consensus regarding the causes of the crisis among the development policy community and in its wake, and there are differences of emphases concerning future policy directions. On the causes, technical explanations focus on: (a) the dangers of a fixed but adjustable exchange rate regime which, in the presence of marked differentials between domestic and international interest rates, led to massive unhedged international borrowings; (b) rapidly rising short-term external debt and, more generally, a large stock of highly mobile capital; and (c) a poorly regulated and supervised domestic financial sector, especially in the presence of an open international capital account. Political and institutional explanations emphasize the widespread corruption and cronyism found in much of the region, and the weak state of the legal system, and 'civil society' more generally. A third set of explanations draws attention to international factors, including the rapid build-up of volatile, short-maturity international capital flows, the weak state of the Japanese economy throughout the 1990s, and the heavy-handed conditionality imposed by the International Monetary Fund (IMF) once the crisis had hit. Extending the latter point, a fourth dimension to the literature seeks an explanation not so much in the precrisis 'vulnerability' indicators as in mismanagement following its onset: Apart from inappropriate IMF medicine, this includes governments intent on protecting vested interests rather than reform (Indonesia and Thailand), inflammatory attacks on the international financial industry (Malaysia's prime minister), and loss of control of monetary policy (Indonesia).

Future policy directions are also the subject of much debate. Should countries allow their currencies to float? Will currency boards become attractive, as they were briefly to Indonesia's Suharto in early 1998? Or is Malaysia's fixed exchange rate a preferred option? The latter will normally entail some sort of supervision over short-term capital controls, which Malaysia instituted for 12 months in September 1998, and which continue to find favor among some intellectual circles in the region. Should the financial sector be open to foreign banks, and can central banks be trusted to supervise this sector? How can effective legal systems be developed in countries with poorly paid and demoralized civil services?

2.2 *The Philippines: Why an Outlier?*

Just as Indonesia's sudden economic collapse in 1998 is difficult to explain, so too is the Philippines' poor economic performance longer-term. In the 1950s, this was the country of hope in the region. It was richer than Korea and Thailand. It had the best education record in East Asia after Japan, and a large English-

speaking community. It had a functioning democracy, an independent judiciary, and a vigorous press. Its special relationship with the USA conferred upon it both security protection and privileged access to the US market. Yet, first the NIEs, then Thailand, and even Indonesia for a period, overtook it. Its real per capita income in 2000 was about the same as it was in 1980.

What went wrong? As with the crisis, there is no simple or single explanation, and a smorgasbord of offerings is available. These include:

(a) Technical explanations, which focus particularly on poor macroeconomic management (manifested in consistently above-average inflation rates) and inward-looking trade policies, including high levels of protection and a disequilibrium exchange rate.

(b) Cultural factors, among them the stereotype of a 'Latin American country located in East Asia.'

(c) Corruption and the 'Marcos factor,' particularly the nature of his regime in the last 6–8 years of his 20-year rule (1966–86); sometimes these arguments are extended to include the control by the alleged '20' (or '40', or some other number) ruling families, many of whom are viewed as nondevelopmental in some sense.

(d) Persistent insurrections, especially in the southern island of Mindanao, and the breakdown of law and order, resulting in frequent kidnappings of Filipino Chinese and foreign businessmen.

(e) Bad luck: In the mid-1970s, Marcos's strategy of external borrowing during OPEC I, sanctioned by the World Bank, came unstuck at the end of that decade, not only because the funds were used unwisely, but also because of the unfortunate conjunction of rising world interest rates, further increases in oil prices, and collapsing export prices (first sugar, then coconuts). In the late 1980s, the precarious post-Marcos recovery was jeopardized by a succession of coups and natural disasters, and serious power shortages. Ultimately, all these factors contribute to an explanation, but the puzzle remains, especially as some of these negative factors were also present in better-performing neighboring countries.

2.3 State vs. Market

Attempts to explain East Asian's economic success, beginning with Japan from the late 1940s, have to confront the fact that rapid growth has been associated with extensive, micro level government intervention. There continues to be a major debate over whether, and if so, how, this intervention has been growth promoting. The issue here is not concerned with government investments in physical infrastructure and the provision of social goods, which have usually generated high rates of return and promoted social cohesion. (Although large infrastructure projects have often been corruption-prone.) Rather, it is whether governments have demonstrated the capacity to 'pick winners,' to anticipate better than markets the industries of the future, and to manipulate interindustry (and sometimes interfirm) incentives accordingly.

The empirical evidence in support of this proposition in Southeast Asia is weak. The rates of return on expensive high-tech programs, commencing in the region mostly around the early 1980s, have generally been low, or even negative, even allowing for long gestation periods and substantial learning exercises. The externalities—broader economy-wide benefits—have been minimal. This applies to virtually all such initiatives—Indonesia's strategic industries (especially former President Habibie's aircraft plant), Malaysia's heavy industry program, and the Philippines' major industrial projects. The problem with these programs was not so much corruption, though there was plenty of that, but a failure to appreciate the evolutionary nature of technological innovation and industrialization, and the fact that 'great leaps forward' in a bureaucratically-driven environment rarely succeed. More generally, there is very little support for the proposition that selective industry assistance—via tariffs, fiscal incentives, credit subsidies, and so on—has paid off. Indeed, very often, the most assisted industries have performed the worst.

This is not to say that all forms of selective intervention in Southeast Asia have been unsuccessful. In Singapore, with its very open economy, well-paid bureaucracy, and fierce anti-corruption campaigns, it may well be that certain selective interventions have paid off—such as the goal of establishing the country as a major electronics base, and pushing the industry to upgrade quickly. Agricultural extension programs in several countries have induced farmers to innovate successfully, especially in the adoption of higher yielding varieties. The real challenge for the policy and research community in the region is to identify genuine cases of market failure, and to develop programs which do not exceed domestic bureaucratic capacities. The weaker these capacities—and most in Southeast Asia at the micro level are weak—the more likely the problem of 'government failure'.

2.4 Managing Ethnic and Regional Disparities

Southeast Asia is a region of great diversity, and one of its challenges is managing this diversity while maintaining the development momentum. Two dimensions are especially noteworthy—both long-standing but also painfully evident in Indonesia since 1997.

One is ethnic diversity. One of the colonial legacies was that disproportionate wealth was in the hands of ethnic minorities, particularly in Indonesia and Malaysia where, because of religious differences, ethnic assimilation has been very limited. In both countries, the minority ethnic Chinese community (less than 30 percent of Malaysia's population, and about 3 percent in Indonesia) traditionally has dominated the private, domestic, 'modern sector' economy.

Both countries have sought to maintain economic growth while experimenting with various affirmative action programs. Malaysia's approach, following the serious ethnic disturbances of May 1969, was to develop explicit goals for asset redistribution, employment, and university entrance. Indonesia adopted a more informal style, which included the promotion of state enterprises (especially during the 1970s oil boom), a preference for *pribumi* (indigenous) groups in government procurement, credit, and cooperatives, and occasional presidential cajoling of Chinese businesses to redistribute some of their assets.

The results have been mixed. There has been a major redistribution of assets in Malaysia, although the rising *bumiputera* share has been achieved mainly at the expense of foreign firms. Indonesia under Suharto witnessed the rise of several large *pribumi* conglomerates, mostly 'palace-connected,' and an expansion of *pribumi* managerial employment. It is sometimes argued that Malaysia avoided Indonesia's traumatic ethnic tensions of 1997–8 precisely because it had earlier and comprehensively instituted these programs. But there have been costs—the well-connected have benefited disproportionately, a new class of rent-seekers has emerged in both countries, and it is not obvious that the above approaches have been the most effective policy instruments. Good quality, widely accessible public education is probably the most effective long-term redistributional strategy. Here, both countries score well, though Indonesia much less so on quality grounds. Much more could be done in the way of enforcing a more progressive tax structure, again especially in Indonesia. The fierce resentment toward Indonesia's Chinese community during the recent crisis underlines the fact that governments need a strategy, and need to be seen to be doing something, but there are no 'quick fixes' in remedying such deep-seated disparities.

The second dimension, regional diversity, is equally complex. The record of regional development in the resource-rich countries of Indonesia and Malaysia has been fairly good, in the sense that some quite effective programs have been introduced to ameliorate sharp regional disparities. But in an era where nation states are under challenge as never before, regions with a rich natural resource base are asking why they have to surrender such a large proportion of revenue to the central government, especially when their own social indicators are sometimes lagging behind the national average. The problem has been particularly serious in cases where there is already a long-standing grievance against the central government, as in the Indonesian provinces of Aceh and Irian Jaya (the latter recently renamed Papua Barat, in an attempt to mollify local sentiment). East Timor was a special case, given its unhappy history under both Portuguese colonialism and heavy-handed Indonesian rule. But it is quite likely that other secessionist attempts will be mounted in Indonesia in coming years. Meanwhile, there will be continuing tension through the region between central governments' desire to maintain territorial integrity and national unity, and pressure from below for decentralization and greater autonomy.

2.5 Economic Growth and Political/Institutional Development

A major puzzle is why and how some Southeast Asian countries—especially, but not only, Indonesia—were able to grow so fast for so long in the presence of extensive corruption, much bureaucratic incompetence, and a weak legal system. As a corollary, the literature extolling the virtues of a strong and able civil service, and invoking it as a key explanatory factor in East Asian growth, has been of little relevance to Southeast Asia, with the exception of Singapore, and to some extent Malaysia.

Part of the explanation is that the high growth Southeast Asian economies with these problems had competent macroeconomic management, at least until the first half of the 1990s. If governments get a few key policy variables more or less 'right'—fiscal, monetary, and exchange rate policy; reasonably open trade and investment regimes; a basic national education program; and a predictable policy environment—economies can 'carry' major deficiencies elsewhere.

Another part of the explanation is that corruption is as much a distributional as a growth issue. Most civil service salaries in poorer Southeast Asian countries are below those in the private sector, especially for middle and senior officials, and thus small-scale corruption is a means, however morally reprehensible, of redressing the imbalance. Even grander corruption—for example, much of Indonesia's huge forestry royalties have tended to accrue to well-connected individuals rather than the state—may not necessarily retard growth if the funds are largely recycled through the domestic economy, as in the main they were. (Of course, in consequence, public programs were starved of resources, with short-term distributional and long-term growth implications.) Indeed, there is even a school of thought which, in seeking to explain the pronounced Indian–Indonesian growth differentials in the presence of similar levels of corruption, maintains that the latter's corruption was more conducive to growth because the recipients were more likely to 'deliver.'

But it is clear now that the past regime and practices are no longer sustainable. Perhaps corruption crosses some sort of 'threshold level,' when it so sours public support for a government (for example, the late Marcos and Suharto periods), that there are macro political ramifications. The presence of highly mobile international capital, which can suddenly leave the country if a political crisis develops, imposes a constraint on these governments which was hardly present in the 1980s and before. Continued IMF financial support for the crisis economies is also

conditional upon major institutional reform. Moreover, weak legal and financial institutions may not be a problem so long as the growth momentum is maintained. But they become a problem in times of crisis: bankruptcy laws have to function in order that debt workouts may proceed, for example.

Wide-ranging institutional reform is a complex and lengthy process. Democratization may hasten the process but it is not a simple cure-all. If indeed substantial reform is a necessary prerequisite for a durable recovery, the poorer countries of Southeast Asia may be in for a prolonged period of slower growth.

3. Summing Up

The Southeast Asian countries are important because they are large in aggregate, strategically located, exceptionally diverse, and intellectually challenging. Some analytical and policy issues in the region, as elsewhere, are reasonably settled: social progress follows economic development, and a few factors are absolutely critical to successful development. But region-wide generalizations for Southeast Asia beyond these basic propositions are hazardous. Rich, high-tech Singapore is a world away from the grinding poverty of East Timor and Myanmar. Some countries in the transition from communist to capitalist development have yet to establish the institutions which underpin a modern state that participates in the global economy. Indeed, some of the these states, particularly those on mainland Southeast Asia, are unsure how, and how far, to embrace globalization. The region's largest state, Indonesia, is now grappling with its territorial integrity and possibly even its survival.

For 30 years, ASEAN was the envy of the developing world. Now, quite suddenly, its economy is again growing slowly, there are serious social problems, and the region's seemingly powerful cohesion has faltered. The age of uncertainty has returned to Southeast Asia, as illustrated not only by its short-term economic prospects but also by the diversity of opinion on the many important social and economic challenges it now faces.

4. Further Reading

There is a huge literature on most aspects of the Southeast Asian economies. The bibliography contains some recent titles, which also include references to many earlier volumes. A 4-volume collection of leading articles on the subject will appear in Hill (2001).

Southeast Asian Studies: Gender

Social science research on Southeast Asia only began to make its mark after World War II. The study of gender (the cultural practices and symbols which construct and assign certain roles for men and women) is very recent, and reflects its origins in Women's Studies and Women in Development programs.

1. Southeast Asia and the High Status of Women

The term 'Southeast Asia' (including Myanmar, Thailand, Laos, Cambodia, Vietnam, the Philippines, Singapore, Brunei, Malaysia, and Indonesia) can be dated to World War II, when it was used to refer to the theater of operations between China and India. Even in very early times, travelers saw this region as distinct from its larger neighbors, despite its cultural diversity. In 1944, in his *Histoire ancienne des états hindouisés d'extrême-orient*, the French scholar

Georges Cœdès (1886–1969) identified a shared corpus of cultural features, among which was 'the importance of the role conferred on women and of relationships in the maternal line.' Since the post-war development of Southeast Asia studies, the high status of women has been frequently invoked as a unifying characteristic of the region.

A number of reasons have been proposed to explain the relative equality of male–female relations in Southeast Asia. Among those most commonly cited are the importance of women in food production, especially rice cultivation; their prominence in marketing and other economic activities; complementary gender roles in ritual, and female prominence as healers and spirit mediums; the prevalence of bilateral kinship patterns, matrilocal residence and bride-wealth; the fact that women commonly inherit family property and maintain their own source of income; low population densities prior to the nineteenth century, which placed a high value on women's work and female fertility; the absence of a strong state structure and a low level of urbanization.

Individuals who incorporated both female and male elements were also important in indigenous belief systems, although this aspect of gender has received less scholarly attention.

2. *Gender in the Social Sciences Before World War II*

The foundations of social science research in Southeast Asia lie in the late eighteenth and early nineteenth century, when Europeans began to compile 'scientific' studies of the region. Apart from Thailand, all Southeast Asia was colonized by Europeans, whose research naturally focused on the areas under their control. By the late nineteenth century work on contemporary Myanmar, Singapore, Malaysia, and Brunei was almost solely the preserve of British scholars, with the Dutch concentrating on Indonesia, the French on Indochina (Laos, Vietnam, and Cambodia); and the Spanish and, after 1900, the Americans on the Philippines. Produced primarily by missionaries and colonial administrators, this research has provided valuable data for understanding gender relations, although that was rarely its focus. Colonial governments, by contrast, did produce periodic reports related to women, notably in regard to community health, literacy, and sex ratios, especially in countries that had sizeable migrant populations. The development of the new field of anthropology in the latter part of the nineteenth century prompted greater interest in local cultures and beliefs. Other social science fields considered the effects of capitalism and colonialism on indigenous society, but provided little room for the discussion of male and female relationships.

Until the 1930s ethnographic literature on Southeast Asia was largely confined to studies of smaller societies or tribal areas, but although the egalitarian nature of male–female relations was usually noted, gender issues were addressed only in passing. This began to change with the growing influence of structural anthropology. In the Netherlands, F. A. E. van Wouden's 1936 dissertation on social structure in eastern Indonesia gave gender relationships a prominent place because of his focus on cross-cousin marriage, the exchange of women, and the connections between matrilineal and patrilineal descent groups. In mainland Southeast Asia Edmund Leach's pre-war research on highland groups in Myanmar (published in 1954), strongly influenced by the work of Claude Lévi-Strauss, discussed the influence of cross-cousin marriages on constructions of hierarchy and equality in social relationships.

In the 1930s the expanding fields of social and cultural anthropology also coincided with a new generation of academic women whose research focused on the family and the domestic economy. Working in Bali, Margaret Mead, one of the foremost anthropologists of her time, gave specific attention to child-rearing, education, adolescence, and sexuality. Another American anthropologist, Jane Belo, also analyzed family relationships within Balinese culture. A different approach was taken by Rosemary Firth in her investigation of Malay village housekeeping in 1939–40. Her socioeconomic study emphasized what has become a truism in descriptions of Southeast Asian societies—women are dominant in marketing and small trading, have a strong entrepreneurial tradition, and control domestic finances.

3. *Gender and Southeast Asian Studies After World War II*

World War II represents a divide in the development of Southeast Asian studies. Not only did it witness the end of the colonial regimes; it also saw the escalation of Cold War hostilities, which enhanced the strategic importance of Southeast Asia. In the United States the government injected considerable funds into area studies, which led to a marked rise in social science research, especially on Thailand. Usually community-focused, this research encompassed a range of topics—nutritional intake, agricultural practices, child-rearing, the practice of magic, cultural values, etc.—which all necessitated an understanding of gender roles. Although comments on the relative equality between men and women in village societies became standard, specialists were cautious about generalizing beyond specific linguistic or ethnic groups. At most, they attempted to identify cultural features considered to be emblematic of a particular society—patron-client relationships in the Philippines, Thailand's loosely-structured social system—but these were rarely broken down in terms of gender.

During the 1950s and 1960s the disciplinary study of Southeast Asia was also introduced to (largely American) universities, but an interest in women's issues was not evident until the 1970s. As the region became more prosperous, local governments began to appreciate the economic importance of Southeast Asian women as well as the need to involve them in rural development programs. In the West social science work on Southeast Asia was influenced by the women's liberation movement and the development of feminist anthropology. The foundation issue of a new feminist journal included an article which identified the major social science research areas relevant to women in Southeast Asia (Papanek 1975), and it is worth noting that Michelle Rosaldo, co-editor of the classic collection, *Woman, Culture and Society* (1974) was a specialist on the Philippines.

The United Nations Decade of Women in 1975–85 was a catalyst for work on women. The combination of development agendas, feminist-inspired research and international concern with the effects of economic change in the Third World gave rise to a new academic field, Women in Development (WID). Pioneering studies focused on Asian women (Ward 1963, Boserup 1970) reasserted the economic autonomy and the high status of Southeast Asian women. The demand for work with practical applications for social policy and human resource management legitimized new research and teaching programs on women in Southeast Asia itself. While primarily concerned with empirical observation and evaluation, the work of Southeast Asian sociologists and developmental theorists has been a salutary reminder that analytical frameworks developed in the West do not necessarily apply elsewhere.

4. *Contemporary Trends*

Contemporary work on women and gender in Southeast Asia is unevenly distributed. The bulk of research has been carried out in Indonesia, where anthropology has traditionally been strong, and in Thailand, the Philippines, Malaysia, and Singapore. Work elsewhere is limited, although research on Vietnam is expanding. The persistence of country and local studies and the lack of comparative material makes generalizations about trends in scholarship difficult. In moving away from macro theories of gender to concentrate on specific groups, social scientists are demonstrating the need to place all research in historicized contexts that take into account factors like ethnicity and class. Historians have also warned against the tendency to place gender relations in a context that sets an exploitative present against an unduly idealized past. By pointing to similarities between Southeast Asian societies and those of southern India and southern China, scholars have questioned the received wisdom that contrasts an essentialized Southeast Asia with China and India. A recognition that the notion of 'Southeast Asian women' is a chimera has led on to the understanding that women's speech does not necessarily reveal a woman's point of view and that women do not always speak from the gender identity of women. The shift to the analysis of gender has made it clear that in order to understand women it is necessary to think about men in different kinds of ways, and be alert to the strategies by which masculinity is culturally created. Research on gay male identity in Thailand and the Philippines, for instance, has shown that male homosexuality, far from being an imported western borrowing imposed on traditional sexual or gender norms, involves redefinitions that are located within a specific sex/gender system.

A dominant paradigm in gender theory since the 1970s, the effects of globalized industrialization on the sexual division of labor, has been particularly relevant in Southeast Asia. In order to establish a manufacturing base Southeast Asian governments have used the lure of a cheap and docile work force to attract capital from the industrialized West. Much of the factory labor, especially in textiles, clothing, and electronics, has been provided by women, usually young and unmarried. From the 1980s a growing body of research, focused primarily on Indonesia, Thailand, Malaysia, and the Philippines, has explored the effects of economic globalization on women's work. Social scientists have not reached a consensus regarding the extent to which Southeast Asian women have benefited from the new employment opportunities. Some have argued that although the nature of work has changed, gender hierarchies have been transferred to the factory floor and social norms which make women subject to family and patriarchal controls have been retained. On the other hand, analyses that depict women as victims of patriarchy and capitalism have been challenged by research that places greater stress on female agency. A common theme has been patterns of resistance that assert female worker solidarity against a male management, and often result in small workplace triumphs. Less researched, however, are the expanding numbers of female entrepreneurs and employers among the middle class.

The study of gender in contemporary Southeast Asian societies has reaffirmed the problem of drawing a divide between the domestic economy and the formal work sector. As in the past, the average woman maintains her own finances independent of her husband, and indigenous economic networks mean that work is often an extension of home-based activities. Again, no Southeast Asian model has been established, in part because of the economic variation across the region, even within countries. In considering gender issues and industrialization, for example, it may be more useful to compare contemporary developments on Java with Gambia or Taiwan than with another part of Indonesia where economic development has not occurred.

Widespread industrialization and rural migration to cities has drawn attention to urban poverty and the tendency of unskilled and unemployed women to drift into prostitution. But in Southeast Asia, as elsewhere, social scientists have argued that the presumed universality of a concept like prostitution requires interrogation if it is to be used in transcultural contexts. Women involved in the sex trade can certainly be seen as victims, but it is also possible that poor women see prostitution as a path for advancement, especially when the customers are white men or there is the possibility of becoming 'temporary wives.' The phenomenon of 'mail-order brides' and the international recruitment of female workers, especially from the Philippines and Indonesia, have also attracted research interest, often in an effort to garner public and official support for greater legal protection of victimized women. In affluent and urbanized Singapore, by contrast, sociological research on gender is concerned less with poverty than with examining how different ethnic groups deal with smaller families and the care of the aged.

The rapid pace of economic change in combination with government goals for development has also stimulated studies of the effects of modernization on rural society, most notably in Indonesia, Malaysia, the Philippines, and Thailand. The literature can be roughly divided into officially sponsored projects of obviously practical application, and more critical and theoretical work, most commonly by anthropologists. Both categories have generated studies of women's responses to family planning and population control, and examinations of the extent to which women's lives have been changed by health and education. In rural Southeast Asia, where it is generally accepted that premodern gender relations were relatively equal, some scholars have contended that increased mechanization and rural development programs have privileged men and disadvantaged women. Similarly, it has been alleged that the increasing value placed on formal educational qualifications and the spread of state health services undermines traditionally female areas such as midwifery and spirit healing.

The argument that globalization has adversely affected women's traditional status has led to some re-examination of cultural constructs of gender, especially in regard to religious teaching. The acknowledged place of sexuality and the male–female relationship in indigenous belief systems has encouraged greater attention to the effects of the male-dominated world religions on gender relations in Southeast Asian societies, and the extent to which imported ideas were localized to suit existing gender relationships. The debate has been most pronounced in Thailand, where textual statements denigrating women's status in Buddhism can be contrasted with the prominence of women in the actual practice of religion. In Muslim societies the emergence of a more fundamental form of Islam that seeks a stricter application of *shari'ah* law has obvious implications for gender relations, especially in Malaysia where Islam is the state religion. In the context of Islam's adaptation to local custom, the combination of matrilineality, economic dynamism and Islamic commitment found among the Minangkabau in Sumatra and Negeri Sembilan in the Malay peninsula continues to attract researchers.

Historians of Southeast Asia are now giving greater attention to gender considerations and are providing social scientists with a stronger basis for discussions of change. Research on the nineteenth and early twentieth century, for example, has explored the interactions between race and gender in the hierarchies created by the colonial state. Another line of inquiry concerns the position of women in Southeast Asian nationalist movements prior to World War II, since it is evident that the call for female education and marriage reform reiterated by women's organizations were rarely accorded priority by male nationalist leaders. These issues were not resolved with independence, and it is evident that the colonial heritage often has a direct bearing on the way modern governments conceptualize gender roles. State involvement in education and the economy has perpetuated notions of gender difference and hierarchy by socializing men and women into different roles. For instance, there has been little encouragement for women to enter political life, except in support of male activities. Though the activities of women's branches of political parties have attracted some research (e.g., in Malaysia), this work has made no impact on mainstream descriptions of political systems. By contrast, the involvement of women in non-Government Organizations (NGOs) holds out the promise of theoretically stronger work, as researchers attempt to discern the extent to which NGOs replicate existing patterns of social hierarchy and gender, or act as agents of change.

Despite a general acceptance of gender complementarity in Southeast Asian societies, gender studies is still developing, and despite a growing interest in constructions of masculinity and gay identity, is currently dominated by work on women. Because of the array of cultures, languages, economies, religions, and modes of government, scholars of Southeast Asia will need to judge the extent to which they can move from case studies to larger generalizations. Specialists recognize that it is necessary to understand how gender operates within a particular social and cultural context before regional and global connections can be drawn. The similarities and contradictions that such investigations uncover may themselves be revealing, and should be actively identified rather than ignored.

Southeast Asian Studies: Geography

As with the classical roots of the discipline of geography, geographical interest in Southeast Asia (in the Western intellectual tradition) can be traced back to the era of discovery and exploration when the mystical Orient first became exposed to European curiosity and conquest. From the beginning of the sixteenth century the expanding European presence in the region was paralleled by a growing need for information about the *terra incognito* of the Orient, and erstwhile geographers were at the forefront of the collection and classification of such information: indeed, to all intents and purposes their activities at the time were geography. The functional need for knowledge and understanding to support colonial commerce and administration constituted what has been called the 'encyclopedic trend' in classical geography.

Towards the end of the nineteenth century geography started to emerge as an educational and academic discipline, and this led to the systematic study by professional academics of regions such as Southeast Asia both in Europe and within the colonies as part of the colonial educational system. Thus, well before Southeast Asia emerged as a recognized region with the creation of the South-East Asia Command during World War II, the geographical study of phenomena and processes therein was already well established.

Southeast Asian geography may be found at several points along a continuum between area studies and 'pure' geography, reflecting scholars' degree of areal specialization. Thus the field includes Southeast Asianists who happen also to be geographers, scholars in mainstream geography departments who take a specialist interest in Southeast Asia, and geographers whose work (e.g., on globalization, industrialization, environmental degradation) includes Southeast Asia. Whilst the inclusion of such a range of scholars makes any categorical overview of Southeast Asian geography difficult, it is equally unhelpful to exclude people simply on the basis of either their institutional location or their degree of disciplinary/area specialization.

Before World War II there would have been less of a dilemma in this regard. Up until the early 1960s the study of 'regions' and 'areal differentiation' constituted an important cornerstone of the geographer's approach, and thus regional geographers with a specialist interest in Southeast Asia were in many regards 'mainstream' geographers. Furthermore, until approximately this time there were no specialist area studies centers in which Southeast Asian geographers plied their trade (see Halib and Huxley 1996, pp. 2–5). In the United States, for instance, the first Southeast Asia program was initiated in Cornell University (and also Yale University) in 1950 by an endowment from the Rockefeller Foundation, but geography was not a prominent discipline in this program (as is still the case today). Similarly, although the School of Oriental Studies was established in London in 1917 (becoming the School of Oriental and African Studies (SOAS) in 1938), it was not until Charles Fisher was appointed the first Professor of Geography with reference to Asia at SOAS, in 1965, that Southeast Asian geography became established there. Similar situations appertained in continental Europe with geography being either absent or peripheral from such prominent Asia-focused institutions as the Koninklijk Instituut voor Taal-, Land- en Volkenkunde (KITLV) in Leiden (specializing on linguistics and anthropology), the École Française d'Extrême-Orient in Paris (anthropology and history), and the Institut für Asienkunde in Hamburg (political, economic, and social developments in Asia).

In the early period, some of the most Southeast Asia-focused geographers were those who were associated with the colonial presence in the region and, later, the strategic imperatives of the Pacific War. A number of Dutch geographers (e.g., S. van Valkenberg, H. Th. Verstappen, F. J. Ormeling) received their first exposure to the region as colonial officers. The French geographer Robert Garry was originally a member of the Colonial Service in French Indo-China. Robert Pendleton was attached to the Philippine Bureau of Plant Industry from 1923–35 during the period of US colonial administration, and later went to the Royal Department of Agriculture and Fisheries in Siam. Joseph Spencer joined the US Office of Strategic Services, and was later assigned to the Far Eastern Division as Assistant Chief. Karl Pelzer became part of a large US team concerned with the development of overseas territories.

Some of the people who were to become leading scholars of the geography of Southeast Asia first became associated with the region as staff members of local universities, including the University of Rangoon, Raffles College Singapore (later to form the University of Malaya), the University of Hanoi, and the University of Phnom Penh. From newly established geography departments within these institutions geographers embarked on fieldwork, sometimes in conjunction with undergraduate students, or otherwise developed their research interests in their host territory. Prominent scholars in this regard included Pierre Gourou, Dudley Stamp, O. H. K. Spate, E. H. G. Dobby, and B. W. Hodder. Dutch geographical scholarship on the East Indies was a little more restricted by virtue of the relatively late (postwar) establishment of departments of geography in universities on Java. Meanwhile, despite lacking a colonial presence in the region, German scholarship on Southeast Asia (e.g., Wilhelm Credner, Albert Kolb) dates back to the late nineteenth century and is distinctive for its ability to transcend national boundaries because of its lack of association with colonial territorialization. Another German scholar (later a naturalized American), Karl Pelzer, was one of the first to use the designation *Sudestasien* (Southeast Asia) in his work, some time before it became more popularly used to describe Mountbatten's South-East Asia Command.

In line with the requirements of war and colonial administration, and reflecting the prevailing orthodoxy in the discipline of geography, a central preoccupation of Southeast Asian geographers at the time was with gathering and presenting information, set within a defined regional or areal context and typically employing various cartographic techniques. A further preoccupation was the drawing together of the physical and human realms of life.

Among the 'area specialists,' two particularly stood out. The American geographer Joseph Spencer specialized on the cultural geography of the region, and was strongly influenced by the classical American geographer, Carl Sauer. Spencer also had wide experience of Asia, and this clearly influenced his identity and approach. The distinguished British Southeast Asian geographer, Charles Fisher, also combined an engagement of contemporary concepts and processes with the insight and 'feel' of the area specialist. He wrote several articles on matters appertaining to political development and international relations within Pacific Asia, but his most significant contribution was his classic text *South-East Asia: A Social, Economic and Political Geography* (1964). Fisher had the ability to cover in equal strength matters appertaining to history, physical geography, politics, society, and economy, a talent few of his more specialized successors possess.

From the 1960s the discipline of geography entered a positivist era as it underwent a 'quantitative revolution' and remodeled itself as a 'spatial science.' Regional geography was pushed to the periphery of the discipline, although it was not so much the emphasis on area, space, and place that was responsible for its marginalization as the predominant use of descriptive and unsophisticated methods. Regional geographers and area specialists continued to be dogged by the tag of 'chorology' (the identification and description of physical forms and human activities): regional geography was no longer seen as the highest form of the geographer's art.

During the 1970s spatial science itself became problematic, not least because of the relegation of context and human values in geographical analysis. Accordingly, in the 1980s a 'new regional geography' emerged which recognized the importance of area, space, place, and locale in the understanding of problems and processes in contemporary society. A new approach to the study of regions emerged which was much more broadly based in the social sciences and in social theory. One of the champions of this new regional geography, Nigel Thrift, was at the time engaged in research on Southeast Asia (especially Vietnam). Southeast Asian geographers have since made a full contribution to this new regional geography, and at the same time have regained a place and respectability within the discipline. This has been aided to a considerable extent by the recent transformation of Southeast Asia, which has increased its prominence within the global system and, at the same time, the level of academic interest. Geographers have been at the forefront of recent analyses of such processes as globalization and the global-local interface, resource exploitation and environmental degradation, regional integration, urbanization, migration, postcolonialism, and cultural change. Southeast Asia thus provides a rich domain for what Doreen Massey has described as the drawing into geography of the traditional realms of other disciplines. Rebecca Elmhirst's article in *Political Geography* (1999) on transmigration in Indonesia is a good example of how geographers are drawing on, and helping to advance,

concepts and ideas that have their roots in other social science disciplines.

The large majority of Southeast Asian geographers today can be found in mainstream geography departments, with many fewer in multidisciplinary area studies centers dedicated to the study of Southeast Asia. Most Southeast Asian geographers therefore have thematic specialisms that draw in Southeast Asia to varying degrees. By and large these are geographers rather than area specialists, the latter being identified by their greater degree of immersion in the region, linguistic capability, cultural awareness, post-Eurocentrism, etc., and their typical location in area studies departments. A perusal of the World Wide Web will reveal a large number of geographers in mainstream departments whose research and teaching draw on Southeast Asian examples; there are by comparison appreciably fewer geographers in dedicated Southeast Asian studies centers, typically seldom more than one, and quite frequently none. There are also a small number of distinctive 'clusters' of Southeast Asian geographers in disciplinary departments in several parts of the world. The following survey aims to convey a sense of the global structure of Southeast Asian geography, but is of necessity selective and thus far from exhaustive.

In Europe, the largest number of Southeast Asian geographers (approximately 30) is found in the United Kingdom, although only a handful are located in the country's two Southeast Asian area studies institutes (SOAS and Hull). The remainder are scattered across the length and breadth of the country, with small clusters in Manchester, Liverpool, and the University of London as a whole. In general, the Higher Education Funding Council for England (HEFCE) provides funding for these posts, whilst the majority of funding for research derives from the Economic and Social Research Council (ESRC) and the Natural Environmental Research Council (NERC). The British Academy Committee for South-East Asian Studies also provides dedicated funding for research in and on the region. Elsewhere in Europe the main loci for Southeast Asian geographers (mirroring the situation almost a century ago) are in the Netherlands (with a major cluster in the University of Utrecht, and individuals in the Universities of Nijmegen, Amsterdam, and Eindhoven), France (with a major cluster in the Centre National de la Recherche Scientifique), and Germany (Hamburg). There has also been a recent growth in Southeast Asian geography in Scandinavia, with the field being particularly well represented in the Universities of Lund and Göteborg in Sweden, and Copenhagen University in Denmark. Within Europe there are also a significant number of Southeast Asia-focused scholars whose work in, for example, demography, urban studies, planning, tourism, and ecology clearly overlaps with that of mainstream geographers. For more information on Southeast Asian geography in Europe, see van Dijk (1998).

The situation in North America is similar to that in Europe, with the vast majority of Southeast Asian geographers being found in disciplinary departments and with negligible representation in some of the long-established Southeast Asian studies programs (e.g., Cornell, Northern Illinois, the East-West Center). Southeast Asian geographers are quite dispersed in the United States (e.g., small numbers at the University of California at Berkeley, the University of Michigan), but there are larger clusters in Canada, most notably the University of Victoria and the University of British Columbia, underpinned by strong financial support for research on Southeast Asia by the Canadian government.

In Australasia there are significant clusters of Southeast Asian geographers at the University of Sydney (where there is a strong emphasis on Australian government-funded research on the Mekong subregion), Flinders University, and Monash University. Meanwhile, the principal area studies center, the Research School of Pacific and Asian Studies (together with the Department of Geography) at the Australian National University contains one of the world's most prominent groupings of geographers specializing on Southeast Asia. In New Zealand there are a number of Southeast Asian geographers in the universities of Canterbury, Wellington, Victoria, Massey, and Waikato.

One of the most important clusters of Southeast Asian geographers is found in the region itself, and it is likely to become even more prominent in the future as a result of changes that are currently taking place in the scholarly world, particularly in connection with the study of 'other' societies. A Southeast Asia Geography Association was formed in 1990 in order to create a forum for academic collaboration and integration within the region. There are several quite large geography departments in the region (e.g., in the University of Malaya, Universiti Kebangsaan Malaysia, Universitas Gadjah Mada, Universiti of Brunei Darussalam, University of the Philippines, and the National University of Singapore), and research-active staff members most typically engage in research work in and on the Southeast Asian region. Historically, much of the earlier work undertaken by Southeast Asian scholars was somewhat 'imitative of the Western academic tradition' (McGee 1995), largely because they received their initial training from the Western scholars who staffed the region's main university geography departments until as recently as the 1970s in many cases, and still today in the case of Singapore. However in recent years, in the National University of Singapore in particular, there has been a strong resurgence of innovative and stimulating indigenous scholarship by local staff who have looked critically at the nature and consequences of, for instance, 'globalization' and 'global-local interaction.'

Meanwhile, postcolonial tendencies in contemporary scholarship in the humanities and social sciences

are forcing Western scholars to look critically at the stifling and arrogant Eurocentrism that has characterized a significant amount of work on Southeast Asia in the past—an accusation from which geographers are far from absolved—and are currently leading to a reappraisal of established scholarship and the search for indigenous theories and concepts. Work by geographers on urbanization, rural-urban interaction, regional integration, and cultural resilience/resurgence has been particularly prominent in this regard, with several Southeast Asian scholars being at the forefront of recent developments (see Savage et al. 1993, Forbes 1997 McGee 1995, Rigg 1998). A 1999 joint publication by Singaporean and Western scholars on the contested territories of globalization in Pacific Asia (Olds et al. 1999) is indicative both of the current direction of geographical scholarship on Southeast Asia and of the fusing of Asian and Western geographical minds.

Southeast Asian geography has therefore experienced fluctuating fortunes as the region itself has waxed and waned in its global prominence over the last century or so. From being at the disciplinary forefront during the colonial era, courtesy of the imperatives of colonial administration and economic transformation, it experienced a largely self-inflicted hiatus during the immediate postindependence era. The development boom of the 1980s, and associated processes of global/regional integration and environmental degradation, rekindled geographers' interest in the region, and at the same time provided a powerful boost for local scholarship and institutions. The post-1997 economic crisis extended the post-boom shelf life of geographical research in and on Southeast Asia, and continuing processes of rapid economic, social, political, and environmental change should provide plenty of ammunition for future geographical enquiry. Whether the enquiring geographical minds will be those of 'area specialists' or 'area incidentalists' is difficult to anticipate: the disciplinary mainstream is once again disparaging the parochialism of area studies. Meanwhile, educational reforms in a neoliberal environment are further limiting the space and scope for 'areal dedication.'

Southeast Asian Studies: Health

Scientific medicine (biomedicine) has had a predominantly mechanistic, individual-oriented perspective, especially since the development of germ theory at the end of the nineteenth century. Health and illness are defined in terms of the presence or absence of pathogens in the body, and treatment relies on specific curative agents. An alternative approach, with an affinity to public health concerns, relates health and illness to the wider social and economic environment. It has its origin in the emergence of the science of political economy at the end of the eighteenth century and the 'consideration of disease as a political and economic problem of social collectivities' (Foucault 1980, p.166). The periodized discussion below of health in Southeast Asia draws upon multidisciplinary scholarship that reflects this social health perspective.

1. Precolonial Period

Anthony Reid (1988) argues that the health status of people in the precolonial period was generally better than their contemporaries in the West, and attributes their good health to good diet and hygiene (due to the abundance of water and habit of frequent bathing, and to the open and elevated houses). The region was by no means free of the afflictions of disease—leprosy, syphilis, and smallpox were especially feared. However, he suggests there was only 'a mild epidemic cycle.' From the fifteenth to the seventeenth centuries, Southeast Asia was very open to world commerce but the habit of washing and the pattern of dispersed village-type dwellings probably limited the spread of the worst urban infections of Europe and India (e.g., plague and typhoid).

Southeast Asian theories of disease causation (etiologies), diagnosis, and healing were characterized by their syncretism. Etiologies were either personalistic (disease caused by the intervention of supernatural beings) or naturalistic (disease caused by metaphysical

imbalance) or a complex amalgam of both. Personalistic theories derived from a prehistoric and indigenous substratum of animistic beliefs. Some naturalistic theories were also indigenous, such as the belief in the need to balance 'hot' and 'cold' substances. Others were adapted by Southeast Asians from Chinese, Indian (Ayurvedic) or Arabic (Unanic) humoral medicine (Owen 1987).

Modes of healing were similarly diverse and there was a great array of healers (astrologers, herbalists, bonesetters, masseurs and masseuses, midwives, exorcists, mediums, etc.). In seeking cures, Southeast Asians were pragmatic, using different modes of treatment in sequence or even concurrently (Owen 1987). How effective were these treatments? Certainly, Europeans were impressed by the variety and efficacy of herbal medicines and the relief provided by massage for rheumatism and soreness. Reid claims that the ubiquitous chewing of betel contributed to the prevention of tooth decay, indigestion, and dysentery (Reid 1988).

Despite the relatively good health of Southeast Asians in this period, population was very low, with an estimated total of a little more than 22 million people in the year 1600 and a population density of only 5.5 persons per square kilometer. Reid's theory (Reid 1988) is that this was due to endemic warfare caused by dynastic instability and succession wars. Battle casualties were actually minimal but crop destruction (resulting in famine) and the transportation of war captives led to great loss of life. Fertility was also probably low due to the constant need for flight during wars, with avoidance of further births until older children were able to run by themselves.

2. *Colonial Period*

In the nineteenth century, colonial governments became increasingly concerned about the heavy toll of death and disease in the colonies. However, initially this concern was limited largely to the high mortality and morbidity of the military. With the expansion of the colonial empires in the second half of the century medical services (including public health measures) were extended to the growing number of colonial administrators and other European expatriates. As colonial economic interests expanded (in the form of plantation, mines, and railways) concern grew for the health of the native populations, which was in large measure due to the realization that poor health affected the productivity of native workers. Thus, the government of British Malaya justified public health measures to control malaria on rubber estates in terms of the economic cost of the disease to planters. Also, the introduction of maternal and child health services in Malaya in the early twentieth century was based on an awareness of 'the importance of biological reproduction to ensure the supply of labor' (Manderson 1989). However, the extension of medical and health services to rural areas had ideological as well as economic functions. The apparent benefits of European 'scientific' medicine and public health served to legitimize the colonial state and to give it moral authority (Manderson 1996).

In Europe, the development of public health accorded doctors a powerful role in society as hygienists and led to a number of authoritarian medical interventions (Foucault 1980). Medical policing was no less evident in the European colonies of Southeast Asia, especially in the twentieth century. In Indonesia, Dutch health authorities adopted draconian measures to fight outbreaks of the plague in Java in the first three decades of the century (Hull 1987). In Malaya, public health surveillance intruded increasingly into the domestic and personal domains to search for vermin, whitewash walls, and disinfect premises as well as to check infant feeding and hygiene (Manderson 1989, 1996).

A noteworthy feature of the period of colonial rule was the rapid and prolonged population growth. The demographic growth began in about the mid eighteenth century and accelerated in the nineteenth century, reaching rates of natural increase of 1–2 per cent per annum. One theory is that the colonial *pax imperica* established an uneasy peace in the region, put a stop to internecine warfare and thereby reduced mortality. Other theories posit an increase in fertility arising from colonial demands for labor (in Java) and an increased demand for children. However, the evidence for these theories is inconclusive. Population growth in this period was definitely not matched by improved nutrition—there is some evidence of an actual decline in per capita food consumption—or reduced morbidity (Owen 1987). Morbidity and mortality were very high in colonial cities in the nineteenth century (at least for the predominantly non-European populations) (see Abeyesekere 1987 on Batavia, and Manderson 1996 on Kuala Lumpur).

Only in the twentieth century did the health situation improve noticeably. Despite some major plague and influenza epidemics, the overall frequency of epidemics declined. Public health measures (e.g., water supply, sewerage, swamp drainage) led to a reduction in cholera, typhoid, and malaria. Also, improved transportation enabled governments to ship food to areas hit by crop failures and epidemics (Owen 1987).

3. *Postcolonial Period*

By the late 1950s almost all the countries of Southeast Asia had achieved independence. Most of these countries became closely allied with the West. Postwar theories of modernization (e.g., Rostow's *Stages of Economic Growth* 1960) attributed the underdevelopment of Third World countries to the lack of diffusion of Western values, capital, skills, knowledge, and technology. Vicente Navarro (1982), writing from the

Table 1
Child (under-5) mortality (deaths per 1,000 live births)

	Per capita GNP ($US) (1995)	1960	1980	1997
Higher income countries				
Singapore	27,730	40	13	6
Brunei	11,990[a]	87	n.a.	12
Malaysia	3,890	105	42	21

perspective of Marxist-oriented 'dependency theory,' has argued that the underdevelopment of Latin American countries, on the contrary, was caused by excessive cultural and economic dependence on the West due to the alliances between national urban elites and their Western metropolitan counterparts. From the health perspective this translates into self-serving, urban and elite-centered 'enclave' medicine that is reliant on Western medical education and technology.

In Southeast Asia, Thailand provides an apt example of such dependency. Donaldson (1982) has highlighted the key role of the Rockefeller Foundation in the dominance of Western scientific medical education in this country and the way it stifled attempts in the 1930s to introduce a low-cost, rural oriented Junior Doctor scheme. Others (e.g., Cohen 1989) have traced the subsequent growth of an elitist, urban centered and entrepreneurial medical profession that has accompanied the expansion of the capital sector in Thailand.

Socialism provided the philosophical basis for alternative health policies. In Vietnam, radical changes to health care accompanied the overthrow of French colonial rule in 1954, land reform, and agricultural collectivization. A socialist health policy was instituted based on principles of preventative medicine, combined use of Western and traditional medicine, and popular participation. The health system was highly decentralized and focused on the commune health center. Decentralization was consistent with socialist principles but was also a practical response to three decades of war (1945–75), including heavy US bombing in the last decade.

It was the success of Vietnamese and Chinese innovatory public health policies that served as models for the World Health Organization's primary health care (PHC) approach and goal of 'Health for All by Year 2000' enunciated in the Alma Ata Declaration of 1978. Since then all Southeast Asian countries have instituted some kind of PHC care system, and at least formal support for PHC principles of equity, popular participation, and affordable and culturally appropriate health care. This support was influenced in part by political unrest during the 1970s and by demands to redistribute wealth and income to satisfy the 'basic needs' of the poor (including improved living conditions and health). However, the level of political commitment to PHC throughout the region has been weak, except in Vietnam.

Nevertheless, there has been a trend toward better health in Southeast Asia (except for a period in Cambodia, which experienced economic decline and massive loss of life during the rule of Pol Pot between 1975 and 1978). At the most basic level, this general improvement in health has been a consequence of economic growth. This is demonstrated in Table 1, which relates per capita gross national product to child mortality (the principal indicator used by UNICEF to measure human and economic progress). In the lower income countries, Vietnam has achieved faster reductions in child mortality despite its low level of income—a consequence of its strong political commitment to PHC and very successful PHC initiatives.

The indicators also highlight the fact that there remain very significant differences in health between countries in the region, with Singapore and Brunei matching the industrialized nations of Australia and Japan, and with Myanmar, Laos, and Cambodia comparable in health status to the poor countries of Africa. However, national statistics for the higher income countries may disguise regions within coun-

tries with health status well below the national average, e.g., West Nusa Tenggara (Lombok, Sumbawa) in Indonesia, and Northeast Thailand.

The health status of urban areas in Southeast Asia is generally better than rural areas, in stark contrast to the pathogenic cities of the nineteenth century. In the postcolonial period, urban health has improved more rapidly than that of rural areas due to better access to safe water, sanitation, and health services. However, national statistics that compare urban and rural areas obscure sizeable pockets of urban poverty, and the existence of urban slums and squatter settlements. Here, appalling living conditions are ideal for the spread of mosquito-borne malaria and dengue fever, and for high levels of infectious and communicable diseases. The growth of urban slums and squatter settlements has been particularly pronounced in Malaysia and Thailand, which have experienced rapid economic growth based on urban manufacturing and rural–urban migration (see Cohen and Purcal 1995).

There are two diseases that have created serious health problems in Southeast Asia in recent years and threaten to reverse the general trend toward improved health in the region. These are malaria and HIV/AIDS; the one is resurgent and the other is emergent. Both are closely connected to poverty and human population movements.

In the 1950s and 1960s malaria was in decline in the region due to DDT spraying and highly effective drugs such as chloroquine. However, since then there has been a significant resurgence of the disease. For example, in 1998, Thailand had 125,013 confirmed cases of malaria. This resurgence in Southeast Asia can be partly attributed to insecticide-resistant mosquito vectors and drug-resistant strains of malaria parasites. Other causes can be found in the changing political economy of the region; for example, population pressure on land resources has forced land-poor and nonimmune families into circular migration in search of supplementary income in forested areas where they were exposed to malaria vectors (Singhanetra-Renard (1993).

The first case of HIV infection in the region was reported in Thailand in 1984. Within a few years the disease had reached epidemic proportions, fueled by international domestic sex industries (exploiting young women from the poor northern and northeastern regions) and by a large population of injecting drug users. By 1997, 780,000 people were HIV infected in Thailand. Here there is some evidence that the rate of growth had been slowed down by 1994 by government campaigns promoting public awareness and condom use. By this time, however, the disease was becoming rampant in other Southeast Asian countries, especially in Myanmar (440,000 cases of HIV infection) and in Cambodia (130,000 cases). The massive scale of population movement in the region, due to the integrative effect of global economic forces, has contributed greatly to the spread of the disease. In 1996 some 2.6 million migrant workers were circulating within the Asian region. Growth zones have encouraged the flow of people, goods, and ideas across international frontiers. For example, the Economic Quadrangle has established commercial and transport links between parts of Thailand, Laos, China, and Myanmar, and has led to an unprecedented movement across borders of poor people who are vulnerable to HIV infection—commercial sex workers, truckers, migrant workers, and ethnic minorities—in a way that greatly increases the chances of HIV transmission (Porter and Bennoun 1997).

Against a backdrop of general trends in health in Southeast Asia—some positive, some negative—I have presented an overview of health studies from a broad range of disciplines (history, anthropology, sociology, demography, and geography). What these studies have in common is a social health perspective. Theoretically, the work of some of these scholars can be identified with Marxist or Foucaultian political economy; others are less obviously associated with a particular theoretical approach but, nevertheless, relate health to political and economic changes in the region.

Southeast Asian Studies: Politics

The study of the politics of Southeast Asia, a subfield of comparative politics, developed as an area of academic research following the regaining of independence of the former colonies of the region after World War II. Driven initially by a desire by outsiders to understand the political dynamics of societies with different cultural and historical origins to those of the West, the study has now become embedded in some national academies, with more work being pursued by local scholars wishing to apprehend the political forces at work in their own and neighboring polities.

The development of the discipline has often been driven and shaped by the often global external security and economic interests of foreign scholars and governments, but more recently local concerns for democratization and the advancement of human liberties have emerged as a catalyst to research. Though a field of comparative politics, little of the published work has been truly comparative but rather has concentrated on the issues of political power, authoritative institutions, and constitutional issues within particular countries. The great political heterogeneity of the region, combined with its religious, cultural, and modern historical diversity, have posed severe constraints on any attempts to develop a truly comparative political theory of Southeast Asia. In several countries, the discipline has not developed to any meaningful extent because of the political constraints that are placed on independent analysis and public debate of governmental actions and political behavior.

1. *Nationalism*

The rise of nationalism as the colonial powers of Southeast Asia lost their desire and capacity to continue to rule in British controlled Burma, Malaya, Singapore, French-run Vietnam, Laos, and Cambodia, the American Philippines, and the Dutch East Indies (Indonesia), stimulated an awareness that these societies had internal political dynamics which were helping to shape the postwar international scene. The existence of powerful left-wing political forces in most of these nationalist movements, emerging at the same time as the United States and its European allies became concerned about the establishment of communist states beyond the Soviet Union, provided a political as well as an academic incentive for the development of Southeast Asian political studies. In the early 1950s, the first American university-based area studies centers devoted to the region began to study the origins and development of nationalism and communism.

These early studies were predominantly the result of research and publication by American and American-trained scholars. They turned, though, in most cases for their historical and cultural understanding of these new polities to the research done by colonial officials and scholars of the pre-war era. The notion that the apparently unique and distinctive cultures of these foreign lands were overwhelmingly important in shaping their politics was very influential at this time. Earlier research, summarizing the cosmological basis of Southeast Asian kingship, such as Robert Heine-Geldern's (1942) essay *Conceptions of State and Kingship in Southeast Asia*, became frequently cited as sources of theories about the nature of the pre-colonial state which, by analogy, had applicability to the then period.

Though nationalism was the predominant theme of these early studies, such as George McT. Kahin's path-breaking *Nationalism and Revolution in Indonesia* (1952), religion and ethnicity were seen as key components of that political phenomenon. Anthropological studies of Southeast Asian societies, which also began to emerge at about this time, had a significant impact on early political studies because of their insights into peasant political values and attitudes. Culture became the leitmotif of most political studies and the discipline as applied to the region tended to develop away from the mainstream political science

topics of industrialized societies. The fact that almost all Southeast Asian economies in the 1950s and 1960s were predominantly agrarian in nature, and that the peasantry formed the largest social category, provided a material basis for this view.

The American historical sympathy with nationalism, following from the dominant understanding of their own country's historical evolution and morally justified struggle against colonialism, made these studies naturally sympathetic to the nationalist cause. In those countries where the left, and especially communist political parties, had a major influence, studies attempted to differentiate between the indigenous, anti-colonial roots of nationalism and the allegedly foreign inspiration and guidance of left wing nationalist movements. Nationalism was not initially analyzed in broader ideological terms, and there was little attempt to distinguish among the often-contradictory origins and purposes of rival organizations and ideological predispositions within nationalist movements.

The religious, ethnic, and geographical diversity of Southeast Asian societies, divisions that frequently paralleled economic and administrative boundaries, were often obscured in the national level analyses that drove the nationalist paradigm. This was shared not only by most foreign scholars but also by national governments and capital-city based researchers. The findings of the postwar pioneers of Southeast Asian political research were summarized in the first, and still useful, major comprehensive review of the politics of Southeast Asia, the multi-author volume edited by George McT. Kahin, *Government and Politics of Southeast Asia* (1959, 1964). This highly influential work, with each country of the region discreetly analyzed with no attempt at any comparative analysis with other states either in or out of Southeast Asia, became the model for most of the next two decades.

2. *Behaviorism and the Collapse of Constitutional Democracy*

As the newly independent states of the region regained their independence between 1945 and 1965, each initially established a form of constitutional democracy, often modeled on the political institutions of the former colonial power. These political systems quickly failed to achieve the idealistic intentions of their formulators. The issue of the failure of constitutional democracy in the politics of Southeast Asia thus became an early issue in political research.

The rise of military and authoritarian regimes, even those which maintained the democratic facade of elections, became the next major research issue for students of the region. Herbert Feith's *The Decline of Constitutional Democracy in Indonesia* (1962) was amongst the most influential of these works. The political failure of constitutional democracy was often attributed to the belief that somehow the cultures of these countries were incompatible with the give and take of democratic politics. In peasant-based societies organized through strong patron-client ties controlling limited resources, the tolerance of criticism and debate that is part of democratic politics was argued to be missing but for cultural, rather than structural, reasons.

Thus while political studies in Western societies tended to focus on interests and institutions of power and authority, political studies of Southeast Asia generally looked to cultural forces and historical patterns. The very variety and complexity of Southeast Asian societies, which themselves posed severe issues of political unity and control on the often uncertain and weak postcolonial governments of the region, were consequently somewhat overlooked or dismissed. The postcolonial states were attempting to hold together what in many cases were artificially created colonial entities containing sharply contrasting communities with diverse and not necessarily coherent interests with fewer financial, administrative, and military resources than the former colonial administrations could have mobilized.

The development of authoritarian, and usually army-led or army-backed, governments in many nations in Asia, Africa, and Latin America during the height of the Cold War in the 1960s, led to a spate of studies on the role of the military in politics. Thailand, Indonesia, Burma, and South Vietnam became cases that were sometimes cited in the wider comparative literature at this time. Such studies tended to be highly descriptive and revealed little of the internal political dynamics of the societies in question.

The divorce between Southeast Asian political studies and the dominant trends in the discipline in the United States and Europe during the 1960s was enhanced by the emergence of behaviorism as an increasingly dominant mode of analysis in Western political science. During that period many American, European, and Asian scholars were trained in these methods that, however, had little applicability to conducting research in Southeast Asian societies. The quantitative methods of behaviorism were difficult to apply to societies with different cultures, little studied histories and institutions, almost non-existent social statistics, and limited political rights and freedom of expression. The failure of behaviorism in Southeast Asian conditions inevitably drove the discipline toward other issues after the early dominance of nationalism as an analytical theme.

3. *New Themes in Southeast Asian Political Research*

The research interests and themes of scholars of Southeast Asian politics have broadened since the 1960s. The political roles of the bureaucracy, lead-

ership, ideology, and political parties, as well as non-governmental organizations, economic policies and forces, the law, and electoral behavior have emerged as themes which have helped to bring the study of Southeast Asian politics into a more comparative position with the study of politics and political economy elsewhere, particularly other areas of Asia. Most of this research has, however, remained country specific, with explanatory theories often rooted in broad concepts of 'modernization' or political culture and development.

Some of the new themes in Southeast Asian political research began to point to possible theories that were thought possibly applicable to other states in the region. One of the earliest and most influential was the concept of Thailand as a 'bureaucratic polity.' Fred W. Riggs 1966, in his *Thailand: The modernization of a bureaucratic polity*, argued that the bureaucracy, including the army in that country, rather than being an instrument of the government as assumed in American and European studies, was the government. The fact that his hypothesis could trace itself back to the pre-modern paradigms of the early Thai monarchy, produced ideas of an indigenous, Southeast Asian political form which might be applicable to other authoritarian states in the region.

The development of research on patron-client relations, showing the political dependence of peasants and poorer urban elements on powerful 'big' men, and in turn the dependence of the patrons on maintaining the support of their clients in order to amass political power, reinforced many of the themes in Riggs' 'bureaucratic polity' model. What was becoming increasingly clear in research of this kind across the region was that political power in Southeast Asian societies was usually derived from wealth, status, and office, rather than from the meritocratic, democratic, or egalitarian assumptions of most Western political theories. Benedict J. Kerkvliet's *The Huk Rebellion: A Study of Peasant Revolt in the Philippines* (1977) and James C. Scott's *Weapons of the Weak: Everyday Forms of Peasant Resistance* (1985) were particularly influential in this genre.

3.1 Political Economy

Two developments within the economies of some of the countries of the region led to the emergence of theories of politics derived from political economy following the rapid, if partial, industrialization of first Singapore, and then Malaysia, Thailand, and Indonesia from the 1970s. Not only did this economic growth draw people from the countryside into the cities, but it also created stronger political, economic, and cultural linkages with the advanced industrial West as well as Japan, South Korea, and Taiwan. These studies were often criticized, as were earlier explanatory theories, for applying Western-derived, neo-classical assumptions to situations that were still in many ways pre-market, as the bureaucratic dominance of Southeast Asian states distorted 'normal' political forces.

A more fruitful line of research, however, was developed by those scholars who began to study the relationship between economic resources and political power. Anek Laothamatas (1992), for example, in his *Business Associations and the New Political Economy of Thailand: From bureaucratic polity to liberal corporatism*, demonstrated how the rise of commerce and industry in the Thai economy was undermining the earlier dominance of the bureaucracy in Thai politics. Elite transformations, as a consequence of economic development, became a theme for research as illustrated in *The Philippine State and the Marcos Regime* by Gary Hawes (1987).

Considerable interest was attracted in the late 1980s and early 1990s, before the Asian financial crisis of 1997, on the so-called 'developmental state' theories which grew from attempts to understand the rapid industrialization of several East Asian economies. Some arguments of political economists drew inspiration from neo-Marxist dependency theories while others looked to varieties of Wallerstein's 'world system' model. To most students of Southeast Asian politics, however, these theories were unacceptable because of their unwillingness to recognize the dynamics of domestic political forces as well as their Euro-centrism. The rise of arguments of political economy was fueled not only by changes in the region itself, but by intellectual trends in much of social science at this time to explain the 'Asian economic miracle.'

The fact that this phenomenon affected only a minority of the polities of the region meant that the study of states with the least developed economies tended to stagnate. This was paralleled by a relative lack of interest in their politics as well as strong political inhibitions against independent research in the poorest Southeast Asian societies. Thus while the indigenous study of Southeast Asian politics grew stronger in Singapore, Thailand, Malaysia and, to a lesser extent, Indonesia, the discipline remained stagnant, if not nonexistent, in Burma, Laos, Cambodia, Vietnam, and Brunei.

3.2 Democratization

The symbiotic relationship between political and economic change and the growth of an indigenous political science can be seen in the development of research on the requirements for the establishment of democratic regimes in more recent Southeast Asian political studies. Just as the global political and intellectual preoccupations of Western students of Southeast Asian politics in the 1950s and 1960s shaped the early development of the discipline, the re-emerg-

ence of democracy as a global political value in the eyes of the West has shaped recent political research.

Some of this research has been often shaped by externally generated optimistic assessments of the rapid speed at which societies can adapt to new political forms and expectations subsequent to earlier economic and social structural changes. At the same time, the existence of a larger core of local students of politics has ensured that external themes and preoccupations have not driven research away from local realities as happened in earlier years.

The democratization theme has often concentrated on creating dichotomies of political forms (military/civilian, democratic/authoritarian, free market/planned economy) that can tend to obscure an analysis of the actual political forces and interests at work in a society. The volume *The Politics of Elections in Southeast Asia* Taylor R H (ed) (1995) brought together a large amount of research which demonstrated the contradictory realities between the widespread practice of elections in Southeast Asia since independence, if not earlier, and the ability of governments to use democratic institutions to assert a powerful hold by the state over the population and other semi-dependent institutions.

3.3 Public Policy and National Security

Because of the threat of criticism of the political behavior of rulers which is often implicit in studies which examine how the politics of societies actually work, even in the most open of Southeast Asian polities, political scientists have often been forced to shape their findings to fit with what is politically acceptable. While very good research is often conducted, such as the useful volumes on Singapore (Quah et al. 1985, *Government and Politics of Singapore*), and Thailand (Xuto 1987, *Government and Politics of Thailand*) much such work tends to be historically oriented and essentially descriptive of institutions. Official documents and speeches by government leaders are often accepted at face value as the justification of particular policies and courses of action. The structural bases of politics are largely ignored and there is little discussion about where power lies in society and with what consequences.

The first American studies of Southeast Asian politics emerged from area studies centers established at major universities with government and foundation support in order to improve the understanding of the region's politics so as to develop more effective internal and external security policy options. Similarly, there has developed in Southeast Asia since the 1960s a set of national political 'think tanks' from which much political research has been conducted and published.

The first such institution to be established was the Institute of Southeast Asian Studies (ISEAS) in Singapore. Though largely funded and led in its first years by Western foundations and scholars, its role in studying the security issues of Singapore and the region has brought it more closely in contact with government interests. During the Cold War, much of the political research of ISEAS and similar centers that were subsequently established in Kuala Lumpur, Jakarta, and Bangkok, centered on issues of relations with China, other communist powers, and internal security topics.

With the ending of the Cold War, and the rapid industrialization of some of the region's economies, economic policy issues have also come under scrutiny by students of politics in the region. In the style of the Association of Southeast Asian Nations (ASEAN), the region's leading international organization, the scholarship emanating from these institutions refrains from criticizing the policies and politics of neighboring countries.

The strains on regional relations arising from the Asian economic crisis of 1997, as well as the establishment of governments with regard for human rights in the Philippines and Thailand in the latter half of the 1990s, placed further strains on this shared policy of self restraint in research and publication. With the expansion of ASEAN to include all ten countries of Southeast Asia, similar think tanks have been established in Vietnam, Cambodia, Laos, and Myanmar, but the political constraints on their activities means that no genuinely independent research by indigenous scholars on these polities has been published within their countries.

3.4 International Politics

International politics and international relations studies have not been central to the development of Southeast Asian political studies. From the earliest post-independence period, most studies of the region have centered around the themes of the foreign policies of particular states, the relations of one or more of the former superpowers with the region as a whole, or the development of regional with the formation of ASEAN as a long standing regional body. Most studies of each country's foreign policy making and purposes have relied heavily on an analysis of the motivations and interests of national leaders. Foreign policy has been less seen as a national political process, or as the pursuit of national interests, and more often as an extension of the personality of one of the region's long dominant leaders.

4. Discourse Analysis

The diversity of Southeast Asia has made the development of a coherent discipline of Southeast Asian political studies impossible. The field is not a large one and there are few scholars. In the approximately 50 years since the first postcolonial studies began to

emerge, however, much progress has been made. While the early studies tended to be highly descriptive and to be the work of scholars who saw themselves as clearly outside their object of study, more recent and increasingly sophisticated studies by both foreign and indigenous scholars have begun to analyze the languages of politics and their diverse meanings in particular circumstances. The depth of cultural and linguistic knowledge required for such work has required Southeast Asian political studies to become in many ways multidisciplinary. Historians, anthropologists, and students of the region's various literatures have contributed as much to this mode of political apprehension as have political scientists.

5. *Conclusion*

Southeast Asian political studies are still in their infancy despite 50 years of development. From the early descriptive and largely derivative studies of the late 1940s, to the more in-depth, locally aware studies of the 1990s, the field has moved away from a vague and amorphous concept of culture as a catchall for political explanation to an understanding which grows out of the region itself. As the field has become increasingly rooted in South East Asia, it has become increasingly a field of study with implications for the development of the discipline more widely.

Southeast Asian Studies: Religion

From their first appearances in Southeast Asia, the world religions have been intimately linked to states and statecraft, and so they remain. This organizing thesis will be used to demonstrate different disciplinary approaches to the study of religion. Archaeological and historical research on the world religions in this region reveal, at the same time, the dawn here of state-level polities. Historical research shows the modern nation-states of the region emerging in the context of a colonial order in which the politics of religion were often formative. The predominant approach to the study of religion in contemporary Southeast Asia, however, combines ethnographic with textual studies. Scholars in religious studies, who once might have focused mostly on textual exegesis, increasingly couple this with contextual participation and observations. Anthropologists, who once considered participant observation the only method they needed to master, now realize that they have to be conversant, too, in the textual legacy of a particular faith if they hope to understand people's religious practice.

The renowned diversity of Southeast Asia owes a great deal to religious differences. On the mainland portion, Buddhism predominates, divided between the Mahayana form found in Vietnam (where it both blends and vies with a Confucian tradition), and the Theravada form practiced in Burma, Thailand, Laos, and Cambodia. Insular Southeast Asia is home to the world's largest Muslim country—Indonesia—and Islam holds a commanding presence in Malaysia and the southern Philippines as well. Christianity is the majority faith in the Philippines, however, but many minorities throughout Southeast Asia, especially those located in the mountainous uplands, also follow this faith. Nowhere in the region have these world religions completely displaced older traces of Hindu cosmology or religious practices, older still, based on the veneration of ancestors and the propitiation of local spirits.

The relationship between states and world religions has been reciprocally advantageous: states or rulers gained legitimacy by association with religious symbols; religious institutions benefited materially from the state's largess, gaining the resources for additional propagation or reproduction of the faith. The world religions in Southeast Asia have comprised the primary criterion of civilization, their absence always marking the terrain of the primitive. Textually based, these world religions demanded literacy among at least

some members of a society and entailed systems of formal education. The distribution of the world religions has thus signaled both the limits of state power and of cultural domestication. The animistic religions of upland or relatively isolated peoples have, therefore, been in retreat for two millennia, as states have grown increasingly capable of penetrating daily life at their peripheries as well as in their centers. Religion in Southeast Asia surely does not reduce to politics, but the patchwork distribution of religions in this region and the dynamics of religious change in the present are hardly comprehensible apart from issues of power, especially state power.

1. *Theocratic Formations in Early Southeast Asian States*

The climatic conditions over most of Southeast Asia hamper archaeological preservation. Despite that obstacle to methods based on excavation, inferences from stone architecture and sculptures, as well as inscriptions associated with these, reveal a close relationship between politics and piety (Fontein 1990). One of the most innovative recent attempts to mine architectural evidence is the exhaustive and exacting measurements undertaken at Angkor Wat, measurements which confirm the close relationship between gods, kings, and cosmology in the classic Khmer world (Mannikka 1996).

The earliest polities deserving the term 'state' in this region began to take shape around the first century CE. They have been termed Indic, owing to the predominance of Indian influence in their architecture and religious statuary, yet this was not an instance of conquest or political colonization. Rather, it appears that kingdoms such as Srivijaya, Champa, Khmer, Pagan, Majapahit, and others appropriated Hindu and Buddhist symbolism via contacts that grew along the trade routes that crossed Southeast Asia linking the circum-Mediterranean world to India and China. Religious monuments such as Angkor Wat, the Borobudur, and Prambanan represent only the most spectacular architectural traces of Indianization. Smaller temples and ritual complexes, such as those scattered throughout East and Central Java and along the Vietnam littoral, bear mute witness as well to the spread of these world faiths. Rulers sometimes adopted one variant in contrast to the religions of neighboring or past regimes, a devotion to Shiva, Vishnu, or the Buddha characterizing different Khmer rulers, for example. At other times, even Buddhism and Hinduism were regarded as non-exclusive. Both permitted avenues for deifying the ruler as a god-king.

These early states have been termed mandalas or galactic polities, connoting a focus on an exemplary center where humanly constructed spaces and rituals mirrored cosmological and astronomical orders. Angkor Wat's highest peak represents the *axis mundi*, and its various measurements inside and out encode astronomical cycles, mythical events, and cosmological relationships, sometimes simultaneously (Manikka 1996). Although measurements such as these would have been esoteric, the bas reliefs and statuary, plainly representational and didactic, would have instructed even illiterate persons who wanted to learn or remember stories about the gods. Amassing the materials and especially the labor to accomplish these massive constructions indexed at once a ruler's wealth and power as well as his devotion and piety. More than mere devotees of the gods, however, kings united mystically with them, becoming themselves earthly manifestations of Vishnu or Shiva.

Buddhist rulers harkened back to King Asoka as exemplar, an Indian monarch (reigned 265–238 BC) whose support of the monastic order and construction of reliquaries in the form of stupas set the standard for monarchs building their legitimacy around Buddhism (Swearer 1995, pp. 64–8). Conceiving of the king's position as one accruing from past merit, Buddhists in Pagan (present-day Burma) saw the king also as a *bodhisattva*, one who helps others achieve salvation through his patronage of the religion and through the righteousness of his rule. As such, he was both *devaraja* and *dhammaraja*, god-king and just-king (Aung-Thwin 1985).

Breaking this pattern of fusing ruler and god, Islam filtered into Southeast Asia via India as well as the Arab world, following paths of transoceanic commerce in the tenth century to take root in coastal locations along the region's archipelago and peninsular portions (Chaudhuri 1985). Since Muslims largely shun religious representational art, the archaeology of Islam's advance derives mostly from gravestone inscriptions that reveal the deceased as Muslim (Drewes 1968). Conversion would have facilitated relationships with the Muslim traders who began to dominate the Indian Ocean trade in this era. To have equated ruler with God would have compromised Islam's insistent monotheism, yet the mutually beneficial relationship between state and religion continued to characterize the Muslim sultanates and rajadoms of the Malay-speaking world of insular Southeast Asia. Malay rajas were often described as the 'Shadow of God on Earth,' or his deputy, and legends sometimes relate that when a ruler converted he commanded his followers to do likewise (Milner 1985). Given the Hindu-Buddhist environment, it is not surprising that Islamic Sufism, a mystical tradition, initially had the greatest success in this region (Woodward 1989).

2. *Colonizing the Spirit: Historical and Ethnographic Qualifications*

Spain and Portugal, in competition with each other to gain access to trade with the East, sacralized their exploration and conquests of new worlds as a religious

competition against Protestants (Chadwick 1972, p. 321). In the Philippines, the Church and the colonial state operated through 'an interpenetration of functions' (Steinberg 1982, p. 64) whereby the colonial church enjoyed virtually full financial support from the government, and Spanish monarchs approved or disapproved the placement of religious personnel. With its vast land holdings, ownership of banks, demands for local labor, and increasingly racist limitations on recruiting clergy, the Church was targeted by the *mestizo* revolutionaries who first came to imagine themselves as independent Filipinos. While nationalism became a secular alternative to religion for some leaders, others sought to indigenize or nationalize the Church. Today, 'the Roman Catholic experience' remains important to a sense of Philippine identity, raising a conundrum for the primarily Muslim inhabitants of the southern islands, peoples still termed as the Spanish labeled them 'Moros.' Militant Moro separatism has smoldered in the southern islands for decades.

However, historical approaches have recently qualified this model of conversion and conquest in the Philippines. Tagalog speakers 'translated' Christianity to leave largely intact a distinctly Filipino worldview (Rafael 1988). Fannela Cannell (1999), an anthropologist, found a similar process in Bicol. The records most accessible to the historian, those of the Church and state, are perhaps the most likely to elide this insight. But by including myth as part of historical consciousness, and by ethnographic attention to beliefs about magic and spirits, Aguilar's (1998) history of labor conflicts on sugar haciendas shows how we might read between the lines of the institutional records to discover how Filipinos localized Christianity and resisted colonial domination.

3. *Religion and Nation*

The trading companies of the Dutch and British that eventually displaced Spain and Portugal in the rest of insular Southeast Asia did not perceive their mission to be one of converting the natives. Toward the end of the eighteenth century, as these mercantile bodies died and European states began to engage directly in colonization, independent Protestant missionary organizations also emerged, following European flags wherever these were planted. Protestant missionaries found Islam and Buddhism, deeply entrenched with institutions of governance and leadership, their major competitors throughout much of the region. Missionaries targeted, instead, the tribal peoples who had remained autonomous from the lowland court centers and resistant to their religions. In some cases, colonial governments limited missionaries to working among tribal peoples, cautious of irritating the majority population and its leaders. Indeed, early nationalistic resistance throughout the region drew strength from Islamic and Buddhist organizations (von der Mehden 1963). But perhaps because in the Dutch and British colonies the state was ostensibly (if not always in practice) neutral toward religion, nationalist opposition to these regimes was far less anticlerical than in the Philippines, moving increasingly toward secular-socialist forms.

Thailand was the only country to have remained free from colonial rule, although it was forced to concede considerable territory to France and substantial commercial rights to Britain. The idea of Thailand as a modern nation, an equal player in a world of nations, indicated a shift from conceptualizing the polity as an exemplary center, the edges of which were of little import, to one where mapped boundaries defined precisely the compass of the state's reach (Tongchai 1994).

The Chakri dynasty, selecting Bangkok for its capital, led Thailand during its transition into nationhood. The fourth of the Chakri kings, Mongkut, lived as a Buddhist monk for 27 years before ascending the throne, and advocated reforms to rationalize and purify the *sangha*, the clerical body of Buddhism. His son, Chulalongkorn, carried out extensive governmental and social reforms, but it was the sixth Chakri ruler, Vajiravudh who brought the nation, the monarchy, and Buddhism together in the basic form that they still hold to this day:

> Vajiravudh's Thai nation (and he was the first to popularize this phrase) was founded on the basic triad of 'nation-religion-monarch' (*chat-satsana-phramahakasat*), a trinitarian mystery in which all three elements were inextricably bound together. Allegiance to any one of the three meant loyalty to all three; disloyalty or disobedience or disrespect toward one meant disrespect toward all. (Some sophistries were engaged in to secure the allegiance of Siam's considerable Muslim and Christian minorities Wyatt 1984, p. 229)

Precisely because the state has a vested interest in melding Buddhism with the nation, scholars have not readily seen the extent to which Thai thought and practice is not Buddhist, or perhaps is nominally Buddhist but substantially indigenous. Nicola Tannenbaum, an anthropologist, discovered this in her research on the Shan (1995, 1999). Like other anthropologists, she looked less at Buddhism as textual tradition than at Buddhists and their practices. In contrast, the methods of scholars in religious studies tend to focus more on the canonical aspects of religion than on the everyday 'heresies' of actual practitioners. This methodological difference between religious studies and anthropology is less and less firm, however. Donald Swearer, for example, a scholar in religious studies who specializes in Buddhism in Southeast Asia, approaches his subject ethnographically as well as historically (Swearer 1995).

As Thai monarchs in the past made merit by building or renovating temples and stupas, so the

current monarch, and the Thai state, remain prominent patrons of Buddhism and the *sangha*. One of the more recent royal projects of this type is the large and well-manicured park, Buddha Monthon, located on the edge of Bangkok. Dominated by a gigantic standing image of the Buddha and a large golden stupa, the park includes a lake, fountains, and quiet trails: a serene and inspirational space for public celebrations and high-level conferences or meetings.

During the 1970s, Thailand allied itself with the United States in attempting to halt the spread of communism in Southeast Asia. Fearing its own communist insurgency from within, the government of Thailand utilized the Village Scout Movement to mobilize sentiment and patriotism in support of nation–religion–monarch. Initiation into this movement that attracted mainly teenagers and young adults began with isolating the initiates for several days in a camp-like setting, then depriving them of sleep while they participated in lectures, skits, songs, and other group activities. At the ritual's climax, when initiates received the scarves that officially symbolized their membership in the Scouts, many were sobbing, some so overcome with patriotic emotion they had to be removed on stretchers (Bowie 1997).

At the same moment, Thailand's neighbor, Laos, was taking a path going in the diametrically opposite direction. With the ascendancy of the Lao People's Revolutionary Party (LPRP) in 1975, Laos attempted to forget its monarchy and to harness Buddhism for socialist ends (Evans 1998). Forming the Lao United Buddhist Association, the LPRP hoped to purge the religion of 'superstition' while supporting the state's reforms and programs:

> For many monks and for many laymen this political reorientation of the Lao *sangha* was unacceptable. As a result some left the order and returned to ordinary life, some fled to Thailand, and among the flood of Lao refugees to Thailand from 1975 until the early 1980s, many cited dissatisfaction with changes to Lao Buddhism among their reasons for leaving (Evans 1998, pp. 62–3).

With the reforms that have swept the communist world since 1989, Laos has also instituted a more market-based economy. What socialism and Lao identity mean in this new era have come under new scrutiny, and 'the regime has turned increasingly to Buddhism in its search of new ideologies of legitimation, and of a reformulated Lao nationalism' (Evans 1998, p. 67). Members of the ageing politburo who have died in recent years have been buried with full Buddhist funeral rites, and the upgraded constitution of 1991 gives more explicit attention to Buddhism than its predecessor did.

Islamic Southeast Asia presents examples of two different solutions to the question of religion and nation. When Britain granted independence to Malaysia, Chinese Malaysians, who made up some 30 percent of the population, controlled most of the urban economy. The indigenous Malays, most of whom lived by agriculture or fishing, comprised the scant majority of the population but were granted constitutional privileges of governorship in the new nation. Added to this ethnic mix was a South Asian population comprising about 10 percent of the population, and a small scattering of tribal aborigines in the mountains. Ethnic tensions erupted in 1969 during two weeks of rioting that caused widespread property damage and hundreds of casualties, mostly of Chinese and Indian Malaysians. Responding to this tragedy, the legislature passed economic policies that included affirmative action for Malays in education and business.

These politics of ethnicity have much to do with Islam's position in Malaysia (Shamsul 1994). The constitution, while providing citizens the right to practice and profess any religion, also establishes that 'Islam is the religion of the nation' (Bunge 1985, p. 239). Specifically, Islam is the religion of the Malays. Islam is so centrally part of Malay identity that, historically, throughout much of the Malay-speaking world, converting to Islam was often termed 'becoming Malay' (*masuk Melayu*). The government's promoting Islam in this context of ethnic politics, therefore, promotes 'Malayness.' This explains why so much public architecture in Malaysia, such as the striking railway station in downtown Kuala Lumpur, looks distinctly Islamic.

The relationship of Islam and nation in Indonesia has been quite different from the situation in Malaysia. Numerically speaking, Islam appears to be even more predominant here than in Malaysia, where but 53 percent were Muslim in 1980. Muslims comprise 88 percent of Indonesia's huge population, yet Indonesia's constitution does not name Islam as the religion of the nation. When the new republic was founded, some voices did call for the formation of an Islamic state, but the adherents of minority faiths, as well as those Muslims who feared the power of the state to enforce an orthodoxy they did not want to practice, opposed this concept. To mollify proponents of an Islamic state, however, the deliberative body drawing up the lineaments of a new nation determined at least to avoid a purely secular stance. Thus, the first of the five ideological 'pillars' (*Pancasila*) underlying the nation is the belief in the Almighty God. Significantly, too, the religiously neutral term *Tuhan* (Lord) is used to denote God in this statement rather than the term Allah. A government ministry to support religion was established at the same time, with different branches to promote the interests of each of five officially recognized religions: Islam, Hinduism, Buddhism, Protestant, and Catholic Christianity (Boland 1971).

Because Suharto's New Order came to power as the result of crushing an attempted coup by the Indonesian Communist Party, communism remained the state's 'enemy number one' long after an estimated 500,000

were killed in recrimination for the coup, a bloodbath that effectively ended organized communism in the country. In this political climate, religion remained a significant tool in Indonesian politics (Kipp 1993). Religious affiliation became a cloak of respectability that shielded one from suspicion in that time of terror that ushered in the New Order, and later, that vouched safe one's claim to be a solid and progressive citizen. Adherence to one of these five official religions was required of all government employees, such as teachers and bureaucrats, as proof of one's immunity to communism. Tribal peoples whose animistic religions were not accorded protection and respect found themselves consigned to categories such as 'backward,' or 'isolated.' While adherents of the five approved religions were protected by law from proselytization, the practitioners of animism were opened to Christian and Muslim missions. Some of these tribal peoples yielded to this pressure by converting; others reconstituted their traditional practices as 'Hinduism,' allying themselves with the Balinese, whose religious beliefs and practices bear a family resemblance to Indian religion (Geertz 1972). While Islam was not set up as the religion of state, and Indonesians have been free to be religious in one of five approved ways, they have been far less free to claim allegiance to other kinds of religions, or to claim no religion at all.

The ethnographic study of Islam in Indonesia was long hampered by the assumption that the rituals and practices of Muslims were universal in the Muslim world, and thus already known (Bowen 1993). Until recently, anthropologists working in Muslim Indonesia attended to those religious practices and beliefs that they presumed were non-Islamic or pre-Islamic, and in the process, underestimated the depth of Islamic faith and Muslim identities (Woodward 1989). Now scholars recognize that Islamic practice—everywhere the heart of this faith—deserves careful study, often leading us to the debates and differences that animate and divide Muslim communities.

Indonesian Muslims whose practices incorporate substantial amounts of local precedent, following revered teachers, are termed Traditionalists. They have been gradually losing discursive ground to those who promulgate more modernist, standardized forms of Islam (Bowen 1993). The political economy of this shift can be attributed to the different positions of power occupied by those who espouse the Modernist variants as compared to the largely rural and less well educated Traditionalists. The state has also helped to tip the balance in this discourse. Religious instruction is a mandated part of the curriculum in all public schools through the high-school level, and the Department of Religion has established a nationwide system of teacher-training schools to prepare teachers of religion. Thus, schoolchildren receive a standardized, textbook version of Islam that may contradict the particulars of religious practice in their communities (Hefner 1994).

4. *Both More and Less than an Instrument of State*

As rulers in Southeast Asia from ancient times to the present have attempted to harness the political power of religion, certain forms of religion acquire the privileges of official recognition and financial patronage, while others are at best ignored if not censured. When 'modern state Buddhism' developed under the patronage of the Chakri dynasty in the late nineteenth and early twentieth centuries, it overpowered many regional monastic traditions (Kamala 1997). A tradition of wandering asceticism, among other local Buddhist traditions, has been all but elided from history. Official Thai Buddhism was shaped by the wish to rationalize the faith in relation to a textual canon, whereas localized Thai Buddhism had been rooted in devotional practices, such as meditation, rather than in textual exegesis, and relied more on firsthand relationships between teachers and students than on the literate transmission of knowledge. The official Thai Buddhism also elevated some peculiarly local elements of central Thai experience as the national standard:

> The system—still in use today—rests on degrees, examinations, and ranks in the *sangha* hierarchy. It defines the ideal Buddhist monk as one who observes strict monastic rules, has mastered Wachirayan's printed texts, teaches in Bangkok Thai, carries out administrative duties, observes holy days, and performs religious rituals based on Bangkok customs (Kamala 1997, p. 9).

The considerable numbers of Thai who speak Lao or some other language may thus feel less than comfortable with the orthodoxy deriving from Central Thai traditions.

Religious faith and expression always go well beyond the designs of people in high places. The deepening Islamization of Indonesia and Malaysia in the closing decades of the twentieth century was not wholly an engineered artifact of the Cold War and internal ethnic politics. Muslims worldwide were experiencing a resurgence of faith and confidence, and as travel and communication have reduced the world's distances, Southeast Asia's Muslims easily participate in discourse within the worldwide *ummah*, the community of Islam. What Indonesians and Malaysians do with or make of their faith is not fully under any government's control. A small handful of Muslim leaders in Indonesia, authorities worry, inspire a 'fanaticism' among their followers that could threaten the peace and security of the regime. Other prominent Muslim leaders want to depoliticize Islam. They have become wary of the government's patronage of Islam, seeing there an avenue for political cooptation and control. They disavow the goal of an Islamic state, calling instead for the deep transformation of society through individuals' adherence to the practices of Islam: a revolution of the spirit rather than of the political structure.

Buddhism in Southeast Asia has experienced similar revivals and reinventions, some of which go well beyond what the state intends. In Singapore, for example, with an explicitly secular constitution and state ideology, Buddhism replaced Taoism as the leading religion according to the 1990 census. Over one-third of Singaporeans profess Buddhism, and it attracts especially university-educated adherents who attend lectures and youth camps, and who utilize the Internet to study Buddhist philosophy. Likewise, urban and educated Thai have become increasingly skeptical of the Buddhism purveyed as a civil religion. New, unorthodox religious movements based on Buddhism have attracted many in the Thai middle class, and, what is more, some monks have dared to oppose openly, and at the risk of arrest, the state's development policies that destroy the environment (Taylor 1993).

Archaeology and art history reveal that the world religions were tied intimately to statecraft in the region's first states. Historical research tells us that religious imperialism was implicated in colonial expansion, and that the dawn of nationalistic movements sometimes drew energy from religious identities forged in opposition to the colonials. Modern research on the world religions in Southeast Asia, whether undertaken by those in religious studies, anthropology, or history takes seriously both the literate tradition of a faith as well as the imperative to find out what the faithful actually do and say. These hybrid methods add nuance to histories of religion, showing us, for example, how people translate religious concepts into locally meaningful forms, resisting religious and political imperialism in the process. At the same time, such hybrid approaches demand that anthropologists investigate the supposedly universal rituals of the world faiths and then place their knowledge of local practices against a more expansive background of regional history and religious literature.

Southeast Asian Studies: Society

1. *Analyzing Southeast Asia as a Form of Knowledge*

Society is both real and imagined. It is real through face-to-face contact and imagined when the idea of its existence is mediated through mediums such as printed materials and electronic images. So, the term society refers simultaneously to a microunit that we could observe and to a macro one that we could only partially engaged with. We, therefore, have observable 'societies' within a macro imagined 'society,' so to speak. Southeast Asia, like other regions in the world, has both. But it is the way that both of these components have been weaved into an enduring complex whole, which seemed to have made Southeast Asia and Southeast Asians thrive and survive even under adverse conditions, such as the recent financial–economic crisis, that has become the source of endless intellectual attraction and academic inquiry to both scholars and others, hence the birth, growth, and flourishing of Southeast Asian studies.

Thus, Southeast Asian studies, dominated by humanities and the social sciences, have been about the study of the 'society' and 'societies' in the region, in their various dimensions, in the past and at present. The complex plurality of these 'society' and 'societies,' or societal forms, that do indeed co-exist, endure, and enjoy some functional stability, have made it imperative for researchers to apply an equally diverse set of approaches, some discipline-based (anthropology, sociology, geography, history, political science, etc.) and others thematically-oriented (development studies, gender studies, cultural studies, etc.) in studying Southeast Asian society. In some cases, it even involved disciplines from the natural as well as applied sciences.

The greatest challenge in Southeast Asian studies, and to its experts, has been to keep pace with the major changes that have affected the 'society' and/or 'societies' and then narrate, explain, and analyze these changes and present the analysis in a way that is accessible to everyone within and outside the region. Therefore, framing the analysis is critical in understanding as to how Southeast Asian studies constitute and reproduce through the study of 'society' and 'societies' within Southeast Asia. The 'knowledge baseline' approach is useful in making sense of the said framing process.

2. *The 'Knowledge Baseline' in Southeast Asian Studies*

Social scientific knowledge (humanities included) on Southeast Asia has a clear knowledge baseline, meaning a continuous and interrelated intellectual-cum-conceptual basis, which emerged from its own history and has, in turn, inspired the construction, organization and consumption process of this knowledge. The two popular concepts that have been used frequently to characterize Southeast Asia are 'plurality' and 'plural society,' both of which are social scientific constructs that emerged from empirical studies conducted within Southeast Asia by scholars from outside the region.

In historical terms, 'plurality' characterizes Southeast Asia before the Europeans came and who, subsequently, divided the region into a community of 'plural societies.' Plurality here signifies a free-flowing, natural process not only articulated through the process of migration but also through cultural borrowings and adaptations. Politically speaking, polity was the society's political order of the day, a flexible nonbureaucratic style of management focusing on management and ceremony by a demonstrative ruler. States, governments, and nation–states, which constitute an elaborate system of bureaucratic institutions, did not really exist until Europeans came and dismantled the traditional polities of Southeast Asia and subsequently installed their systems of governance, using 'colonial knowledge,' which gave rise to the plural society complex.

Historically, therefore, plural society signifies both 'coercion' and 'difference.' It also signifies the introduction of knowledge, social constructs, vocabulary, idioms, and institutions hitherto unknown to the indigenous population (such as maps, census, museums, and ethnic categories), the introduction of market-oriented economy and systematized hegemonic politics. Modern nation–states or state–nations in Southeast Asia have emerged from this plural society context.

It is not difficult to show that the production of social scientific knowledge on Southeast Asia has moved along this plurality-plural society continuum. When scholars conduct research and write on pre-European Southeast Asia they are compelled to respond to the reality of Southeast Asian plurality during that period; a period which saw the region as the meeting place of world civilizations and cultures, where different winds and currents converged bringing together people from all over the world who were interested in 'God, gold and glory' and where groups

of indigenes moved in various circuits within the region to seek their fortunes. As a result, we have had, in Java, a Hindu king with an Arabic name entertaining European traders. In Champa, we had a Malay raja ruling a predominantly Buddhist populace trading with India, China, and the Malay archipelago. Whether we employ the orientalist approach or not, we cannot avoid writing about that period within a plurality framework, thus emphasizing the region's rich diversity and colorful traditions. In other words, the social reality of the region to a large extent dictates our analytical framework.

However, once colonial rule was established and the plural society was installed in the region, followed later by the formation of nation–states, the analytical frame, too, changed. Not only did analysts have to address the reality of the plural society but also the subsequent developments generated by the existence of a community of plural societies in the region. We began to narrow our analytical frame to nation–state, ethnic group, internation-state relations, intranation-state problems, nationalism, and so on. This gave rise to what could be called 'methodological nationalism,' a way of constructing and using knowledge based mainly on the 'territoriality' of the nation–state and not on the notion that social life is a universal and borderless phenomenon, hence the creation of 'Indonesian studies,' 'Malaysian Studies,' 'Thai Studies,' and so on.

With the advent of the Cold War and the modernization effort analysts became further narrowed in their frame of reference. They began to talk of poverty and basic needs in the rural areas of a particular nation, also focusing on resistance and warfare, slums in urban areas, and economic growth of smallholder farmers. The interests of particular disciplines, such as anthropology, became narrower still when it only focuses on particular communities in remote areas, a particular battle in a mountain area, a failed irrigation project in a delta, or gender identity of an ethnic minority in a market town.

In fact, in numerical terms, the number of studies produced on Southeast Asia in the plural society context supercedes many times those produced on Southeast Asia in the plurality context. Admittedly, social scientific studies about Southeast Asia developed much more rapidly after the Second World War. However, the focus became increasingly narrow and compartmentalized not only by academic disciplines but also in accordance to the boundaries of modern postcolonial nations. Hence, social scientific knowledge on Southeast Asia became, to borrow a Javanese term, *kraton*ized, or compartmentalized.

It is inevitable that a substantial amount of social scientific knowledge about Southeast Asia itself, paradigmatically, has been generated, produced, and contextualized within the plural society framework, because 'nation–state' as an analytical category matters more than, say, the plurality perception of the Penans of Central Borneo, who, like their ancestors centuries ago, move freely between Indonesia and Malaysia to eke out a living along with other tribal groups and outside traders, ignoring the existence of the political boundaries. In fact, anthropologists seem to have found it convenient, for analytical, scientific, and academic expedience, to separate the Indonesian Penans from those of Malaysia when, in reality, they are one and the same people.

Therefore, the plurality–plural society continuum is not only a 'knowledge baseline' but also a real-life social construct that was endowed with a set of ideas and vocabulary, within which people exist day-to-day in Southeast Asia.

3. *Constituting and Reproducing the Knowledge on Southeast Asia*

There are at least four major axes along which the construction, organization, and reproduction of social scientific knowledge about Southeast Asia and its societies have taken place.

The first axis is that of *discipline/area studies*. There is an ongoing debate between those who prefer to approach the study of Southeast Asia from a disciplinary perspective, on the one hand, and those who believe that it should be approached from an area studies dimension, employing an interdisciplinary approach, on the other.

The former prefer to start clearly on a disciplinary footing and treat Southeast Asia as a case study or the site for the application of particular set of theories that could also be applied elsewhere globally. The aim of such an approach is to understand social phenomena found in Southeast Asia and to make comparisons with similar phenomena elsewhere. Those preferring the latter approach see Southeast Asia as possessing particular characteristics and internal dynamics that have to be examined in detail using all available disciplinary approaches with the intention of unraveling and recognizing the indigenous knowledge without necessarily making any comparison with other regions of the world.

The bureaucratic implications of these two approaches can perhaps be discerned clearly in the way social scientific knowledge about Southeast Asia is reproduced through research and teaching. This brings us to the second axis, namely, the *undergraduate/graduate studies* axis.

Those who favor area studies often believe that Southeast Asian studies can be taught at the undergraduate level hence the establishment of Southeast Asian studies departments or programs, in a number of universities in Southeast Asia, combining basic skills of various disciplines to examine the internal dynamics of societies within the region. Acquiring proficiency in one or two languages from the region is

a must in this case. The problem with this bureaucratic strategy is that these departments have to be located in a particular faculty, say, in the arts, humanities, or social science faculty. This denies, for instance, those with a background in the natural sciences the opportunity to study in-depth about Southeast Asia.

Therefore, those discipline-inclined observers would argue that Southeast Asian studies should be taught at the graduate level to allow those grounded in the various disciplines, whether in the social or natural sciences or in other fields of study, to have an opportunity to specialize in Southeast Asian studies. Therefore, a geologist or an engineer who, for instance, is interested in the soil and irrigation systems of Southeast Asia could examine not only the physical make-up of Southeast Asia but also the human–environment relationship. This is particularly relevant at the present time since environmental and ecological issues have become global concerns.

This has made many individuals, institutions, and governments think carefully how they should invest their precious time and money when they are requested to support the setting up of, say, a program, center, or institute of Southeast Asian studies. They often ask whether universities should continue to have the prerogative on the teaching, research, and dissemination of knowledge about anything connected with Southeast Asia and its societies. Why not in nonuniversity institutions?

This takes us to the third axis, namely, the *university/nonuniversity* one. For many years, we imagined that only at the university we could acquire and reproduce knowledge about Southeast Asia, whether approached from the disciplinary or area studies perspective. However, many governments and international funding bodies felt that to obtain knowledge about Southeast Asia one need not go to university, but could acquire it through nonacademic but research-oriented institutions established outside the university structure to serve particular purposes. National research bodies such as LIPI (Indonesian Institute of the Sciences) in Jakarta and ISEAS (Institute of Southeast Asian Studies) in Singapore have been playing that role. 'Think-tanks,' such as the Center for Strategic Studies (CSIS), Jakarta, or the Institute of Strategic and International Studies (ISIS), Malaysia, have also played the role of the producer and reproducer of knowledge on societies in Southeast Asia outside the university framework. However, there seems to be a division of labor, based on differences in research orientation, in the task of producing and reproducing knowledge between the academic and nonacademic institutions.

The final axis is an *academic/policy-oriented research* one. While academic endeavors pursued within the context of Southeast Asian studies in the universities are motivated by interest in basic research, which is by definition scholarly, those pursued outside the universities are often perceived as not being scholarly enough because they are essentially applied or policy-oriented in nature and serving rather narrow, often political, interests of the powers that be in Southeast Asia.

It is argued that the critical difference between these two approaches is that the academic one is always open to stringent peer-group evaluation as a form of quality control, but that the applied one is not always assessed academically. In fact, the latter is often highly confidential and political in nature, thus denying it to be vetted by the peer group, hence its perceived inferior scholarly quality. The basic research-based academic endeavors are, therefore, seen as highly scholarly, whereas the nonacademic ones are perceived as highly suspect as scholarly works and not considered to contribute to the accumulation of knowledge on Southeast Asia societies.

However, research institutes like ISEAS in Singapore would argue that, even though it is essentially a policy-oriented research institute mainly serving the interests of the Singapore government, it still produces scholarly work of high quality and encourages basic research to be conducted by its research fellows either on an individual or a group basis. In other words, a nonuniversity research institute of Southeast Asian studies, such as ISEAS, could simultaneously conduct applied and basic research without sacrificing the academic and scholarly qualities of its final product; or put in another way, it is 'policy-oriented yet scholarly.'

The moot question is who are really the consumers of knowledge on Southeast Asians societies, hence Southeast Asian studies; the Southeast Asians or outsiders?

4. *Consuming the Knowledge on Southeast Asia*

It could be argued that social scientific knowledge about Southeast Asia and its societies is a commodity with a market value. Often the 'market rationale,' and not the 'intellectual rationale,' prevails in matters such as the setting-up of a Southeast Asian studies program, center, or institute, even in the government-funded academic institutions. However, the funding of research on Southeast Asian studies has often been dictated not by idealistic, philanthropic motives but by quite crass utilitarian desires, mainly political or economic ones. There are at least three important 'sectors' within which knowledge on Southeast Asia societies has been consumed: the public, the private, and the intellectual sectors.

Since the governments in Southeast Asia have been the biggest public sector investors in education, through public-funded educational institutions, they have been the largest employment provider. They have set their own preferences and priorities, in accordance to their general framework of manpower planning, in deciding what type of graduates and in which fields of

specialization they want to employ them. The pattern in Southeast Asian countries has been well established, that is, there is a higher demand for science graduates than the social sciences and the humanities. But amongst the latter there is no clear, expressed demand for Southeast Asian studies graduates. However, there seems to be a significant demand for the inclusion of the Southeast Asian studies content in all the non-natural science courses at the undergraduate level in most of the government-funded academic institutions in Southeast Asia. This is not unrelated to the fact that the awareness about ASEAN as a community has now become more generalized amongst the public hence the need for a more informed description on the different countries and societies within ASEAN (read Southeast Asia).

Outside Southeast Asia, such as in Japan and the United States of America, very rarely, specialization in Southeast Asian studies, or components of, has been considered highly desired in the job market of the public sector. Perhaps having a graduate-level qualification in Southeast Asian studies is more marketable in the public sector especially in government of semi-government bodies that deals with diplomatic relations or intelligence.

In the private sector, the demand for Southeast Asian studies as a form of knowledge and the demand for a potential employer who possesses that knowledge are both limited and rather specific. However, the number could increase depending on how large is the investment and production outfit a particular company has in Southeast Asia. Since some of the demand for the knowledge is rather short-term, often specific but detailed, therefore it has to be customized to the needs of a company, 'think-tanks,' or 'consultant companies' have often become the main supplier of such tailored knowledge. Many of such organizations are actually dependent on 'freelance' Southeast Asianists or academics who do such jobs on a part-time, unofficial basis.

It has been observed that the Japanese seem to be regular consumers of knowledge on Southeast Asia. This is hardly surprising because they have massive investments in Southeast Asia. There is, therefore, a constant need to know what is happening in the region. Research foundations from Japan, in particular the Toyota Foundation, have been very active, since the 1990s, in promoting 'Southeast Asian studies for Southeast Asians,' and supporting other research and exchange programs. Taiwan and Korea are the two other Asian countries having their own Southeast Asian studies research centers, along with the United States, United Kingdom, France, and The Netherlands, former colonial powers in Southeast Asia.

A more generalized demand for knowledge on Southeast Asian societies relates to marketing and this trend must not be underrated with the recent expansion of the middle class in the region. As the markets and clients in Southeast Asia become more sophisticated the need for in-depth knowledge on sectors of the Southeast Asia societies has increased. This in turn has increased the demand for graduates who have followed courses related to Southeast Asian studies.

In the intellectual sector, knowledge on Southeast Asia has been consumed generally by the NGOs, namely, those that are national-based ones as well as those that have regional networks. Because most of the NGOs are issue-specific based interest group, such as environmental protection, abused housewives, social justice, and the like, and often seeking funds for their activities from the governments and NGOs in developed countries, they find it more advantageous to operate on a regional basis because they get more attention and funding from the said source. The strength and success of their operation is very much dependent on the amount of knowledge they have about Southeast Asian societies in general as well as the specific issue that they are focusing on as a cause in their struggle.

With the popularity of the Internet and its increased usage around the world and within Southeast Asia, it has now become an important medium through which academic and popular knowledge on Southeast Asian societies has become available. The source of the knowledge could be located outside or within the region but are now much more accessible for commercial and noncommercial purposes.

As a conclusion, it could be said that Southeast Asian studies and what it constitutes is, first and foremost, a knowledge construct that represents only part of the region's social reality. In spite of this, it is the most important element, amongst the many, that gives Southeast Asia, the geo-physical region as well as its people and environment, its history, territory, and society. Because of the co-existence of different societal forms in the region, hence the unevenness of the tempo of social life in the region, the speed of social change thus also differs from one community to the other, from one area within the region to another. Only a multidisciplinary approach could capture these complexities embedded in the societies of Southeast Asia.

As the importance of the region increases in the globalizing world, both generalist and specialist knowledge about Southeast Asia become critical to the world and the region itself. In that sense, Southeast Asian studies as a knowledge construct transforms itself into a lived reality, especially for the Southeast Asians themselves. This knowledge, therefore, becomes indispensable both to those who study Southeast Asia and its society as well as to the Southeast Asian themselves.

Southern Africa: Sociocultural Aspects

The southern African region comprises South Africa, Lesotho, Swaziland, Botswana, Namibia, Mozambique, Malawi, Zimbabwe, and Zambia. The recent history of the region, during the last half of the twentieth century, was dominated by the decolonization process and its aftermath. With a few exceptions, countries have struggled to establish viable political systems and bureaucratic states, to overcome ethnic, racial, and regional conflict, to diversify and stabilize economies often dominated by only one or two industries (such as copper mines in Zambia, tobacco in Zimbabwe), and to achieve economic development. The small countries of Lesotho, Botswana, and Swaziland are, for the most part, monoethnic states with little ethnic conflict, but have had significantly different internal political arrangements and economic fortunes. South Africa is the most economically and ethnically diverse country in the region, with the strongest state and institutions of civil society.

It dominates the region's economy. Lesotho is entirely surrounded by South Africa and almost completely dependent on it. All other countries, especially land-locked Zimbabwe, Zambia, and Malawi, depend to a large degree on South African transport services and harbors. South African investments and companies increasingly dominate the economies of its regional neighbors.

The southern African region shares similar and inter-related colonial histories, postcolonial interactions, and the broad outlines of the cultural histories of the majority of their populations. Close cooperation among governments of the region fostered by a half-century of political struggle has created tight political integration of the whole. The largest trading partners still remain outside of the region, primarily in Western Europe. At the beginning of the twenty-first century, all countries had begun to seek increasing intraregional cooperation in order to reverse the effects of conflict, isolation, economic decline, and political weakness of state structures. This was articulated by Thabo Mbeki, President of South Africa, as the search for an African Renaissance.

1. History

Archaeological evidence shows that southern Africa was 'the cradle of mankind.' The earliest prehumans and *Homo sapiens* evolved here. There is, however, no evidence that would link these early humans any more strongly to contemporary southern African populations than to the rest of humanity.

All languages in the region derive from only two of the six major language families of Africa (Greenberg 1966). The entire population of speakers of the Khoisan language group have lived in the region, and only here, from at least 20,000 years ago. Beginning around 2,000 years ago, Bantu-speaking peoples appear to have moved into the region quite rapidly from north of the Congo forest zone, in the region of today's Cameroun. They possessed technology to smelt iron and make durable fired pottery, and raised cattle, goats, and a mixture of crops from the Sudanic zone (millets and sorghum) and from the Indian Ocean region (sweet potatoes, bananas). At some time they acquired the New World crop, maize, which became central to the diet of the entire region well before European incursions.

Before the arrival of the agricultural and pastoral Bantu, most of southern Africa was sparsely populated by the Khoisan people. The 'Khoisan' language family includes two major branches, the 'Bushman' or 'San' languages and the KhoiKhoi. The primary distinction between these two groups, however, is social and economic. The Bushman were hunters and gatherers, living in small mobile bands of no more than 35–40 people. The Khoi were cattle and sheep-herders, living in larger tribal groupings. Early European settlers at the Cape of Good Hope began to trade with the Khoi peoples (then known as 'Hottentots') in the seventeenth century, but as trade relationships broke down and the European farmers ('Boers') began to move inland in the eighteenth century, the Khoi were

gradually absorbed as clients and laborers by the Boers. Bushman were killed in skirmishes, displaced to remote deserts, or incorporated as servants and wives by European people moving inland from the south, and by Bantu-speaking Africans moving southwards. By the nineteenth century Khoisan speakers remained only in the dry areas inland from the west coasts of South Africa, Namibia, and Angola, and in the Kgalagadi (Kalahari) desert of Botswana. There is still a relatively large Nama (Khoi) speaking group in Namibia. Indeed, the name 'Namibia' means 'land of the Nama.' In South Africa where 'Colored' people preserve much of the San and Khoi genetic heritage, Bantu languages such as Xhosa and Zulu preserve their linguistic heritage in the form of some vocabulary and the characteristic 'click' sounds found nowhere else among the world's languages. Their art, painted on rocks throughout the region, gives testament of a rich culture.

Although 'Bantu' refers strictly to a linguistic category, people who speak Bantu languages also share broadly similar cultures. With the exception of their spread to Indian Ocean islands such as the Comores and Zanzibar, they are restricted to tropical and subtropical continental southern, central, and eastern Africa. The culture and political economy of early Bantu speakers was characterized by residence in small dispersed agricultural and/or pastoral settlements led by a 'chief' who delegated authority to subchiefs or headmen, and to a council of senior or royal males in a form of informal democracy that usually excluded women. Precolonial religious beliefs focused on reverence for the spirits of (male) ancestors who were propitiated during regular ceremonies by individuals, families, clans, or larger tribal or village groupings. While there were generally no 'priests' in these traditional religious systems, all societies relied on diviners, healers, and prophets who acted either as mediums for spirits during healing rituals or occasionally interpreted the will of the spirits in a political context. The institution of religious prophecy continues to have significant political and social effects. The role of traditional prophets and spirit mediums in the *Chimurenga* or 'war of liberation' fought in Rhodesia/Zimbabwe was especially important, but resistance movements led by traditional prophets appeared in all southern African countries during colonial times as well. Strong beliefs in the existence of witches—individuals who caused evil or illness often unbeknown to themselves—and beliefs in the existence of animal familiars of witches or other kinds of spiritual powers inherent in plants and animals are also widespread. Today, majorities in all countries are at least nominally Christian, with small numbers of Muslims such as the Yao of Mozambique, and the Swahili-speakers in Mozambique, Malawi, and eastern Zambia. Many aspects of precolonial belief have been incorporated into indigenous Christian beliefs and practices, while minorities of people continue to practice traditional religion in preference to, and sometimes in combination with, Christianity or Islam.

The rapid establishment after 1816 of the Zulu kingdom under the warrior king Shaka, together with the British colonial advance in the latter half of the nineteenth century, provide the historical skeleton that unites the region's cultural diversity. Shaka was a member of the small Nguni-speaking 'Zulu' clan. He is credited with introducing a number of military innovations that eventually led to the establishment of his hegemony over a large conquest state in what is now northern KwaZulu-Natal Province of South Africa. Repercussions were felt as far north as Malawi and eastern Zambia, southern Tanzania and Mozambique, where groups of people fleeing Shaka's power established temporary hegemony. These people were known as the 'Ngoni' in the north, or Nguni in South Africa.

The rise of the Zulu Kingdom, together with movements inland of the Portuguese from the east coast, and the Boers from the Cape of Good Hope, led to general disruption of settled life in south central Africa. This, in turn, created opportunities for widespread incursions, first by African and Arab slave and ivory traders from the east coast, and later for European adventurers, hunters, traders, settlers, and missionaries. The general lack of strong centralized states or other large-scale political organizations in the region contributed to the advance of colonial rule and expropriation of land by Europeans for farms and mines. European Christian missionaries established mission stations in Nyasaland (now Malawi) in response to the devastation and social dislocation caused by Ngoni incursions and led the way for the British government to declare Nyasaland a Protectorate. Zulu offshoots established the Gaza kingdom in the southern central region of Portuguese Mozambique over the Tsonga-speaking people and settled in large numbers in southern Zimbabwe as the 'Ndebele' people. (The Ndebele of South Africa derive from an earlier Nguni expansion into Sotho-Tswana areas, and are historically and culturally distinct from the Zimbabwe Ndebele.) The Kololo people, a Tswana-speaking group originally deriving from the Hurutshe in what is now Botswana, fled north in response to Zulu incursions and established temporary hegemony over the Lozi people in western Zambia. They managed to impose much of their language and culture on the previously independent populations. In South Africa, the Zulu expansion and its repercussions had the effect of disrupting virtually all previous settlements of people during the *Mfecane* (or *Difeqane* in Sotho, 'the crushing'), a period of vast population movements and reorganization lasting through the middle of the nineteenth century. Out of this emerged several strongly integrated 'tribes' as followers of powerful chiefs: the Sotho of Basutoland (Lesotho), the Swazi of Swaziland, and the Tswana tribes of

Bechuanaland (Botswana). It also created an opportunity for white Afrikaans-speaking farmers, the Boers, to move north out of the Cape Province, a British Colony since 1802. After the Great Trek of 1835 they established several independent republics, including the Orange Free State and the Suid Afrikanse Republiek ('South African Republic,' known as 'The Transvaal').

2. *Colonialism and Independence Struggle*

In the second half of the century, Swaziland, Basutoland (now Lesotho), and Bechuanaland (Botswana) were declared British Protectorates after treaties were signed by their chiefs, partly in order to secure them as labor reserves to provide labor for European farmers and the mines, and partly to keep them from the hegemony of the Zulu on the one hand and the Afrikaner (Boer) states on the other. The Zulu, unwilling to enter into negotiations, were eventually defeated in 1879 by British forces. Their king was exiled briefly but eventually returned as king of the Zulu people under the authority of the Colony of Natal. The hyphenated name of the current province of South Africa, 'KwaZulu-Natal,' still reflects the regional power of the Zulu kingdom.

Mozambique was colonized by Portugal in the fifteenth century but only came under effective control in the late nineteenth century. Namibia was brought under German control as a result of the partition of Africa at the Berlin Conference in 1884. The remainder eventually came under the direct or indirect control of Britain. Zimbabwe and Zambia were given as concessions to the British South Africa Company under Cecil John Rhodes as Southern and Northern Rhodesia. In 1924, the British South Africa company was dissolved, and Northern Rhodesia and Southern Rhodesia became Crown Colonies under local white settler control. Together with the Protectorate of Nyasaland, they joined together in the Central African Federation in 1951 until independence was achieved by Northern Rhodesia and Nyasaland in 1964. The colony of Northern Rhodesia was renamed Zambia, while Nyasaland became Malawi.

Military conflicts in the later decades of the twentieth century severely limited the pace of economic and political development throughout the region. Zimbabwe/ Rhodesia, Namibia/South West Africa, and South Africa witnessed protracted guerrilla struggles between white settler populations and black African nationalist organizations that spanned most of the half-century and generated large cross-border refugee movements.

Southern Rhodesia continued to be ruled by its white minority settler population as Rhodesia, and declared its independence from Britain in 1965. Though unconstitutional and condemned by Britain and the United Nations, the largely white government continued to rule Rhodesia until 1980, despite massive trade and political sanctions. After the Zimbabwe African National Union (ZANU), with an ethnic base among the Shona, and the largely Ndebele Zimbabwe African Peoples Union (ZAPU) succeeded in defeating the white settler regime, Rhodesia became Zimbabwe under Robert Mugabe, the leader of ZANU. Independence was followed by a period of repression by ZANU against the Ndebele followers of ZAPU in the middle of the 1980s, though peace was eventually restored. Mugabe continued to rule Zimbabwe with an increasingly heavy hand. Twenty years after independence, he again declared 'war' on the country's white farmers who still retained about half of the arable land. At the turn of the millennium, Zimbabwe was on the brink of economic and political collapse.

The defeat of the Smith's Rhodesian government was made possible by close cooperation between ZANU and African nationalist forces in Mozambique. These had begun by the late 1960s to wage a war of liberation, and offered safe havens for ZANU forces. Operating from Tanzania, FRELIMO had succeeded in gaining control of northern Mozambique in the early 1970s. In 1974, the Portuguese government fell, due in large measure to the cost of its colonial wars in Angola and Mozambique. Mozambique was granted independence in the following year but suffered years of destructive civil war from shortly after the Portuguese withdrawal. To the west, the increasing success of the South West Africa Peoples Organisation (SWAPO) against the forces of the South African Apartheid government had also helped ZANU to achieve its aims in Zimbabwe. South West Africa had been wrested from German control by South African forces acting under British authority during World War I. It was then ceded to South Africa as a Trust Territory under the terms of the Armistice, and in accordance with a mandate of the League of Nations. After a protracted liberation struggle, it became independent Namibia.

Despite its Portuguese colonial heritage, Mozambique is clearly part of the Southern African region culturally and historically. The Tsonga-speaking people of southern Mozambique straddle the border with South Africa. Mozambicans have long been intensively involved in the South African economy, first as labor migrants to white farms from as early as the eighteenth century, and later as laborers on South African mines from the late nineteenth century until the present. South African capital has flowed strongly into Mozambique after the end of its protracted civil war. The African National Congress came to power in South Africa in 1994 after the release in 1990 of Nelson Mandela from 24 years of imprisonment. With the end of colonialism, in all countries except South Africa, large numbers of white people withdrew, either moving back to European countries or into South Africa. Today, well over 95 percent of the population of all countries except South Africa is black African.

3. States and Politics

State institutions in southern Africa are all relatively weak. The colonial states of Mozambique and North and South Rhodesia were never very strong, focusing mainly on controlling black labor migrations and political movements, and on delivering security and services to white farmers, miners, and business interests. The activity of liberation forces also removed large areas from effective government control. Parts of these countries remained effectively beyond the reach of the state, neither paying much in taxes nor receiving many services from the central authorities. At the end of the twentieth century, all except Swaziland had democratic governments elected under universal franchise. The benefits of the postcolonial transition to democratic politics have been limited, however, by long liberation struggles in some cases (Zimbabwe, South Africa, Namibia), postcolonial civil war (Mozambique), rampant corruption, mismanagement (Zambia, Malawi), and, for most, increasing poverty and environmental damage. Throughout the last half of the twentieth century the political process was dominated by relatively few persons and parties.

All countries have been ruled for long periods by one party or by only one or two presidents. Free political expression has often been suppressed. In South Africa the National Party, dominated by white Afrikaners, ruled from 1949 until 1994, one of the longest periods of rule by a single party anywhere in the postwar world. The National Party implemented a set of laws and practices known as Apartheid ('separateness') that attempted to maintain exclusive political and economic power by whites. Racism was institutionalized, and black opposition parties were banned. Their members were either jailed or forced into exile. Only whites were allowed to vote. Within these limits, however, the political process was orderly, with presidents stepping down after their terms of office had expired. Following this trend, Nelson Mandela, the first president of a free South Africa and leader of the African National Congress, stepped down after serving one five-year term to make way for Thabo Mbeki, his elected successor.

The problem of how to integrate 'traditional' African politics of the rural areas with the 'modern,' urban-centered political systems deriving from Europe (either liberal-democratic or centralist-Marxist) has persisted to the present. While Botswana, Lesotho, South Africa, and Zimbabwe maintained 'advisory' constitutional roles for 'traditional authorities' (that is, predominantly rural tribal 'chiefs'), others such as Mozambique abolished chiefship altogether. Tribal groups such as the Himba in Namibia and the Lozi of Zambia maintain chiefs or kings, but without recognition by the state's constitution. With the exception of Swaziland, all possessed more or less liberal democratic parliamentary political systems by the end of the twentieth century. Swaziland alone possessed an absolute monarch based on precolonial African traditions of chiefship. Botswana institutionalized traditional rulers who have a role in government through the House of Traditional Authorities.

In white-ruled Zimbabwe and South Africa, chiefs were brought under government control and seen as part of the system of oppression. In South Africa, during Apartheid, the internal 'homeland' republics also utilized the institution of 'modernized' (salaried and provided with minor bureaucratic support) chiefships that were based on traditional institutions. Nevertheless, the beginning of the twenty-first century saw a renaissance of chiefship in South Africa and Mozambique, with remnants of precolonial traditional political systems often playing public roles in most other countries of the region.

4. Livelihood

In the later decades of the twentieth century, all countries in the region in one period or other suffered increasing isolation from world markets as the result of political sanctions (Rhodesia/Zimbabwe and South Africa), distance from markets (Lesotho, Malawi, Zambia), warfare (Mozambique), or declining market prices for their primary products (Zambia). Worldwide political and economic sanctions were applied first to Rhodesia (Zimbabwe) throughout the 1970s during the period of white settler rule, and then to South Africa during the final decades of the struggle against Apartheid.

A polarity between the 'modern' urban centers and the surrounding 'traditional' rural regions has characterized the broad politico-economic structure of the region since colonial times. A long-term, occasionally rapid, migration of rural agriculturalists to urban areas has, in the past, skewed gender balances as males moved to urban areas in search of wage labor, while women tended to stay in the villages. Damage to family structures, unemployment, urban crowding, severely limited police capacity, and poor urban planning have often led to high levels of social insecurity and criminal violence. Rural–urban migration had stabilized by the end of the millennium, but high levels of mobility between city and country remain, with kin groups attempting to maintain bases in both.

In Zambia, urbanization proceeded rapidly during the colonial period, with miners and work-seekers clustering in the 'Copper belt' in the north-central Zambia. With collapsing copper prices during the 1980s and mismanagement of mines, many people returned to rural areas. By the beginning of the twenty-first century, over 95 percent of Whites and Indians in South Africa were living in urban areas. Black South Africans are nearly equally divided between urban and rural. Rural areas are characterized by dispersed residence, subsistence agriculture and pastoralism, producing no significant economic surplus for trade.

Urban areas throughout the region are weakly centralized and sprawling. All large urban areas derive from colonial patterns of segregated 'suburbs' loosely grouped around multiple trading and industrial centers. Single houses (or complexes of houses, outbuildings, and shacks) surrounded by walled 'gardens' or yards comprise the formal urban settlement pattern, while large informal shack settlements surround them.

The colonial economy based on mining, large-scale farming, and labor migration contributed to disruption of family life and systems of social control, especially in rural areas of Zambia, Zimbabwe, and South Africa. While mining and agriculture now account for less than 10 percent of the GDP in South Africa, these two sectors dominate the economies of other southern African countries as they did in South Africa in the early twentieth century. Lesotho and Malawi, lacking natural resources except water, have been largely labor-exporting countries, relying on remittances sent home by miners who work mainly in South Africa, but also Zambia and Zimbabwe. The bulk of Botswana's GDP is derived from diamond mines, while Zambia relies on exports of copper, cobalt, and other minerals. Namibia is mostly arid, and depends on mineral exports, especially uranium, for foreign exchange earnings. All countries, however, participate in sending labor to the mines located throughout the region but dominated by South African mining houses.

At the beginning of the twenty-first century, economic and social prospects are dimmed by the threat of HIV/AIDS pandemic. Southern Africa emerged as the hardest hit region in the world. As a consequence, the rate of population growth is predicted to fall below replacement rates in the first decade of the twenty-first century.

5. *Language and Communication*

The process of urbanization has resulted in the emergence of distinctive urban cultures with small manufacturing, trade, mining, and transport industries initially attracting large numbers of formerly rural people to urban areas where different languages and cultures came into contact. They blended to form new urban-based languages and cultures. Examples include *Isicamtu*, 'talking' or *tsotsitaal*, 'gangster language,' in South Africa, based on Zulu grammar but blending English, Afrikaans, and Sotho or Twana words; or *Fanagalo*, meaning 'Do-like-this,' a pidgin based on Zulu used on the mines and farms throughout southern Africa. New forms of music, dance, and religion blending African traditions and Western forms also arose.

No indigenous African language has achieved status or acceptance as a single national language or *lingua franca* anywhere in southern Africa. South Africa has 11 official languages, of which those with the largest number of speakers are Zulu (8.7 m speakers), Xhosa (6.8 m), Afrikaans (6.2 m), Pedi ('Northern Sotho'; 3.8 m), English (3.5 m), Sotho (Southern Sotho; 2.7 m), and Tswana (2.8 m) in addition to the smaller linguistic communities of Tsonga ('Shangaan'), Venda, Ndebele, and Swati ('Swazi'). Other languages spoken include Gujerati, Urdu, Hindi, Tamil, and Bhojpuri from India. Portuguese, Greek, and German is spoken by smaller communities from Europe. Chinese is spoken by recent immigrants from China and Taiwan, although the small community of Chinese who arrived in the nineteenth century speak only English. French is spoken primarily by central African refugees and migrants in South Africa.

The linguistic diversity is even greater in Zambia where 41 languages are spoken, including Bemba, Tonga, Nyanja (Chewa), and Lozi. Thirty-three languages are spoken in Mozambique and 28 in Namibia. Although over 70 percent of the population of Botswana speak Tswana, there are many small, nearly-extinct languages spoken by Khoisan people, and by refugees from surrounding countries.

There is some mutual intelligibility among some of these languages. For instance, Sotho, Pedi and Tswana are mutually intelligible, as are Zulu, Xhosa and Swazi in South Africa, Botswana, Swaziland and Lesotho. Several languages have become *lingua francas* within limited areas of these countries—for instance Zulu in South Africa, or Bemba and Nyanja/Chewa in Zambia and Malawi. Almost all people speak several regional languages. As a consequence of diversity, with the exception of Mozambique, English has increasingly become the dominant public language of government and the media. It is also the language of trade and diplomacy. While Mozambicans use Portuguese as the language of government and education, they are increasingly turning to English, too, as they develop deeper political and economic links with other nations. Nevertheless, the large majority of all people in the region continue to rely on local Bantu languages in their homes.

Until 1994, South Africa treated both English and Afrikaans as 'official,' but Afrikaans now figures as only one of the 11 official languages. Afrikaans is indigenous to South Africa where it evolved from dialects of Dutch in the Dutch colonial settlements at the Cape of Good Hope in South Africa. Today it is spoken throughout South Africa and Namibia, with small pockets in other southern African countries. In South Africa, Afrikaans is spoken by a larger number of people than English as a home language.

Within the region, South African society is the most complex with respect to color, 'race,' religion, language and dialect, region, and class. Ethnic, political, and other kinds of identities—such as preference for certain sports, or foods—are based on these differences, and also help to create and sustain them. None of these primary indicators of social difference, however, tend to define a consistent or bounded category

of people. In other words, people of many different colors or race speak the same language or set of languages, while people of the same region or class vary widely in what religion they follow, or in their political allegiances. People sharing the same religion and language—which is often a combination that defines a fairly closely-knit ethnic or national community in Europe, or Asia—may span widely different colors, classes, and regions in southern Africa. For instance, while the majority of South Africa's 'Colored' people speak Afrikaans and belong, like most White Afrikaners, to some denomination of the Reformed Church, until recently they considered each other to be eternally divided by their 'race.'

Surprisingly, while virtually all schools and public places were rigidly divided by 'race' in the 1980s, by the end of the century, schools, shopping centers, and other public places had quietly integrated with no more than a handful of violent or other racial incidents. On the other hand, as the business center of Johannesburg gradually became 'black,' the entire economic geography of this city of six million people shifted, with largely white owned business moving north into newer, dispersed business centers within the last few years of the 1990s. Despite the previously enforced divisions and centuries of conflict across many different cultures and language groups, South Africa exhibits a degree of cultural, economic, and political unity that is perhaps unique in Africa. Virtually all of its people manage to communicate with one another in one or several common languages, shop in the same stores, watch the same television channels, furnish their houses in similar ways, and—ironically—share the belief that they are much more different from one another than they actually are in terms of many objective measures of cultural or social difference.

Sovereignty: Political

Sovereignty is a set of principles or rules that define appropriate governance structures. These rules were first explicated with the greatest clarity by Bodin and Hobbes in the sixteenth and seventeenth centuries, and elaborated by later thinkers including Jeremy Bentham and John Austin. The defining principle of these initial efforts to clarify the meaning of sovereignty was that there could be one, and only one, source of the law, and that this source, the sovereign, was either in practice or in theory not subject to any higher authority. A corollary is that each sovereign state is independent, subject to no external authority.

In the contemporary world, the meaning of sovereignty has become less certain. Sovereignty has become associated with several different rules and practices, rather than with some single notion of supreme authority within a given territory. The realization of any pure version of sovereignty of the sort that Bodin, and especially Hobbes, embraced is precluded by three factors. First, the relationship between order and a single hierarchy of authority has been belied by actual practice, especially the experience of modern democratic states in which authority is fragmented and divided. Second, power asymmetries and the absence of any final authority at the international level has meant that, for some states, juridical autonomy has been an empty or half empty shell because their domestic political structures have been infiltrated or organized by other, more powerful, states. Third, the sovereign right of states to enter freely into any agreement means that political leaders may in some cases choose to compromise the domestic autonomy of their own polities; one element of sovereignty, the right to make treaties, confounds another, the independence of domestic political structures.

1. Origins of Sovereignty

The concept of sovereignty was associated initially with the domestic ordering of authority and control. At its core was the notion that there can be only one supreme authority. Even if divine authority or natural law existed (which even Hobbes admitted) in practice, only the sovereign could make laws. There could not

be any earthly authority above the sovereign, because then the sovereign would not be sovereign. There could also be no external authority, no international or transnational actor, that could negate the will of the sovereign. A political order based on sovereignty or the sovereign state can be contrasted with the medieval world, in which there were overlapping authority claims within the same territory, and the traditional Sinocentric world in which China alone was supreme; other political entities, such as Korea, were subordinate or tributary states yet not part of the imperial core.

In Europe, a political world in which states with defined territories and some degree of autonomy from external, especially transnational authority (most notably the Catholic Church), evolved over several hundred years as a result of material factors, including long-distance trade and technological changes in warfare that favored states over other political entities such as city leagues, the Holy Roman Empire, or the Papacy, and ideational ones, most notably the Protestant Reformation (Tilly 1990, Spruyt 1994, Skinner 1978). It was, however, the European religious wars which provided the motivation to develop a doctrine that could legitimate a political order populated with one, and only one, final source of authority within a given territory. The antagonisms bred by sectarian beliefs precipitated bloody civil conflicts in the major polities of Western Europe. Bodin, who was almost killed in religious riots in France in 1572, wrote his *Six Books of the Commonwealth* in response to the Huguenot rebellion and the Huguenot writings that justified rebellion against tyranny. For Bodin, the fundamental objective of any government must be to insure order, and not to protect liberty. Sovereignty, which for Bodin was intimately associated with the right to give laws and not just to make judgments, had to be lodged somewhere, and he argued that monarchy was preferable to either an aristocracy in which sovereignty would rest with a few, or a democracy in which it would rest with the many. Bodin, like Machiavelli, dwelt on the frailty of political order. He acknowledged that a sovereign who became a tyrant might justly be killed by a foreigner, but he rejected any rationale for domestic resistance (Skinner 1978, pp. 284–8, Hinsley 1986, p. 120).

Bodin did not, however, regard the sovereign as unconstrained. The sovereign was bound by the laws of God and nature, and by custom. Because natural law dictated that promises ought to be kept, the sovereign was obligated to honor treaties made with other sovereigns, and agreements made with his own subjects. Taxation required the consent of the governed, because arbitrary confiscation of property would violate the laws of nature. In France, Bodin averred that the king could not change the Salic law, a customary practice, which limited succession to males (Skinner 1978, pp. 273, 289, Bodin 1992, Bk. I, Chap. 8).

Hobbes, writing 80 years later, was more emphatic in his defense of the power of the sovereign. Hobbes rejected even the modest constraints that Bodin had imposed, arguing that it is the sovereign who interprets the laws of God and nature. Once individuals had entered into a social contract they could not or ought not challenge the sovereign, although Hobbes acknowledged that individuals had a right to run away in the face of violent death. The alternative to the Leviathan, the sovereign, was the state of nature in which life was 'nasty, brutish and short.' The line of argument focusing on sovereignty as an attribute of domestic political structures was developed further by legal positivists, such as Austin, who asserted that the law properly understood emanated from one single source of authority untrammeled by any constraints. Bentham, for instance, argued that natural law was a nonsensical concept.

2. *Sovereignty in Practice*

While in theory sovereignty has often been associated with the concept of a single lawgiver untrammeled by any higher source of authority, except perhaps God, in practice the actual exercise of authority has been much more complicated. The kind of state envisioned by Bodin, and especially Hobbes, never came into existence. In Britain itself, the strife of the seventeenth century led to a political system in which authority was divided between king and Parliament. In the United States, the Founding Fathers established a constitutional order with a division of power among the executive, legislative, and judicial branches, as well as between the individual states and the federal government. In the twentieth century, centralized hierarchical systems such as Nazi Germany and the Soviet Union provided neither prosperity nor domestic tranquillity for their citizens. The classic view which associated political order with a single hierarchy of authority is irrelevant in the contemporary world.

2.1 *Sovereignty in the International System*

The notion of sovereignty however, continues to be invoked at the international level, where it is defined by two principles. First, the right to domestic autonomy or independence: regardless of their internal structure of authority (unitary, federal, democratic, autocratic, etc.), sovereign states exclude both *de jure* and *de facto* external sources of authority. Second, the right to make treaties: sovereign states can enter freely into contracts with other entities. In practice, the first of these principles, autonomy, has been contested persistently, and the second, the right to enter freely into contracts, can result in agreements that contradict the first. Although a few states have approximated the sovereign ideal of actual, and not just formal juridical autonomy, the United States being the most important

example, there has never been an historical moment during which the world could be described as divided among such states, each enjoying exclusive authority within its own territory. Even if states have had a monopoly over the legitimate use of force within their own borders, the purposes toward which such force might be used frequently have been influenced or determined by external actors.

2.2 Dilemmas of Sovereignty

There are two factors that preclude the full realization of any idealized form of sovereignty. First, because there is no authority above states, powerful states can violate the autonomy of their weaker neighbors. Second, because sovereignty implies that states have the right to make any agreements that they please, there is nothing to prevent them from entering into treaties that might subject them to external authority structures.

The most obvious violations of the principle of autonomy involve military force. Major powers have not been reluctant to dictate the domestic political structures of their weaker counterparts, especially within their own spheres of influence. The United States has intervened frequently in the smaller states of the Caribbean and Central America because of concerns about security, financial stability, human rights, and illegal drugs. After World War II the Soviet Union imposed communist regimes on its satellite states in central Europe. In 1999, the member states of NATO conducted an extensive bombing campaign over Yugoslavia designed to coerce the Yugoslav government into changing its practices toward Kosovo Albanians while at the same time continuing to recognize Kosovo as a part of Yugoslavia.

External influence on the domestic political structures of states has not, however, been the result of direct military action alone. All of the major peace treaties, beginning with the Peace of Westphalia of 1648, have legitimated to some extent external legitimation of domestic authority structures, sometimes as a result of fully voluntary and mutually beneficial accords, but at others as an outcome of asymmetrical bargaining power. The Peace of Westphalia, often described as a critical moment in the development of the modern state system, did delegitimate the Catholic Church as a transnational source of authority and initiate a long period in European history in which the secular balance of power rather than some notion of a unified Christendom defined the way in which leaders conceived of and practiced international politics. But at the same time, the specific provisions of the Westphalian Peace established a new constitution for the Holy Roman Empire including religious toleration within Germany, a position supported by the victors in the Thirty Years' War, France and Sweden, and accepted only reluctantly by the Habsburg monarch, Ferdinand III. The Peace did not create a world of autonomous political entities; the political units within the Empire (principalities, electorates, free cities) were still embedded within the larger institutional arrangements of the Empire which were, as a result of the Westphalian Peace, now subject to international guidance. The Vienna settlement following the Napoleonic Wars guaranteed the rights of Catholics in The Netherlands. During the nineteenth century the European powers, fearing that ethnic conflict in the Balkans would destabilize Europe (which, indeed, happened in 1914) insisted on religious toleration as a condition for recognizing all of the successor states of the Ottoman Empire, beginning with Greece in 1832 and ending with Albania in 1913. Perhaps most clearly, the peace settlements following World War I included extensive provisions for the protection of minority rights. Poland, for instance, as a condition of recognition and admission to the League of Nations, agreed to bilingual education in some primary schools, and to refrain from holding elections on Saturday because such balloting would have violated the Jewish Sabbath. While a few states, such Hungary, which had a small domestic minority population but many co-ethnics living in other states, welcomed these minority rights arrangements, most of the 30 or more states that were affected regarded them as a necessary evil, accepted only to secure their international status.

The interwar efforts at international constraints on domestic practices were a dismal, albeit internationally legitimated, failure, and after World War II, human rather than minority rights became the focus of attention. The United Nations Charter, for instance, endorsed both human rights and the classic sovereignty principle of nonintervention. Disheartening developments associated with the disintegration of Yugoslavia in the 1990s, however, revived earlier concerns with minority rights. Recognition of the Yugoslavian successor states was conditioned on their acceptance of constitutional provisions guaranteeing minority rights, and in Bosnia the Council of Europe established a set of external authority structures including a Human Rights Commission, a majority of whose members were appointed by the Council.

Political leaders may also use their sovereign right to enter freely into treaties to compromise voluntarily the autonomy of their own polity. In the contemporary environment, the clearest example of the tension between the right to contract and domestic autonomy is the European Union. The European Commission, the European Court of Justice and the European Parliament are supranational authority structures that can, in some issue areas, make decisions that are binding on member states, even states that have not agreed to them explicitly. The rulings of the Court, for instance, have a direct effect in national judicial systems and supremacy over domestic law, doctrines that emerged through judicial practice rather than any explicit treaty. The Single European Act adopted in 1987, and the Maastricht Treaty ratified in 1993

provided for majority or supramajority, but not unanimous, approval for decisions in many issue areas. Mutual recognition, which obligates member states to recognize each others' national regulatory measures, creates extraterritorial authority because legislation in one state governs the activities of enterprises in others.

The European Union is a particularly dramatic example of the tension between sovereignty understood as the right to enter freely into contracts, and sovereignty understood as autonomy or independence from external authority structures, but it is not unique. The member states of International Monetary Fund have accepted conditionality arrangements covering not only specific policy targets such as the level of the public debt, but also domestic authority structures such as the establishment of an independent central bank or the creation of a corruption commission.

3. *The Significance of Sovereignty*

The tensions between different attributes of sovereignty, the coercive and legitimated efforts by external actors to influence authority structures within specific states, and the abandonment of the notion that sovereignty requires some one single source of domestic authority, does not mean that the concept is inconsequential. Sovereignty remains a widely understood script, comprehensible not only to political leaders but to wider populations as well. Sovereignty is a rallying cry for dispossessed populations even in situations where the best possible outcome would be a state whose authority structures would not be of its own making as is, for instance, the situation in East Timor. The salience of sovereignty may make alternative arrangements more difficult, especially in situations where compromises reached by political leaders could be undermined by counter elites deploying the language of sovereignty. Other forms of political order require either coercion, as in the former Yugoslavia, or explicit agreement, as has occurred in Europe. Innovative structures, such as the relationship that China established with Hong Kong in the late 1990s which included the participation of a foreign judge on the Court of Final Appeal and a separate Hong Kong passport, have been explained in terms of the modern language of sovereignty even when they are more reminiscent of different ordering principles, such as the traditional Sinocentric tributary state system.

Sovereignty has become a set of principles more associated with the nature of political entities in the international environment (states as opposed to, for instance, protectorates or empires) and their relationship with each other (nonintervention), than with the organization of domestic political authority, which was the primary concern of most important early writers on sovereignty. But the absence of any ultimate source of authority in the international system, the conflicting norms embraced by political leaders and their followers, and clashes over issues of both security and material welfare mean that while sovereignty remains a consequential idea influencing political choices, it will also be persistently contested.

Soviet Studies: Culture

Soviet studies, like its other regional studies counterparts, is primarily a European and North American academic response to post-World War II geopolitics. It overlaps with *Slavic Studies* but also includes a research on non-Slavic cultures living on the territory of the Soviet Union, and makes a reference to the history and culture of the Russian Empire before 1917. Soviet Studies grew rapidly during the Cold War, and were generously supported by the US government in its effort to 'understand the enemy.' It integrated a number of disciplines including history, economics, literature, linguistics, sociology, and ethnology, but gave primacy to political science. From the outset, such study took the supranational unity of the Soviet Union as the master frame of reference for the study of languages, cultures, and social institutions, however diverse.

The status of *culture* in Soviet studies is complex and changing. Interest in the political origins of the Soviet system underwrote a long-term emphasis within Sovietology (the Cold War title for Soviet Studies) on *political culture*. Forms of governance, the nature of domination and subordination, the mechanisms of legitimation of the regime, and the emergence of a self-selected ruling elite were among the principal concerns of this type of research. At the other end of the spectrum was research on *artistic culture*, which was treated as expressive of national culture in general, and its producers, Soviet intelligentsia.

The 'cultural turn' of the mid-1980s in Western social science stimulated new development in Soviet studies. Increasingly, studies of Soviet society directed attention to social discourses, practices, and everyday life. This anthropologically informed idea of *culture* as a realm of socially shared meanings and a system of representations now proliferates in this regional research.

This article traces the development of Soviet and post-Soviet studies with an emphasis on how culture was used as an analytical framework. It also considers the diverse lines of influence that run between Western (post) Soviet studies and internal studies of culture in the Soviet Union and Russia. Throughout, the term 'Soviet culture' refers to cultural developments of the socialist period from 1917 to 1991. 'Post-Soviet culture' defines the contemporary stage of cultural development in the territory of the former Soviet Union.

1. *Culture in Russian Society and Russian Social Sciences*

The concept of *culture* has a complex provenance in the Soviet and Russian contexts. One sense of the term refers to education and the level of self-possession of an individual—*kul'turnost'*. The second meaning symbolizes people's unity based on language, tradition, and heritage, and reflects the profound role of culture in nationalist discourse. Finally, culture in its expressive forms, and literature in particular, constitute a relatively independent domain of meaning.

The term 'culture' did not enter widespread use in Russian society until the 1880s. Before then, occasional use of the word referred either to 'literary culture' or to the broader attainments of education, enlightenment, and civilization. As the process of national self-definition gathered speed in the late nineteenth century, a series of cultural dualisms emerged. Perhaps most significant was the opposition between East and West, which became central to discourse on national identity. As the twentieth century began, cultural dualism of this kind informed increasingly powerful notions of the 'Russian way of life' and 'Russian culture.' At the same time, non-Russian ethnic groups were ascribed particular cultures. 'Culture' became, in this context, the container of difference, and as such underwrote a variety of inquiries into the material culture and 'vanishing traditions' of 'traditional peoples,' including folklore studies. This interest became more pronounced in the Soviet era, reflecting a perceived need to study the effects of socialist modernization on the 'hinterlands' (Dunn and Dunn 1974).

Another formative distinction within Russian/Soviet culture is that between 'high' and 'low.' Originally the subject of nineteenth century debates between Slavophiles and Westernites, high–low distinctions became a major concern of communist rule. Communist party ideologues attempted to do away with the notion of a distinction between elitist and popular cultures by forging a 'culture for the masses.' New cultural initiatives were meant to speak to the peasants and the workers. Beginning in the 1920s, *kul'tura* was carefully planned and designed to eliminate cultural divides. In Stalin's time the word 'culture' acquired a distinctive suffix—*kul'turnost'* ('cultured-ness'). The suffix signified the inclusiveness of the new cultural order—embracing the new artistic cannon (Socialist realism) manners, and styles of life (Boym 1994). High art, for its part, would be democratized through museums, education, and cultural associations. Although greatly influenced by political constraints and censorship, this set of cultural policies produced a number of progressive trends in art and literary criticism that profoundly influenced Western cultural and linguistic theory.

The school of linguistics known as *Russian formalism* was one of these. It developed in the mid-1910s around Viktor Shklovsky and Yuryi Tynyanov, and in the 1920s merged with the Moscow Linguistic Circle, led by Roman Jackobson. Russian formalist theory tried to overcome the dualism of form and content by emphasizing the study of poetic language as such: the interplay of verbal forms, tropes, sounds, syntactic

constructions, etc. Their method of 'functional poetics' sought the underlining structure of works through the relationships between their internal elements (Erlich 1965).

Mikhail Bakhtin and Vladimir Voloshinov formed another group situated between the formalists and the official Marxist line on culture. Their work became an extensive study of what Bakhtin called the *dialogic* dimension of language—the construction of meaning in a linguistic field shaped by competing discourses such as official and popular cultural forms. Prohibited in the Soviet Union, these theorists found an audience among Western literary and cultural analysts, particularly in the areas of structuralism and semiotics (Holquist 1990).

Other movements were important within Soviet scholarship. During the 1960s, 1970s, and 1980s, the *Tartu School* associated with Yurii Lotman became prominent. These scholars developed a sophisticated approach to cultural history that emphasized cultural wholeness and totality in its search for the key to Russia's duality. They accorded culture a near metaphysical status—culture as an abstract force that reasserted itself onto national patterns of life (Lotman 1984).

As a result of political constraints and censorship, more analytical attention was paid to literary and art criticism than to other forms of cultural analysis. In response, literary and art criticism became a common means of articulating broader critiques of the Soviet system. This was the case with Boris Groys' *The Total Art of Stalinism* and Vladimir Papernyi's *Kul'tura 'Dva.'* Indigenous Soviet scholarship produced an extensive body of knowledge of Russian culture—though one that remained independent of Western theoretical influences until the 1990s.

2. *The Development of Soviet Studies in North America*

Although culture held a marginal position in Western Soviet studies until quite recently, the immediate postwar period between 1946 and the early 1950s provides a brief exception. For a time, linguists, sociologists, anthropologists, and even psychologists became interested in the study of Soviet society. They were encouraged in their work by the wave of war refugees who could provide first-hand knowledge about the life of the region. This effort collapsed shortly after it began. The comprehensive Soviet control of information thwarted Western inquiries until *Perestroika* in 1985. The inaccessibility of Soviet society to independent observers put severe methodological constraints on most forms of social science inquiry. Moreover, political considerations from the 1950s to mid-1980s played a major role in prioritizing certain kinds of research. High politics and economics were deemed crucially important and the Soviet political system became the focus of most attention. The 'ordinary man' nearly disappeared as a subject of inquiry. Political scientists and in some cases historians came to dominate this research agenda. Sociologists and anthropologists were more or less removed from the field.

One result of this reconfiguration was the so-called 'totalitarian model,' best represented by the line of political theory running from Hannah Arendt's *The Origins of Totalitarianism* (1953) to Martin Malia's *The Soviet Tragedy* (1994). The totalitarian model focused on the one-party political system and its methods of control: primarily terror and the destruction of meaningful social bonds outside the Party. This scholarship tended to suffer from several related problems. (a) It tended to take state ideologies at face value, reproducing Cold War prejudices about the diametrical opposition between capitalist and socialist systems, at the political as well as the economic level. (b) It took the indoctrination of the Soviet 'masses'—another self-proclaimed success of the Communist Party—as empirically proven.

Change came in the late 1970s and early 1980s, as debates arose between advocates of the totalitarian model and those who challenged totalitarian thinkers for overemphasizing the power of the Soviet political system. 'Revisionists' raised political questions about the nature of popular support and argued for evidence of more complex negotiation between the regime and the society. This is the moment in which 'culture' came to wider attention. Class identity, gender issues, social movements, and nationalism were introduced as necessary complements, and often as alternatives, to the political models. On their side, revisionists exposed themselves to the criticism of 'whitewashing' communist repression and purges.

The fall of the Soviet regime in 1991 transformed studies of culture on both sides. On the one hand, it provided access to Russia for Western scholars. Archives were opened and sociological studies of the general public became possible. On the other hand, it put Russian scholars, with their knowledge of the language and culture, in contact with the West. This new wealth of information and intellectual exchange was accompanied by subtler shifts in approach. In reaction to the revisionist effort to 'de-ideologize' the Soviet regime, a new generation of scholars returned to the question of how ideology created new and durable social structures. They did so, however, while retaining the focus on culture and organization of everyday life. The following section considers the major directions in research on culture in Soviet and post-Soviet studies that emerged around questions of social identities, everyday life, consumer, and popular cultures. It pays less attention to political science that continues to view culture as limited to 'political culture'—the expressions of economic and political processes.

3. Areas of and Research in Soviet and Post-Soviet Studies

Questions of 'modernity' and 'modernization' are common denominators for much of the Soviet and post-Soviet studies, from the official communist ideology of socioeconomic development to a broader trajectory of rationalization implicit in notions of 'modernity.' Against this backdrop, a number of cultural phenomena have attracted analytical attention.

3.1 The 'Soviet Individual'

The relationship between the regime and the society and the way it shapes individual identity is among the 'oldest' concerns in Soviet studies. From the 'totalitarian model' to the contemporary challenges of creating a civil society, many scholars have been preoccupied with what it meant to be a 'Soviet Individual.' Soviet modernization specified the need for an 'all-round personality' appropriate to a 'non-exploitative society,' and the state and the Party took responsibility for creating it. Facilitated by rapid urbanization, this 'socialization' proceeded through the imposition of cultural regulations and norms, altering the existing structures of identity (Volkov 2000). The state initiatives to reform individuals were not without limitations. Recent studies of socialist individuation show that a difference between public adherence and private life allowed for complex strategies of avoidance of Party control. Thus emerged the 'dissimulating subject' (Kharkhordin 1999). As the Soviet system calcified and as socialist prosperity became an increasingly remote fiction, endorsement of the official ideology became a means of securing a private existence out of reach of the intrusive power of the state (Yurchak 1997). Alexei Yurchak suggests that although the 'objective conditions of socialism' were seen as false, Soviet individuals continued to act as if they were true believers. This collective 'pretense of misrecognition' strengthened social solidarity and allowed for meaningful life in other areas.

3.2 Class and Stratification

Through the creation of the Soviet individual, the Soviet state aimed to remove distinctions among social groups. 'Class' became a focus of social policies and, as a result, of political studies. In Soviet studies, the Soviet Union provided a contrasting case for Western economic upward mobility. While Soviet officials insisted on 'giving power to a class,' Western Sovietologists viewed mobility primarily in individual terms, as resulting from individual opportunities to improve social standing. Other critiques treated the Soviet claim of the disappearance of a class society as a necessary fiction of the regime. Discussions of mobility and stratification were enriched in the 1980s by culturalist accounts of class consciousness as a formed and learned identity, drawing especially on E. P. Thompson's work on nineteenth century Britain. These directly challenged the dominant Soviet conception of class as an ascribed characteristic that had little connection to socioeconomic position (Fitzpatrick 1993). They were central to emerging work on a range of largely unexplored types of social behavior—especially the patterns of dissimulation, unmasking, and stigmatization that structured social identity and the relationship between individuals and the regime. Studies of class have been far less frequent in post-1991 scholarship, however, reflecting the rise of interest in other registers of identity.

3.3 National Identity

Socialist modernization also made claims to cultural progress in ethnic relations while preserving the national distinctiveness of Soviet society. The fate of non-Russian people under Soviet rule was the subject of numerous studies in the Soviet era, including historical studies of Central Asia (Eickelman 1993) and Siberia (Balzer 1997). Western Sovietologists also produced studies of non-Russian people—although these were, with rare exceptions, heavily influenced by cultural evolutionary paradigms. Modern anthropological approaches emerged only later (e.g., Caroline Humphrey's ethnography of collective farming in Buryatia (1983)).

Because nationalism was officially represented as an obstacle to communist internationalism and ostensibly suppressed, studies of post-Soviet ethnic relations reproduce a 'repressive hypothesis.' When, the argument goes, 'political opportunities' arose in the late 1980s, ethnic conflicts resulted from the discontent of the Russian 'core' and the intensifying local nationalisms of the non-Russian periphery (Kaiser 1994).

Yet, as Yuri Slezkin has argued, it may be more instructive to consider how socialism cleared the way for contemporary nationalism (Slezkin 1994). Despite opposition between socialism and nationalism on many levels, the principle of national difference was officially sustained in the federated states. The individual 'nation' was the only permitted form of social association other than the Communist party itself. This provided an opportunity for group mobilization along nationalist lines when the opportunity arose.

How this opportunity was translated into processes of cultural formation after the 1991 break-up is a complex story that is only beginning to be told: identity formation in the Ukraine (Wanner 1998) draws on different resources than that of 'traditional' peoples in Siberia (Grant and English 1999). The prominence of new concepts such as the *Russian diaspora* and the *near abroad*—designating Russians living in the republics—also reflects the new, post-Soviet realities of

national co-habitation. Research on population diasporas on the territory of the former Soviet Union offers new conceptual questions: what does it mean to become an ethnic and linguistic minority without having emigrated in any conventional sense (Shlapentokh et al. 1994)? David Laitin (1998) discusses new national identities in the post-Soviet space as outcomes of a 'tipping game'—a rational choice to learn new languages and cultural norms if one wishes to enjoy the benefits of citizenship. Laitin argues that under post-Soviet conditions, cultural assimilation depends neither on cultural nor linguistic similarity, nor on ethnic closeness, but rather on the degree to which the structural conditions of economic, political, and social life stimulate a desire to chose some and not other forms of identification (Laitin 1998).

3.4 History and Collective Memory

The interpretation of national history was also important for Soviet modernization. Soviet culture, although future-oriented, was deeply rooted in a particular historical vision. Peter the Great stood as a symbol of modernization, linked first to Bolsheviks and then to Mikhail Gorbachev; the French Revolution was a predecessor of the Russian Revolution, and the victory over Germany in World War II completed the genealogy of Russian military glory (Clark 1994). Stories of redemptive suffering in World War II, especially, sponsored belief in the unique position of Russia in world history. They provided a narrative of 'all-national struggle' and a precedent for the patriotic mobilization of a 'cynical and apathetic populace' (Tumarkin 1994, p. 277). Especially under Brezhnev, these narratives counterbalanced the numerous tensions that strained national unity while giving priority of place to ethnic Russians as the leaders of the Soviet people. After 1991, socialism itself became a form of narrative and came under scrutiny as a subject of historical interpretation.

3.5 Gender and Sexuality

One of the goals of socialist modernization was to solve the 'women question.' Western Sovietology tended either to accept communist claims that gender inequality had no place in the new society—Ella Winter's (1933) *Red Virtue* and William Mandel's (1975) *Soviet Women* took this line—or to severely criticize communists for indulging in mostly empty rhetoric on these issues, as Manya Gordon did in *Workers Before and After Lenin* (1941). The latter perspective reflected the tension between the official policy of women's emancipation and gender equality, and *de facto* sexism and inequality in everyday life (Lapidus 1978). The post-Soviet period has, by most accounts, seen further deterioration of this situation, as measured by discrepancies in male and female employment, sexual harassment in the workplace, and sexism in the media. Though some have argued that these phenomena are products of the rapid restructuring of society, most scholars of gender in Russia see connections between the formal promotion of women rights under socialism and the current regression. Many have argued that the Soviet constitutional definition of women as workers *and* mothers is partly responsible for discrimination directed against women in practice. In addition, the imposition of feminist ideology 'from above' did not reflect popular support 'from below' (Muller and Funk 1993). As the post-Soviet state fell into crisis, it has been unable to defend the full range of formal rights for women. One of the consequences, Mary Buckley (1992) notes, is that women have been increasingly driven away from participation in the public sphere.

Sexuality, as distinct from gender, was rarely examined in Soviet studies. Because studies of sexuality are methodologically demanding and complicated, they were severely restrained by Soviet censorship and rigid cultural norms. Peter Stanford's 1967 book, *Sexual Behavior in the Communist World*, presented an interesting but fragmented view of sexual practices under socialism. Most work on sexuality in Western Soviet studies was based on the analysis of available legal or literary texts and other cultural artifacts (Dunham 1961, Levitt and Toporkov 1999). Only in the 1990s has more theoretical, fieldwork-based research developed—partly in response to the dramatic reorganization of sexual norms in Russia. Laurie Essig's research on homosexuality in Russia is exemplary in this regard, offering not only rich empirical material but a critical comparative analysis of the distinctive formation of sexual subjectivity in Russia (Essig 1999).

3.6 Popular and Consumer Culture

During the Soviet years, the 'shortage economy' placed a premium on the hoarding, rather than consumption, of goods by individuals. Yet consumer goods were vitally important to socialist ideology. Images of communist abundance were crucial in securing the regime's legitimacy—especially in the context of the current sacrifices. In reality, the shortage of goods resulted in their informal distribution through a 'second economy.' Access to goods was a coveted and largely political privilege: those who possessed it were in some respects analogous to the Western moneyed and propertied class (Osokina 1998).

As new goods flow into the post-Soviet space and as the new consumer culture develops, new questions arise. Do the new relations of capitalism dissolve the fabric of pre-existing, socialist-era social relations? Does the international flow of goods homogenize cultures? How are we to understand the capitalist

'break': is there a link between the Soviet and post-Soviet consumer cultures (Humphrey 1995)?

Russian scholars and Western scholars of Russia alike have shown tremendous interest in the recent flowering of popular culture—a new feature of post-communism. Youth culture, night life, and new media are just a few areas of recent scholarly interest. As more cultural artifacts are imported to Russia from the West, the post-Soviet cultural landscape changes further. The study of popular culture's contemporary forms, however, requires careful consideration of the peculiar trajectory of the concept in the Soviet and Russian contexts (Barker 1999).

4. *New Social Realities And The Future of Post-Soviet Studies*

The demise of the Soviet Union in 1991 opened a new chapter in the studies of the region. It also brought considerable confusion to the field. The break up of the old territorial unit challenged the geographical coherence of the former Soviet Studies. It yielded new geographical groupings. Central Asia, for instance, could be plausibly integrated into Middle Eastern studies, while the Baltic republics, with their effort to join the European Union, could be approached in the context of Western Europe. Yet the shared socialist past underlies considerable similarity in the social, economic, and political development of these countries and precludes easy redefinition of the region.

The fall of the Soviet regime made it clear that certain perceptions of the Soviet Union were an integral part of the national fabric in Europe and the United States. Political scientists bore the most criticism for letting these perceptions cloud their understanding of fundamental social developments in the Soviet Union, leading to their collective failure to predict the end of communism. Despite this fact, revisions of totalitarian and modernization theories continue to be produced. New Russia centered accounts of capitalism's inevitability—part of a body of 'transition theory' modeled on European and North American capitalism—have come to the fore (Burawoy and Verdery 1999). Opposed to such visions of predetermined change are diverse efforts on the part of younger scholars to understand how family, work, and community refashion themselves in creative and resistive processes of change.

In spite of the accumulation of empirical research, few Cold War-era studies of Soviet culture were theoretically innovative. The opening of post-Soviet society and its ongoing transformation pose new challenges for Western cultural theory and studies of culture, from theories of capitalist development to nationalism and models of historical rupture. If taken critically, this challenge presents remarkable opportunities, both for the new Russian and regional studies, and for the study culture in general.

Soviet Studies: Economics

With growing intensity during the years following World War II, Western economists studied the economy of the Soviet Union and similar East European variants bound loosely in the West by the paradigm of Soviet studies. Systematic analysis of the Soviet economy after World War II was motivated by a variety of factors. The dominant pragmatic motivation for studying the Soviet economy was the emergence of the Soviet Union, functioning in a Marxist–Leninist framework, as a major political and potential economic power, and the related Cold War typology of East–West relations as the dominant geopolitical framework in which the competing economic and social systems of East and West would interact. Beyond the obvious interests of national security in the West, analysis of the Soviet economy and similar systems of Eastern Europe was driven by a variety of other forces.

Economists understood that the economic system and related economic policies of the Soviet Union were fundamentally different from those found in Western market capitalist economies. These differences were arguably very important in determining how resources were allocated in these different economic systems, the core of the field of comparative economic systems. The Soviet Union became the dominant example of what would later be termed the administrative command economy. Moreover, economists realized that it would be a challenge to apply the research methods and traditional tools of neoclassical economic analysis to the peculiar organizational arrangements of the Soviet economic system, especially in a setting of Soviet secrecy.

In addition to issues of national interest and the inherent scholarly interest in the command economy, study of the Soviet Union was driven by pragmatic factors. The Soviet Union had, by most indicators, grown rapidly in the 1930s, a decade critical to understanding the subsequent Soviet economic experience. Moreover, the Soviet Union emerged from World War II to experience rapid economic growth in the 1950s, a decade when the subsequent pervasive growth slowdown was not evident. In an era when Soviet economic prospects looked bright, the issue of economic performance, and especially economic growth, was viewed as important. In addition, there was growing interest in pragmatic issues such as major sectors and regions, defense spending, foreign trade, and technology transfer for a largely closed economy functioning in an increasingly global economic environment. How would Western market-based firms interact with their Soviet counterparts, the Soviet firms operating in an isolated, secretive, and fundamentally different economic environment? Ironically, similar pragmatic interest would motivate later Western interest in other sectors of the Soviet economy, for example Soviet agriculture, the poor performance of which led to growing Soviet activity in foreign grain markets during the 1960s and thereafter. The growing world demand for energy has sustained interest in energy rich countries, the Soviet Union being a major example.

These factors led to a growth of interest in the Soviet economy and recognition of the need for a cadre of scholars whose research interests would focus on understanding resource allocation in the very different Soviet setting. This need to know led to the creation of area studies programs, most of which combined the usual postgraduate training in the discipline (economics) with associated area training in disciplines such as geography, political science, languages, and the like. Courses devoted to the Soviet economy and the more general issues of comparative economic systems became common in most colleges and universities. While economists understood the need to apply the tools of economic analysis to the Soviet case, they also understood the importance of a broader perspective. For such a broad scholarly objective, group identity in area studies programs and research centers was attractive, and yet there were costs associated with the pursuit of these objectives.

Study of the Soviet Union was a difficult task. Scholars were required to learn the Russian and possibly other languages. Moreover, access to all source materials was difficult, and for economists, much effort was required to assemble and to utilize

even minimal amounts of data, so critical for even basic statistical analysis. Soviet isolation from world agencies meant that data sources standard for any Western researcher were unavailable. Survey research was not generally possible, and Soviet official statistical publications (*The National Economy of the USSR*) contained limited information often of unknown origin and definition. Statistical and other information on the Soviet economy was limited, uneven, and often of questionable reliability. Archival research presented a major challenge notwithstanding the later availability of excellent guides to the information potentially available (Grimstead 1988). Field experience in the Soviet Union was essential, though the scholarly benefits of travel and work in the Soviet Union were difficult to realize in a setting of pervasive secrecy and limited access to information.

Finally, in the Western academic setting, it was not always easy to combine the professional demands of the discipline (economics) with the important but peripheral pursuits of area studies. Put differently, the postwar era witnessed major strides in the development of neoclassical economic analysis. In addition to debate over the appropriate paradigm within which to analyze the very different Soviet experience, major areas of development in neoclassical economics, for example, econometric theory and practice, and the development of computer technology for data analysis, were of only limited applicability in our study of the Soviet economy, given the limited availability of meaningful disaggregated data on the Soviet economy. In this context, there was often a pervasive gap between analysis of issues in Western economies and the analysis of comparable issues in Soviet-type economies. For example, as the availability of data and expanded computer access led to important new developments in the analysis of labor allocation in the West, analysis of labor allocation in the Soviet context remained difficult.

1. Soviet Studies: The Framework in Economics

The content of Soviet studies (economics) is very broad, probably best understood from a chronological perspective. Although it is arbitrary to identify specific time periods, the early postwar years were dominated by a major effort to assemble meaningful data series, and to begin an analysis of how the Soviet system actually worked (plan formulation and plan execution), an understanding essential to any meaningful assessment of performance. Thereafter, there was growing interest in sectoral analysis of the Soviet economy and issues of economic reform, especially following the reform attempts of the late 1950s and 1960s. Through the 1970s, economic analysis of the Soviet economy improved, though unevenly. For some sectors such as foreign trade, data availability facilitated more sophisticated analysis, while for other sectors such as labor, data limitations constrained the level of analysis that could be done. In general, data on money and price issues was almost nonexistent. However, through the 1980s, our analysis of the Soviet economy grew in both depth and breadth, with significant attention paid to important subjects such as consumption, investment, income distribution, and technological change. More information became available, new topics were investigated, and new methodological approaches applied, expanded by the new era of *perestroika*.

There is, however, an important sense in which a chronological approach is imperfect. During the transition era of the 1990s, the importance of the Soviet past for understanding the transition continued to be recognized. Likewise, throughout the postwar era, analysts of the Soviet economy recognized the fact that much of the Soviet system as we knew it emerged during the 1930s. Thus research interest in the early years of the Soviet economic experience sustains, and much research on these early years has helped analysts to understand later contemporary events (Davies 1980, Davies 1990, Nove 1982, Zaleski 1980).

In yet another dimension, the breadth of Soviet Studies is evident. While a chronological survey of the postwar era correctly identifies performance as a broad but key focus of research, scholars also developed and sustained an interest in issues well beyond performance narrowly defined. Thus in a country so large, naturally wealthy and diverse, a substantial literature emerged on a broad range of issues such as regional economic development, population, urbanization, and the like. As economists moved beyond the immediate frontiers of the discipline of economics, the richness of Soviet studies became evident. Moreover, there was often a close relationship among disciplines; geographers who studied regional issues often did so with methods familiar to economists; the work of political scientists was important for our understanding of bureaucracy.

2. The Content of Soviet Studies: Economics

Although considerable work on the Soviet economy was done prior to World War II, the dominant era of Soviet studies as an identifiable paradigm was the period 1950 through 1991. While intelligence analysis of the Soviet economy was done during World War II, the decade following the end of the war witnessed the growth of interest in the Soviet economy in the United States, Great Britain, France, and Germany in several major directions.

First, the Soviet economic system was dominated by state ownership with resource allocation conducted through a national economic plan, a document formulated by central planning authorities and implemented through ministries by industrial enterprises, agricultural enterprises, and other organizations. It was

evident from analysis of the early years of the command economy, that if this system was to be understood and its progress assessed as an alternative to market arrangements, it would be necessary to understand how it worked and how well it worked. To achieve these tasks, it would be necessary to assemble meaningful data on national income and its components. The focus on data collection and analysis dominated analysis of the Soviet economy and was complicated by Soviet methods of data collection and dissemination, official Soviet secrecy, and the use of a Marxian (conceptual) framework by the Soviet Union. The initial work on national income (Bergson 1961) became the basis for early assessment of Soviet economic growth and subsequently Soviet productivity, key elements for understanding the broader issues of Soviet economic performance and economic growth.

In addition to the development of meaningful data for analysis, it was necessary to understand both plan formulation and plan execution. Early efforts to understand plan formulation were cast primarily within the framework of input-output analysis, though subsequent work would also use mathematical modeling to understand the planning process. Plan implementation was the focus of early work (Granick 1954, Berliner 1957) combined with extensions into important sectors of the Soviet economy such as monetary and fiscal issues, capital accumulation, labor allocation, consumption, investment, and thereafter foreign trade.

From the 1960s through the 1970s, there was increasing attention paid to the Soviet economy, especially a growing number of in-depth sectoral studies, for example, in agriculture, and the growing use of econometric methods for statistical analysis and modeling (Green and Higgins 1977). Attention to the gathering of data took a major step forward in the late 1970s when the Soviet Interview Project (Millar 1987) resulted in a major database on the Soviet household. At the same time, interest in Soviet economic reform continued, albeit with a recognition that reform in the Soviet Union was having very limited impact on performance (Hewett 1988) even during *perestroika*, the last major reform of the Soviet era.

Western analysis of the Soviet economy continued to evolve through the 1980s with continuing emphasis on economic growth and productivity (Ofer 1986). In an era of declining performance, new themes emerged, while the analysis of basic issues sustained with important extensions. For example, while the theory of planning was in a sense the macroeconomics of the Soviet economy, the pervasive shortages and growing purchasing power of citizens led to interest in issues such as monetary overhang, arguably the beginnings of new thinking about the Soviet macro-economy.

Interest in sectoral allocation continued with growing interest in capital allocation and especially the issue of technological change. Moreover, analysis of the household permitted greater depth in the analysis of labor allocation. This depth was important, because it brought Western analysis of the Soviet economic system much closer to levels of sophistication present in the West and facilitated better understanding of the issues underlying Soviet economic growth and especially the continuing growth slowdown.

The latter years of the Soviet era witnessed the development and application of new theoretical and statistical methods. For example, the theory of the Soviet firm, so critical to understanding Soviet plan implementation, had been conducted by Western economists virtually in isolation from Western analysis of the firm. While variations of profit maximization dominated Western analysis of the firm in market settings, the analysis of the Soviet firm was thought to be more readily understood within the context of organization theory. This distinction was eroded as neoclassical theory placed new emphasis on property rights, agency theory, and information economics. Western analysis of the Soviet micro-economy assumed new dimensions, important for understanding the pervasive problems of the Soviet economy such as incentives, information problems, shortages, poor plan fulfillment, lack of technological change, and the like. During the 1980s, disequilibrium economics was applied with increasing frequency to analyze the peculiar allocation arrangements of the Soviet economy, and especially to understand the emergence of the second or informal economy. The development of the shortage economy (Kornai 1992) provided a broad theoretical underpinning to facilitate statistical investigation of the socialist economic system.

Finally, throughout the 1970s and 1980s, interest in the Soviet economy and similar examples elsewhere grew. Emphasis continued to be placed upon developing improved databases. While the Central Intelligence Agency continued to develop and disseminate data, other agencies provided important sectoral information. For example, the US Department of Agriculture was a major source of data and analysis on agriculture and the Soviet rural economy, while the Foreign Demographic Analysis Division of the Department of Commerce provided and analyzed population and labor force data. During these years, the publications of the Joint Economic Committee on China, Eastern Europe, and the Soviet Union became a basic resource for analysis of these economies. In addition to a growing volume of work on key economic aspects of the Soviet economy, important collections of scholarly work (Bergson and Kuznets 1963, Bergson and Levine 1983) became guideposts to the field of Soviet economics.

Throughout the postwar era, the Soviet economic experience was chronicled in a variety of additional sources. In addition to general guides (Konn 1992), attention to data problems (Marer et al. 1992, Treml and Hardt 1972) continued. There are a number of basic texts devoted to the Soviet economic experience

(Gregory and Stuart 2000, Nove 1961, Lavigne 1974, Campbell 1974, Sherman 1969).

3. Soviet Studies: The post-Soviet era

Understandably, the collapse of the Soviet empire fundamentally changed the dimensions of Western interest in Soviet-type command economies. Although there has been sustained interest in different economic systems from a scholarly perspective, interest in transition has assumed a central focus, with the demise of the Soviet Union as the primary example of the administrative command economy and the basic changes in the geopolitical framework of East–West relations. Our current interest in the Soviet economic experience is in part as a model for understanding the continuing issue of resource allocation in differing economic systems, interpreting the Soviet era and especially the impact of that era on the contemporary economies of Russia and the newly independent states of the region.

Soviet Studies: Education

The vast majority of Soviet and Western studies of Soviet education since the 1930s have focused in positive ways on the curricular and instructional rigor of the educational system, and its contribution to Soviet social and economic development. The official line that dominated Stalinist and postwar Soviet research argued that the history of Soviet education was essentially unproblematic, with the Communist party–state leading the people upwards into enlightenment through literacy, science and technology, and militant materialism. Perhaps ironically, much of this was echoed in contemporary Western research and in modernization theory, which also considered the contribution of Soviet education to social and economic development to be direct and unproblematic. The only real point of contention was over the ultimate effects of rising literacy and the growth of an increasingly educated mass society. While Soviet scholars argued that these developments would lead to the realization of true Communism, Western scholars tended to argue that they would result in inevitable social differentiation and cultural liberalization on the Western model. Neither group seemed to consider the possibility that the Soviet educational system could be maladaptive or dysfunctional in its ability to contribute to sustainable social and economic development.

This unanimity in almost all studies of Soviet education since the 1930s also obscured the distinct historical phases and sharp policy conflicts that actually characterized the history of Soviet education. In fact, this history is much more contentious and significant for comparative international developments than the official Soviet line would suggest. As will be detailed below, the years after the Russian revolutions of 1917 were characterized by an official

Soviet policy of radical progressive education that was very much influenced by, and contributed to, international trends in educational policy. This was followed by increasingly conservative educational policies in the Stalinist 1930s and afterwards, when the enduring foundations of the Soviet educational system were created. In fact, while obscured by Soviet social and behavioral science, which always claimed that Soviet developments were utterly unique, this traditionalist restoration was actually also part of a broader international turn away from Deweyan progressive education in many nations during the middle decades of the twentieth century. Many of these historical shifts and policy changes, and the political and professional struggles that shaped them, have long been obscured by official Soviet historiography. The limits and failures of the Soviet educational system in terms of actual access and achievement have also long been obscured by opaque official Soviet statistics. More recent post-Soviet research, both Western and Russian, has begun to detail how, throughout its history, Soviet education was successful in many ways, and yet also heavily politicized, narrowly vocational, bureaucratically inflexible, and subordinated to the Soviet state and the Communist Party of the Soviet Union. Ultimately, it could be argued that the inflexibility of the system, and its difficulty in adapting to the needs of postwar social and economic development, caused Soviet education to become a serious obstacle to the viability of Soviet socialism. During the post-Stalinist period, from the 1950s through the 1980s, various reforms were attempted in an effort to 'humanize' and differentiate the highly bureaucratized and standardized system. The alleged failure of these reform efforts in the 1980s then led, in the post-Soviet years after 1991, to attempted radical reforms, questioning of the entire Soviet legacy, and deep systemic crisis in the 1990s.

1. The Soviet Educational Experiment and Radical Progressive Education

The models for what became Soviet education were sketched out in the decades before the Russian revolutions of 1917 in response to the need for rapid social and economic development, and especially in response to the poverty and social dislocations caused by World War One. The fundamental principles of Soviet progressive education included expanding the conception of education and culture to include a broad array of programs for adults, working people, and children of all ages. These policies also entailed the provision of extensive public health and welfare services through educational institutions, and a radical rethinking of the nature of curriculum and instruction to bring learning 'closer to life' and industrial work. Finally, educational access and promotion were to be radically expanded to make education open to all regardless of ethnic identity, class, or gender (Pinkevitch 1929).

These early Soviet educational policies were inspired by European and American progressive education, and were hailed as revolutionary by Western radicals and educators. However, Soviet education then went far beyond Western influences in its emphasis on including previously disadvantaged populations, as well as in its increasingly dogmatic emphasis on political indoctrination (Harper 1929). Soviet educational experiments in the 1920s were, in many ways, far ahead of their time (on this and what follows, see Kalashnikov and Epshtein 1927–1929). Soviet educators sought to synthesize general and vocational education for all students in a common curriculum that was known as polytechnicalism, although this rapidly proved impractical, and some vocational tracking was reintroduced. The educational experiments of the 1920s also included the use of interdisciplinary and thematic curricula, and sophisticated developmental instruction that was targeted to stages of students' psychological and intellectual development. Other innovations included student and faculty self-government, a focus on experiential learning and community service, and the curtailing of most formal assessments and criteria for promotion in the name of equality and universal access to education. Early Soviet education was also characterized by the extensive use of Western-style child study and psychological testing, which was known as pedology in Soviet practice. Resources were also invested in the mass provision of new media, libraries, and extracurricular activities for all ages. Finally, the 1920s also witnessed the development of written languages, new alphabets, primers, and comprehensive educational services for many indigenous peoples and small ethnic minorities.

Almost all accounts in the 1920s, both Soviet and Western, were extremely positive about these early progressive experiments, although some Western observers such as John Dewey were also critical of the Soviet educators' emphasis on ideological indoctrination and their philosophical dogmatism (Dewey 1929). For all of the early Soviet educators' idealism, however, there were clearly also many internal contradictions and serious problems with the progressive educational experiments of the 1920s. For example, while expanding access to previously disadvantaged populations, the regime also sought to deny educational opportunity to members of the prerevolutionary elites, or to imagined political or class enemies. This created serious social tensions, and drove out of the new system many of those who could have become leading teachers and students. Public education was often funded on a 'residual' basis, which meant that it was financed only after other budgetary obligations were met, even as the Soviet regime struggled to prevent private financing or tutoring from compensating for inadequate state provision. Nonetheless, early Soviet progressive edu-

cation, for all its utopianism and politicization, was undeniably an unprecedented and truly revolutionary experiment in the provision of mass education and culture for all.

2. *Stalinist Traditionalism and System Building*

However, as detailed in subsequent Soviet and Western research, the many problems with these early experiments effectively discredited them, and provoked a sharp reaction in the 1930s. Soviet accounts during the Stalinist period tended to blame the progressive educators for their allegedly 'anti-Leninist' errors, and often accused them of deliberate sabotage and counter-revolutionary 'wrecking' (Svadkovskii 1938). In fact, many of the progressive educators were purged in the 1930s, and their lives and work erased from the historical record, to be partially rediscovered only when the Soviet archives began to open up in the late 1980s (Fradkin 1990). Later Soviet accounts glossed over the distinctive policies of the 1920s, obscured the sharp conflicts of the time, and blamed the progressive educators for their impracticality and adherence to inappropriate 'bourgeois' theories (Kuzin et al. 1980). Most Western analyses simply argued that the progressive policies were not conducive to true social and economic modernization, and that it was virtually inevitable that more 'stable' and traditional curricula and instruction be restored to fit the Soviet educational system to the needs of modern industrial society (Anweiler 1964). Other Western analyses of the failure of the progressive educators focused on problems such as the acute lack of funding that crippled the attempted reforms in the 1920s, or the disruptions caused by conflicting party–state policies. Later Western authors focused on the popular and political backlash against the progressive experiments, and the broad social support for the upward mobility opened up by Stalinist educational policies (Fitzpatrick 1979). Almost all accounts since the 1930s agree that the progressive experiments became increasingly unpopular as they were accused of undermining the authority of teachers and parents, weakening curricular integrity and instructional rigor, and failing to produce the highly-trained technical specialists and skilled workers needed to 'build socialism.' From a broader and more critical perspective, with the coming of Stalinism in the 1930s, the task became less to mobilize and empower all citizens through progressive education, and more to discipline and train subjects for state-directed development.

Struggles over educational policy raged on in the 1930s, and resulted in the thorough repudiation of progressivism and the forging of a new and intensely conservative model of Soviet education. This also entailed the rejection of all child-centered or developmental schooling in the name of the struggle against 'pedological deviations,' and a return to a school-centered system and highly ritualistic formal 'didactics' (Kairov 1939). This Stalinist model was intensely traditional in curriculum and instruction; thoroughly politicized, especially in the social sciences; heavily dominated by the physical sciences and technology; and rigidly bureaucratized in its governance. From a broader perspective, it could be argued that the system of rigid party–state control over Soviet intellectual and professional life that resulted from these struggles became, over the following decades, debilitating for Soviet education as a whole. The fundamental principles of this Stalinist or traditionalist restoration are well known through the international attention they received in the postwar era, especially after the launch of the first satellite (Sputnik) in 1957. This system of Stalinist education entailed curricula organized along the lines of the traditional subject disciplines, and instruction that focused on the content of knowledge and its reproduction. The system was built upon a canon of standardized textbooks, lesson plans, and teaching guides; and emphasized lecturing, memorization, and rigorous oral examination. A central goal throughout was to reinforce the authority of the teacher or professor over their students, and of school directors and administrators over their staff. Formal assessments and rigid criteria for promotion were elaborated, with harsh sanctions for failure, lack of discipline, or dissidence. Many of the programs that sought to cultivate the languages and cultures of indigenous peoples and national minorities were curtailed, and many ethnic groups subjected to involuntary linguistic Russification and cultural Sovietization, often enforced through police terror. Overall, Soviet education in the 1930s and after became increasingly rigorous, hierarchical, and formal (Medynskii 1951). Stalinist education was permeated with a spirit of discipline and order, and was closely coordinated with the Soviet planned economy and national security state.

There were, undeniably, real successes for Soviet education in the Stalinist period, especially in raising literacy rates and building a comprehensive public education system. It also seems that the traditionalist restoration was quite popular with the new Soviet elites, many professional educators and teachers, and many culturally conservative parents. The system did produce unprecedented numbers of technical specialists and skilled and semiskilled workers, albeit in increasingly narrow vocational specializations. The system also proved successful at research and development, especially in mathematics, the physical sciences, and military technologies. As the Stalinist regime embraced conservative educational practices and cultural values, it also fostered significant compensatory legitimacy for Soviet socialism, as demonstrated by both Soviet and émigré memoirs. Yet for all its claims to universality and unanimity, unofficial cultural and educational traditions did survive, especially among religious and national minorities, as

well as among the Soviet intelligentsia in the form of unsanctioned teaching practices, and private and family tutoring (Kline 1957).

Official Soviet research in this period was, by definition, triumphal about the onward and upward march of literacy and enlightenment, and the indispensable leadership of the Soviet party–state (Konstantinov and Medynskii 1948). There was also a distinct tone of xenophobia, with Soviet developments depicted as both indigenous and superior to all comparable international trends. The emphasis on the role of state power tended to obscure the more complex relations between the party–state and admittedly dependent elements within the profession, as well as the role and interests of the Soviet public. While the disillusioned Western progressive George S. Counts was quite harsh in his judgement of the repressive and dogmatic aspects of Soviet education, he also acknowledged its rigor and utility for a forced-march version of modernization (Counts 1957). Almost all other Western and Soviet émigré accounts were positive in their judgment of the system's pedagogical principles and effectiveness, even if they sometimes acknowledged its rigidity and limitations.

However, alongside the successes and popularity of the conservative policies, there were severe problems as well. The human cost of Stalinist terror in education and culture was devastating, and resulted in the repression of many talented researchers, educational leaders, and teachers, especially among the national minorities. While adhering to the basic principles of modernization theory, some Western authors did draw attention to the more ambiguous effects of standardized Soviet education for the development of the non-Russian peoples of the Soviet Union (Bereday et al. 1971). Soviet education in this period became increasingly dogmatic and dominated by rigid official orthodoxy, with especially devastating effects in the social sciences and humanities. The system became top heavy and driven by administrative interests, with little space for professional autonomy or innovation. Research was often separated from teaching, and there was a clear assumption that theory and content should drive instructional practice. Furthermore, educational institutions and professional networks were isolated from one another through bureaucratic parallelism, as each economic sector and industry created its own educational and research hierarchies. Educational institutions and even individual teachers were closely supervised, even as many contrived elaborate and creative ways to subvert party–state controls. Most importantly, the entire system was structured into narrow vocational specializations that limited the development of the job skills and professional talents that were needed for sustainable postwar social and economic growth. These more critical perspectives only began to coalesce in the 1990s as some post-Soviet and Western authors began to focus on the more maladaptive or dysfunctional aspects of Stalinist educational policies. In conclusion, and taken as a whole, the Stalinist reforms in Soviet education successfully built a mass public education system, but at the price of bureaucratic rigidity, intellectual stagnation, and vocational obsolescence.

3. *The Potential and Limits of Postwar Reform*

Ironically, even as Western researchers were popularizing the curricular and instructional rigor of Soviet education in the post-Stalinist period after 1953, Soviet educators began to debate the inflexibility and limits of their own system. Attempted postwar reforms encompassed both more 'progressive' as well as quite 'traditional' ideas. For example, an attempted reform associated with Communist Party leader Nikita Khrushchev in 1958 sought to restore the polytechnical principles of the system, only this time as more rigorous and involuntary vocational tracking. This attempted reform sought to 'force down' the educational aspirations of the Soviet public through a requirement that all students entering higher education have at least two years of work or production experience (Goncharov and Korolev 1960). Significantly, this reform was essentially blocked by the combined resistance of enterprise managers, parents concerned about their childrens' upward mobility, and more traditionalist educators resistant to such experiments. The regime also attempted, throughout the post-Stalinist period, to strengthen proper 'civic–political' socialization in response to what was seen as growing juvenile delinquency and alienation from official ideological values.

Other reforms in the post-Stalinist period reflected the progressive innovations of the 1920s, especially the tradition of psychological research pioneered by Lev S. Vygotskii (1896–1934, see Vygotskii 1991). Vygotskean cultural psychology and developmental instruction, which also received significant attention from Western researchers in the 1980s and 1990s, may well prove to be the most internationally significant and enduring contribution of Soviet education. Other attempted reforms included greater curricular differentiation, the introduction of electives for students, and the development of programs for elite education in the arts, sciences, and sports (Matthews 1982). There was also a relaxation of linguistic Russification, with relatively more flexibility offered to educational institutions in the national minority regions. Yet it must be noted that, for all the potential of these reforms, they were often thwarted by the combined power of the party–state regime and the conservative educational establishment, especially in the various republic-level Ministries of Education and the Academy of Pedagogical Sciences.

Taken as a whole, the reform movements in Soviet education from the 1950s through the early 1980s did have the effect of consolidating the system, while also

diversifying and enriching curricular and instructional practices. Perhaps most importantly, the Soviet educational system by the 1970s had trained a vast new body of professional teachers, and essentially achieved universal literacy and nearly universal secondary education. Not surprisingly, official Soviet accounts focus on these achievements with little or no acknowledgement of any persistent problems or struggles over policy or practice (Kolmakova et al. 1986). Yet these achievements were, to a significant degree, gained at the expense of individual and professional freedom, creativity, and systemic flexibility. It must also be noted that, for all of its rhetoric of equality and universality, severe inequities persisted, especially between urban and rural areas, and that literacy and educational provision lagged behind in many national minority areas. The Soviet educational system was also slow to introduce new instructional technologies, and was especially weak in the provision of non-political continuing education and vocational retraining. It seems that little Western attention was paid to these systemic problems, perhaps in part because the significant Western research on Soviet education, which began in the 1950s, had narrowed considerably by the late 1970s. It also seems that international cooperation in this area was constrained by the conservatism of the neoStalinist educators and officials who continued to dominate the Soviet system into the early 1980s.

4. *The Crisis of Soviet Education and its Ambiguous Legacies*

The final phase of Soviet education in the 1980s and early 1990s witnessed both radical reforms and severe systemic crises. Several attempted reforms in the mid-1980s sought to tighten vocational tracking and increase party–state controls, but in a very real sense, Soviet educated society as a whole, as well as leading elements within the educational profession, were no longer willing to tolerate such reactionary policies. There was a growing sense that Soviet public education was in crisis, which led to the emergence of a growing 'innovation movement' among educators and teachers. This movement sought to humanize and democratize Soviet education; to loosen party–state controls over curriculum, instruction, and governance; to recover the spirit of the child-centered progressive experiments of the 1920s; and to expand contacts with international researchers and practitioners (Eklof and Dneprov 1993). After the collapse of the Soviet Union in 1991, the newly independent republics embraced an array of educational policies. Some tried, unsuccessfully, to simply preserve the old Soviet system, as in Belarus and parts of Central Asia. Others struggled to radically reform the old system through attempted privatization and decentralization, as in the Baltic states and the Russian Federation (on Russia, see Dneprov et al. 1991). The reforms of the 1990s have, undeniably, unleashed a veritable pedagogical revolution of innovation in curriculum and instruction, and finally joined together the long isolated Soviet educational community with its international counterparts. Much of this reintegration into the world community of educational research and practice has been facilitated by an unprecedented level of international assistance provided to post-Soviet educators and students in the form of research grants and exchanges. Yet, it must also be noted, all of the Soviet successor states have experienced severe if not catastrophic crises in the funding and provision of public education, and that both excellence and equity have suffered. In other words, now that post-Soviet educators have finally rejoined the world community from which they have been isolated since the 1920s, many lack the financial resources to remain in the profession or to take full advantage of the new opportunities for international or even domestic professional cooperation and development. Furthermore, the economic and demographic crises that have gripped the entire region threaten the health and readiness to learn of virtually an entire generation of children and young adults.

5. *Conclusions*

In conclusion, Soviet education both shaped and constrained the building of Soviet socialism. While Soviet and Western studies of Soviet education diverged sharply on some points of interpretation, almost all agreed that the Soviet educational system, as built in the 1930s and as endured into the 1980s, was fundamentally functional and conducive to modernization. While later Russian and Western authors have expressed some skepticism about the viability and functionality of the Soviet educational system, it did undeniably contribute, if in complex ways, to the development of a modern and literate mass society. Finally, the most rigid and repressive aspects of Soviet education were repudiated in the 1990s, and there have been some real successes in recent reform efforts. However, these years may ultimately be judged a historical tragedy of monumental proportions if the legacy of secular, free, and public education for all that was pioneered by Soviet educators is lost as well.

Soviet Studies: Environment

Environmental studies are by nature interdisciplinary, and this holds for Soviet studies of the environment. Yet approaches to the study of the Soviet environment were, like many topics, politicized within the USSR. Secrecy and ideological constraints made it difficult for Soviet biologists, geographers, and economists to discuss the full extent of pollution or the structural factors responsible for environmental waste and degradation. Political aspects of pollution were especially sensitive. Social scientists could at best only obliquely criticize the central planning, bureaucratic socialism, and militarized economy that were responsible for much of the country's environmental ills. Western experts had to rely on fragmented and incomplete data, yet they managed to construct reasonably accurate accounts of Soviet environmental practice.

The Soviet approach to the natural environment encapsulated, *in extremis*, all the elements that James C. Scott (1998) has identified as necessary for disastrous twentieth-century social engineering: the administrative ordering of nature and society; a high-modernist ideology relying on science and technology for problem solving; an authoritarian state fully willing to use its coercive powers for social experimentation; and a prostrate civil society unable to resist the authoritarian state's transformative plans. Seven decades of rapid, forced industrialization, ill-conceived agricultural experiments, botched industrial and irrigation projects, waste and mismanagement of natural resources, and disregard for the human consequences of development left a legacy of environmental destruction unrivaled in Europe or North America. With the collapse of communism the obstacles to serious environmental analysis have been removed; however, economic decline and political paralysis in the postcommunist era have severely constrained the former USSR's ability to address its environmental crisis.

1. Ideology and Attitudes

Soviet practices and policies toward the natural environment mirrored the political system's *raison d'être*. In ideology, the Soviets turned the environmental determinism of Marxism on its head, glorifying the radical transformation of nature through sheer political will. Soviet leaders formulated socialism into a doctrine that equated anthropogenic transformation of the environment with progress. As political scientist Joan DeBardeleben noted in *The Environment and Marxism–Leninism* (1985), ideology provided a conceptual framework that shaped and limited policy discourse.

The Soviet dictatorship showed respect neither for nature nor for humankind. Both were subordinated to the regime goal of constantly expanding material production, without regard for the wellbeing of the population, their quality of life, or for the natural environment. From an environmental perspective, the Soviet fixation with production focused the question: production to what end? However, Soviet scholars were not allowed to address such questions: while environmental economists in the West discussed

capitalist production in terms of the external costs associated with industry, Soviet economists had to echo the Party position that externalities were not possible in a socialist economy.

Soviet environmental studies, policies, and practices were molded and distorted by communist ideology. In the *Communist Manifesto*, Marx and Engels had praised capitalism's success in subjecting nature to man and machinery; Soviet communism's goal was to surpass this record of accomplishment. In addition, Marxism's labor theory of value denigrated natural resources to a position of secondary importance in the economy. This attitude was compounded by the belief that the USSR, by far the largest nation on earth, had illimitable stores of coal, land, timber, natural gas, and minerals. Only late in the history of the USSR did the regime acknowledge limits to exploiting nature. Even then, scholars focused on narrow technical issues of resource use and pollution, to avoid placing blame on government policies (Gerasimov et al. 1971).

2. *Industrial Development and Pollution*

Vladimir Lenin was favorably inclined toward conservation, including the system of nature preserves (*zapovedniki*) that predated the revolution. His primary emphasis, however, was on modernizing Russia in order to lay the foundations for communism. Joseph Stalin's comprehensive program of forced industrialization and agricultural collectivization embodied a strong anti-environment bias. Soviet developmental policies resulted in an all-out assault on nature by planners and workers. This determination to transform the natural world was comparable to the high modernist ideology found in late nineteenth- and early twentieth-century industrializing nations; layered on top, however, was the Communist Party's goal of subordinating all social and productive forces to its conscious guidance, and the insulation of the governing elites behind the regime's authoritarian political structure. The focus on industrial growth as the system's preeminent goal made continuous, linear progress a vital component of regime legitimacy, particularly after Marxist–Leninist ideology lost its appeal.

Maintaining conservation values was problematic in the highly-charged political atmosphere of Soviet politics. Some scientists urged caution in exploiting the natural environment, even during the most repressive period of Stalinism, at great personal risk, and small, relatively independent social movements dedicated to protecting the environment persisted into the Stalin era. Historian Douglas Weiner describes these subtle forms of resistance in his book *A Little Corner of Freedom* (1999). But all of Soviet science, including ecology and conservation, was adjusted to support the regime's political goals. Weiner's earlier *Models of Nature* (1988) details the impact of Stalinism on conservation in the Soviet Union. For example, acclimatization—the introduction of non-native species into certain environments in order to transform nature and enhance productivity—was advocated by the biologist Trofim Lysenko during the Stalin and Khrushchev eras. Constrained by a poor understanding of science and arrogance toward nature, the regime's acclimatization efforts proved disastrous for both the introduced species and the local ecology. Soviet biologist Zhores Medvedev chronicled how ideology, politics, and careerism affected Soviet genetics in *The Rise and Fall of T.D. Lysenko* (1969). More conventional genetics replaced Lysenkoism by 1966, after Party First Secretary Nikita Khrushchev had been ousted.

Geographers and economists wrote the earliest Western studies of Soviet environment. Philip Pryde's *Conservation in the Soviet Union* (1972) and economist Marshall Goldman's *The Spoils of Progress* (1972) laid the groundwork for later studies. These scholars found the major polluters of the environment to be heavy industry, particularly the energy, chemical, and metallurgical sectors favored by Soviet planners. Large urban areas suffered air and water pollution caused by dense concentrations of steel plants, oil refineries, ore smelters, and pulp and paper mills. Automobile pollution was generally less of a problem, since few people owned cars, but poorly maintained buses and trucks spewed tons of pollutants into the air. Contamination from radioactive waste, military installations, and nuclear power plants posed another serious hazard to public health. Agricultural runoff and inadequately treated industrial wastes polluted much of the Soviet Union's surface and subsurface water sources.

3. *The Late Soviet Era*

Public awareness of Soviet environmental issues emerged in the late 1960s, roughly parallel with the growth of environmentalism in the developed, industrialized democracies. The Soviet regime's focus on industrial development, official secrecy toward all systemic failings, and Communist Party assertions that environmental degradation characteristic of capitalist economies was not possible under socialism made it dangerous to criticize government policies openly. But the threatened pollution of Lake Baikal, the largest body of fresh water on the planet, led to open controversy over the building of two cellulose plants on its shores. Grigorii Galazii, Director of the Limnological Institute of the Siberian Academy of Sciences, led a crusade in the controlled press against the danger to the lake. Blunter criticism was expressed in an underground (*samizdat*) publication, the *Destruction of Nature*, published in the West by a pseudonomous Boris Komarov (Ze'ev Wolfson) (1978). Carefully managed public discussions on the environment did take place during the Brezhnev era, largely to highlight the regime's 'commitment to

environmental protection' and publicize ineffective factory managers, bureaucrats, or poachers.

Genuine discussion of environmental problems, and serious efforts to combat pollution and environmental degradation, however, were constrained by the authoritarian character of the system and the emphasis on covering up failings. A major theme in Komarov's manuscript was the pernicious effect of censorship and secrecy. The Soviet military frequently invoked national security to justify a range of environmentally destructive practices, such as locating cellulose plants to produce cord for aircraft tires on Lake Baikal, dumping nuclear wastes underground and in the oceans, and poaching in *zapovedniki*. But environmental destruction took its toll on the military, as it did on civilians. Recruits were often unfit for military duty because of poor health. Unhygienic living conditions, including contaminated drinking water and air pollution, led to high incidents of dysentery, skin disease, and respiratory illnesses within the military (Feshbach and Friendly 1992).

The Soviet experience forced environmentalists and economists to rethink many of their assumptions. Economic theory had held pollution to be an externalized cost to society resulting from production by private enterprise. Theoretically, social ownership internalized these costs, and a socialist economy therefore should pollute less than a capitalist economy. However, natural resources were not treated as scarce in the Soviet economy, which resulted in tremendous waste and inefficiency. A dominant theme in studies by Western economists (Goldman 1972), geographers (Pryde 1972, 1991), and political scientists (Ziegler 1987) was that concentrating power in the Communist Party and state bureaucracy inhibited the formation and implementation of responsible environmental policies. Socialist, centrally planned economies did not fully internalize external costs; rather, the absence of clearly identifiable property owners encouraged waste and abuse of the environment.

Soviet agriculture was possibly more environmentally destructive and more wasteful of natural resources than industry. Millions of hectares of land were impoverished or eroded by unscientific attempts to extract higher yields. Lysenko's ill-considered experiments in agrobiology caused significant damage to Soviet agriculture, as Medvedev (1969) documents. Khrushchev's Virgin Lands project and his determination to plant maize on unsuitable land constituted additional examples of gross agricultural mismanagement. Chemical fertilizers and pesticides were overused and applied haphazardly on the collective and state farms through ignorance, carelessness, and a skewed incentive structure. In Central Asia, diversion of the Amu Darya and Syr Darya rivers for cotton irrigation depleted the Aral Sea, saturated the land with salt and chemicals, and altered the region's microclimate. Structurally, socialized ownership of agricultural land generated a psychology in which farm workers and administration valued only short-term production and ignored long-term damage to the earth. Farmers were more careful with their private plots (and these were far more productive), but only 3 percent of land was set aside for private agriculture.

Western political scientists naturally argued that politics played an important role in Soviet environmental degradation, claiming authoritarian political systems were less responsive to environmental concerns than democratic, pluralist systems. Charles Ziegler, in *Environmental Policy in the USSR* (1987) found the lack of accountability to voters and the absence of environmental interest groups in the USSR ensured that decision makers could safely ignore public opinion. Until Gorbachev's *glasnost* eased controls, scholars within the USSR could publicly criticize neither the general policies nor the specific decisions of high Party and government officials.

Weak adherence to the rule of law also contributed to environmental degradation. The Soviet government adopted impressive environmental and conservation legislation, but these laws were largely symbolic and were consistently ignored by factories and ministries tasked with meeting production quotas. Enforcement of environmental regulations by government agencies was sporadic, and environmentalists could not utilize lawsuits, an effective tool of their Western counterparts.

Soviet scientific studies and government pronouncements consistently maintained that socialist economic planning, the national ownership of land and resources, and centralized regulation ensured a superior approach to environmental protection that could not be realized under capitalism. But in the Brezhnev period cautious scientists admitted that, in practice, natural resource use was inefficient and wasteful, and that erosion and water pollution were serious problems (Gerasimov et al. 1971). Studies by Western scholars suggested that Soviet environmental performance was no better than that of capitalist states, and often much worse, due to the distorting influence of bureaucratic state socialism. Using a comparative approach, political scientist Barbara Jancar found that political–economic factors in one-party systems played a greater role in defining environmental management than did regulation, regardless of whether the state was centralized, as was the USSR, or decentralized, as was Yugoslavia (Jancar 1987).

Perhaps unique to the Soviet Union was the environmental impact of the militarized Soviet economy. Military-related production accounted for approximately one-quarter of the total gross domestic product. Environmental concerns were routinely sacrificed in the interests of national security and, at least until *glasnost*, questioning military imperatives was forbidden. Issues like global warming might be treated skilfully, as they were in *The Night After … Climactic and Biological Consequences of a Nuclear War* (1985),

an edited collection of articles by prominent Soviet scientists. Nonetheless, these essays were published through an official government outlet and served a Soviet national security priority; namely, mobilizing opinion against the Reagan administration's Strategic Defense Initiative.

Given official secrecy and the politicizing of environmental issues, simple descriptive studies were an important contribution to the field, and a damning indictment of the Soviet system. Both Feshbach and Friendly (1992) and Komarov (1978) described how military bases contaminated towns and coastlines with fuel and lubricants, dumped garbage and scrap equipment indiscriminately, and polluted groundwater supplies. Troop exercises destroyed forests and ruined agricultural land. More pollution was generated by the production and storage of chemical weapons, while the production and testing of Soviet nuclear weapons contributed to radioactive pollution at the Semipalatinsk range in Kazakhstan and Novaya Zemlya in the Arctic. The Soviet navy dumped 135 reactors from decommissioned nuclear submarines in the waters around the Barents and Kara seas, and disposed of liquid nuclear waste from the Russian Far East by discharging it into the Sea of Japan. In postcommunist Russia the military continued to obfuscate and deny responsibility for environmental destruction, and officers were prosecuted for exposing the military's role in pollution.

Environmental legislation meant little in a nation not based on constitutional principles. Impressive sounding resolutions on air quality were adopted by the Council of Ministers as early as 1949; in the following decades additional laws were passed to protect water, forests, wildlife, and agricultural land. Scholars and officials could point to such progressive legislation as examples of the regime's commitment to the environment (see Galeeva and Kurok 1979, for the range of legislation). In reality, Soviet legislation consisted of grand pronouncements and largely unenforceable standards. Producers routinely violated environmental laws with impunity. Enforcement was entirely in the hands of government bureaucracy and, given the regime's emphasis on rapid and continuous economic growth, the enforcement of environmental laws that might interfere with production was actively or implicitly discouraged (Ziegler 1987).

4. *Reform and Collapse*

Environmental issues played a key role in the liberalization of the Soviet system during the Gorbachev era. By officially acknowledging the scope of environmental degradation, however grudgingly, the Communist Party admitted failing in its promise to provide a better life for its people, and undermining its claim to legitimacy. Guarded criticism had been voiced by scientists, journalists, and literary figures in the 1960s and 1970s of the issues of air and water contamination, the Aral Sea disaster, and planned diversion of Siberian rivers southward to Central Asia. With the easing of censorship under *glasnost*, and widespread fears of government deception and incompetence after the April 1986 explosion at the Chernobyl nuclear reactor in Ukraine, environmental activism mushroomed and scholars turned their attention to the new environmental politics (Ziegler 1991, Pryde 1991, pp. 246–65). Public opinion surveys discovered that an overwhelming majority of the population was concerned about the environmental problems and the threat to public health. Environmental groups dominated the new 'informals' (*neformaly*), nascent interest groups that emerged in the late 1980s. Women, concerned as they were with pollution-related birth defects and the health of their children and families, figured prominently in these movements.

Many of these spontaneously formed environmental groups linked environmental with national and separatist demands, especially in the more nationalistic Caucasian and Baltic republics. Under Soviet federalism Moscow treated the non-Russian republics like colonies, exploiting their natural resources, degrading the land, locating polluting industries on their territory, and in the process jeopardizing the health of the population. Soviet development strategies also led to an influx of ethnic Russians, who were concentrated in vital economic and political positions within the republics and who diluted the ethnic homogeneity of titular nationalities. Once political controls were relaxed, national discontent coalesced around the more obvious sources of Russian dominance—the Ignalina nuclear power plant in Lithuania, chemical plants in Armenia, nuclear testing in Kazakhstan, and oil pollution along Azerbaijan's coastline.

5. *Environmental Studies and the Transition*

Postcommunist Russia no longer promotes a transformationist ideology. Full representative democracy has proved elusive, but the government is no longer authoritarian. Environmental information is easily available, and there are few formal restrictions on environmental activism. The Transboundary Environmental Information Agency, for example, regularly publishes an electronic *Russian Environmental Digest* of newspaper and magazine articles. Drawing in part on studies of the Soviet environment, political scientists have theorized that democratic political systems should be more responsive to public demands for environmental protection (Payne 1995). But transitional Russians have become more concerned with acquiring material goods than with cleaning up the environment, notwithstanding the serious health implications of the legacy of Soviet pollution. These problems—which include higher morbidity and declining longevity rates, widespread birth defects, and outbreaks of such infectious diseases as diphtheria, cholera, and typhoid—have prompted a demo-

grapher–journalist team (Feshbach and Friendly 1992) to propose the Soviet Union's epitaph as death by ecocide.

Russia's natural environment may have improved in the 1990s as a result of the precipitous decline in industrial production, but the evidence is mixed. Viktor Danilov-Danilyan, head of Russia's State Committee for Environmental Protection, claimed air pollution from industrial sources at the beginning of 1999 was down 35 percent from 1991, while water pollution had decreased by 15–18 percent (Wren 1999) But Boris Porfiriev (1997), a systems analyst with the Russian Academy of Sciences, estimated that in 1995, 41 percent of Russia's population lived in cities where the maximum permissible concentrations of pollutants were exceeded, compared with only 18 percent in the USSR in 1989. While approximately 25 percent of Soviet waste water went untreated in 1989, 40 percent was untreated in Russia in 1995. Overall, investments for environmental protection measures decreased 20 percent between 1990 and 1995 (Porfiriev 1997, pp. 147, 152).

Environmental protection is guaranteed in the 1993 Constitution, but legal provisions remain inadequate. Resource-exploiting companies and ministries occupy advantageous, monopolistic positions relative to environmental agencies and lobby groups. Large budget deficits constrain Moscow's ability to address a range of social problems, of which the environment is only one. Local and national priorities often clash over development and environmental protection issues. Bureaucratic arrogance and ignorance, political neglect, entrepreneurial exploitation, and public indifference relegated environmental protection to a low priority on Russia's political agenda during the first postcommunist decade. And in a move disturbingly reminiscent of Soviet practices, in 2000 President Vladimir Putin dissolved Russia's State Environmental Committee, distributing its oversight functions to the Ministry of Natural Resources, an agency tasked with exploiting the environment.

With political restrictions largely gone, and institution-building on the agenda, a proliferation of environmental studies by social scientists might have been expected. This has not been the case. Western studies of Russia's transition have focused on privatization, the development of a market economy, ethnic questions, and democratization, with few according much attention to the natural environment. Studies by conservationists Michael Wells and Margaret Williams (1998) and Swedish economist Patrik Soderholm (1999) found the absence of legal, administrative, and regulatory institutions in transitional Russia complicated environmental protection measures. Russian natural scientists have continued to pursue environmental studies, but social scientists have not devoted much attention to environmental issues. Several articles in the 1998 and 1999 issues of the Russian journal *Military Thought* addressed various aspects of military-induced pollution, and Boris Porfirev (1997) has dealt with legal and organizational issues. However, there is still a great deal of work to be done on the Russian environment by researchers both inside and outside the country.

Soviet Studies: Gender

This article will discuss the meaning of the term 'gender,' the changing pattern of gender roles throughout Soviet history, and the ways in which Western and Soviet writers have tackled gender issues in the Soviet Union from the time of the Revolution in 1917 up to the country's collapse in 1991.

1. *Clarification of Terms*

'Gender' refers to the personality traits and behavior associated with either men or women that are not rooted in biology but are determined by culture. Western feminists have been careful to distinguish between the terms 'gender' and 'sex,' the latter referring to the biological differences between men and women. However, Soviet writers and thinkers only acknowledged this distinction shortly before the disintegration of the Soviet Union, when, in 1990, the Centre for Gender Studies was founded in Moscow. The Soviet authorities always insisted, throughout the 70 years of the Soviet Union's existence, on their commitment to complete equality for men and women, but no attempt was made to analyze or understand the extent to which differences between men and women were biologically or culturally produced. Alexandra Kollontai, the country's principal theoretician on the 'woman question' at the time of the Revolution, did come close to addressing the concept of gender (though without actually using the term), but dismissed it as an irrelevancy, indeed, as a bourgeois preoccupation. What was important, she argued, was that all people, male and female, developed their personal potential. In her words:

> Leaving it to the bourgeois scholars to absorb themselves in discussion of the question of the superiority of one sex over the other, or the weighing of brains and the comparing of the psychological structure of men and women, the followers of historical materialism fully accept the natural specificities of each sex and demand only that each person, whether man or woman, has a real opportunity for the fullest and freest self-determination, and the widest scope for the development and application of all natural inclinations (Kollontai 1977, p. 581).

Yet despite their refusal to address the issue of gender openly, Soviet politicians were in reality very much concerned with it, and made determined attempts at different times either to eradicate or strengthen the cultural differences between men and women.

2. *Historical Overview*

In its first decade the Soviet Union concerned itself with challenging the traditional understandings of appropriate male and female behavior and social roles. At a time when the West was promoting and preserving separate male and female spheres, Soviet propagandists were urging women to leave that female bastion, the home, and enter the public world of work and politics, until then a largely male environment. Women were assured that State institutions would take over their domestic tasks. In any case, the family would become less important as people got used to living communally. Some theorists went so far as to argue that the family would serve no purpose at all in a communist society and in due course would simply 'wither away.'

However, there was no attempt to rethink both male and female roles. Women were simply to be incorporated into the hitherto male sphere of public service. Nor were women to be truly free of domestic responsibilities. Articles on the organization of communes made it clear that women would still be responsible for the cooking, laundry, child care, etc., but they would now take on this work collectively, for the commune as a whole, rather than individually, for their own families. There was also no question of them choosing not to have children. Rearing the next generation of workers was a patriotic duty, not a choice.

Widespread unemployment in the 1920s meant that few women were actually drawn into social production. This began to change in the late 1920s, when Stalin came to power. In 1929 he launched a huge industrialization drive. All workers were now needed, women as well as men, and by 1932 the number of women workers was almost double what it had been in 1928. At the same time, the pledge to free women from their traditional domestic duties was quietly abandoned. All resources were now required for industry, and if women were still willing to perform those traditional functions for free, the State would hardly fight for the right to fund them. Predictions about the demise of the family also ceased. On the contrary, the family was now held up as the 'basic cell' of Soviet society. There are a number of reasons for this change in approach. The first Five-Year Plan had produced an enormous social upheaval, one of the results of

which was an alarming drop in the birthrate, and it was hoped that rehabilitating the family might help reverse this trend. The familiarity of traditional family life might also provide some stability in people's lives in the face of such radical change. Furthermore, the family now took on a symbolic function; Soviet society as a whole was depicted as one large family, with Stalin the ultimate patriarch. Far from being an outdated institution that had no place in a communist society, the family assumed a new significance.

Women now found themselves laboring under a 'double burden.' They were required to go out to work: there were simply not enough men to bring about industrialization at the speed or to the extent required by Stalin; but they also had to perform their traditional domestic and nurturing functions. They were to do this with no assistance from men, nor, given the concentration on heavy rather than consumer industry, from any services or products that could relieve the domestic workload. Yet this combination of functions was ironically hailed as evidence of women's equality, and the basis of their self-fulfillment. The 'woman question' was declared solved.

When Khrushchev came to power and launched his 'destalinization' program, the 'woman question' was partially reopened once again. The press on the whole continued to applaud the country's successful establishment of women's equality, but some authors now acknowledged that the real situation was more complex, and that women fell behind men in both professional and political hierarchies. At the same time, sociologists began conducting 'time budget studies' which made it clear that women devoted an enormous amount of time to domestic work, and suggested that this was a significant factor in their inferior standing in public life. There were now some suggestions, albeit tentative, that husbands might be persuaded to ease their wives' burden by 'helping' them in the home.

From the 1970s, with Brezhnev now in charge, there was another shift in policy. The notion that women's sense of self-fulfillment rested on their combining the traditionally female roles in the family with the traditionally male roles in politics and social production began to be questioned, largely because of the seemingly intractable demographic implications: the birthrate, at least in the European republics of the Soviet Union, had remained stubbornly low. At the same time, women workers were essential in the Soviet Union's labor-intensive economy, and it was not possible simply to remove them from the workforce. Instead, there was an attempt to alter the balance between work and family in their lives, to persuade them to see the family as paramount and work as secondary. This meant that they would continue to work, but would devote less time and energy to trying to improve their qualifications and climb the professional ladder. Instead, they would see raising a family as their main source of satisfaction. Accordingly, a media campaign and a new school course were launched to raise the status of the family, persuade women to have more children, and encourage boys and girls to develop more traditional gender-specific traits. If having children had never been a choice for women, the attempted manipulation of their reproductive patterns now reached a new height.

Gender, though it was still not named as such, had become a major issue. Theorists now insisted that 'the study of psychological differences between members of the male and female sex is an important scientific and practical question, no less important than the continuing study of their biological and physical differences' (Khripkova and Kolesov 1981, p. 74). In the West there was also concern at this time with studying 'psychological differences between members of the male and female sex,' but in order to understand how they came about, the extent to which they challenged equality, and what could be done to overcome them. In the Soviet Union, the primary concern was to reinforce them.

When Gorbachev came to power in 1985, his program of economic reform introduced the prospect, for the first time since the 1920s, of widespread unemployment. The high level of female employment that had characterized the Soviet Union since the beginning of the Stalin era was no longer necessary. Women could now be withdrawn from the workforce, and this could result in two positive outcomes: an increase in the birthrate, and a reduction in the unemployment figure. This was presented to women themselves as a positive development: at last they had the 'luxury' of staying home with their children.

Yet the new openness (glasnost) of the Gorbachev era also meant that criticism of government policy was possible. Articles heatedly defending women's right to work began to appear in the press. This extended even to the Communist Party's own theoretical journal, *Kommunist*, in which three female scholars from the Institute of Socio-Economic Problems challenged what they saw as a clear trend to improve economic performance by shedding the less effective elements of the work force: 'and that means, in the first place, women.' This, they argued, lay behind the introduction of what seemed to be new benefits for women:

> In order to facilitate this female "exodus" from social production, it has been suggested that they be granted a series of privileges which will result in the reduction of their work load: the work day will be shortened, the period of paid leave to look after a new-born baby lengthened, and so on (Zakharova et al. 1989, p. 58).

Within two years of this article appearing its authors had founded the Centre for Gender Studies in Moscow and, as well as publishing material hitherto unimaginable in the Soviet Union, were mounting university courses and hosting conferences on gender issues in Soviet society.

3. Research on Gender Issues in the Soviet Union

Since the 1970s, Western research on Russia and the Soviet Union, in virtually all fields—literature, history and the social sciences—had paid considerable attention to the experience of women. Feminist scholars were initially attracted to the study of Russian and Soviet women, as the historian Linda Edmondson explains, because:

> it seemed (from a Western perspective) that a degree of equality and recognition had been won by women in the Soviet Union that had not been achieved in the West … they were impressed by Soviet claims not only to have legislated complete sexual equality, but also to have provided the conditions for its full realization; if not in the present, then at least in the foreseeable future (Edmondson 1992, p. 1).

They soon realized their mistake. However, it still seemed paradoxical that despite the Soviet Union's professed commitment to women's equality there was such apparent disinterest on the part of its scholars in discovering how it had supposedly been achieved, and that Western researchers working in the field 'were obliged to provide almost all the answers to their own questions' (Edmondson 1992, p. 2). Accordingly, the creation of the Centre for Gender Studies and the emergence of an indigenous feminist movement were greeted with considerable interest and enthusiasm.

Yet when Russian scholars did start providing their own answers, they made somewhat uncomfortable reading for their Western counterparts. The experience of living under state socialism, perhaps inevitably, led them to an understanding of equality and women's rights that did not accord with that of Western feminism. While feminist theory in the West had drawn attention to the distinction between the private and the public, Soviet women saw the main dichotomy as that between the family and the state. Western feminists had been largely critical of the patriarchal nature of the family, but for women in the Soviet Union it was seen as a refuge from the state-dominated bureaucracies that controlled the worlds of work and politics. While Western feminists tended to promote paid work as the essential route to women's financial independence and self-realization, women from the Soviet Union had experienced it as a form of exploitation which, in the words of Nanette Funk and Magda Mueller, reduced them 'to a cheap source of labor that could be plugged in anywhere without regard to specific capabilities, prerequisites, and ambitions' (Funk and Mueller 1993, p. 87). Western feminists had pointed to men's vested interest in keeping women in their place, but women in the Soviet Union were more inclined to see men as fellow sufferers under the yoke of state oppression. Indeed, some Soviet feminists now argued that men had had a harder time than women, since the latter were able to use their family responsibilities as an excuse to withdraw as far as possible from the public realm, where state control was at its greatest.

The supposed successes of the Soviet Union in securing women's equality—the high level of female involvement in paid work, the relatively strong representation of women at least in the lower echelons of politics, the extensive, if still inadequate, provision of pre-school childcare institutions—were also looked at with a critical eye by the new Soviet feminists. State socialism, it was argued, had been so obsessed with the idea of work that it had reduced women's equality to nothing more than their mass entry into social production. Being equal meant being treated like men, except that they also had the major responsibility for childrearing and domestic work. Many Soviet women began to define liberation in a surprising new way: as the right not to work, and to be treated as innately different to men. This essentialist position, which saw women as naturally oriented towards the home, was anathema to many Western feminists, but it was an understandable response to the conditions in which women had lived under what they now described as 'really existing socialism.' The differences which emerged in women's attitudes in East and West have not precluded a fruitful dialogue between them, but this has had to be conducted with considerable sensitivity and understanding.

Soviet Studies: Geography

The field of Soviet geography has undergone tremendous change. As a result of the significant social, economic and political changes of the post-1985 era, many practitioners of Soviet geography found the physical borders of their inquiry change. More often than not, the region of focus shifted from the Soviet Union to one or more of the former republics. In addition, research themes and theoretical approaches to scholarship expanded. Accordingly, the subject of Soviet geography has two distinct periods. Geographic research about the Soviet Union before *perestroyka* or the mid-1980s generally focused on amassing information and analyzing spatial patterns related to the natural environment, demographic patterns and economic activity (see Pryde et al. 1989 for an exhaustive review of research during this period). The post-Soviet period has continued previous traditions and added many new themes such as political change and the social and economic consequences of transition (see Engelmann et al. 2001) for a review of research themes and issues during this period).

1. *Soviet Geography*

During the Soviet period, the scope of geographical research often coincided with the strategic needs of policy makers. Because of Soviet secrecy regarding information about the natural environment and the location of natural resources, the location of economic activity and population dynamics, much of the work outside of the Soviet Union focused on amassing and interpreting information at a subnational scale in order to satisfy the demand for such knowledge among the policy-making community. As a result, geography was one of the few disciplines within Soviet studies to focus on regional and local issues throughout the Soviet period.

Despite limited interaction among Soviet colleagues and their counterparts elsewhere during the Cold War era, work by geographers in the Soviet Union became accessible to outsiders through various translation projects such as the journal *Soviet Geography and Translation*, founded by Theodore Shabad and renamed *Soviet Geography*, and a volume by Fuchs and Demko (1974)

Geographers in the Soviet Union and elsewhere published widely on the location of natural resources and the changing distribution of natural resource extraction, particularly on strategic resources like oil and natural gas. Several important volumes (e.g., Shabad 1969, Pryde 1972, Jensen et al. 1983) document the location of natural resources and discuss the wider implications such as economic development and conservation. Additional work by geographers brought to light important environmental issues related to renewable natural resources like the drying up of the Aral Sea and the resulting regional scale environmental degradation (e.g., Micklin 1988).

Numerous geographers traced the progress of various large-scale Soviet industrial projects related to natural resources and industrial development. Soviet officials perceived these projects as critical to national welfare, and other governments perceived understanding them as critical to their own national security. For example, geographers followed projects like the diversion of major Siberian rivers to provide water resources to Soviet Central Asia and the construction of a new railway line across Siberia, the Baykal–Amur main-line, to facilitate the transportation of natural resources. Many debated the strategic and economic consequences of constructing the new line. The journal *Soviet Geography* provided current information on these and many other projects related to natural resources and industrial development in its ten annual issues.

The location of economic activity and demographic dynamics comprised two other significant and interrelated research topics in Soviet geography. Geographers inside the Soviet Union and elsewhere analyzed urbanization patterns and the Soviet policy of city size limitations (e.g., Khorev 1971). In the United States, Harris (1970) initially promoted the study of Soviet urbanization using approaches and techniques that were standard at that time in Western urban geography, (e.g., central-place theory) and functionally categorized Soviet urban places. These works along with others (e.g., Lewis and Rowland 1979) evaluated aspects of Soviet central policy, like city size limits, and suggested that such policies did not appear to change overall urban growth rates.

Other works attempted to demystify the Soviet central planning system and show how regional and spatial planning occurred under this system and affected spatial development (e.g., Pallot and Shaw 1981). Shabad in his News Notes section of the journal *Soviet Geography* and elsewhere (Shabad 1984), provided data and analytical information about the location of economic activity and population. For example, he showed how the Soviet urban classification system according to population size and function could be used to reveal locations where central planners located economic activity or changed its nature. Liebowitz (1987) contributed to the ideologically generated debate over the effectiveness of

Soviet regional equalization policies. By using an oblast level scale of analysis, he concludes that the Soviet government had a strong commitment to reducing spatial inequality.

Investigative works such as those cited above distributed information to the scholarly and public policy communities about a mysterious place and system. They filled an important information gap about a significant part of the world. Salient questions in the field revolved around identifying what happens where and for what reasons. Other geographers often labeled the work as overly descriptive or devoid of theoretical or conceptual content. In reality, research during this period was implicitly theoretical and generally fell into two underlying and opposing frameworks: (a) Soviet exceptionalism due to the combination of communism, totalitarianism, and central planning; and (b) universalism due to the belief that human behavior is fundamentally the same irrespective of social, cultural, or economic context. Both perspectives mirrored broader trends in social sciences such as cold war dogma and modernization theory.

Even before the break up of the former Soviet Union, the field of Soviet geography began to change. New and expanded sources of information reduced the demand for amassing and publishing subnational data. Soviet geographers began to shift focus away from identifying spatial trends to interpreting and conceptualizing them. A new political imperative arose to document and interpret the spatial implications of 'democratization' and marketization. A modified set of supply and demand issues faced the scholarly community and produced a substantially increased set of research themes and theoretical perspectives.

2. *Post-Soviet Geography*

As a result of the break up, the geographical scope of research has generally narrowed to Russia as many Soviet specialists interested in other former Soviet states have aligned with regional specialists interested in Europe, the Middle East, and Asia. The research emphasis in the subdiscipline continues on regional and local issues in Russia with several changes. Among the most important changes is the increased collaboration with and access to colleagues in Russia. A review of articles in *Post-Soviet Geography and Economics* (formerly the journals *Soviet Geography* and *Post Soviet Geography*), shows much greater collaboration among international scholars and among non-regional specialists.

Also important are the increased amount of information available (usually through purchase) and the ability to conduct original field research (including ethnographic and survey studies). New ethical considerations have arisen. For example, we have begun to consider how non-Russian academics profit from interactions with Russian colleagues and informants. Many also consider the advantages to Russian colleagues who participate in joint research. In addition, the need to purchase information brings up issues related to the accessibility and dissemination of scholarly information as well as quality. The possibility of generating new forms of scholarly evidence leads to the ability to expand theoretical and methodological perspectives in Russian geography. Scholars within the field are not only in the business of amassing and interpreting information, but also of producing that information. While these changes have wrought considerable excitement among practitioners and new entrants into the field, the cohesiveness of the Soviet period seems to have disappeared.

Traditional research themes remain with a new emphasis on political issues. For example, while geographers still provide information on the location of natural resource extraction and the state of the natural environment, new themes related to the broader subdiscipline of nature–society relations have emerged. New work using ethnographic research methods includes a focus on the issue of the rights of indigenous people (e.g., Fondahl 1998). Research continues to document the nature of demographic change during this transition period. Several authors note important trends such as reversals of traditional demographic patterns, including population losses and deurbanization in the Russian East, which had traditionally been an urban migration destination (e.g., Heleniak 1997 and Rowland 1996). Other researchers place a new emphasis on the political dimensions of demographic change and ethnic identity politics (e.g., Kaiser 1994). These works continue the tradition of providing information about the region while explicitly showing a change in the intellectual content of the field by incorporating methods and topics that speak to the broader community of social scientists as well as to policy makers.

While documenting the location of economic processes still predominates, research during this period looks at the political aspects of economic relations and activity. Using theoretical approaches to study local governance in other countries, Mitchneck (1998) cites the example of the use of historical imagery for economic development to show that Russian local governments increased their participation in promoting local economic development. A focus on political relations also permeates the work of economic geography of Russia. Bradshaw and Lynn (1994) argue for the integration of new theoretical approaches into our study of economic relations in Russia. They use the example of world systems theory to show how we can enrich both the study of transition and social sciences at large by bringing analysis of Russia and the former Soviet Union into broader scholarly debates.

The direct examination of politics as a geographical process has also entered into the lexicon of Russian geography. Craumer and Clem produced a series of articles on electoral processes in Russia at various

scales of analysis (e.g., 1997) and O'Loughlin et al. (1996) also studied electoral processes. Also new to Russian geography is the analysis of the impact of broader social and economic change on the individual—especially differences across gender—and the introduction of social theory to the study of the transition period in Russia (see Bell 1997 and Pavlovskaya 1998).

In many ways, thematically, and theoretically, Russian geography appears more integrated into the overall field of geography than was Soviet geography. Research themes, methods, and theoretical approaches mirror the discipline at large more explicitly. The future of the discipline, however, is still quite uncertain. The productivity of scholars both in Russia and abroad seems somewhat sidetracked due to the need to restructure. In addition, the political imperatives that generated both scholarly interest and immense funding for research appear to have waned.

A promising area of future research for geographers studying Russia and other former Soviet countries would be contributing to transition theory and studying the impact of marketization on both the natural and built landscapes. Relatively few works to date have begun to deal directly with such issues (for exceptions see Bradshaw 1997, Ioffe and Nefedova 1998, Bradshaw and Hanson 1998, Smith 1999), in part, because of the limited time that has elapsed. But in this ever-evolving field, we have learned to expect the unexpected.

lution of its political leadership, its social structure, and the cultural roots of Communist totalitarianism.

With the fall of the Soviet Union and Communism in 1991, Soviet studies ceased to exist as an area of research. Today, a review of Soviet studies is primarily of historical interest. It is notable that, in its traditional form, Soviet studies was first and foremost exclusively the product of a Western community of researchers and politicians. Moreover, this brand of social science was largely an outcome of the Cold War between the West and the USSR, and served as the ideological and theoretical basis for that war. It was distinguished by a descriptive, narrative, and heavily ideological nature. The strong ideological undercurrent present in Soviet studies is understandable, given that its focus of research was the totalitarian Soviet regime, the very opposite of liberal democracy. Soviet studies was a closed area of research, removed from mainstream social science, and it effectively ignored modern research methods (i.e., comparative analysis). The field was a typical instance of area studies in that researchers felt little need to search for analogies and parallels beyond its confines. Indeed, Soviet studies (particularly those in the US) was dominated by émigrés who, in many cases, had left Communist countries as a result of persecution. This could not help but tinge their work with a certain amount of bitterness and strong emotion that were hardly conducive to objective analysis. Soviet studies, with their zeal and passionate condemnations, was not unlike Soviet social science and its attacks on the Western democratic system.

In any case, Soviet studies was unable to explain Gorbachev's *perestroika* or the collapse of the USSR that, incidentally, was not foreseen by any of the scholars in the field. This gives some indication of the standard of scientific analysis in the area. Still, a number of Sovietologists did provide the West with unbiased assessment of specific problems in Soviet development and of the processes that followed the collapse of Communism. Among these the most notable are Alex Dallin, Robert Legvold, Adam Ulam, George Breslauer, Arnold Horelick, Robert Tucker, Robert Daniels, Steven Cohen, Gail Lapidus, and Angela Stent.

After the fall of Communism, traditional Soviet studies petered out, not only in the US but also throughout the West. Effective research into the developments that shaped post-Communist Russia and other successor states of the USSR adopted new approaches developed by Western social inquiry. A complex analysis of post-Communism began to develop on the basis of transformation studies across all dimensions: politics, economics, culture, and the social sphere. The greatest progress in understanding post-Communism was achieved once researchers borrowed models from transition and comparative studies and started to explore both general and specific features of Russia's transformation from the perspective of other transition societies. At this stage, Juan Linz, Alfred Stepan, Terry Karl, Phillipp Schmitter, and Valery Bunce made significant contributions to the understanding of post-Communist Russia. Among the books that discuss the developments in the former USSR form a new perspective see Bunce (1999), Elster et al. (1998, Brown (1996).

Social science as practiced in the USSR prior to the fall of Communism was a discipline encumbered by ideological clichés. It was only in the *perestroika* years that research began to delve into the nature of the Soviet system, its evolution, and its relationship with historical tradition and national characteristics. With the breakup of the USSR and the fall of Communism, Russia's research community was faced with the need to reconsider its research methods completely and turn to international literature on social development. This has not been an easy process for Russian scholars and many have not been able to break free of Marxist philosophy and social science. Still, the 1990s have seen a gradual emergence of select social science disciplines that make use of internationally accepted research tools to study various social dimensions. Emerging areas of research include comparative political science, geopolitics, international relations, and transition studies. However, such research is largely concentrated in large university centers (such as Moscow, St. Petersburg, and Yekaterinburg) and around key magazines and journals (most importantly *Polis, Pro et Contra, Vlast*, and *Voprosy Philosophii*). Additionally, new communities of philosophers and political and social scientists have sprung up. In short, Russian social science has largely completed the initial phase of organizational and institutional development. It has done so with valuable support from the Western research community and financial assistance from certain Western funds and institutions, including the McArthur, Carnegie, Ford, Soros, and some European foundations.

Core works of Western social science have been translated into Russian and translations of contemporary research are readily available. Social science learning at Russian universities conforms with international standards to an ever-increasing extent. A new crop of researchers has done much to investigate various developments in Russian society. Among these are German Diligensky, Mikhail Ilyin, Andrey Melvil, Andranik Migranian, Igor Klyamkin, Vladimir Pastukhov, Oleg Bogomolov, Alexander Nekipelov, Nikolay Shmelev, and Yuri Levada.

Nevertheless, Russian social science is still in a transitional phase and its development remains difficult. There is a clear lack of stable avenues of interaction between various schools and perspectives, while research efforts are poorly differentiated and integrated. Inflows of new academic talent are limited. Sadly, some Russian observers consider Russian social science to be mired in crisis and apply this conclusion to all key social disciplines: political science, law,

history, social and cultural studies, etc. Russian research is relegated to the periphery of international research. Its investigation of major trends in social development is empirically weak and likewise flawed in a theoretical approach. Many research projects still rely on an oddly eclectic combination of outdated Marxist research methods and modern Western techniques, without due regard for the overall research context. This is a result of the parochial nature of Russian social sciences, their estrangement from international research, the belief in a unique Russian experience, and the reluctance of many scholars to study Russia in the context of other transformations and transitions from authoritarian rule. Knowledge of superior international works on the development of post-Communist Russia and other successor states of the USSR remains inadequate.

How can the weakness of Russian social science be explained? The first reason for it is the continuing crisis in Russian society and the indifference of authorities and the public to the development of science in general. Also part of the problem is the adverse tradition of excessively ideologizing research, the habit of some researchers to work for the authorities as well as the corresponding conformist attitudes that this engenders, and the lack of objective analyses, particularly when contemporary Russian developments are in question. Scientific prospects are blighted by an inadequate consolidation of the scholarly community, a lack of funding, the concentration of research effort in a handful of large cities, and the often-inadequate knowledge of foreign languages (particularly English) on the part of researchers, which prevents Russian science from breaking its parochial confines. The coming phase in the development of Russia's social science, i.e., its integration into the global framework, largely hinges on society's ability to overcome the current period of crisis and stagnation and acquire new perspectives and hopes. One of the major goals of the newly founded (1998) Russian Political Association which unites a major part of Russia's political scientists is the creation of a new framework for discussion and itellectual intercourse.

Thus, in 2001 Russian political studies have a complicated agenda. On the one hand, its goal is to integrate Russian studies into the general mainstream of world political science using its newest accomplishments, instruments, and approaches, on the other hand, its goal is to preserve the emphasis on area studies. The new step in the development of Russian political studies will demand more effort in analysis of the major problems of political history and traditions; of the political regimes; of the correlation between economic and political reform; of continuity and change; of stability and instability; and of the interaction between domestic and foreign policy. The success of this endeavor will depend on the ability of scientists to cooperate and share the results of their studies, and on the attempts to organize the collective effort of analysts from different fields in order to get a systemic and deeper understanding of the nature and puzzles of the post-Communist transformation.

Soviet Studies: Society

'Soviet society' refers fundamentally to the society of the former Soviet Union (the Union of Soviet Socialist Republics). More broadly, scholars refer to a 'Soviet type of society,' i.e., a society structurally similar to that of the Soviet Union.

1. Main Perspectives

Social scientists have approached the study of Soviet society from several main perspectives. For some, Soviet society is of particular interest for what it can reveal about one of the world's superpowers. Those taking this view tend to observe and analyze all aspects of Soviet society through a political lens. They stress societal features potentially influencing or especially affected by its political system and policies. At another extreme, for those studying societies comparatively, Soviet society may be just another data point like American, British, Chinese, French, Indian, or Turkish society. Those adopting this perspective seek

to discern relationships among societal characteristics rather than the inner workings of Soviet society *per se*. For those with yet another perspective, Soviet society is a distinctive type of society; they think that studying its distinctive features can give a deeper understanding of how political, economic, and social structures are linked, and how history and culture impact the linkages among these structures.

These various perspectives have not received equal attention. The first was dominant during much of the twentieth century, especially in periods when the Soviet Union was regarded as a major military threat to the West. The second almost never leads to publications manifestly on Soviet society and has not predominated at any time; it is not covered in this article. The third, more sociological perspective has become prevalent since the Soviet Union collapsed.

2. *Soviet Society as a Distinctive Societal Type*

As a societal type, Soviet society was historically unique because its basic institutions were designed with the intent of implementing a particular theory of societal development and ideals, namely, that of Karl Marx. Although other societies were later constructed to realize Marx's vision, the Soviet Union's society was regarded as the prototype and the model to be followed.

According to Marx's theory of history, feudalism was succeeded by capitalism, and capitalism would be followed by communism. Communism would usher in a communist society, a superior stage of societal development. Although Marx wrote prolifically, his work mainly dealt with broad changes in economic and political systems and with his critical understanding of capitalism and capitalist society. Ironically, his writings furnish only a few general ideas about the nature of a communist society.

In the picture of a communist society painted by Marx, private capital and exploitation would be eliminated as the bases of society. There would be no social classes and no inherited privileges. People would be free to choose their activities; consequently, they would not be alienated from their work. Social relations would be based on cooperation rather than competition and exploitation; hence people would not be alienated from one another. Communist society would initiate a truly human and humane history. Communism would not only foster humane social relationships but also be economically more productive than other systems.

As evidenced in general by the actual societies designed to be communist and in particular by Soviet society, Marx's utopian vision of communism and of communist society proved to be wishful thinking. Its leaders pursued policies of rapid industrialization and urbanization, and it indeed achieved a relatively high level of economic output and became a largely urban society. Further, it succeeded in reducing (if not in eliminating) social inequalities and inheritance of social privileges. But productivity and economic growth were not as great as in capitalist countries, and the widespread use of force and repression to control people's lives gainsaid the claim that Soviet society was humane and had ended alienation.

Marx's contemporaries as well as succeeding generations of social thinkers challenged his theory and many of his claims, but few offered a different view of human history and human societies that was as broad and as encompassing as Marx's. In his monumental work, *A Study of History*, Arnold Toynbee (1947), was among the first to propose a vision of societal development that was not based on social classes. Like most scholars who have attempted to classify societal types, including Marx, he thought that at each stage of societal development, a certain mode of production was the driving force behind economic and social relations in a society. In Toynbee's scheme, pastoral societies were followed by agricultural societies, which were in turn succeeded by industrial societies. Later Daniel Bell (1973) argued that a new type of society came into being in the twentieth century: post-industrial society. Other scholars subsequently suggested particular kinds of postindustrial societies (e.g., information, service-based, postmodern).

Soviet society does not fit very well into the usual classifications of societal types, however, because it differed sharply from industrialized, urbanized societies that had market economies and democratic polities. Its structures for the organization of productive activities and for the allocation of economic outputs were so distinctive that the industrial basis of its economy provides comparatively little help in understanding Soviet society. The failure of the concept of 'industrial society' to identify fundamental differences between Soviet society and industrial societies in North America and West Europe has motivated scholars to study Soviet society as a distinctive type—to seek to identify its basic features that distinguish it from industrial societies with market economies and democratic polities.

3. *Origin and Key Elements of Soviet Society*

Communist ideology promised a better way of life to the many people living in industrializing societies who were relatively (and sometimes absolutely) deprived. In the nineteenth and early twentieth century, it was hard not to attribute much deprivation to the social upheavals that resulted when small numbers of entrepreneurs and other 'captains of industry' built large factories and other enterprises employing great numbers of men, women, and children who toiled very long hours at very low wages. Arguably even more deprived were the jobless and those without land to till. Not surprisingly, the communist vision was attractive to

many workers, peasants, intellectuals, and members of suppressed nationalities and ethnic groups. Some of them were mobilized by this vision and organized to change society.

According to Marx, social revolution is the only way that a working class exploited by the capitalist class can gain power in order to build a new communist society. In 1870 the Paris Commune tried to create the first communist society, but its efforts failed. Other attempted communist revolutions were sparked by the heavy losses of life and material destruction during World War I and by the hardships in core European countries in this war's aftermath.

Surprisingly, the first successful revolution of self-proclaimed communists occurred, not in a highly developed capitalist country, as Marx and Engels (1848/1962) had expected, but in Russia in 1917 where industrialization had then barely begun. A small group of intellectuals headed by Vladimir Lenin (née Ulyanov) was able to snatch power from Russia's ineffectual tsarist elite with comparative ease. They then managed to fight and win a three-year civil war (1918–1921) and to suppress dissenting factions in the communist movement. As a result, the Union of Soviet Socialist Republics (USSR) emerged as the world's first communist state.

During the early stages of the Soviet Union, its communist leaders—first Lenin and then his successor, Joseph Stalin—eliminated much of Russia's previous elite, not only its nobility but also its few industrialists. Numerous intellectuals with different ideas about societal goals were also removed. Well-to-do peasants, most of whom were suspicious of communism, were also got ten rid of. The Soviet Union's leaders justified the massive use of force to implement communist doctrine partly by the country's backwardedness: its largely peasant population was illiterate and had short time-horizons, and peasants were too disorganized, except on the village level, to create a new countrywide social system. In addition, the ideology itself excused the use of force by communist leaders. Social revolutionaries believe that their destiny is to force society to change in order to bring about a better society. The notorious ruthlessness of Russia's tsarist elite made this rationale more acceptable to many people.

Thus, it came about that Soviet society was built and maintained through the use of excessive force. Power and decision-making were concentrated at the very top. The real head of the Soviet Union was never elected, not even by the Central Committee of the Communist Party of the Soviet Union, which was officially the Party's leading body. The wishes and will of the general population were neglected.

In the Soviet Union's command economy, the state owned and controlled all productive resources. The Soviet system of extreme concentration of control over resources could be very effective. For example, it permitted this formerly backward country with its predominantly peasant population to industrialize with surprising speed, eliminate illiteracy and educate the general population, win World War II despite its initial unpreparedness, develop the first hydrogen bomb, launch the first satellite to orbit the earth, put the first cosmonaut in space, and become one of the world's two main superpowers during most of the twentieth century. It also achieved a considerable degree of social equality, though at a lower average level than in the United States and West Europe. While not overlooking the negative features of Soviet society, one should acknowledge its accomplishments.

Although the Soviet Union began as a dictatorship of the head of the Communist Party, the political system gradually evolved. By the 1960s, the apparatus of the Communist Party had been merged with the state apparatus, creating a party-state. During the final decades of the USSR, the *party-state* was the only actor in Soviet society that no one could legitimately contest; its authority was supreme.

The party-state's monopoly on public action greatly limited the circle of people able to influence how society developed. Individual initiative was condoned only in a person's private life. This depressed the populace's motivation to act in the interest of themselves personally or of the general public. It led people to shun responsibility in public life. Since individuals depended on the state for their basic sustenance, and since the economic system offered few incentives for hard work and achievements, ordinary people sensibly chose to focus on their own private, personal lives: their families, a few close friends, and their personal hobbies. Because material wellbeing was secure (though low), the average person living in the Soviet Union was able to concentrate on his or her personal interests and have a private life offering considerable personal satisfaction.

Soviet society did not, however, allow a civil society to come into being. It lacked a level of social organization above family and friends—a level of voluntary organizations and private clubs—that many scholars (e.g., Putnam 1993) regard as a major foundation of a democratic society. The party-state controlled not only all productive resources in the economy but also all social organizations linking individuals who were neither family members nor close personal friends (e.g., even choral groups and clubs of birdwatchers). Private individuals were not allowed to meet and form associations, even ones intended to foster private and personal goals.

The Soviet system successfully indoctrinated its citizens in Marxist ideology and established a public mentality oriented to the collectivity. In this ideology, a person's life had value only as a tool for the attainment of collective societal goals.

In the early decades of the Soviet Union, its leaders experimented even with ways to change family life. To emancipate women, marriage and divorce were made very easy. To dilute the influence of families on new generations, state organizations for tending young

children and for educating and training older children were instituted. Some of these experiments had unintended adverse consequences and were later abandoned. For example, it was discovered that in practice easy divorce meant a huge upsurge in unmarried mothers trying to raise children without the father's assistance. Because it was in the state's interest for fathers to support their children, the law was changed again to make divorce in the Soviet Union almost impossible. Nevertheless, despite various planned interventions of the party-state into family life, on the whole, family life and other personal aspects of individuals' lives in Soviet society seem to have been determined largely by the same kinds of factors as in noncommunist industrialized societies. Empirical research on this topic is, however, still scanty.

Two key institutions in modern capitalist societies, money and law, were not very important in Soviet society. The Soviet party-state did not need money to motivate people or to act as the medium of economic exchanges. Nor did it rely on laws to control people's behavior or to regulate economic activities. These ends were accomplished primarily through administrative orders and, when necessary, the threat of punishment. Indeed, both money and law were seen as potentially limiting the absolute power of the party-state and therefore as best avoided.

4. *One Society or Many?*

The Soviet Union was comprised of many different nations (ethnic groups) having different cultures, traditions, and histories. Within its borders, hundreds of different languages were spoken. While all national groups were predominantly rural before being incorporated into the Soviet Union, not all of them fit the prototypical image of Russian peasants living in villages. In Central Asia, there were nomadic herders; in Siberia, there were small tribal groups who survived by hunting. In some of the Baltic countries and in certain parts of Russia, there were independent farmers, some of whom produced food for world markets.

Forging its diverse national groups into a Soviet people and creating a 'homo Sovieticus' (Soviet man/woman) was an important objective of Soviet leaders. They used a wide variety of means, ranging from overt repression, to economic incentives, to formal indoctrination in schools and in compulsory lectures given at work sites, to more subtle efforts in songs, films, plays, and various literary works. After 70 years, these efforts could claim a moderate degree of success.

Even during the harshest years of repression under Stalin, however, people's ways of living were noticeably different in the various regions of the Soviet Union. Although the party-state institutional organization penetrated every part of the Soviet Union, every institution operated somewhat differently in the various major regions of the country. Not surprisingly, similarities were greatest in state institutions, where there were definite efforts to impose uniformity. For example, schools throughout the Soviet Union taught pupils of a given age the same subjects using essentially the same books. Remnants of traditional cultural patterns were most evident in family life and in patterns of interpersonal relations and friendships.

The last region conquered by the Russian Empire in the tsarist period was Central Asia. This enormous area has never been densely populated. Its native inhabitants are descended from many different ethnic groups that followed Islam and were tribally organized. However, it was not the Islamic religion as much as the traditional clan-based communities that made this part of Soviet society distinctive.

Uprisings in this region began during World War I. The Soviet state succeeded in restoring calm only after a series of mass slaughters in the 1930s. A colonial strategy of 'divide and conquer' was used to control it. Uzbeks, Kazakhs, Tajiks, Turkmens, and Kirgizes were given their own Soviet republics to establish the dominance of new nations in Central Asia.

Toward the end of the Soviet era, the Central Asian part of the Soviet Union was still predominantly rural and inhabited by nonSlavic peoples. But it also had capital cities and a few other urban centers with large industrial complexes inhabited and staffed by immigrant Slavic laborers. To a large extent, these urban areas were separate social oases whose residents had a way of life very different from that of those living in the other parts of these republics. The collapse of the Soviet Union left a large Russian diaspora in Central Asian cities. The titular nations who assumed the rule of their own countries have largely driven out the Russian diaspora. There remains a tiny, Soviet-educated native elite that has a say about who rules in this region, but the influence of this tiny native elite seems unlikely to endure. Leading groups, once again based on clans, are already being formed, and Central Asian societies formerly part of the Soviet Union are becoming more similar to other Central Asian societies, such as Afghanistan.

A second very distinctive part of the Soviet Empire was the Caucasus region in the south. The people of this region had distinctive religions and cultures. In the North Caucasus, some nations, such as the Avaris and Chechens, followed Islam; others were part of Orthodox Christianity; still others had their own distinctive and ancient national religions. The native peoples of this region were also organized in clans, but many had developed a more elaborate culture than was found in Central Asia.

To a considerable extent, the various peoples of the Caucasus region developed a national identity in the process of confrontations with Russians who sought to control their homelands. During the Soviet era, members of the national minorities in the Caucasus

were deeply involved in the Soviet power structure. Native elites sought to accommodate Moscow in some matters while at the same time acquiring more autonomy in handling affairs in their own traditional homelands. The top elite in the Caucasus in the Soviet era was politically very competent and has successfully protected its own turf. Evidence for their success is found in the fact that First Secretaries of the Communist Party in the former republics in this region have become the heads of some of the newly independent countries in this region (e.g., E. Shevardnadze in Georgia, G. Alijev in Azerbaijan).

A third tiny but clearly distinctive group lived in the western part of the Soviet Union, the Baltic peoples. The Baltic countries enjoyed independent statehood between World Wars I and II. In 1940 they were occupied by Soviet troops but were brought fully under Soviet control only after World War II ended. Soviet leaders used migration of nontitular peoples into the Baltic region as a method of sovietization. This policy was most successful in Latvia, where the 1989 Soviet Census revealed roughly equal numbers of Latvians and nonLatvians (most of whom were Russians or other Slavs). It was least successful in Lithuania. According to this same census, Lithuanians were still four-fifths of the population in 1989, and they stubbornly remembered the distant past when a Lithuanian Empire extended to the Black Sea.

Since the process of sovietization of the Baltic peoples and their societies was shorter than elsewhere in the Soviet Union, it never succeeded in erasing an antiSoviet mentality. Opposition to the Soviet regime in the Baltic region was silent but overwhelming. At the first opportunity presented by *perestroika*, mass movements organized in popular fronts along with native political leaders began to push for greater autonomy in the Baltic republics. Their aim was eventual restoration of independent Baltic countries, a goal achieved in 1991, the year when the USSR collapsed.

At the core of Soviet society were the major Slavic nations: Russians, Ukrainians, and Belarusians. In tsarist times, their languages were distinctive but mutually intelligible, and most of them were followers of Russian Orthodoxy. They also shared a largely similar heritage based on the life of peasants living in small villages loosely linked by towns functioning as trading posts. Stalin's program of collectivization destroyed village life and pushed many former peasants into new Soviet factories in cities. The destruction of the old way of life was as important as other direct methods in creating a new Soviet person.

The sovietization of Slavs reached its culmination during World War II, the Great Patriotic War. This war brought the greatest hardships in modern Russian history. Victory over Hitler's military forces was achieved only through millions of people sacrificing their lives and by millions of others toiling to support the Soviet war effort. This victory in the face of tremendous odds and losses bolstered the legitimacy of communist ideology and its collectivistic orientation. It made Soviet citizens proud and united them, especially those of Slavic origin. In the postwar period until the 1960s, the Soviet Union experienced rapid economic development and achieved important 'firsts' in the race to space. Soviet Slavic citizens' pride grew as their country acquired the status of a world superpower and leader in many arenas (e.g., science, sports).

Once the peoples of these regions were largely peasant Slavs, many of whom were descendants of former serfs. In the Soviet era, a majority of Slavs became city dwellers who lived in state-owned apartment complexes while working on factory assembly lines or doing various white collar jobs. They experienced great intergenerational mobility: geographical (rural to urban), educational (illiterate to a secondary education or higher), and social (peasant to manual or white collar worker). This great mobility reshaped people's personalities and mentalities and obliterated many memories of and allegiance to traditional ways of life.

When a period of high growth ends (which inevitably it does), educated people usually begin to wonder about their collective as well as personal future. After the Soviet Union crushed the Prague Spring in Czechoslovakia in the late 1960s, there came dreary years of ritualistic procedures of the Kremlin gerontocracy and little economic progress. Indeed, there were signs of economic retrenchment. Outside economic observers would label this as a shift from extensive to intensive economic development, but Soviet citizens of Slavic origin realized only that their lives were not getting better. The educated core of the Slavic people living in large cities (and not only the few public dissidents like Andrei Sakharov and Aleksandr Solzhenitsyn) began to speculate about the Soviet Union's future. Faith in the Soviet leadership, and even in a communist future, began to wither. A growing and widespread but diffuse view of Soviet society as collectively 'treading water' set the stage for the political and economic system to collapse from within.

5. *Studies of Soviet Society*

5.1 *Studies During the Soviet Era*

During most of the Soviet Union's existence, it was hard for observers to acquire objective information about Soviet society. In this situation, the study of Soviet society became very specialized and was not closely linked to other areas of social science research. *Sovietology* was the special field of social studies that addressed all aspects of Soviet society, though it focused especially on its political system and economy.

This special field arose as part of the political and ideological confrontation between communist and capitalist countries during the Cold War era. Specialists sought to reconstruct the reality of social life in Soviet society. Scholars were successful primarily in analyzing official Soviet documents and writings that gave evidence about the declared and actual policy goals of the Soviet Union.

Sovietological types of studies helped to manage the ideological and political confrontation between communist and Western democratic systems, but they were less valuable in providing a social scientific understanding of how Soviet society actually functioned. The basic bottleneck for Western social scientists was the dearth of high quality data on a wide array of topics.

During the Cold War era, social scientists conducted only a few sizable empirical projects that were intended to gather in-depth information about Soviet society *per se*. One of the best known was the so-called Soviet Émigré Project conducted by scholars at Harvard University in the late 1970s (cf. Millar 1987). In this project, émigrés from the Soviet Union were interviewed about their beliefs and their life experiences in the Soviet Union. These interviews were regarded as the best available substitute for direct surveys of random samples of individuals within the Soviet Union. This project indeed produced a richer and more complex picture of Soviet society than had been put together from scrutiny of the Soviet mass media and official public documents.

There were also careful and in-depth studies of the Soviet Censuses of Population and other official Soviet statistics (e.g., Clem 1986). A major conclusion was that the factual basis of official sources of Soviet data was highly suspect. At that time, it was widely believed that most errors in official data were intentional, designed to hide the true state of affairs in the Soviet Union. This was sometimes the case; however, mistakes often resulted from the same low level of quality control that was endemic in all nonmilitary production in the Soviet Union.

In a society designed to implement a particular view of history and societal development, there was no thirst for independent evidence that might reveal a picture different from the one offered by the party-state's leadership, or even worse, that might contradict the claims of the official view and expose actual flaws in the supposedly socialist society. Nevertheless, scholars within the Soviet Union made some useful studies of Soviet society.

In the 1960s, Yuri Levada initiated some theoretical analyses of the Soviet type of society. His analyses contained criticisms of how it worked, which led him to be barred from sociological work for the next two decades. In the 1970s, Boris Grushin began the Taganrog project that investigated the limits of the influence of mass media on society. In this same period, Aleksandr Yadov worked to develop middle-range theories justifying empirical sociological research outside an ideological framework, and Igor Kon applied Western sociological thought to various topics in Soviet society. Tatiana Zaslavskaya founded a program of sociological research that provided high-quality data on work behavior in Soviet industries and agriculture. Mikk Titma initiated longitudinal surveys designed to compare life careers of youths and young adults in various regions of the Soviet Union. The works of these and other Soviet scholars were published almost solely in Russian, and very few are available in English translation.

5.2 *Studies in the Post-Soviet Era*

With the demise of the Soviet Union, Soviet society is no longer of great political interest. As a major social experiment with important influences on the history of the twentieth century, Soviet society is now primarily of historical and social scientific interest.

Huge amounts of information about Soviet society and the Soviet system were released in the last years of the Soviet Union and during the first years of the new Russia Federation. Formerly secret archives, documents, and statistics became available to social researchers to study and analyze using the research methodologies and theoretical questions developed in the West. It also became much easier for social scientists to collect new data through interviews, social surveys, and various other kinds of field work. The first few years of this new openness allowed the quality of research on Soviet society and post-Soviet societies to reach the normal standards of the top journals in sociology, demography, economics, and political science in the United States and West Europe.

5.2.1 New insights into soviet society. Sovietological studies in the Cold War had usually depicted the Soviet system and society as not only highly centralized but monolithic and exceedingly stable. An important conclusion supported by new archival information is the remarkable evolution of the Soviet system during the seven decades of its existence. It developed from a crude personal dictatorship into a totalitarian society and then into a party-state with a complex system of institutions staffed by relatively educated officials.

The Soviet Union began as a relatively uncomplicated state with a top-down command system operated by the Communist Party apparatus, with terror used to guarantee that commands were obeyed. With a growing economy and a huge external empire in East Europe after World War II, the Soviet Union needed to expand the state and to develop a state apparatus having a legal basis to operate. A large new stratum, an intelligentsia with higher education, was

formed to serve in the state apparatus. Secondary education spread quickly and had become compulsory by the 1980s. University education expanded during the same postwar period. By the 1960s, the number of university graduates was already close to that in the United States. In the 1980s, white-collar workers had become a third of the labor force, an especially astonishing transformation when one considers that the Soviet Union was essentially a country of peasants in 1917.

It has become apparent that the Soviet Union's educated workforce transformed the state and Communist Party apparatus. The Constitution was changed to make the Communist Party the ruling party officially and as a matter of law. The Soviet Union developed a state bureaucracy that functioned relatively well. State institutions began to operate like typical bureaucracies pursuing their own organizational interests. Major Soviet institutions contested for power, largely in bureaucratic ways. Power became more widely dispersed among different state institutions and parts of the state apparatus. Even the KGB and other parts of the security apparatus were brought under the control of party-state in the postwar era. In the final years of the Soviet Union, most members of the Communist Party's Politburo were leading representatives of key economic ministries or of important republics within the Soviet Union. The Politburo, the Soviet Union's top executive organ, came to be comprised of the country's top executives; it was no longer just a group of Communist Party leaders.

Under Brezhnev's mediocre rule, internal dissatisfaction with a command system that limited initiative and restricted independent action even by loyal Soviet citizens soared. Cronyism and loyalty to a person's superior started to be the operative principle guiding behavior within the party-state apparatus. As repressiveness diminished and the threat of terror receded, criticism of the Soviet system became increasingly widespread, although initially not public. Gorbachev's policies of *perestroika* and *glasnost* brought these general feelings into the open. Though the top leaders of the Soviet state and Communist Party realized that change was needed, they had no clear idea what changes might have the desired effects of increasing efficiency while maintaining the basic power structure and its ideological foundation. Attempts to reform the command system failed. The finale came when the top ranks of party-state hesitated to use force to reestablish their complete control. They realized that they had no more positive alternative than the past and that they had lost the support of even the state bureaucracy, not to speak of the intelligentsia, which was actively opposing their leadership.

The collapse of the Soviet Empire and the party-state is a subject of special interest. There continue to be multiple explanations. The heavy burden of competition with the United States in the arms race certainly surpassed the capacity of the Soviet economy, but it cannot explain the regime's internal collapse. In 1991, the Soviet state could still marshal sufficient resources to have survived for some years. Challenges from the republics with strong nations were clearly a factor in the disintegration but could have been met and managed by applying sufficient force, as had been done in the past. Openness to the rest of the world during *perestroika* gave the Soviet elite a clear understanding that the Soviet Union offered a lower standard of living than the Western world. This realization eroded many people's faith in the communist ideology and system. A crucial factor was the paralysis of the party-state apparatus as a result of the loss of this faith in the long-term viability of the communist system, which thereby limited the capacity of the party-state's elite to govern.

5.2.2 Post-Soviet society and the transition process. In many instances, Soviet society and market societies are now seen as exemplifying very different ways in which an industrialized society can be organized. Rapid changes in postsocialist countries, but along different paths, permit rich comparisons between various postsocialist countries as well as between them and the well-developed societies in capitalist, democratic countries. It is often presupposed that all postsocialist societies are moving on a path toward a Western-type of society, that is, a democratic society with a well-developed market economy. Although some post-Soviet countries have unambiguously moved in this direction, it is too soon to be sure about some others.

The transformation of post-Soviet states from the previous system has raised a number of basic problems: the development of the state; strategies for developing democratic and market institutions; the basic principles of citizenship (ethnic or civic); the transformation of enterprises from the state sector to the private sector; factors promoting entrepreneurial activities; the emergence of greater and different kinds of social inequalities; the legacy of privileged positions in the Soviet era; the demographic crisis (a plummeting birth rate coupled with a rising mortality rate).

The Soviet Union's collapse has had an especially strong impact on studies of ethnicity and nationality. The emergence of fifteen post-Soviet states plus nearly a dozen other new nation states in the Soviet Union's 'outer empire' (i.e., the Soviet bloc in East Europe), most with sizable minority populations and many with unexpectedly high levels of ethnic hostilities, has stimulated social scientific studies of interethnic relations, nation building, and the role of nation states in the development of civil societies. Interethnic relations may be an issue in a multiethnic state, or between a majority and minority ethnic group within a single state, or between neighboring states each having an

ethnic diaspora in the other country. National self-determination is a different issue that develops when a cultural identity turns into a political identity. In a democratic regime, the outcome can be a peaceful divorce as occurred in the emergence of separate Czech and Slovak states. There is a clear difference between ethnic rights for cultural, social, economic, and political self-determination in the historic homeland of an ethnic group on the one hand and civic principles of interethnic relations in a modern state on the other hand. A civic society is only established with great difficulty when there are historical animosities between nationalities. Communist regimes suppressed ethnic divisions along with other features of a civil society. In contrast, a modern market-based society is premised upon civic principles. These civic principles allow ethnic tensions and hostilities to grow and offer no clear means to check them.

There has also been particular interest in the gains and losses from economic transformation for both individuals, groups, and society as a whole. In terms of the last, the main issue has been the advantages and disadvantages of economic shock therapy rather than a gradual transformation to a market economy. Available data on various postsocialist countries suggests that shock therapy does not always lead to quick improvements in economic and social life and that a gradual transition, as in China, tends to be more effective. Evidence also suggests that a macroeconomic, top-down approach to development excludes most people from participation in building a market economy. In contrast, a bottom-up approach motivates many people to seek and seize opportunities that markets provide. It allows a majority to participate, although naturally not everyone succeeds in the new economic competition. Indeed, a bottom-up process is how market societies emerged historically.

Both theory and comparative research have also debated the role of elites in the transformation of socialist societies. In post-Soviet and East European countries, the issue was initially politicized and often presented as the old (communist = bad) elite versus a new (noncommunist = good) elite. Sociological research has, however, focused mainly on whether the old elite retained their advantages in postsocialist societies, whether position in the old elite (e.g., political versus managerial elite) mattered, and whether members of the old elite tended to gain or lose relative to members of the non-elite who were otherwise comparable (e.g., in educational achievement). A related issue has been the value of social connections as contrasted with personal know-how. The old elite tended to be advantaged in both, and even in the level of formal education. To date, there have been no definitive conclusions about issues pertaining to the role of the former elites. Clearly, however, many members of the former elite have been able to retain an elite status although keeping an elite status has often involved moving into a different kind of social role (e.g., a former party functionary might become an entrepreneur or manager of an enterprise).

5.2.3 Major research projects. Information about Soviet society, and especially the societal transitions in post-Soviet states, has provided Western sociologists, demographers, political scientists, and economists with opportunities to gather new data and to test a wide array of hypotheses. In the post-Soviet era, a basic problem is the quality of data rather than its simple availability. Direct control over data collection is necessary to monitor and evaluate data quality, and Western researchers often lack direct control.

Major empirical research projects focusing on post-Soviet and East European countries include Hout and Wright's study of social stratification (see Hout et al. 1992, Gerber 1999); I. Szelenyi and Treiman's study of postcommunist elites, begun in 1994 (see Eyal et al. 1998); Kohn's surveys of class consciousness (see Kohn et al. 1997); Burawoy's case studies of the political economy of the transition from socialism (e.g., see Burawoy and Krotov 1992); and the longitudinal study of health and related issues by social scientists at the University of North Carolina (e.g., Zohoori et al. 1998, Lokshin and Popkin 1999). In the former Soviet Union *per se*, the longitudinal study of the life careers of secondary school graduates begun by Titma in 1983 has had two follow-ups in the post-Soviet period, one in 1993–94 and the other in 1997–98 (see Titma and Tuma 1995, Titma 1997). O'Brien and Patsiorkovski (1999) have collected data over time on households in Russian villages.

Many post-Soviet countries, especially Russia and the larger East European countries once in its sway, have been included in large cross-national studies. These include Inglehart's study of world values (see Inglehart and Baker 2000, World Value Survey Study Group 1994); the Eurobarometer surveys (see Reif et al. 1996); and numerous studies of elections (e.g., White et al. 1997) and public opinion (e.g., Clarke 1993). These various projects have enormously enlarged the amount of data relevant to many fields of sociology that come from postsocialist countries in general and post-Soviet countries more specifically.

A basic consequence of the greatly expanded base of data on Soviet and post-Soviet societies is that sociological research on the Soviet Union and post-socialist states has entered the mainstream of Western social science. It is no longer an area of specialization with strong connections to the foreign policies of Western States.

Space and Social Theory in Geography

Human geography's engagement with social theory has been enormously influential, leaving no part of the discipline untouched. 'Social theory' encompasses a heterogeneity of postpositivist philosophies, including, but not limited to, Marxist political economy, humanistic thought, structuration theory, feminism, postmodernism, and postcolonialism.

1. *Marxist Political Economy*

Starting with radical geography in the 1960s, Marxist geography stressed the analytical centrality of labor and the production process in the creation and transformation of economic landscapes (see *Marxist Geography*). Through labor, human beings enter into social relations, materialize ideas, and transform nature. Marxists emphasized the powerful role that class plays in the social and spatial division of labor, as

a vehicle through which social resources are distributed, as a central institution in shaping labor and housing markets, as a defining characteristic of everyday life, and as a fundamental dimension of political struggle. Underpinning this view is the labor theory of value and its implication that class relations rest upon the extraction of surplus value from the working classes, a process pregnant with politics. The Marxist perspective moved beyond simplistic dichotomies (e.g., base–superstructure) to incorporate the multiplicity of class relations over space and time, gender, the state, and ideology and culture. Marxism is thus not just an economic analysis, but a social, political, and moral one as well.

Marxist geography allowed landscapes to be understood as the creation of modes of production, most notably that of capitalism. Harvey (1982, 1989b) initiated a fascination with uneven development, in which regions are created, transformed, and annihilated by flows of capital over space in search of maximum rates of profit. Capital creates a geography of the built environment, a 'spatial fix' that must be recreated periodically over time. The uneven development of cores and peripheries was analyzed at several spatial scales, i.e., within the metropolitan region, within nation-states, and internationally. Competition forces innovation and induces an acceleration in the turnover rate of capital that rhythmically reconfigures the landscape of commodity production (Harvey 1982). Periodic crises emanate from the overaccumulation of surplus value, leading to broad restructurings of production and location. Viewed systemically, crises are necessary for capitalism's existence; commodity production is not only crisis-ridden, but crisis-dependent.

Marxist geography diversified in several ways. Marxist analyses of the state, or government, arose primarily from French structuralism. In contrast to neoclassical views of the 'public sector,' social theory highlighted social origins and the multiple ways in which the state shapes the territorial reproduction of social relations. Long dominated by a focus on capital, Marxists have examined the geography of labor, including, for example, the spatial dimensions of class struggle and unions.

In the 1980s, economic geography established linkages to French regulation theory, which theorized the multiple forms of capitalism over time and space (see *Regulation Theory in Geography*). The latest of many restructurings historically, late twentieth century capitalism, underwent a profound transformation from Fordism—characterized by large scale production, economies of scale, vertically integrated firms, oligopolies, homogeneous products, mass consumption, assembly lines, interchangeable parts, and Taylorism—to a post-Fordist regime, characterized by small-scale production, networks of cooperative firms, niche markets, and flexible (computerized) production methods clustered in large urban agglomerations. When local production complexes were linked to the global economy, Marxism offered a nuanced understanding of how regions are constructed around industries (see *Technology Districts*).

Geography's engagement with political economy led to an important retheorization of space. Improved transportation and communication systems create rounds of time–space compression, or in Marx's apocryphal words, the 'annihilation of space by time' (see *Time–Space in Geography*). Massey (1984) reincorporated the local uniqueness of places within wider divisions of labor, holding that the reproduction of uneven development occurs through the layering of different rounds of accumulation upon the physical and social landscapes of individual locales. The localities project recovered local places as fundamental to the understanding of how broad processes play out in specific contexts. The enormous time–space compression of late twentieth century capitalism, particularly through telecommunications, has embedded places within a worldwide 'space of flows' (Castells 1996). In the context of hypermobile, post-Fordist, postmodern capitalism, such processes are central to an increasingly service-dominated, globalized economy dominated by streams of money and information (see *Finance, Geography of*).

2. *World-systems Theory*

Political economy's engagement with geography extended to the origins and structure of the world-system, including colonialism and imperialism, the geopolitics of nation-states, multinational corporations, and the possibilities of socio-economic development. Widespread dissatisfaction with modernization theory led dependency theorists to reject neoclassical views of the international division of labor (see *Development Theory in Geography*). Third World poverty—indeed, the construction of the developing world itself—did not, in this view, simply 'happen,' but was the product of centuries of colonialism and continued neocolonial exploitation through transnational corporations, i.e., the development of underdevelopment. Dependency theory represented the first application of Marxist geographical thought on a global scale, locating the cause of poverty in the materialist, external workings of the world economy, not the ideological, internal order of societies, as did modernization theory. Dependency theory rejected the promise that imitation of the West would bring prosperity and liberty to developing nations. Rather, it argued, development and underdevelopment constitute two sides of global capital accumulation, i.e., the wealth of the developed world was, and is, derived from the extraction of surplus value from underdeveloped places. Every moment in the penetration of commodity relations into non-capitalist social formations, therefore, was viewed as inevitably an act of exploitation.

Wallerstein (1979) advanced understanding of the political economy of global geographies with world-systems theory. The capitalist world-system, in contrast to earlier world empires dominated by a single political structure, consists of numerous, independent nation-states, which collectively exert no effective control over the global market. The political geography of capitalism is the interstate system, not the nation-state *per se*. World-systems views divide nations into three broad categories, the core, i.e., the world's leading powers (typically dominated by a single hegemon); the periphery, which comprises large numbers of weak, impoverished states; and the semi-periphery, consisting of wealthier members of the developing world and less developed members of the West. Unlike dependency theory, which takes the nation-state as its unit of analysis, world-systems theory insists upon viewing the entire planet as an indivisible totality, overcoming the dualism between the global and the local. The possibilities of economic development are seen as more open-ended than in dependency theory. The success of the East Asian Newly Industrialized Countries (NICs) since World War II boosted the appeal of world-systems views considerably.

Political geography witnessed sophisticated interpretations of hegemony and territoriality at several spatial scales (see *Political Geography*). Agnew and Corbridge (1995), for example, dissect the 'power container' of the nation-state and its mounting 'leakages' to and from the world-system. O'Tuathail (1996) offers a poststructuralist critical geopolitics, that emphasizes the social origins of statecraft, foreign policy, and geographical knowledge.

3. *Humanistic Geography*

A parallel moment in geography's embrace of social theory occurred with the adoption of humanistic philosophies, particularly phenomenology. Humanists insisted emphatically on the central role of human consciousness, and sought to return purposeful human agents to the center of spatial analysis, as did Renaissance humanists. Philosophically, this line of thought drew upon Husserl, Heidegger, and, more recently, the semiotics of perception, cognition, and language (Buttimer 1976). Humanistic thought successfully refuted the assumption of naturalism, i.e., that there are no substantive differences between the human and natural sciences, revealing that social science is qualitatively different from the physical or natural sciences, so that metaphors drawn from those disciplines are inappropriate to the study of society (Barnes 1996). Because the human subject was poorly theorized in structural Marxism, humanists criticized its economic determinism and teleological reading of history (Duncan and Ley 1982).

Humanistic geography, with roots in the French Vidalian tradition, made numerous contributions to the analysis of place, including the roles of understanding and hermeneutics, the body, experience, and intentionality, and everyday life. Its form of understanding emphasized thought rather than behavior: 'truth,' in this view, could never be grounded simply in objective facts, but in the subjective interpretations that people give to them. This school gave cultural geography a badly needed platform to appropriate hitherto unavailable sources of data, such as literature, poetry, art, and mythology. Tuan's (1977) 'sense of place' studies elaborated upon places as abstract, intangible webs of symbolic meanings produced by and for people, emphasizing the notion of landscapes as authored by agents, for a purpose. Humanism also legitimized later geographical explorations of ethics, morality, and justice (e.g., Smith 1994). Finally, the emphasis on human consciousness was an important antidote to the teleology of structural Marxism; humanistic thought, emphasizing choice and contingency, revealed that history never rolls along a predetermined track.

However, humanistic geography also suffered from serious flaws. Most importantly, lacking any conception of social relations and the social construction of the individual subject, it lapsed into the atomistic ontologies of positivism and neoclassical economics. Unable to appropriate for itself the conceptual foundations necessary to comprehend production, class, the state, power, and struggle, humanism serves largely as a critique but not as an alternative to more structurally-oriented forms of social theory.

4. *Structuration and Realism*

Giddens's (1984) structuration theory effectively overcame the long-standing micro–macro division between social structures that act on their own accord on the one hand and ahistorical individuals on the other. Structuration theory began with the recognition that culture is what is taken-for-granted in daily life, i.e., common sense, the matrix of ideologies that people use to negotiate their way through their everyday worlds. Unlike the ahistorical subject of humanism, culture is acquired through a lifelong process of socialization: individuals never live in a social vacuum, but are socially produced from cradle to grave. Viewing culture as social practice upstaged the prevailing superorganic view in cultural geography, which reified culture as a force suspended above people's heads (Duncan 1980). By emphasizing that the deeply internalized rules and resources that people draw upon everyday simultaneously enable and constrain ways of thinking and acting, structuration theory rescued the living subject from the twin abysses of structural overdetermination and individualistic vol-

untarism. Social formations both produce, and in turn are produced by, their inhabitants (see *Time-geography*).

The counterpart to the unacknowledged preconditions of everyday life are the unintended consequences, the ways in which social relations continually escape the intentions of their creators. Drawing on Marx's famous aphorism that 'Men (sic) make history, but not by means of their own choosing,' structuration theory holds that social and spatial change occurs through intentional action, but not intentionally: in forming their biographies everyday, people unintentionally reproduce and transform their social worlds; individuals are simultaneously produced by, and producers of, history and geography. Thus, everyday thought and behavior do not simply mirror the world, they constitute it (Sayer 1984). Societies and regions are neither reducible to, nor independent of, the everyday lives of their inhabitants. This view linked the macrostructures of social relations to the microstructures of everyday life (Thrift 1983, Pred 1984).

Epistemologically, structuration theory was complemented by the philosophy of realism (Sayer 1984) (see *Critical Realism in Geography*). As with structuralism, realism holds that the interrelations among observations are ontologically real, even if they cannot be measured directly; social relations are thus 'real' even if they are not directly 'observed.' Explanation in realism centers on the distinction between necessary and contingent relations. Necessary relations, identified through theoretical abstraction, concern the essential mechanisms that produce change, not events or observations *per se*; contingent relations, in contrast, are specified empirically in concrete contexts. Whereas necessary conditions must exist in every social explanation, whether the causal properties they describe are activated or not empirically is contingent and indeterminate. The parallels here to structure and agency in structuration theory are clear. This distinction ruptures the unity of generalization and explanation: because different causal powers may generate similar empirical patterns, regularities are not sufficient for explanation; because necessary properties are contingently activated and may occur in only one instance, generalizations are not necessary for explanation either.

5. *Feminism*

Feminist scholarship arose from and contributed to dramatic changes in the status and lives of women, particularly since the women's movement of the 1960s. Feminism is not one unified school of thought, but a series of overlapping discourses, including liberal, Marxist, ecofeminist, radical, and postmodern variants (see *Gender and Feminist Studies in Geography*). Differentiating between the biological category of sex and the social category of gender, feminism stressed gender as a form of resource organization, power relation, and matrix of deeply sedimented presuppositions that underpin daily life. To ignore gender is to assume that mens' lives are 'the norm,' that there is no fundamental difference in the ways in which men and women experience and are constrained by social relations. Feminism served a critical role asserting gender as the first nonclass-based form of social determination.

Central to feminist critiques is the dissection of patriarchy, the domination and oppression of women by men, which is, if not a universal feature of social relations, extremely widespread historically and geographically. Are patriarchy and capitalism necessarily, and not contingently, related? As a political project, feminism is committed to the eradication of patriarchy, to the difference that gender makes in the life opportunities of men and women, to gender as a relation of power. It does not follow that feminism is about eradicating gender differences *per se*; as Hanson (1992) argued, the task is to theorize difference without power.

Feminist scholarship revealed how space is constructed around gender relations, including housing, work, and commuting patterns, access to public and private resources, and the meanings and behaviors that typically favor men and disadvantage women (Bowlby et al. 1990). While early feminist work focused simply on the 'geography of women,' later scholarship explored how gender is intertwined with relations of power, culture, ethnicity, and ideology.

Feminists played a major role in gendering economic geography, including spatial divisions of labor (Massey 1984) and gender differences in commuting patterns (Hanson and Pratt 1995). Feminists exposed as patriarchal the traditional equation of male roles with public spaces and female roles with private ones, which mirrors the broader schism between production and reproduction. Feminists also plunged into epistemology, showing how the construction of knowledge itself is pervasively gendered. Rose (1993) describes how geography's very maleness long colored its construction, arguing for an emancipatory geography that empowers women.

Gender, by definition, includes males. To equate 'gender' with women is to assume men have no gender, that it is not socially constructed or geographically instantiated. Like femininity, masculinity in its multiple forms is reproduced spatially through specific sites, practices, and discourses. Lastly, while gender and sexuality are far from synonymous, recent social theory has also explored the role of sexuality in the construction of personal spaces (see *Sexuality and Geography*).

As geography embraced political economy, it expanded the 'economy' to include the culture of the firm (Schoenberger 1997), the gendered nature of knowledge (Gibson-Graham 1996), and the role of

language and metaphor (Barnes 1996). These works emphasized the role of human actors rather than mechanistic institutions in the unfolding of economic processes, focusing on trust, knowledge, reputation, uncertainty, indeterminacy, and contingency rather than modes of production, class struggle, or technological change. The result has been a more thoroughly 'humanized' economic geography sensitive not only to time and space but to the complexities of social life.

6. *Postmodernism, Representations, Identity, and Postcolonialism*

Following the 'linguistic turn' of many social sciences, geographers exhibited a sustained interest in the politics of knowledge, ideology, discourse, language, symbols, and representations (Barnes and Duncan 1992) as well as the unity of knowledge and power. Far from constituting a web of selfpropelling ideas, all knowledge arises from and in turn contributes to power relations, either by naturalizing or challenging them. Every discourse and representation, whether self-consciously or not, is politically laden, serving some interests and not others; every theory, therefore, is not only an explanation but a legitimation of a particular interest.

Postmodernism contrasts sharply with the Enlightenment quest for universal metanarratives and the modernist assumption that reality is fundamentally ordered; postmodernism emphasizes complexity, randomness, disorder, and chaos. The postmodern picture of reality consists of a multitextured kaleidoscope that can never be adequately captured in a single theory: reality is more complex than any language can describe. Postmodernism celebrates heterogeneity, not commonalities; it accepts uncertainty and ambiguity; it emphasizes ephemerality rather than permanence. However, the simple dichotomy between modern and postmodern fails to do justice to the complexity of both. Marxists conceptualize postmodernism as a cultural response to the material and social transformation of post-Fordist capitalism (Harvey 1989a).

This view destabilized many received categories of geographic thought (Benko and Strohmeyer 1997) (see *Postmodernism in Geography*). Postmodernism's engagement with feminism problematized the unified metanarrative of gender that underpinned feminist work. Postmodernism and Marxism share an uneasy relationship (Harvey 1989a, Soja 1989). In the context of the localities debate, postmodernism holds that theory must be adapted to the temporal and spatial specifics of places.

Postmodernism also paved the way for the injection of semiotics into geographic thought and a wide-ranging debate about the nature of representations of space. Orthodox views, grounded in the correspondence theory of truth, portray representations as claims to truth, not attempts at persuasion; in this view, objectivity is both possible and necessary, and the act of interpretation is unproblematic. Under postmodernism, this perspective gave way to deconstructionist interpretations that emphasize every representation is a simplification, inevitably filled with silences (Barnes and Duncan 1992). Like landscapes, representations are always authored, situated in a context, inescapably partial and biased; thus, representations can only be understood intertextually, within the context of other representations. Further, the manner in which representations are interpreted/consumed is not necessarily how they are intended/produced: meanings of texts and landscape generally escape their authors. This line of thought is insistent that representations are social constructions: while discourses often become taken-for-granted as 'natural,' acquiring an asocial 'objective' status, there can be no value-free representations. Rather, representations of place are inescapably linked to power relations. Thus, they have social consequences (though not always intended ones), becoming part of the social reality that they describe: word-making is also world-making. Cartographers, for example, revealed maps to be discourses, laden with power relations, that constrain perceptions of space along some avenues and not others (Wood 1992, Harley 1989). Pickles (1995) argues that Geographic Information Systems have become implicated in the discursive rewriting of space, essentially underpinning a resurgence of positivist thought.

Human geography has also exhibited an interest in personal and social identity, the processes that shape human experience, establish the individual's boundaries of the self, and define their place in the world. Building on a long tradition of phenomenology, psychotherapy, and symbolic interactionism, this genre stressed the social construction of the individual self and sutured the formation and reproduction of individual and collective identities to place and space (Pile and Thrift 1995). Identities are power relations that reflect and contest relations of normality and marginality. In this light, identities are constructed by establishing difference, by the drawing of boundaries, by defining what they are not: there is always an Other, and 'othering' is a power relation. In contrast to the Enlightenment assumption of the unified human subject, identities can be contradictory bundles, constantly in flux, and inevitably interwoven with power relations, a view suited to the realities of late twentieth century, post-Fordist, hypermobile capitalism, in which the electronic mediation of experience is widespread, rapid time-space compression commonplace, and hyperreality the norm.

Social theory in geography only recently turned to race and ethnicity (Jackson and Penrose 1994), to the complex ways in which it is constructed and negotiated in everyday existence, how it interacts contingently with class and gender, and the complicated manner in

which it plays out over space. Racial and ethnic identity is fundamentally a power relation that typically reflects, reinforces, and naturalizes existing lines of inequality, although it may challenge hegemonic norms as well. The racialized geographies of urban poverty and the underclass have received attention as the products of restructuring, state policy, and local discrimination. To equate 'ethnicity' with nonwhites, however, presumes that whiteness is the norm, or 'default option;' for this reason, geographers have turned to the social construction of whiteness and its multiple political connotations.

The geographical understanding of ethnicity, discourse, and identity was greatly advanced by Said's (1978) *Orientalism*, which opened the door to an imaginative reconceptualization of the politics of spatial representation and identity formation at the worldwide level, revealing colonialism to be as much an ideological process as an economic or political one. Gregory (1994) laid bare geography's complicity in the power relations of global (see *Postcolonial Geography*) modernity: by framing space within 'occularcentric' worldviews of the Enlightenment—essentially, the assumption that the world is knowable, that it can be subjected to the dissection in terms of an all-seeing observer—modernity discursively constructed images, ideas, and identities that deepened the Western penetration of its Other, the non-West.

7. Concluding Comments

Paradoxically, contemporary geography illustrates both greater unity and greater divisions than perhaps at any time in its history. While enormous differences of opinion remain, a broad consensus has emerged that takes seriously political economy and social relations of knowledge and power as fundamental to the understanding of space. Social theory raised class, gender, ethnicity, and power as central foci of spatial analysis, including both their historically constituted material forms on the landscape and their ideological, taken-for-granted dimensions that inform daily life, discourse, and individual and social identities. Social reproduction has been put on a par with the dynamics of production as a key moment in the dissection of spatialities. In the process, geography became highly sensitized to issues of difference, to the politics of knowledge and the diverse ways in which places, and the people who inhabit them are represented to one another and to observers. The ways in which social and spatial relations are explained, justified, and described in politically-laden terms—in short, the manner in which discourse does not simply reflect the social world, but constitutes it—have also figured prominently. As a result of its intercourse with social theory, geography—long a discipline that lagged behind other fields in theoretical vigor—was catapulted from a naïve, atheoretical discipline into a theoretically informed and informative (i.e., generative) one.

Space: Linguistic Expression

Spatial cognition is at the heart of much human thinking, as evidenced for example in the explanatory power of spatial metaphors and diagrams, and the explication of spatial concepts has thus played a key role in the development of Western mathematics and philosophy over two and a half millennia (see Jammer 1954). It is therefore easy to assume that spatial notions form a robust, universal core of human cognition. But naïve human spatial language turns out to vary significantly across languages, both in the way it is semantically organized and the way in which it is coded. This has major implications for how we should think about universals in human thought and language.

The Western intellectual tradition has provided an elaborate metalanguage for spatial concepts, but the conceptual underpinnings of naïve human spatial language utilize only a small subset of these concepts. Moreover, there are many aspects of our spatial perception and motor control which utilize much richer and more precise representations of space than are coded in language. The study of the representation of space in language, and its relation to cognition, must therefore be treated as an empirical enterprise, and this article reports on the still quite limited cross-linguistic information about how different languages structure the spatial domain (see Levinson and Wilkins in preparation).

1. *Space as a Semantic Domain*

Languages tend not to treat space as a single, coherent semantic field in the same way that they treat e.g., color (q.v.), kinship (q.v.), or ethnobotany—rather, space is structured as a large semantic field with many distinct subdomains, each of which is closely structured (and often varies considerably across languages). Nearly all languages have 'where'—questions which cover the entire field related (that is with the same or morphologically related forms for 'where-to,' 'where-from,' 'where-at') and describe the location of one object primarily with respect to another. But beyond these general properties, spatial expressions are structured in distinct subdomains, notably topology, frames of reference, and motion, with place names and spatial deixis as complementary areas. These subdomains cross-cut in certain ways (e.g., frames of reference may play a role in motion description), but because they have their own internal organization they need to be kept analytically distinct.

Although, the philosophical and scientific literature gives us many different ways to talk about space, natural languages tend to structure spatial description more in accord with the ideas of Leibniz than of Newton. That is, location is thought about as the place of one thing relative to another (rather than, as in Newtonian thinking, as specifications in the coordinates of an infinite, abstract three-dimensional 'box'). We will call the object to be located the 'figure,' and the object with respect to which the location is specified 'the ground' (other equivalent terms in the literature are 'theme' vs. 'relatum' or 'trajector' vs. 'landmark'). As Talmy (1983) noted, a good ground or landmark object is larger than and less mobile than the figure object to be located. The problems of location specification then largely boil down to the following functional considerations:

(a) Where figure F and ground G are contiguous or coincident, a static F may be said to be 'at G.' Where G is large, it can be subdivided, so that F can be said to be 'at the X-part of G.' This is, roughly, the subdomain of topology.

(b) Where F and G are separated in space, the problem is to specify an angle or direction from G in which F can be found (the search domain). This involves a coordinate system of some kind, a 'frame of reference,' of which there are three main types found in languages.

(c) Where F is in motion, two kinds of ground are especially relevant: the source or the goal of the motion. To indicate the progression of motion (i.e., the increase or decrease of distance from a ground), motion can be specified as 'F is moving towards goal G' or 'F is moving from source S.' In addition, motion can be thought of as bringing about, or destroying, a topological relation, as in 'F moves into G.' But to indicate a direction or vector of motion, both S and G must be specified, or a coordinate system of the kind mentioned in (b) utilized. (Of course, motion can also be specified as taking place within a location, in which case the systems in (a) and (b) can be utilized.

These functional distinctions give us a number of cleavages: stasis (or location) vs. kinesis (or motion), non-angular topological relationships vs. angular relations specified in frames of reference, with potentially cross-cutting domains as in Fig. 1.

Figure 1
Cross-cutting subdomains of spatial language

Some further details in Fig. 1, like the three frames of reference, will be described below. But two subfields which will not receive further discussion need to be mentioned here. One is *deixis*, which concerns the way in which the location of the speech participants can constitute a special ground or landmark (as in *here*), which then makes interpretation dependent on determining that location (as in *He used to come here*). Languages universally seem to provide a structured set of deictic elements with distinctions that are often spatial (demonstratives like 'this' vs. 'that,' adverbs like 'here' vs. 'there'). Deictic anchoring of spatial expressions is, however, often implicit or pragmatic: *the local pub* implies a pub close to some reference point, which unless specified is taken to be the place of speaking.

A second subfield not treated further here is toponymy, or systems of place names. Place names have been much investigated from an historical point of view: since they are highly conservative they reveal much about the locations of ancient languages and peoples. However, the theory and cross-linguistic typology of place names—e.g., why some are descriptive, others not—is hardly developed at all (see e.g., Hunn 1993).

2. *Universals and Variation in the Semantic Parameters in Spatial Subdomains*

In this section, the semantic parameters involved in spatial description in two major subdomains are described to illustrate the different ways in which languages structure the spatial domain.

2.1 *Topology*

This subdomain, as mentioned, concerns contiguous relations between figure and ground. The term is potentially misleading—topology proper is a branch of geometry concerned with constancies under continuous distortions such as stretching, but is used in studies of spatial language following Piaget to describe the sort of spatial relations covered by the English prepositions *on*, *in*, *at* (Herskovits 1986). These spatial terms are amongst the earliest learnt by Western children, and it has therefore been supposed that they form a universal innate core of spatial notions. However, cross-linguistic studies show that universal semantic concepts are only to be found at a more abstract level. Take, for example, the spatial relations covered by English *on*, as in *The cup is on the table*, *The picture is on the wall*, or *The fresco is on the ceiling*—clearly the term covers a wide area, which is already subdivided in the adpositions (prepositions or postpositions) of many other European languages. Some languages (like Japanese) conflate 'on'-relations with 'over'-relations (as in *The light is over the table*) in their adpositions; others (like Yukatek) even include 'under'-relations as well (as in *The ball is under the table*). A detailed analysis of a dozen languages from different families suggests that universal semantic concepts in this domain lie at a more atomic level (Levinson and Wilkins, in preparation). If we think of the core prototype of English *on* as consisting of the notion of vertical superposition of figure over ground, with a horizontal ground supporting a non-attached figure, then the kind of notions that look universal are at the level of 'vertical superposition,' 'contact,' 'horizontal supporting surface,' (non) 'attachment.' Clearly these more abstract atomic concepts can be rearranged in many different ways to constitute the semantic relations expressible in an individual language.

Topological relations are coded in the European languages primarily in adpositions or case, but as we shall see these are not the only possibilities—some languages code topological relations entirely in nouns or verbs.

2.2 *Frames of Reference*

Linguists have presumed that there are two main frames of reference, which are often called 'deictic' and 'intrinsic,' and which can be illustrated by the ambiguity of *The boy is behind the bus*—either the bus is between the boy and us ('deictic') or he is at the rear of the bus ('intrinsic'). Psychologists have long known, however, that on the vertical dimension our perceptual systems use three frames of reference against which to measure uprightness: an object-centered frame, a viewer-centered frame, and an environmental frame. Cross-linguistic research shows that in fact these three frames of reference, which we will call the intrinsic, the relative, and the absolute frame respectively, may be used on the horizontal plane too (Levinson 1996). These three frames appear to be universally available, yet not all languages make systematic use of them all—some use the absolute frame, others the relative

frame, while most use the intrinsic frame, and some use all three (the main universal constraint appears to be that the relative frame is dependent on the possession of the intrinsic frame).

The intrinsic frame of reference, as its name implies, has to do with the intrinsic parts of ground objects. Recollect that frames of reference have to do with specifying angles or directions from a landmark. One way to achieve this is to designate a side or facet of an object, so that the figure can be said to be lying on an axis drawn from the center of the object through the designated side. Most languages provide a vocabulary for parts of objects, but the ways in which they partition objects can be very variable. In English, for example, the criteria for assigning the *front* of an object involve a complex mix of functional and orientational information: the front of a bus is the direction in which it canonically moves, the front of a building is the side in which it is normally entered, and the front of a television the side designed to be watched. In English the *top* of a bottle remains the top even when tipped over, but in other languages (like Zapotec) a more strictly orientational approach may assign the 'top' to whatever side is currently uppermost. Alternatively (as in Tzeltal), the assignment may rely entirely on the internal axial geometry of the object, so that e.g., the 'face' of an object may be a flat side on a secondary axis, even if normally this is undermost. What all these systems have in common is that they provide a system of designated sides which is independent of the position of the viewer, and (apart from the vertical axis) independent of an environmental orientation — how they achieve this differs not only in detail but in fundamentals.

Another way of obtaining angular distinctions on the horizontal plane is to use the body-axes of the viewer. We can then say that something is, for example, to the 'left' of something else in the visual field. Full versions of such systems use a left/right axis and an orthogonal front/back axis, but again the way in which they map bodily axes onto the ground object is very variable. Although these systems are often called 'deictic' in the literature, this is misleading—they typically have a deictic centre but they need not (as in *He kicked the ball to the left of the goal*), and the other two frames of reference can also have deictic centers. Hence these systems are here said to be 'relative' frames of reference, because they are relative to the body-axes of some observer. Some languages translate the bodily coordinates onto the ground object without rotation: in such languages (like Hausa) *The boy is to the left of the tree* means just what it does in English, but *The boy is in front of the tree* means what in English is described as *The boy is behind the tree*. In contrast, some languages rotate the axes, so that the front of the tree is towards us, but the left of the tree is what we would in English call its right (this is probably a minority option, but is found in some dialects of Tamil). Some languages reflect the axes, as in English, so that left and right remain in the same directions as the viewer's body, but front and back are reversed or 'flipped' over.

Notice that terms like 'front' and 'back' and 'left' and 'right' have intrinsic interpretations (as in *He's sitting at the chairman's left*), and for that reason ambiguities arise of the kind illustrated above with *The boy is behind the bus*. Relative systems are based on the intrinsic sides of humans, and probably arise as extensions of an intrinsic system to objects (like trees or balls) which resist the assignment of named sides. Hence the implicational relation: all relative systems are associated with intrinsic systems, but the possession of an intrinsic system does not necessarily imply the use of a relative one. Relative systems had been thought to be universal, but in fact it turns out that perhaps as many as a third of the world's languages do not employ them, instead making use of absolute systems.

Absolute systems rely on environmental gradients or 'geocentric' coordinates. Such systems use absolute directions, or fixed bearings, a bit like English North, but unlike in English, they are often used on all scales (as in *The cup to the north of yours is mine*, or even *There's a spider on your northern leg*), completely replacing the need for relative systems. There are many different varieties of such systems. Some of them (as in Australian Aboriginal languages) are fully abstract cardinal direction systems, with terms that may gloss 'North,' 'South,' etc., but which denote quadrants or arcs of specific angle, and are often based on bearings rotated from our cardinal directions. To use a system of this kind, speakers must always orient themselves precisely, using multiple environmental clues (wind directions, solar angles, sidereal ecliptics, landscape features, and the like). Other systems are based more directly on one major environmental cue, like prevailing winds (as in languages of the Torres Straits), river drainage (as in Alaska), or prevailing slopes in mountainous terrain (as in the Himalayas). For example, Tenejapan Tzeltal uses an 'uphill,' 'downhill,' 'across' system, based on the general lie of the land in the territory of Tenejapa (Chiapas, Mexico), but the system has been abstracted from the terrain to provide fixed orientation, so that the bearings remain constant outside the territory. Many systems use fixed orthogonal axes, but not all: for example, the Austronesian languages in the Pacific islands typically use the monsoon winds as the basis for one axis, but an inland-sea opposition as the basis for another axis—as one moves around the island, the angles between the axes constantly change.

3. *How Spatial Distinctions are Coded in Language Forms*

Much of the literature gives the impression that spatial distinctions are primarily coded in adpositions, as in

the prepositions of English. In fact, in most languages spatial information is distributed throughout the clause. Some languages have a score or more local cases (nominal suffixes) covering roughly the same distinctions as English prepositions (e.g., Finnish or the NE Caucasian language Avar). Other languages use a combination of case and adposition (as in Tamil), or case and spatial nominal (as in many Australian languages). Special classes of spatial nominals do a lot of the work in isolating languages like Chinese, and they play special roles in other languages (cf. *front* in the English complex preposition *in front of*, and *North* in the adverbial use *He went North*). Many spatial oppositions are made constructionally, as when German prepositions like *auf* take the dative to indicate location, and the accusative to indicate motion towards. Finally, verbs play a crucial role in spatial description. In the case of motion, there is often a special form-class of motion verbs, and languages tend to conflate motion with manner (as in English *crawl*) or direction or 'path' (as in Spanish *salir* 'to go out'), but not generally both (Talmy 1983). In many languages (e.g., Dutch), there is a small set of contrasting verbs (often derived from posture verbs) used to describe static location, encoding properties of the figure, or ground, or both. Some languages have a larger set (as in Tzeltal), and in this case most of the semantic load is taken by the verbs, which may encode such specific details as 'be located in a bowl-shaped container.'

In conclusion, it is clear that spatial concepts form a complex semantic field made up of structured linguistic subdomains. The semantic parameters involved may ultimately have a universal base, but the ways in which the semantic subdomains are organized displays considerable cross-linguistic variation. There is also considerable cross-linguistic variation in the way in which such distinctions are encoded in the form-classes of languages. This linguistic variation is especially interesting given the centrality of spatial concepts in human thinking—and indeed it can be shown that linguistic differences in frames of reference make a difference to how humans memorize and reason non-linguistically (Levinson 1996, in press, Pederson et al. 1998).

Spatial Analysis in Geography

The proliferation and dissemination of digital spatial databases, coupled with the ever wider use of geographic information systems (GIS), is stimulating increasing interest in spatial analysis from outside the spatial sciences. The recognition of the spatial dimension in social science research sometimes yields different and more meaningful results than analysis which ignores it.

Spatial analysis is a research paradigm that provides a unique set of techniques and methods for analysing events—events in a very general sense—that are located in geographical space (see Table 1). Spatial analysis involves spatial modeling, which includes models of location-allocation, spatial interaction, spatial choice and search, spatial optimization, and space-time. Other entries in the encyclopedia take up these models (e.g., see *Location Theory*; *Spatial Interaction Models*; *Spatial Optimization Models*; *Spatial-temporal Modeling*); this article concentrates on spatial data analysis, the heart of spatial analysis.

1. Spatial Data and the Tyranny of Data

Spatial data analysis focuses on detecting patterns and exploring and modeling relationships between such patterns in order to understand processes responsible

Table 1
Popular techniques and methods in spatial data analysis

	Exploratory spatial data analysis	Model-driven spatial data analysis
Object data		
Point pattern	Quadrat methods Kernel density estimation Nearest neighbor methods *K*-function analysis	Homogeneous and heterogeneous Poisson process models and multivariate extensions
Area data	Global measures of spatial associations: Moran's *I*, Geary's *c*	Spatial regression models
	Local measures of spatial association: G_i and G_i* statistics, Moran's scatter plot	Regression models with spatially autocorrelated residuals
Field data	Variogram and covariogram Kernel density estimation Thiessen polygons	Trend surface models Spatial prediction and kriging Spatial general linear modeling
Spatial interaction data	Exploratory techniques for representing such data	Spatial interaction models
		Location-allocation models
	Techniques to uncover evidence of hierarchical structure in the data such as graph-theoretic and regionalization techniques	Spatial choice and search models
		Modeling paths and flows through a network

for observed patterns. In this way, spatial data analysis emphasizes the role of space as a potentially important explicator of socioeconomic systems, and attempts to enhance understanding of the working and representation of space, spatial patterns, and processes.

1.1 Spatial Data and Data Types

Empirical studies in the spatial sciences routinely employ data for which locational attributes are an important source of information. Such data characteristically consist of one or few cross-sections of observations for either micro-units such as individuals (households, firms) at specific points in space, or aggregate spatial entities such as census tracts, electoral districts, regions, provinces, or even countries. Observations such as these, for which the absolute location and/or relative positioning (spatial arrangement) is explicitly taken into account, are termed spatial data (e.g., see *Spatial Data*).

In the socioeconomic realm, points, lines, and areal units are the fundamental entities for representing spatial phenomena. This form of spatial referencing is also a salient feature of GIS (e.g., see *Geographic Information Systems*; *Spatial Data Infrastructure*). Three broad classes of spatial data can be distinguished:

(a) *object data* where the objects are either points (spatial point patterns or locational data, i.e., point locations at which events of interest have occurred) or areas (area or lattice data, defined as discrete variations of attributes over space),

(b) *field data* (also termed geostatistical or spatially continuous data), that is, observations associated with a continuous variation over space, given values at fixed sampling points, and

(c) *spatial interaction data* (sometimes called link or flow data) consisting of measurements each of which is associated with a link or pair of locations representing point or areas.

The analysis of spatial interaction data has a long and distinguished history in the study of a wide range of human activities, such as transportation movements, migration, and the transmission of information (see *Spatial Interaction*; *Spatial Interaction Models*). Field data play an important role in the environmental sciences, but are less important in the social sciences. This article, therefore, focuses on object data, the most appropriate perspective for spatial analysis applications in the social sciences. Object data include observations for micro-units at specific points in space, that is, spatial point patterns, and/or observations for aggregate spatial entities, that is, area data.

Of note is that point data can be converted to area data, and area data can be represented by point reference. Areas may be regularly shaped such as pixels in remote sensing or irregularly shaped such as statistical reporting units. When divorced from their spatial context such data lose value and meaning. They may be viewed as single realizations of a spatial stochastic process, similar to the approach taken in the analysis of time series.

1.2 The Tyranny of Data

Analyzing and modeling spatial data present a series of problems. Solutions to many of them are obvious, others require extraordinary effort for their solution. Data exercise a power that can lead to misinterpretation and meaningless results; therein lies the tyranny of data.

Quantitative analysis crucially depends on data quality. Good data are reliable, contain few or no mistakes, and can be used with confidence. Unfortunately, nearly all spatial data are flawed to some degree (e.g., see *Spatial Data*). Errors may arise in measuring both the location and attribute properties, but may also be associated with computerized processes responsible for storing, retrieving, and manipulating spatial data. The solution to the data quality problem is to take the necessary steps to avoid having faulty data determining research results.

The particular form (i.e., size, shape, and configuration) of the spatial aggregates can affect the results of the analysis to a varying, usually unknown, degree as evidenced in various types of analysis (see, e.g., Openshaw and Taylor 1979; Baumann et al. 1983). This problem generally has become recognized as the modifiable areal units problem (MAUP), the term stemming from the fact that areal units are not 'natural' but usually arbitrary constructs. For reasons of confidentiality, social science data (e.g., census data) are not often released for the primary units of observation (individuals), but only for a set of rather arbitrary areal aggregations (enumeration districts or census tracts). The problem arises whenever area data are analyzed or modeled and involves two effects: one derives from selecting different areal boundaries while holding the overall size and the number of areal units constant (the zoning effect). The other derives from reducing the number but increasing the size of the areal units (the scale effect). There is no analytical solution to the MAUP, but questions of the following kind have to be considered in constructing an areal system for analysis: What are the basic spatial entities for defining areas? What theory guides the choice of the spatial scale? Should the definition process follow strictly statistical criteria and merge basic spatial entities to form larger areas using some regionalization algorithms (see Wise et al. 1996)? These questions pose daunting challenges.

In addition, boundary and frame effects (i.e., the geometric structure of the study area) may affect spatial analysis and the interpretation of results. These problems are considerably more complex than in time series. Although several techniques, such as refined K-function analysis, take the effect of boundaries into account, there is a need to study boundary effects more systematically.

An issue that has been receiving increasing attention relates to the suitability of data. If the data, for example, are available only at the level of spatial aggregates, but the research question is at the individual respondent level, then the ecological fallacy (ecological bias) problem arises. Using area-based data to draw inferences about underlying individual-level processes and relationships poses considerable risks. This problem relates to the MAUP through the concept of spatial autocorrelation.

Spatial autocorrelation (also referred to as spatial dependence or spatial association) in the data can be a serious problem (e.g., see *Spatial Autocorrelation*), rendering conventional statistical analysis unsafe and requiring specialized spatial analytical tools. This problem refers to situations where the observations are nonindependent over space. That is, nearby spatial units are associated in some way. Sometimes, this association is due to a poor match between the spatial extent of the phenomenon of interest (e.g., a labor or housing market) and the administrative units for which data are available. Sometimes, it is due to a spatial spillover effect. The complications are similar to those found in time-series analysis, but are exacerbated by the multidirectional, two-dimensional nature of dependence in space rather than the unidirectional nature in time. Avoiding the pitfalls arising from spatially correlated data is crucial to good spatial data analysis, whether exploratory or confirmatory. Several scholars even argue that the notion of spatial autocorrelation is at the core of spatial analysis (see, e.g., Tobler 1979). No doubt, much of current interest in spatial analysis is directly derived from the monograph of Cliff and Ord (1973) on spatial autocorrelation that opened the door to modern spatial analysis.

2. Pattern Detection and Exploratory Analysis

Exploratory data analysis is concerned with the search for data characteristics such as trends, patterns, and outliers. This is especially important when the data are of poor quality or genuine *a priori* hypotheses are lacking. Many such techniques emphasize graphical views of the data that are designed to highlight particular features and allow the analyst to detect patterns, relationships, outliers, etc. Exploratory spatial data analysis (ESDA), an extension of exploratory data analysis (EDA) (Haining 1990, Cressie 1993), is geared especially to dealing with the spatial aspects of data.

2.1 Exploratory Techniques for Spatial Point Patterns

Point patterns arise when the important variables to be analysed is the location of events. At the most basic level, the data comprise only the spatial coordinates of events. They might represent a wide variety of spatial phenomena, such as cases of disease, crime incidents,

pollution sources, or locations of stores (e.g., see *Spatial Pattern, Analysis of*). Research typically concentrates on whether the proximity of particular point events, their location in relation to each other, represents a significant (i.e., nonrandom) pattern. Exploratory spatial point pattern analysis is concerned with exploring the first and second order properties of spatial point pattern processes. First order effects relate to variation in the mean value of the process (a large scale trend), while second order effects result from the spatial correlation structure or the spatial dependence in the process.

Three types of methods are important: Quadrat methods, kernel estimation of the intensity of a point pattern, and distance methods. Quadrat methods involve collecting counts of the number of events in subsets of the study region. Traditionally, these subsets are rectangular (thus, the name quadrat), although any shape is possible. The reduction of complex point patterns to counts of the number of events in quadrats and to one-dimensional indices is a considerable loss of information. There is no consideration of quadrat locations or of the relative positions of events within quadrats. Thus, most of the spatial information in the data is lost. Quadrat counts destroy spatial information, but they give a global idea of subregions with high or low numbers of events per area. For small quadrats more spatial information is retained, but the picture degenerates into a mosaic with many empty quadrats.

Estimating the intensity of a spatial point pattern is very like estimating a bivariate probability density, and bivariate kernel estimation can be adapted easily to give an estimate of intensity. Choice of the specific functional form of the kernel presents little practical difficulty. For most reasonable choices of possible probability distributions the kernel estimate will be very similar, for a given bandwidth. The bandwidth determines the amount of smoothing. There are techniques that attempt to optimize the bandwidth given the observed pattern of event location.

A risk underlying the use of quadrats is that any spatial pattern detected may be dependent upon the size of the quadrat. In contrast, distance methods make use of precise information on the locations of events and have the advantage of not depending on arbitrary choices of quadrat size or shape. Nearest neighbor methods reduce point patterns to one-dimensional nearest neighbor summary statistics (see Dacey 1960, Getis 1964). But only the smallest scales of patterns are considered. Information on larger scales of patterns is unavailable. These statistics indicate merely the direction of departure from complete spatial randomness (CSR). The empirical K function, a reduced second-moment measure of the observed process, provides a vast improvement over nearest neighbor indices (see Ripley 1977, Getis 1984). It uses the precise location of events and includes all event–event distances, not just nearest neighbor distances, in its estimation. Care must be taken to correct for edge effects. K-function analysis can be used not only to explore spatial dependence, but also to suggest specific models to represent it and to estimate the parameters of such models. The concept of K-functions can be extended to the multivariate case of a marked point process (i.e., locations of events and associated measurements or marks) and to the time-space case.

2.2 Exploratory Analysis of Area Data

Exploratory analysis of area data is concerned with identifying and describing different forms of spatial variation in the data. Special attention is given to measuring spatial association between observations for one or several variables. Spatial association can be identified in a number of ways, rigorously by using an appropriate spatial autocorrelation statistic (Cliff and Ord 1981), or more informally, for example, by using a scatter-plot and plotting each value against the mean of neighboring areas (Haining 1990).

In the rigorous approach to spatial autocorrelation the overall pattern of dependence in the data is summarized in a single indicator, such as Moran's I and Geary's c. While Moran's I is based on cross-products to measure value association, Geary's c employs squared differences. Both require the choice of a spatial weights or contiguity matrix that represents the topology or spatial arrangement of the data and represents our understanding of spatial association. Getis (1991) has shown that these indicators are special cases of a general formulation (called gamma) defined by a matrix representing possible spatial associations (the spatial weights matrix) among all areal units, multiplied by a matrix representing some specified nonspatial association among the areas. The nonspatial association may be a social, economic, or other relationship. When the elements of these matrices are similar, high positive autocorrelation arises. Spatial association specified in terms of covariances leads to Moran's I, specified in terms of differences, to Geary's c.

These global measures of spatial association can be used to assess spatial interaction in the data and can be visualized easily by means of a spatial variogram, a series of spatial autocorrelation measures for different orders of contiguity. A major drawback of global statistics of spatial autocorrelation is that they are based on the assumption of spatial stationarity, which implies *inter alia* a constant mean (no spatial drift) and constant variance (no outliers) across space. This was useful in the analysis of small data sets characteristic of pre-GIS times but is not very meaningful in the context of thousands or even millions of spatial units that characterize current, data-rich environments.

In view of increasingly data-rich environments, a focus on local patterns of association ('hot spots') and an allowance for local instabilities in overall spatial

association recently has been suggested as a more appropriate approach. Examples of techniques that reflect this perspective are the various geographical analysis machines developed by Openshaw and co-workers (see, e.g., Openshaw et al. 1990), the Moran scatter plot (Anselin 1996), and the distance-based G_i and G_i* statistics of Getis and Ord (1993). This last has gained wide acceptance. These G-indicators can be calculated for each location i in the data set as the ratio of the sum of values in neighboring locations (defined to be within a given distance or order of contiguity) to the sum over all the values. The two statistics differ with respect to the inclusion of the value observed at i in the calculation [included in G_i*, not included in G_i]. They can be mapped easily and used in an exploratory analysis to detect the existence of pockets of local nonstationarity, to identify distances beyond which no discernible association arises, and to find the appropriate spatial scale for further analysis (e.g., see *Spatial Association, Measures of*).

No doubt, ESDA provides useful means to generate insights into global and local patterns and associations in spatial data sets. The use of ESDA techniques, however, generally is restricted to expert users interacting with the data displays and statistical diagnostics to explore spatial information and to fairly simple low-dimensional data sets. In view of these limitations, there is a need for novel exploration tools sufficiently automated and powerful to cope with the data-richness-related complexity of exploratory analysis in spatial data environments (see, e.g., Openshaw and Fischer 1994).

3. *Model Driven Spatial Data Analysis*

ESDA is a preliminary step in spatial analysis to more formal modeling approaches. Model-driven analysis of spatial data relies on testing hypotheses about patterns and relationships, utilizing a range of techniques and methodologies for hypothesis testing, the determination of confidence intervals, estimation of spatial models, simulation, prediction, and assessment of model fit. Getis and Boots (1978), Cliff and Ord (1981), Upton and Fingleton (1985), Anselin (1988), Griffith (1988), Haining (1990), Cressie (1993), Bailey and Gatrell (1995) have helped to make model-driven spatial data analysis accessible to a wide audience in the spatial sciences.

3.1 *Modeling Spatial Point Patterns*

Spatial point pattern analysis grew out of a hypothesis testing and not out of the pattern recognition tradition. The spatial pattern analyst tests hypotheses about the spatial characteristics of point patterns. Typically, complete spatial random (CSR) represents the null hypothesis against which to assess whether observed point patterns are regular, clustered, or random. The standard model for CSR is that events follow a homogeneous Poisson process over the study region, that is, events are independently and uniformly distributed over space, equally likely to occur anywhere in the study region and not interacting with each other.

Various statistics for testing CSR are available. Nearest neighbor tests have their place in distinguishing CSR from spatially regular or clustered patterns. But little is known about their behavior when CSR does not hold. The K-function may suggest a way of fitting alternative models. Correcting for edge effects, however, might provide some difficulty. The distribution theory for complicated functions of the data can be intractable even under the null hypothesis of CSR. Monte Carlo tests is a way around this problem.

If the null hypothesis of CSR is rejected, the next obvious step in model-driven spatial pattern analysis is to fit some alternative (parametric) model to the data. Departure from CSR is typically toward regularity or clustering of events. Clustering can be modeled through a heterogeneous Poisson process, a doubly stochastic point process, or a Poisson cluster process arising from the explicit incorporation of a spatial clustering mechanism. Simple inhibition processes can be utilized to model regular point patterns. Markov point processes can incorporate both elements through large-scale clustering and small-scale regularity. After a model has been fitted (usually via maximum likelihood or least squares using the K-function), diagnostic tests have to be performed to assess its goodness-of-fit. Inference for the estimated parameters is often needed in response to a specific research question. The necessary distribution theory for the estimates can be difficult to obtain in which case approximations may be necessary. If, for example, clustering is found, one may be interested in the question of whether particular spatial aggregations, or clusters, are associated with proximity to particular sources of some other factor. This leads to multivariate point pattern analysis, a special case of marked spatial point process analysis. For further details see Cressie (1993).

3.2 *Modeling Area Data*

Linear regression models constitute the leading modeling approach for analyzing social and economic phenomena. But conventional regression analysis does not take into account problems associated with possible cross-sectional correlations among observational units caused by spatial dependence. Two forms of spatial dependence among observations may invalidate regression results: spatial error dependence and spatial lag dependence.

Spatial error dependence might follow from measurement errors such as a poor match between the spatial units of observation and the spatial scale of the

phenomenon of interest. Presence of this form of spatial dependence does not cause ordinary least squares estimates to be biased, but it affects their efficiency. The variance estimator is downwards biased, thus inflating the R^2. It also affects the t- and F-statistics for tests of significance and a number of standard misspecification tests, such as tests for heteroskedasticity and structural stability (Anselin and Griffith 1988). To protect against such difficulties, one should use diagnostic statistics to test for spatial dependence among error terms and, if necessary, take action to properly specify the spatially autocorrelated residuals. Typically, dependence in the error term is specified as a spatial autoregressive or as a spatial moving average process. Such regression models require nonlinear maximum likelihood estimation of the parameters (Cliff and Ord 1981, Anselin 1988).

In the second form spatial lag dependence, spatial autocorrelation is attributable to spatial interactions in data. This form may be caused, for example, by significant spatial externalities of a socioeconomic process under study. Spatial lag dependence yields biased and, also, inconsistent parameters. To specify a regression model involving spatial interaction, one must incorporate the spatial dependence into the covariance structure either explicitly or implicitly by means of an autoregressive and/or moving-average interaction structure. This constitutes the model identification problem that is usually carried out using the correlogram and partial correlogram. A number of spatial regression models, that is, regression models with spatially lagged dependent variables (spatial autoregressive models), have been developed that include one or more spatial weight matrices which describe the many spatial associations in the data. The models incorporate either a simple general stochastic autocorrelation parameter or a series of autocorrelation parameters, one for each order contiguity (see Cliff and Ord 1981, Anselin 1988).

Maximum likelihood procedures are fundamental to spatial regression model estimation, but data screening and filtering can simplify estimation. Tests and estimators are clearly sensitive not only to the MAUP, but also to the specification of the spatial interaction structure represented by the spatial weights matrix. Recent advances in computation-intensive approaches to estimation and inference in econometrics and statistical modeling may yield new ways to tackle this specification issue. In practice, it is often difficult to choose between regression model specifications with spatially autocorrelated errors and regression models with spatially lagged dependent variables, though the 'common factor' approach (Bivand 1984) can be applied if the spatial lags are neatly nested.

Unlike linear regression, for which a large set of techniques for model specification and estimation now exist, the incorporation of spatial effects into nonlinear models in general—and into models with limited dependent variables or count data (such as log-linear, logit and tobit models) in particular—is still in its infancy. The hybrid log-linear models of Aufhauser and Fischer (1985) are among the few exceptions. Similarly, this is true for the design of models that combine cross-sectional and time series data for areal units. See Hordijk and Nijkamp (1977) for dynamic spatial diffusion models.

4. *Toward Intelligent Spatial Analysis*

Spatial analysis is currently entering a period of rapid change leading to what is termed intelligent spatial analysis (sometimes referred to as geocomputation). The driving forces are a combination of huge amounts of digital spatial data from the GIS data revolution (with 100,000 to millions of observations), the availability of attractive softcomputing tools, the rapid growth in computational power, and the new emphasis on exploratory data analysis and modeling.

Intelligent spatial analysis has the following properties. It exhibits computational adaptivity (i.e., an ability to adjust local parameters and/or global configurations to accommodate in response to changes in the environment); computational fault tolerance in dealing with incomplete, inaccurate, distorted, missing, noisy and confusing data, information rules, and constraints; speed approaching human-like turnaround; and error rates that approximate human performance. The use of the term 'intelligent' is, therefore, closer to that in computational intelligence than in artificial intelligence. The distinction between artificial and computational intelligence is important because our semantic descriptions of models and techniques, their properties, and our expectations of their performance should be tempered by the kind of systems we want and the ones we can build (Bezdek 1994).

Much of the recent interest in intelligent spatial analysis stems from the growing realization of the limitations of conventional spatial analysis tools as vehicles for exploring patterns in data-rich GI (geographic information) and RS (remote sensing) environments and from the consequent hope that these limitations may be overcome by judicious use of computational intelligence technologies such as evolutionary computation (genetic algorithms, evolutionary programming, and evolutionary strategies) (see Openshaw and Fischer 1994) and neural network modeling (see Fischer 1998). Neural networks models may be viewed as nonlinear extensions of conventional statistical models that are applicable to two major domains: first, as universal approximators to areas such as spatial regression, spatial interaction, spatial choice, and space-time series analysis (see, e.g., Fischer and Gopal 1994); and second, as pattern recognizers and classifiers to allow the user to sift through the data intelligently, reduce dimensionality, and find patterns

of interest in data-rich environments (see, e.g., Fischer et al. 1997).

Spatial Association, Measures of

In the context of the following discussion, association means connectedness or relationship. If spatial association exists, the connectedness is over space (the earth's surface), and it is mappable. If variables are somehow held together tightly or loosely in space, as if a magnet were pulling them into a pattern reminiscent

of the well-known iron filings demonstration, one can say that the variables are spatially associated.

1. Introduction

Spatial association can characterize a single variable or many variables simultaneously. A single variable may be *spatially autocorrelated*; that is, values of the variable are somehow connected or related spatially (see *Spatial Autocorrelation*). Many variables—say, environmental variables such as air quality, water quality, certain species location, and human activities—may be associated one with another at one or more sites. In addition, spatial association and *spatial interaction* are related (see *Spatial Interaction*). If there is spatial interaction, for example, the movement of commuters to workplaces, there is also spatial association since home places are spatially connected to work places.

The scientist interested in the study of spatial association is motivated by the need to understand the spatial relationships between variables at specific sites or how variables of interest are spread across the earth's surface. Many disciplines are particularly concerned with the study of spatial association. Among them are geography, regional science, ecology, epidemiology, regional and urban economics, geology, hydrology and geomorphology. Since this is a broad and popular interest area, many methods and techniques of analysis have been created to confirm notions of spatial association between and among variables. Scientists test or theorize about variables to determine whether spatial association, either observed or expected, actually can be confirmed. As a result of this interest, statistical procedures have been developed for identifying and measuring the existence of spatial association. After a short discussion of maps depicting spatial association, the remainder of this entry will outline the characteristics of measurement procedures.

2. Maps Showing Spatial Association

Maps depicting spatial association fall into several categories: *in situ*, flows, time series, distance decay, and residuals. *In situ* maps reveal by means of overlays the possible association of two or more variables in a region (see Fig. 1). Flow maps show the interaction between sites (see Fig. 2). Time series usually are shown as a series of map views over time (days, years, etc). These represent spatial relationships as they evolve or change over time (see Fig. 3a, b, c). Distance decay maps emphasize Tobler's *First Law of Geography* that 'everything is related to everything else, [but] near things are more related than distant things'. A distance decay map might show that the effect of an earthquake declines with distance from its epicenter or

Figure 1
The study area represented by the black square indicates that there may be an *in situ* relationship among the three variables shown by different shading

Figure 2
The width of the arrows indicates the magnitude of the interaction

Figure 3
Over time {(a), (b), (c)}, there is an increase in the number of events at the same time as spacing between events is reduced

Figure 4
On the plane, as distance increases from A to B the effect on A of the variable indicated by the vertical triangle declines

Figure 5
In standard deviational units, the map shows residuals from a regression model. It remains to be determined whether or not there is a spatially statistically significant association among the residuals

that the influence of a retail store declines with distance from its site (see Fig. 4). Residual maps show the remaining 'unexplained' variation after a model has been used to statistically explain a relationship between two or more variables (see Fig. 5). The unexplained spatial variation represents that part of whatever total variation exists in a mathematical model that is not accounted for by the variables included in the model. Residual maps help researchers identify new variables that might belong in a more complete model, such as a transportation cost, a regional effect, or a previously unidentified physical or human anomaly.

3. *Spatial Association in Matrix Terms*

In order to answer scientific questions about spatial association, one can reduce the complexities of what one sees on a map to a mathematically manipulable set of numbers (Hubert et al. 1981, Getis 1991). The following simple cross-product formula represents spatial association:

$$\Gamma = \sum_{i}^{n}\sum_{j}^{n} w_{ij}\, y_{ij} \qquad (1)$$

(a)

W =

	A	B	C	D	E	F	G	H	I	J

(c)

Figure 6
The spatial pattern shown in (a) is reduced to a **W** matrix of spatial associations (b) and a **Y** matrix (c) made up of absolute differences between values associated with each region

Γ is the measure of spatial association, and the w_{ij} are contained in a matrix, **W**, of values that represent the relationship of each location of interest to all other sites (see Fig. 6a and b). Figure 6a is a hypothetical map of ten regions. The numbers in parentheses represent the value that a hypothetical variable, Y, takes in each of the regions. Suppose it is decided that regions that are contiguous to one another are associated. The **W** matrix (Fig. 6b) indicates the spatial relationship of each region to every other. For 6b, the convention is

	A	B	C	D	E	F	G	H	I	J
A	0	**2**	0	**1**	0	0	0	0	0	0
B	**2**	0	**6**	**3**	0	0	0	0	0	0
C	0	**6**	0	0	**1**	**2**	0	0	0	0
D	**1**	**3**	0	0	**2**	0	**1**	0	0	0
E	0	0	**1**	**2**	0	**3**	0	**0**	0	0
F	0	0	**2**	0	**3**	0	0	0	0	**1**

H	0	0	0	0	**0**	0	**3**	0	**1**	0
I	0	0	0	0	0	0	**2**	**1**	0	**5**
J	0	0	0	0	0	**1**	0	0	**5**	0

Gamma = 66

Figure 7
The value of Γ is made up of the sum of numbers shown in bold

adopted of placing a 1 in the matrix if a link (contiguity) exists and zero otherwise. The **Y** matrix (see Fig. 6c) contains numbers that are the absolute difference between values for all combinations of the regions. For example, the absolute difference between values in regions C and E is shown as an element of the matrix in row C and column E, that is, $|6–7| = 1$.

The two matrices, when summed as a cross-product as shown in Eqn. 1 (see Fig. 7), give the value of Γ. If the values in the **Y** matrix are small for those same rows and columns that correspond to the $w_{ij} = 1$ values in the **W** matrix, the value of Γ will be small. For the example shown, Γ equals 66, an average of 2.2 for each of the 30 links between contiguous regions. If the number 1 appeared in all the **W** cells, the total Γ would have been 300 or a mean of 3.3 for each of the hypothetical 90 links. The implication here is that the contiguous neighbors that characterize **W** gives a smaller gamma value than one might expect if the values y_{ij} were randomly placed in the 10 regions. Γ indicates that there may be a spatial association among the Y values. We use the term 'may be' to indicate that we have not yet used a statistical test to confirm that Y is in fact a spatially associated variable.

3.1 The W Matrix

In the preceding paragraph, we outlined a simple form of a **W** matrix, one that was constructed based on contiguous spatial relationships between regions. The **W** matrix embodies our preconceived or derived understanding of spatial relationships. If we believe, or if theory tells us, that a particular spatial relationship is distance dependent, then the **W** matrix should reflect that supposition. For example, if it is assumed that a spatial relationship declines in strength as distance increases from any given site, then the **W** matrix will show that nearby areas are weighted more highly than sites that are far from one another. Various distance-decay formulations theorized or derived for such phenomena as travel behavior, economic interaction, or disease transmission would require the elements within the **W** matrix to reflect these effects. Thus, a typical **W** matrix might contain elements of the form $w_{ij} = 1/d_{ij}^{\alpha}$ (α greater than 1). Thus, short distance relationships would be weighted more heavily than the long distances.

3.2 The Y Matrix

The nonspatial matrix, **Y**, gives us a view of how a variable(s) whose elements are georeferenced, that is, values of the variable are indexed at certain sites, *might* be associated with one another. The elements of the **Y** matrix, y_{ij}, represent the interaction of values of **Y**. Values can interact in a number of ways: addition, subtraction, multiplication, division, or combinations of these. An important type of interaction is that of covariance, that is, a value at one site may vary from the mean of all sites (the variation) and this difference is multiplied by the variation at another site. Taken over all sites, the *covariation* is

$$\sum_{i}^{n}\sum_{j}^{n} (y_i - \bar{y})(y_j - \bar{y})$$

and the *covariance* is this sum divided by the sample size, n.

3.3 Γ

When the matrix **W** and the matrix **Y** are similarly structured, one can conclude that **Y** values interact very much as the individual regions are spatially associated. Thus, Γ reveals the spatial association in the **Y** variable. In our previous example, we purposely created a **W** matrix that represented a relationship between contiguous regions. The fact that the values of the **Y** variable tend to be similar to one another when regions are contiguous allows us to conclude that the two matrices are similarly structured.

In the literature on spatial association, much attention has been given to the structure of **W** and **Y**. Each, in a sense, represents a related area of research. Those concerned with the **W** matrix have devised ever increasingly complex representations of spatial relations among spatial units. From the simple contiguity structure presented above, empiricists and theorists have constructed **W** matrices that represent supposed migration distances, disease transmission distances, assumed hierarchical spatial relations, political boundary effects, psychological distances, barriers to communication effects, economic effects of distance, social distances, and so on. In experimental work, the matrix **W** has also been used to represent concentric bands measured from various spatial foci or as representative of cumulative distances. These latter matrices help researchers to identify 'critical' distances, that is, distances at which association reaches some peak.

Research on the structure of the **Y** matrix usually is a response to a particular type of possible spatial

association. For example, the researcher may wonder whether the association is that of positive covariance. **Y** is structured in such a way that statistical tests can be carried out on the research hypothesis that statistically significant spatial association exists. Several of these formulations are given below. Each is an alternative method of identifying spatial association.

4. Spatial Association as Covariance

Typical Formula:

$$\mathrm{I} = n\sum_i^n\sum_j^n w_{ij}(y_i-\bar{y})(y_j-\bar{y})/\sum_i^n\sum_j^n w_{ij}\sum_i^n(y_i-\bar{y})^2, i \neq j \tag{2}$$

This is the well-known *Moran's I statistic*, explicated by Cliff and Ord (1981), and used widely as a measure of spatial association for spatial residuals from regression analysis. When the data used for testing purposes are georeferenced, the basic form of the linear regression model requires that the error term be spatially randomly distributed. Moran's *I* is used as a test for the randomness of residuals from regression. The elements of the **W** matrix are represented as w_{ij}. The **Y** matrix is the covariance and the remainder of the equation is a scaling device used to give the statistic useful testing properties.

5. Spatial Association as Difference

Formulas:

$$\gamma(h) = \sum_i^{n-h}\sum_{j-1+h}^{n} w_{ij}(y_i-y_j)^2/2n(h) \tag{3}$$

$$c = n-1\sum_i^n\sum_j^n w_{ij}(y_i-y_j)^2/2\sum_i^n\sum_j^n w_{ij}\sum_i^n(y_i-\bar{y})^2, i \neq j \tag{4}$$

The better known of these formulas is the first, called the *semivariance* or *variogram*. Widely used among geoscientists, this measure helps to identify the decline in spatial association as distance (h) increases away from the sites in question. It is the backbone for the large research area that yields continuous map surfaces common in studies of meteorology, geography, and geology (Cressie 1991). **W** is again represented by w_{ij}. **Y** is made up of $(y_i-y_j)^2$ and the remainder of the equation is used to scale the semivariance in terms of the variance. Equation 4 is known as Geary's c.

6. Spatial Association as Clusters

Formula:

$$K(d) = \left[A\sum_i^n\sum_j^n w_{ij}(d)/\pi n(n-1)\right]^{1/2} \tag{5}$$

This measure, called the *K-function*, helps to identify *spatial clustering* (Ripley 1981) within the region A. It is used primarily in ecological and epidemiological studies (Diggle 1983). The **W** matrix is made up of the w_{ij} elements, represented as ones, up to an arbitrary distance d. The **Y** matrix is invisible but is assumed to have each element equal to one. In practice, K values are found for a series of distances. Tests are usually carried out by simultating alternative patterns of points (see *Spatial Pattern, Analysis of*).

7. Focused Spatial Association

Formula:

$$G_i^*(d) = \sum_j^n w_{ij}(d)y_j/\sum_j^n y_j \tag{6}$$

For each type of measure shown above there is a counterpart (usually with some variation) that allows one to determine whether or not spatial association exists within the proximal region surrounding a georeferenced point. A popular measure of this type is the *Getis–Ord statistic*, G_i^*(d), which for the **Y** matrix each georeferenced point i is weighted (Getis and Ord, 1992). As distance increases from the site in question, values of G_i^* increase if clustering is in evidence, otherwise they decrease. Anselin's *Local Indicators of Spatial Association* or *LISA* statistics are designed for focusing Moran's and Geary's statistics (Anselin 1995).

8. Spatial Association as Interaction

The basic formula:

$$T_{ij} = y_i y_j / w_{ij}^{-\beta} \tag{7}$$

There are a number of interaction models; the one shown above is the simplest. These widely used models enable transportation and economic researchers to estimate the flow of automobiles, aircraft, migrants, goods and services, and so on, between places (Haynes and Fotheringham 1984). The **W** matrix usually represents a distance decay function while **Y** is usually a multiplicative interaction matrix.

All of these models have the Γ form. All can be used to test hypotheses about or to measure the extent of spatial association. Recent summaries on the measurement of spatial association can be found in Getis (1966, 1999) and Bailey and Gatrell (1995).

Spatial Autocorrelation

Spatial autocorrelation is the term used to describe the presence of systematic spatial variation in a variable. The variable can assume values either (a) at any point on a continuous surface (such as land use type or annual precipitation levels in a region); (b) at a set of fixed sites located within a region (such as prices at a set of retail outlets); or (c) across a set of areas that subdivide a region (such as the count or proportion of households with two or more cars in a set of Census tracts that divide an urban region). Positive spatial autocorrelation is the tendency for sites or areas that are close to one another to have similar values of the variable (i.e., both high or both low). Negative spatial autocorrelation is the tendency for adjacent values to be dissimilar (high values next to low values) which can arise in cases (b) and (c). The presence of spatial autocorrelation in map data has often been taken as indicative that there is something of interest in the map that calls for further investigation in order to understand the reasons behind the observed spatial variation (Cliff and Ord 1981). Whether identified formally through some statistic (see Sect. 3 below) or otherwise, if geographic phenomena display systematic spatial variability then this may provide the starting point for theorizing about the spatial outcomes of processes that may have their roots in, for example, economic, political, or sociological theory.

If spatial data display spatial autocorrelation, this has important implications for the application of statistical methods to such data. The term spatial autocorrelation arises in several different data analysis contexts. For example it arises in the fields of spatial statistics (Ripley 1981, Cressie 1991, Berliner), spatial econometrics (Anselin 1988) and geostatistics (Cressie 1991, Isaaks and Srivastava 1989, Berliner). If the values of a variable are known for a set of locations (or areas) then if there is spatial autocorrelation each value provides some information on the values of the same variable at nearby sites or for adjacent areas. One implication of this is that within the spatial data set there is information redundancy and for the purposes of hypothesis testing the size of the sample is not the same as the number of independent observations of the process. It is with the recognition of this property that statistical methods for analyzing spatial data part company with methods commonly employed in traditional statistics, sharing ground instead with the sorts of methods used to analyze time series data. The following sections will describe how spatial autocorrelation arises; how it is measured and its presence tested for; and the implications of spatial autocorrelation for spatial sampling, exploratory spatial data analysis, map interpolation, and confirmatory analysis including correlation and regression.

1. *How Does Spatial Autocorrelation Arise?*

Spatial autocorrelation can be a property of data that are conceptualized as either the outcome of a deterministic process or a stochastic (random) process. In the case of a deterministic process there is conceptually only one set of values (namely those that are observed) and it is the arrangement of values across the region that are defined as autocorrelated or not. The reference point for deciding whether such a distribution of values is autocorrelated is the geographic distribution of values that would have been obtained had those values been allocated at random across the region. In the case of a stochastic process, the observed values are but one set of realized values from an infinite set of possible realizations (a 'superpopulation') that can be generated by a spatial process or probability model. The variable may display spatial autocorrelation because it is a realization of a model where the random variables are spatially dependent. An example of such a model is the following, which is a particular case of the simultaneous autoregressive model (Whittle 1954). Let:

$$y(i) = \rho \sum_j w_{i,j} y(j) + e(i) \tag{1}$$

where $y(i)$ is the value of the variable for area i, ρ is a parameter, $w_{i,j}$ is non zero if area j ($j \neq i$) is a neighbor of area i (for example area j shares a common boundary with area i) and is zero otherwise, and $e(i)$ is independent and identically distributed and drawn

from a normal distribution with mean zero and variance σ^2. It can be seen from (1) that if $\rho > 0$ then the set of realized values of the variable Y will be positively spatially autocorrelated because the value at i will be a function of values in the neighboring areas. For other examples of these types of models see Besag 1974, 1975 and for reviews see Haining 1990, Cressie 1991, and Richardson 1992. There are other generators for spatially dependent variables and such models may derive from models that incorporate both space and time into their specification (see Berliner). In yet other contexts it is parameters (rather than the variables themselves) that are realizations of a spatially dependent probability model. This spatial dependency is transmitted to or inherited by the variables (Marshall 1991, Mollie 1996).

In the context of a stochastic process, the term spatial autocorrelation has a closely proscribed meaning and is associated with the second order moment (correlation) properties of the model. When thinking about actual problems or processes then spatial autocorrelation in a variable can arise in a number of different ways. Here are some examples:

(a) Many geographic phenomena display spatial continuity. If the spatial framework used to record the occurrence or the level of the phemonena is at a smaller scale than the scale at which the phenomena varies across the region, then values in adjacent areas of the spatial framework will tend to be similar. Remote sensing provides an illustration of this point. If land use remains the same over large tracts of land, and if a grid of small pixels records land use, then neighboring pixels will tend to record the same value of the variable. The pixel values are spatially autocorrelated.

(b) Even if the scale of the spatial framework used for recording data values is the same as the scale at which the phenomena varies across the landscape, measurement error can introduce spatial autocorrelation. This can occur with certain types of land use survey where recorders are given blocks of land to survey so that any operator-specific biases in the recording process will be similar within blocks and may therefore induce a form of spatial autocorrelation in the errors (Milne 1959). Spatial autocorrelation in errors also arises with remotely sensed data due to the nature of the recording device on the satellite. Due to light scattering, what is recorded by the sensor in one pixel, which supposedly refers to one parcel of land on the ground, is actually a function in part of terrain characteristics in neighboring parcels (Foster 1980).

(c) Variable values may show spatial autocorrelation because they depend on an underlying process in which spatial relationships affect the way the process unfolds. There are a number of examples. Diffusion processes are processes where some attribute, like an infectious disease, spreads through a fixed population and the probability of a new individual becoming infected depends on spatial proximity to an already infected individual (Cliff and Ord 1981). Spillover processes are processes where the attribute at some location is a function not only of conditions at that location but also of conditions in neighboring areas, for example, house prices as a function of local neighborhood conditions (Anas and Eum 1984), or city income levels as a function of income levels in neighboring cities and rural areas arising because of expenditure spillovers (Haining 1987). Interaction processes are where actions at one location influence actions at another location, such as price setting at one retail outlet influencing the prices set at other competitor sites (Haining 1983, 1984). Dispersal processes are where individuals themselves disperse (like seeds around a parent plant or new settlers colonizing a region) so that population counts are autocorrelated (Cliff and Ord 1981). In all these cases, at any point in time or when the process reaches some steady state then the variable may show evidence of spatial autocorrelation.

(d) The measured variable may not itself be the outcome of any of the foregoing situations but may be causally linked to another variable which is. In this case the spatial structure of the dependent variable inherits the spatial structure of the independent variable to which it is related. Spatial autocorrelation in a variable may also arise because of spatial autocorrelation in underlying parameters. The incidence of a non-infectious disease like a respiratory condition may be autocorrelated because the relative risk of the disease (which is a parameter and is itself a function of environmental characteristics such as air quality) is autocorrelated.

(e) Spatial autocorrelation can be a property of a derived set of values such as the residuals from a regression model. In this case spatial autocorrelation may have arisen because the regression model failed to include an important covariate in the model which had a spatially autocorrelated structure. The spatial structure of the omitted independent variable is then inherited by the regression residuals.

2. *Measuring and Testing for Spatial Autocorrelation*

2.1 *Autocorrelation Tests*

There are several statistics for measuring and testing for spatial autocorrelation. In the case of nominal data, the Join-Count test developed by Krishna Iyer (1949) is often used. The statistic is based on counting the number of joins of a particular color or colors on a map. Suppose each area is colored either black (B) or white (W). The Join-Count test is based on counting the number of BB, WW or BW adjacencies on the map. If a map is positively spatially autocorrelated then the number of BB and WW joins should be large and the number of BW joins small. If a map is

negatively spatially autocorrelated then the number of BW joins should be large and the number of BB and WW joins small (Haining 1990). The terms 'large' and 'small' are taken with reference to the number of such counts that would be expected if the black and white colors were allocated at random across the areas. This statistic can be generalized to handle maps where areas are classified into three or more colors (Dacey 1965).

In the case of ordinal and interval level data the two tests most commonly used are the Geary test and the Moran test (Geary 1954, Moran 1948). The Geary test is based on differences between the values of adjacent areas: $(y(i)-y(j))^2$ where $y(i)$ denotes the value observed in area i and $y(j)$ denotes the values observed in area j. If areas i and j are adjacent and if the map is positively autocorrelated then $(y(i)-y(j))^2$ should be small. The Geary statistic is based on summing these squared differences across the map:

$$\sum_i \sum_j \delta_{i,j}(y(i)-y(j))^2 \tag{2}$$

where $\delta_{i,j}$ is 1 if areas i and j are adjacent neighbors and zero otherwise ($\delta_{i,i}=0$). The measure (2) will be 'small' in the case of positive spatial autocorrelation relative to the case of a random distribution of values. On the other hand (2) will be 'large' in the case of negative spatial autocorrelation.

The Moran coefficient is based on cross products for adjacent areas:

$$\sum_i \sum_j \delta_{i,j}(y(i)-\bar{y})(y(j)-\bar{y}) \tag{3}$$

where $\bar{y}$ is the mean of the observations on Y. In the case of a positively autocorrelated map pattern, (3) will be positive since usually both terms in the cross product will be positive or negative. In the case of a negatively autocorrelated map pattern the terms will be negative, as if one of the terms is positive the other will usually be negative.

These statistics are appropriate to regular lattices but less appropriate for situations where the areal framework is irregular. Both (2) and (3) are invariant under certain alterations to the areal system but for any given area i some adjacencies are likely to be more important than others and should arguably therefore have greater weight in the calculation of any spatial autocorrelation statistic. In this case the binary weight ($\delta_{i,j}$) is replaced by a more general weight ($w_{i,j}$). The weights may be chosen to reflect some hypothesis about the degree of contact between areas (Cliff and Ord 1981). For example $w_{i,j}$ can be defined to reflect the length of the shared boundary between the two areas i and j, or the distance between the geographic centres of the two areas, or to reflect some measure of the intensity of interaction between the two areas in terms of, say, traffic flow.

The inference theories for the Geary and Moran statistics have been developed under two different conceptualizations of the null hypothesis of randomness or no spatial autocorrelation. In one case (the randomization hypothesis) the means and variances of the statistics are obtained assuming that the observed values are distributed at random across the region. In the other case (the normality assumption) the means and variances of the statistics are obtained assuming that the observed values are independent drawings from a normal probability distribution with the same mean and variance for each area. The assumption of equal variance is a strong assumption and often questioned in the case of irregular areal partitions where population counts vary substantially between areas and where the population count appears in the denominator of the variable (Waldhor 1996).

There are other techniques for exploring spatial autocorrelation. Perhaps he simplest technique is the scatterplot of paired data values $\{y(i), W^*y(i)\}$ where $y(i)$ is the value observed in area i and $W^*y(i)$ is the value in the ith position of the matrix product of W^* with y. W^* is the matrix of general weights $\{w_{i,j}\}$ where each row has been standardized to 1. So $W^*y(i)$ is a weighted average of the local values of y around i. If there is positive spatial autocorrelation present the scatterplot will have a distribution of points sloping upward from the bottom left of the graph. If there is negative spatial autocorrelation the scatterplot will have a distribution of points sloping downward from the top left of the graph. If the distribution of values is random the scatterplot will have no discernable trend. Cressie (1984) describes other graphical methods for inspecting for spatial structure.

2.2 Spatial Correlograms and Semi-variograms

The tests for spatial autocorrelation described above can be implemented at any number of spatial scales. That is, the neighbors of any area i need not be restricted to the adjacent neighbors but can be extended to include more remote neighbors. It may be informative to examine spatial structure at a range of distances simultaneously. Spatial correlograms (and semi-variograms) provide plots of spatial structure at a range of different distances. The correlogram at distance g has similarities with the Moran statistic. It is based on the expression:

$$\sum_i \sum_j w_{i,j}(g)(y(i)-\bar{y})(y(j)-\bar{y})$$

where $w_{i,j}(g)$ identifies all areas (j) that are a distance g from the area i. Distance g can be defined in terms of a metric or in terms of a shortest path on a graph that connects adjacent areas (Haining 1990). The spatial correlogram plot ($g = 1, 2, 3, \ldots, G$) thus provides a description of how spatial structure varies with distance.

The semi-variogram has similarities with the Geary statistic and is based on the expression:

$$\sum_i \sum_j w_{i,j}(g)(y(i)-y(j))^2$$

This, like the correlogram, provides a plot of spatial structure with distance thereby showing how spatial structure varies with distance (Isaaks and Srivastava 1989, Berliner). Both the correlogram and the semi-variogram may be used to suggest spatial models for the distribution of values across the map.

2.3 A Test for Local Autocorrelation

The statistics in 3.1 are often refered to as 'global' or 'whole map' tests of spatial autocorrelation because they compute an average measure for the entire map. It is recognized, however, that spatial autocorrelation might be a property of just a subset of the data. There might be a local tendency for similar values to cluster together but that this is not a general or 'global' property of the data.

A local test for spatial autocorrelation has been developed which computes the probability of getting the observed collection of values in a subset of the region if all the data values had been distributed at random over the area. The local Moran statistic is given by (Anselin 1995):

$$I(i) = (y(i)-\bar{y})\sum_j w_{i,j}(y(j)-\bar{y}) \quad i = 1, \ldots, n$$

where n is the number of areas so there are as many tests as there are cases. A high positive value of $I(i)$ signals a local spatial clustering of similar values, whilst a high negative value signals a local spatial clustering of dissimilar values.

3. Spatial Autocorrelation and Spatial Data Analysis

The presence of spatial autocorrelation in a variable has implications for a number of different areas of data collection and data analysis. These include spatial sampling, map interpolation, exploratory spatial data analysis, and confirmatory analysis including modeling. Each of these areas is briefly discussed in turn.

3.1 Spatial Sampling

Spatial sampling is the process of taking a subset of data drawn according to some specified rule and on the basis of this subset making inferences about the spatial population from which the data have been drawn. Consider the case where the aim is to estimate the proportion of an area covered by a particular type of land use. In this case we do not adopt a 'superpopulation' view of the problem but rather focus on the 'here and now' of the land use geography. A conventional estimator for the quantity is the sample mean:

$$\bar{y} = \frac{1}{n}\sum_i y(i)$$

where n is the size of the sample and $y(i)$ is 1 if sample site i is occupied by the particular land use, zero otherwise. The problem is to choose the most efficient sample design from random sampling, stratified random sampling, and systematic sampling. The spatial autocorrelation in the land use surface has an important influence on the relative efficiency of these three designs because, as noted above, the presence of spatial autocorrelation signals that data values recorded at one location carry information about data values at nearby locations. The stronger the spatial autocorrelation on the surface the more important it is to select sample sites that ensure that each sample point is not duplicating information contained in the rest of the sample. Random sampling is the least efficient sample design because there is no guarantee that sample points will not be clustered in particular areas of the map. Stratified random sampling overcomes the worst features of random sampling by ensuring coverage but sample sites can still be adjacent to one another on either side of a strata boundary. Systematic sampling is frequently the best because it ensures a minimum separation distance between sample sites (Dunn and Harrison 1993).

3.2 Map Interpolation

A range of estimators have been constructed to estimate values at specified locations where as yet data have not been collected. One of the more widely used methods, the kriging estimator, has the form:

$$\hat{y}(k) = \sum_j \lambda_{k,j} y(j)$$

where $\hat{y}(k)$ is the value to be estimated at location k where currently no data value is available (Berliner). The values $\{y(j)\}$ are known and $\{\lambda_{k,j}\}$ are coefficents that are a function of the spatial autocorrelation between locations k and j (Isaaks and Srivastava 1989). In this case the presence of spatial autocorrelation can be used to construct estimates of missing or unobserved values and in addition confidence intervals can be attached to the estimates. This confidence interval is influenced by how much information about the surface is available in the vicinity of the site. Confidence intervals will be large if the site k is far from sample points for which information is available, small if there are sample points with known values nearby.

3.3 Exploratory Spatial Data Analysis

Disease atlases are constructed to represent the geographic variability of a disease. Maps of standardized mortality rates (SMRs), for example, display the geography of relative risk for a particular disease and may be used to provide an indication of where the disease risk might be highest—perhaps as a preliminary to exploring for particular risk factors. Maps constructed using small geographic areas suffer from a number of problems including that the estimated rates tend to be unstable with the most extreme rates often associated with areas with the smallest populations. Bayes adjustment methods are often used to adjust such standardized rates. These methods incorporate information from the rest of the map in order to eliminate some of the random variation that is present in each area's SMR. A subset of these methods do not just use the SMRs from the rest of the map but place greatest emphasis on those estimates closest to the area to be adjusted. For this adjustment, spatial process models are used and incorporate the spatial autocorrelation in the relative risk rates into the adjustment process (Mollie 1996).

Other, simpler smoothing methods may also be employed to provide evidence on broad patterns in a spatial data set, for example, mean and median smoothers (Haining et al. 1998). These techniques all implicitly exploit some aspect of the concept of spatial autocorrelation—that places near to an area, i, provide information on the variable value at i. Similar methods have been used to 'clean' remotely sensed data where noise has blurred the image (Green 1996).

3.4 Information Loss in Statistical Tests

Spatial autocorrelation can undermine the use of classical statistical techniques. The correlation coefficient (r) is a common statistic for measuring the linear relationship between two variables (X and Y). The Pearson correlation coefficent varies between -1 and $+1$ with $+1$ signifying a perfect positive relationship between X and Y (as X increases, Y increases). The inference theory for the correlation coefficient is based on:

$$(n-2)^{1/2}|\hat{r}|(1-\hat{r}^2)^{-1/2} \tag{4}$$

where n is the sample size and $\hat{r}$ is the estimated correlation coefficient. Under the null hypothesis that the correlation in the population is zero (4) is t distributed with $(n-2)$ degrees of freedom. However the amount of statistical information carried by the n observations when the data are (positively) spatially autocorrelated is less than would be the case were the n observations to be independent. In the terminology of Clifford and Richardson (1985) the 'effective sample size' is less than the actual sample size n so the degrees of freedom for the test is less than n. The solution to the problem is to compute this effective sample size (N') which is obtained from the spatial correlogram (see Sect. 3.2). Then in (4) N' replaces n and it is t distributed with $(N'-2)$ degrees of freedom.

3.5 Modeling Spatial Variation

One of the statistical assumptions underlying the application of the classical regression model is that the errors are independent. If this assumption is violated tests of significance on the parameters of the independent variables are affected (the risk of a type I error is increased) and the coefficient of multiple determination measure of goodness of fit is inflated. This assumption has to be tested via the regression residuals (which are estimates of the errors). In the case of spatial data, an adaptation of the Moran test is often used although other tests are available (Anselin 1988, Cliff and Ord 1981). The inference theory of the Moran test has to be adapted in this context because the mean of the residuals is zero by construction. If the null hypothesis of no spatial autocorrelation is rejected then remedial action is needed to avoid mis-specification error. One approach is to seek out other independent variables that, because they were originally (and wrongly) excluded and because they were spatially autocorrelated, caused the residual autocorrelation. Other forms of model specification may also need to be considered depending on the analyst's conceptualization of the process underlying the behavior of the dependent variable. Thus there may be a need to include interaction terms, diffusion process terms or spillover terms (see Sect. 2). Thus a respecified regression model might include spatially lagged terms of the dependent variable, one or more of the independent variables or a spatial error model. (Examples of these and other models are described in Ord 1975, Anselin 1988, Haining 1990, Cressie 1991.)

Spatial Choice Models

The interrelationship between spatial structure and individual choice behavior has traditionally been at the forefront of geographic research. Geographers have realized that spatially varying consumer demand constitutes the basis for the evolution of spatial structures. In turn, the supply of facilities across space provides opportunities for individuals and households to conduct their activities, but at the same time also sets the space-time constraints that restrict behavior.

Over the years, many different attempts at modeling spatial choice behavior have been reported in the literature. These models predict the probability that an individual will choose a choice alternative as a function of its locational and non-locational attributes. In this article, the background, theoretical underpinnings, and basic methodology of these modeling approaches are examined. From the outset, it should be clear that limited available space prevents us from discussing modeling approaches in considerable detail.

1. Gravity Models

The modeling of spatial choice behavior gained considerable momentum when Wilson (1971) introduced a family of spatial interaction models, based on the principle of gravity, to describe and predict social phenomena. This principle states that the interaction between two bodies is proportional to their masses, and inversely proportional to the square of distance. Wilson elaborated this principle in a number of ways. First, he suggested that any distance decay function that reflects the notion that, *ceteris paribus*, the intensity of interaction decreases with increasing distance may be used to replace straight distance. Secondly, he argued that in spatial problems often the number of departures from particular origins and/or the number of arrivals at particular destinations is known, implying that so-called balancing factors have to be introduced in the model to satisfy these constraints.

Wilson distinguished an unconstrained spatial interaction model (departures and arrivals are not known), a production-constrained spatial interaction model (number of departures per zone is known), an attractions-constrained spatial interaction model (number of arrivals per zone is known), and the doubly constrained spatial interaction model (both number of departures and number of arrivals per zone are known). In the context of spatial choice behavior, the production constrained spatial interaction model is most interesting as it predicts which destination will be chosen. It can be expressed as:

$$p_{ij} = A_i O_i \mathbf{W}_j f(d_{ij}) \tag{1}$$

where, p_{ij} is the probability that an individual in zone i will choose destination j; A_i is a balancing factor, guaranteeing that the number of predicted interactions from zone i is equal to its number of observed interactions; O_i is the number of observed interactions from zone i; $\mathbf{W}_j$ is a vector of variables, representing

the attractiveness of destination j; $f(d_{ij})$ is some function of the distance between origin i and destination j.

Although much empirical work has been conducted on spatial interaction models since this seminal work, most of the relevant literature has been concerned with operational problems. Theoretical progress has been limited. For example, different measures of distance (straight-line distance, Euclidean distance, city-block metric, and travel time) and attractiveness have been suggested. Likewise, different functions for representing the distance decay effect have been proposed (power, exponential, and more complex functions). Finally, an exponent has been added to the specification of attractiveness term to allow for the fact that the larger destinations tend to have extra attraction beyond their size because of the benefits of economies of scale.

The estimation of spatial interaction models is typically based upon aggregate, zonal data of interaction flows (shopping, recreation, migration, traffic, etc). To that effect, the study area is delineated carefully to avoid large external flows, and divided into a number of smaller homogeneous zones. The spatial interaction model is calibrated using observations about interactions between these zones as input.

As a result, the parameters of the spatial interaction model are highly influenced by the geometry of the study area. This caused a search for improvements of the model, and for alternative modeling approaches. In this context, some authors suggested the development of models that estimate the effects of attraction variables endogenously. Another way of dealing with this problem was to incorporate some measure of spatial structure into a spatial interaction model (Fotheringham 1983). The simplest approach to the specification of this additional term is the use of a Hansen-type accessibility measure. This so-called competing destinations model may be expressed as:

$$p_{ij} = A_i O_i \mathbf{W}_j C_j^{\delta} d_{ij}^{-\beta} \tag{2}$$

where

$$A_i = \left[\sum_j \mathbf{W}_j C_j^{\delta} d_{ij}^{-\beta} \right]^{-1} \tag{3}$$

and

$$C_j = \sum_{k \neq j} \mathbf{W}_j d_{jk}^{-\gamma} \tag{4}$$

2. The Revealed Preference Model

The fact that the spatial interaction model is heavily influenced by the geometry of the study led Rushton (1969) to develop a preference-scaling model. The purpose of the model was to derive rules of spatial choice behavior.

To that effect, choice alternatives were classified into so-called locational types, which are a combination of an attractiveness category and a distance category. Spatial choice behavior is assumed to reflect a trade-off between attractiveness and distance separation. Pairwise choice data are then used to calculate the proportion of times a particular locational type is chosen, given that both are present. Based on this data, the locational types are positioned on a unidimensional preference scale using a nonmetric multidimensional scaling algorithm.

Over the years, this basic model has been elaborated in a number of important ways. First, Rushton (1974) showed how graphical methods, trend surface analysis, or conjoint analysis might be used to decompose the preference scale into the contributions of the two basic variables. Second, Girt (1976) suggested linking the preference function to overt behavior by relating distances on the preference scale to choice probabilities. Third, Timmermans (1979) suggested deriving the choice sets of individuals from data on information fields and consumer attitudes, and using these to scale the alternatives. Although Rushton's preference scaling model does have considerable appeal, it never received any major following. One of the reasons might be that the model is based on two explanatory variables only, while heterogeneity in preferences is not accounted for. The model has also been criticized because of its conceptual basis. It has been suggested that the model may not represent preferences at all, but rather inconsistencies in individual choice behavior.

3. Discrete Choice Models

The spatial interaction model has been criticized for its reliance on aggregate, zonal interaction flows. This criticism has led to the development of disaggregate discrete choice models that are based on individual choice behavior.

Discrete choice models may be derived from at least two formal theories: Luce's strict utility theory and Thurstone's random utility theory. In particular, Luce assumed that the probability of choosing a choice alternative is equal to the ratio of the utility associated with that alternative to the sum of the utilities for all the alternatives in the choice set. Luce thus assumed deterministic preference structures and postulated a constant-ratio decision rule.

In contrast, random utility theory is based on stochastic preferences in that an individual is assumed to draw a utility function at random on each choice occasion. An individual's utility for a choice alternative is assumed to consist of a deterministic component and a random utility component. Given the principle of utility maximizing behavior, the probability of choosing a choice alternative is then equal to the

probability that its utility exceeds that of all other choice alternatives in the choice set.

The specification of the model depends on the assumptions regarding the distributions of the random utility components. The best-known model is the multinomial logit (MNL) model. It can be derived by assuming that the random utility components are independently, identically Type I extreme value distributed. It can be expressed as:

$$p_{ik} = \frac{\exp[U(X_k, S_i)]}{\sum_j \exp[U(X_j, S_i)]} \tag{5}$$

where $U(X_k, S_i)$ is the deterministic part of the utility of choice alternative k of individual i with socioeconomic characteristics S_i.

One of the most important criticisms that have been expressed against the multinomial logit model concerned the fact that the utility of a choice alternative is independent of the existence and the attributes of other alternatives in the choice set (the Independence from Irrelevant Alternatives or IIA property). It predicts that the introduction of a new, similar choice alternative will reduce market shares in direct proportion to the utility of the existing alternatives, which is counterintuitive in the case of a high degree of similarity between particular alternatives.

Therefore, various alternative models have been developed to relax the IIA assumption (Timmermans and Golledge 1990). Similar work in this regard has been conducted by Williams (1977). The best-known model that circumvents the IIA-property is the nested logit model. Choice alternatives that are assumed to be correlated are grouped into the same nest. Each nest is represented by an aggregate alternative with a composite utility, consisting of the so-called inclusive value, and a parameter to be estimated. To be consistent with utility-maximizing behavior, the inclusive values should lie in the range between 0 and 1, and the values of the parameters should change consistently from lower levels to higher levels of the hierarchy.

4. *Conjoint Preference and Choice Models*

Unlike discrete choice models, the parameters of the conjoint preference and choice models are not derived from real-world data, but from experimental design data. Conjoint models involve the following steps when applied to spatial choice problems (e.g., Timmermans 1984).

First, each choice alternative is described by its position in a set of attributes, considered relevant for the problem at hand. Next, a series of levels for each attribute is chosen. Having defined the attributes and their levels, the next step involves creating an experimental design to generate a set of hypothetical choice alternatives. This design should be created such that the necessary and sufficient conditions to estimate the model of interest are satisfied. Respondents are then required to evaluate the resulting attribute profiles. Their responses are decomposed into the utility contribution of the attribute levels. Once part-worth utilities have been estimated, choice behavior can be predicted by assuming that an individual will choose the alternative with the highest overall evaluation. Alternatively, different probabilistic rules can be postulated.

To avoid such *ad hoc* rules, Louviere and Woodworth (1983) suggested estimating the preference function and choice model simultaneously. To that end, the attribute profiles should be placed into choice sets. Again, the composition of the choice sets depends on the properties of the choice model.

Over the years, the basic conjoint preference and choice models have been elaborated in many different ways. To avoid the problem of information overload and reduce respondent demand, Louviere (1984) suggested the Hierarchical Information Integration method. It assumed that individuals first group the attributes into higher-order decision constructs. Separate designs are constructed for each decision construct, and a bridging experiment is designed for measuring the tradeoff between the evaluations of the decision constructs. Oppewal et al. (1994) suggested an improved methodology by using multiple-choice experiments to test the implied hierarchical decision structure.

Other recent advances include the development of group preference models, the development of models of portfolio choice, the inclusion of contextual effects and constraints, and the combined use of experimental design and revealed preference data, to name a few.

5. *Complex Spatial Choice Behavior*

The previous models are all typically based on single-purpose, single-stop behavior. Over the years, however, it became clear that an increasing proportion of trips involved multistop behavior. Moreover, Hägerstrand's time geography had convincingly argued that behavior does not reflect preferences only, but also constraints. Thus, various attempts have been made to develop models of trip chaining and activity-travel patterns.

Originally, most models relied on semi-Markov process models or Monte Carlo simulations. More recently, utility-maximizing models have dominated the field. An important contribution in this regard was made by Kitamura (1984), who introduced the concept of prospective utility. It states that the utility of a destination is not only a function of its inherent attributes and the distance to that destination, but also

of the utility of continuing the trip from that destination. Dellaert et al. (1998) generalized Kitamura's approach to account for multipurpose aspects of the trip chain.

Trip chaining is only one aspect of multiday activity/travel patterns. Several models have recently been suggested to predict more comprehensive activity patterns. These models can be differentiated into the older constraints-based models (e.g., Lenntorp 1976), utility-maximizing models (e.g., Recker et al. 1986), rule-based or computational process models (e.g., Golledge et al. 1994, ALBATROSS – Arentze and Timmermans 2000).

6. *Conclusions*

This article has given a very brief overview of spatial choice modeling. Due to the limited available space, we have focused on some of the key modeling approaches, disregarding alternatives (e.g., dynamic models) altogether.

If we examine the accomplishments, one cannot escape the conclusion that the models developed over the years have been increasing in complexity. The theoretical underpinnings of the recent activity-based models are much richer than the Markov or gravity models of the 1960s. Moreover, the brief overview indicates that geographers have been using alternative data, such as experimental design data and activity diaries, in addition to the more conventional survey data.

Spatial Cognition

Spatial cognition concerns the study of knowledge and beliefs about spatial properties of objects and events in the world. Cognition is about knowledge: its acquisition, storage and retrieval, manipulation, and use by humans, nonhuman animals, and intelligent machines. Broadly construed, cognitive systems include sensation and perception, thinking, imagery, memory, learning, language, reasoning, and problem-solving. In humans, cognitive structures and processes are part of the mind, which emerges from a brain and nervous system inside of a body that exists in a social and physical world. Spatial properties include location, size, distance, direction, separation and connection, shape, pattern, and movement.

1. The Geographic Study of Spatial Cognition

Geographers study spatial cognition for three reasons. First and foremost, spatial cognition provides questions of geographic interest in their own right, given that cognition about space and place is an expression of human-environment or human-earth relations. Second, geographers have hoped that spatial cognition would improve their understanding of traditional phenomena of interest; for example, where people choose to shop should depend in part on their beliefs about distances and road connections. Finally, there has been an interest in improving the use and design of maps and other geographic information products which depend in part on human understanding of depicted spatial relations.

In addition to geographers and cartographers, researchers from many different disciplines study spatial cognition, including psychologists, architects and planners, anthropologists, linguists, biologists, philosophers, and computer scientists. While overlapping and interacting with these disciplines, the geographer's interest in spatial cognition is distinct in some ways. Geographers are interested in the earth as the home of humanity. Their concern is with the cognition of humans, not the cognition of barn swallows or underseas robots. Geographers focus on spatial scales relevant to human activities on the earth's surface, such as temporary travel, migration, settlement, and economic activities; a geographer wants to understand human conceptualizations of the layout of a city or a region, not of an atom or the solar system. Finally, the geographer ultimately desires to describe, predict, and explain external human-environment relationships, and focuses on internal mental and neuropsychological structures and processes only insofar as it helps in the understanding of external relationships.

1.1 History of Spatial Cognition in Geography

The notion that a subjective understanding of space partially mediates human relationships with an objective physical world is undoubtedly quite old. Within the modern discipline of geography, the study of spatial cognition first appeared with work on geographic education early in the twentieth century. However, interest in spatial cognition flowered during the 1950s and 1960s. The subdiscipline of experimental cartography emerged with the insight that maps could be improved by understanding how humans perceive and think about information depicted in map symbols. In an attempt to explain human responses to floods and other natural hazards, the subdiscipline of environmental perception began to study people's subjective beliefs about the occurrence and consequences of hazard events. Most importantly for the study of spatial cognition, behavioral geographers began developing theories and models of the human reasoning and decision-making involved in spatial behavior e.g., migration, vacationing, and trip scheduling. This approach gained insight from the work of Kevin Lynch (1960), a planner who argued that 'images' of cities guide people's behavior and experiences of those cities. All of these historical developments constituted a new focus on disaggregate or microscale approaches within human geography, approaches that focused on the geographic behavior of individuals as an accompaniment to traditional approaches that focused on human settlements and larger aggregations of people.

2. Topics in the Geographic Study of Spatial Cognition

The study of spatial cognition in geography sheds light on questions such as how spatial knowledge and beliefs are acquired and develop over time; the nature of spatial knowledge structures and processes; how people navigate and stay oriented in space; how people use language to communicate with each other about space; and how aspects of spatial knowledge and reasoning are similar or different among individuals or groups.

2.1 Acquisition and Development

Humans acquire spatial knowledge and beliefs directly via sensorimotor systems that operate as they move about the world. People also acquire spatial knowledge indirectly via static and dynamic symbolic media such as maps and images, 3-D models, and language. Geographers are interested in how different media have consequences for the nature of acquired knowledge.

Spatial knowledge changes over time, through processes of learning and development. Both changes in the child's spatial knowledge and reasoning, and that of an adult visiting a new place for the first time, are of interest to geographers. Both physical maturation and experience influence development. A person's activity space; the set of paths, places, and regions traveled on a regular basis, is an important example of spatial experience that influences people's knowledge of space and place, no matter what their age. Most people know the areas around their homes or work places most thoroughly, for example (as in the anchor-point theory of Couclelis et al. 1987).

A widely accepted model of spatial learning suggests that spatial knowledge of places develops in a sequence of three stages or elements. First is landmark knowledge, unique features or views that identify a place. Second is route knowledge, based on travel routines that connect ordered sequences of landmarks. The final element is survey knowledge, knowledge of two-dimensional layouts that includes the simultaneous

interrelations of locations; survey knowledge would support detouring and shortcutting. Not everyone has detailed or comprehensive survey knowledge of their surrounds, and exposure to maps of places clearly advances the development of such knowledge.

2.2 Spatial Knowledge Structures and Processes

The metaphor of a cognitive map was coined by Tolman in a 1948 paper to refer to internally represented spatial models of the environment. The cognitive (or mental) map includes knowledge of landmarks, route connections, and distance and direction relations; nonspatial attributes and emotional associations are stored as well. However, in many ways, the cognitive map is not like a cartographic 'map in the head.' It is not a unitary integrated representation, but consists of stored discrete pieces including landmarks, route segments, and regions. The separate pieces are partially linked or associated frequently so as to represent hierarchies such as the location of a place inside of a larger region. Furthermore, spatial knowledge is not well modeled by metric geometries such as the Euclidean geometry of high school math. The ways in which spatial knowledge is internally represented in human minds lead to certain patterns of distortions in the way people answer spatial questions. For example, people often believe the distance from place A to B is different than from B to A. Turns are frequently adjusted in memory to be more like straight lines or right angles. At larger scales, most people have somewhat distorted ideas about the sizes and locations of continental land masses on the earth; for example, South America is thought to be due south of North America when it is actually rather far to the east as well.

2.3 Navigation and Orientation

Humans travel over the earth's surface to reach destinations. This typically requires planning and the ability to stay oriented while moving. Navigation is this coordinated and goal-directed travel through space. It consists of two components, locomotion and wayfinding. Locomotion refers to the guidance of oneself through space in response to local sensorimotor information in the immediate surrounds, and includes such tasks as identifying surfaces of support, avoiding obstacles, and moving toward visible landmarks. Locomotion generally occurs without the need for an internal model or cognitive map of the environment. Wayfinding refers to the planning and decision-making that allows one to reach a destination that is not in the immediate sensory field, and includes such tasks as choosing efficient routes, scheduling destination sequences, orientating to nonlocal features, and interpreting verbal route directions. Wayfinding tasks generally do involve a cognitive map of the environment. Various locomotion and wayfinding tasks vary greatly in their demand on attentional capacity. Following a familiar route is not very demanding on attention; finding one's way in a new city may be quite demanding.

Orientation is knowing 'where you are,' although the precision and comprehensiveness of this knowing varies greatly in different situations and for different people. Two fundamental processes are involved in orientation during navigation. The first process is the recognition of external features or landmarks–pilotage. In some cases, the recognized landmark is the goal, but more commonly the landmark aids orientation by serving as a key to knowledge of spatial relations stored in an internal cognitive or external cartographic map. The second process is dead reckoning, updating a sense of orientation by integrating information about movement speed, direction, and/or acceleration without reference to recognized features.

People also use symbolic media such as maps to navigate and stay oriented. Maps used for navigation show robust alignment effects, a common confusion in using maps when the top of the map is not the direction in the surrounds that one is facing when looking at the map. It results from the fact that spatial perception is 'orientation-dependent'; objects and pictures have a top and a bottom in the perceptual field. In the case of road or trail maps, many people turn the map to bring about alignment. Unfortunately, this option is not available with ubiquitous 'You-Are-Here' maps, which are surprisingly often placed in a misaligned way with respect to the viewer's perspective. The resulting alignment effect is reflected by the fact that misaligned maps are interpreted more slowly and with greater error by most people (Levine et al. 1984). While an annoyance in many situations, misaligned emergency maps placed in public buildings are potentially disastrous.

2.4 Spatial Communication via Language

Spatial information is often communicated verbally, in natural language such as English. People give and receive verbal route directions, read spatial descriptions contained in stories, and increasingly interact with computer systems via verbal queries. There are two notable characteristics of the way language expresses spatial information. One is that language expresses mostly nonquantitative or imprecise ('fuzzy') quantitative information about space. Statements about connections and approximate location are more important than precise statements. For example, people say 'turn left at the gas station' rather than 'turn 80° after you go 0.6 miles.' Great precision is typically unnecessary or even confusing. A second characteristic is that various aspects of the context of

communication are critical in interpreting spatial language. Context is provided by knowledge of who is speaking, where they are, physical features in the situation, the previous topic of conversation, and so on. 'The bicycle is near the church' is generally understood differently than 'Wisconsin is near Michigan.'

2.5 Individual and Group Similarities and Differences

No two individuals know exactly the same things or reason in exactly the same way about space and place. Some people are better at tasks such as wayfinding, learning spatial layouts, or reading maps. In some cases, there may be different ways to think about such problems, all of which may be effective. In such cases, one might speak of 'stylistic differences' in spatial cognition rather than 'ability differences.' Geographers are interested in measuring and explaining such individual differences. Traditional psychometric paper-and-pencil tests of spatial abilities tend not to measure these differences very well (Allen et al. 1996).

There are many factors that may contribute to variations in spatial cognition: body size, age, education, expertise, sex, social status, language, culture, and more. A first goal for geographic research is to measure and document ways these factors might covary with spatial cognition. Females and males appear to differ in some ways in their spatial abilities and styles, for example, but not in others (Montello et al. 1999). In addition to describing such covariations, geographers have the research goal of distinguishing their underlying causes. For example, the two sexes likely differ in their spatial cognition in part because of different travel experiences afforded them by their socialized roles. Explanations for such covariations are generally quite difficult to determine, however, as one cannot readily do randomized experiments on person characteristics such as age, sex, culture, and activity preferences.

3. Technologies and the Future of Spatial Cognition Research

A variety of technologies are poised to have a large impact on the questions and methods of spatial cognition research in geography. Global positioning system (GPS) receivers have recently become small and inexpensive, and are increasingly used by sailors, hikers, and other outdoor enthusiasts. A GPS receiver provides information about one's location by geometrically combining distance signals it picks up from several geosynchronous satellites constantly orbiting the earth. This system is also part of the technology of automated navigation systems built into automobiles to provide drivers up-to-date and locally relevant information about routes and destinations. Several research issues concern how locational information is best displayed or communicated, and how the availability of such information might change people's experiences and behaviors in space and place.

Other computer technologies will lead to new research and thinking in spatial cognition. There are a host of spatial cognition questions inspired by efforts to improve the effectiveness and efficiency of geographic information systems (GISs). How can complex geographical information be depicted to promote comprehension and effective decision-making, whether through maps, graphs, verbal descriptions, or animations? How does exposure to new geographic information technologies alter human ways of perceiving and thinking about the world? There are also research issues concerning the way that people do or do not spatialize their understanding of other types of information networks such as the World Wide Web; one often speaks metaphorically of 'navigating' the Web. However, undoubtedly the most dramatic technological development in spatial cognition will be the advent of computer-simulated worlds known as virtual environments or virtual reality.

Spatial Data

Spatial data are the sum of our interpretations of geographic phenomena. Taken literally, spatial data could refer to any piece of information that associates an object with a location—from stars in the heavens to tumors in the human body. Typically, however, when used in a geographical context, spatial data is restricted to describing phenomena on or near the earth's surface. In digital form, the data are the primary information needed by geographic information systems (GIS), the software tools used for spatial-data analysis.

1. *What Are Spatial Data?*

'Spatial data' is used as an all-encompassing term that includes general-purpose maps, remotely sensed images, and census-tract descriptions, as well as more specialized data sets such as seismic profiles, distribution of relics in an archeological site, or migration statistics. Information about buildings, bridges, roads, streams, grassland, and counties are other examples of types of spatial data. Broadly, spatial data refers to any piece of information that has an absolute or relative location (see *Location: Absolute/Relative*). More commonly, spatial data are associated with information shown on maps and images of natural and man-made features that range in size from 1 m to 10 km. Such data are often referred to as geospatial data (see *Geographic Information Systems*; *Spatial Data Infrastructure*; *Remote Sensing*; *Landsat Imagery in Geography*; *Remote Sensing and Geographic Information Systems Analysis*; *Global Positioning System* for examples of the varying types and usages of spatial data). Spatial data sets are collections of locational and nonlocational information about selected geographic phenomena. This collection of information forms the heart of a spatial database. Once the information is in the database, computers provide the capabilities to handle geographic data in ways that were previously impossible.

2. *Data Models*

A digital spatial data set represents a certain model of geographic reality. These models describe both the locational and nonlocational aspects of the phenomena of interest. For users to make sense of the data they are receiving, they must understand the conceptual model underlying the data.

Table 1
Terminology for describing geographic features

Feature type	Example	Digital database term (and synonyms)
Point feature	Benchmark	Node (vertex, 0-cell)
Linear feature	Road centerline	Arc (edge, 1-cell)
Areal feature	Lake/pond	Polygon (face, 2-cell)

The locational aspect of a spatial data set is usually described by one of two types of models, either grid-cell (sometimes called raster) data models, or vector data models. Grid-cell data models use collections of fixed units of space, for example, cells of land 50 m on a side, to describe the location and extent of a geographic phenomenon. Digital remotely sensed images are collected in this form. Vector data models use graphic elements (points, lines, and polygons) to describe the location and extent of the phenomenon under study. Most digital map data are in this form.

The spatial data also must include all of the nonlocational information used to describe the features in the database. In the case of digital-image data, the amount of nonlocational data is relatively small, usually a set of values measuring characteristics such as the greenness of vegetation. With vector data the amount of nonlocational, or attribute, data can be quite large, even exceeding the amount of spatial data. This includes information about the various features included in the database (for example, the number of lanes of a highway) and their relationships to each other (for example, that the railroad tracks lie between the stream and the highway). In the context of GIS, features are the sum of our interpretations of geographic objects or phenomena. Buildings, bridges, roads, streams, grassland, and counties are examples of features.

2.1 *Feature Data Structures*

The real world of geographical variation is infinitely complex and often uncertain, but must be represented digitally in a discrete, deterministic manner. In one method of describing geographic reality, characterized by the information shown on maps, we think of the world as a space populated by features of various kinds—points, lines, and areas. This is commonly referred to as the vector or feature data model. Features have attributes that serve to distinguish them from each other. Any point in the space may be empty, or occupied by one or more feature. These features may exist in one combined database, or may be separated according to a theme or variable into a number of layers or classes. The terminology used to describe these features is given in Table 1.

The relationships between the nodes, arcs, and polygons are called topological relationships. In simple terms, the topological relationships are that arcs start and end only at nodes, and that polygons are enclosed by a series of arcs. Attention is given to neighboring geographical entities when coding arcs. For instance, the topological description of each arc includes not only the starting and ending bounding nodes but also the left and right designations of the co-bounding regions. In this way an arc is directed, that is, the first coordinate is that of the start node and the last coordinate that of the end node. Each polygon record might also include the identification of any interior islands or, if the polygon is itself an interior island, the identification of the single exterior polygon. This data structure not only accommodates the natural pattern of mapped features efficiently, but also provides the information needed to facilitate automated editing and manipulation of the database.

2.2 Raster Data Structures

Instead of describing discrete geographic objects, geographical variation can be represented by recording the locational pattern of one variable over the study area. When the spatial interval of this sampling is regular (e.g., rectangular), the resulting matrix of observations is called a raster data structure. If there are n variables, then n separate items of information are available for each and every point in the area. Digital terrain models data and digital images are typically stored in this structure. Other types of information such as categories of land-cover could also be encoded in a raster data structure. The cells of raster data (particularly raster data of images) are commonly referred to as pixels (derived from the term picture element).

2.3 Modeling Solids

So far our discussions have dealt with data on a surface. However, certain types of spatial data require a more complete modeling of the third dimension. Solid bodies, such as geologic structures (ore bodies, petroleum reservoirs, etc.), need to be encoded not only with x, y locations, but also with z or depth information. The surface models mentioned earlier can encode z values, but only one z value is permitted for each location. This results in what is termed a 2.5-D model. True solid or 3-D modeling requires that multiple z values can exist at a given x, y location.

One mechanism to model such data is to extend the raster data model into an additional dimension. Thus the 2-D squares become 3-D cubes. The cubes are often termed voxels (for volume elements). Each voxel is encoded with attribute data (such as rock type). The geolocation of any given voxel is implied by its location in the x,y,z array and the size of the cubes. The voxel representation allows us to model such things as hollow spheres, with a varying thickness of the shell, or solids with holes through them.

Another way to model solids is to use a technique called boundary representation. This is an extension of the vector data model to 3-D. A solid object is defined by its bounding surface. Just as one-dimensional lines bound two-dimensional areas, 2-D planar areas are located in 3-D space and are used to bound a 3-D solid. The various planar areas bound solids, much like the facets bound the shape of a jewel.

3. Describing Geographic Features

As noted earlier, spatial data models, in addition to providing locational data, must handle all of the nonlocational information used to describe the features in a database. For users to understand the nature of the data there must be a complete specification of the features being described. A comprehensive data specification includes the definition of the features as well as definitions of their attributes and attribute values. Other information required for a complete understanding includes delineation guidelines, data extraction rules, and representation rules. Understanding how the locational component of a feature is represented is of little use unless the user understands the nature of what is being described. What is really meant by terms such as 'forest,' 'marshlands,' 'residential land,' or 'bridge'? For example, one could declare a 'bridge' to be a feature. A bridge is one of a number of built-up structures on or near the surface of the earth. Its definition may be further refined to a structure erected to carry traffic over a depression or obstacle. Thus, the feature 'bridge' is an element of a set of phenomena (an 'erected structure'), with the common attributes of function ('to carry traffic') and location. It also has the common relationship of spanning another feature ('over a depression or obstacle'). The definitions and specifications of the data producers hopefully match to some degree the expectations of the user.

To help solve this data-definition problem a feature data specification can be used to provide a detailed definition of each feature and how it is modeled. This technique is used by national mapping agencies in the USA, France, and Germany. The feature data specifications define the domain of features that may be represented in a spatial database. For each feature in the feature data specification, a domain of attributes is defined. Each attribute is assigned a value, taken from the domain of values specified by the attribute definition authority. In addition to the definitions, guidance is given on how a given feature is delineated, when it is collected, and how it is represented in the spatial data model.

Specific relationships, termed semantic relationships, are used to express interactions that occur between features that are otherwise difficult to rep-

resent either with locational data, topological relationships, or feature descriptions. Such relationships can include the following: to flow, the relationship that occurs among the two-dimensional features composing a river system; to connect, the relationship that occurs (at junctions) among the two-dimensional transportation features composing a road network; to bound or to be bounded, the relationship that occurs between the perimeter of a city and its city limits; to be composed of, the relationship that occurs between a designated route of travel and the transportation features that compose it, or of the stream and pond features that comprise a watercourse; and to be above, the relationship that occurs between the features in an overpass or underpass of a freeway interchange. The intent of all of these relationships is to model the interactions between features sufficiently to support GIS applications and automated cartographic-product-generation requirements.

4. *Modeling Time*

Just as maps change over time and must be revised, so do spatial databases. There are two basic ways to handle the temporal dimension associated with spatial data. The simplest way is to maintain multiple versions of a database, akin to keeping a historical map file. When changes occur a new edition of the database is produced, released with the current data, and the previous edition is placed in a historical archive.

A more comprehensive, yet more complex, strategy is to maintain one database, where every database feature (and potentially its attributes) has time information associated with it. This is fairly straightforward for information in a raster form. For each cell, a variable-length list of attributes is maintained, noting any change in attribution and the time at which the change occurred. For feature-based vector data sets, the process is more complicated. Information is encoded into the database on when the feature was first incorporated into the database, if it presently exists, when it ceased to exist (e.g., a pond was filled in), and when it was recreated, perhaps in a different form (e.g., a road was rerouted). In this fashion the existence and modification of any given feature can be traced.

5. *Data Quality*

The utility of spatial data in GIS depends directly on the quality of the spatial data used in the process. Geospatial data quality is measured along at least three different axes: space (location, places), time, and theme (content, characteristics). The space axis characterizes positional accuracy; the time axis indicates temporal accuracy and completeness; and the theme axis reflects semantic accuracy, attribute accuracy, and completeness. These qualities are not independent, however. Indeed some data-quality aspects, such as logical consistency, directly refer to the interrelationships of these data-quality elements. Not all of these quality elements have well-defined quality metrics associated with them. Metrics of semantic accuracy, for example, are not well understood. And some of the measures used for other quality elements may be inadequate.

Also needed are linkages between the quality information present in the data and the GIS-processing algorithms, so that software can produce error estimates on the end results. The results of GIS analyses have often been presented as definitive to decision makers (e.g., this is the best site for the municipal water well), with little or no qualification. One would expect that decision makers would insist on qualifying statements on any results presented to them. The methods for doing this are not well understood. For example, due to the cumulative effects of error, it has been conjectured that as the number of data sets used in a GIS analysis increases, the accuracy of the result decreases. This runs counter to common practice, where multiple data sets are used with little regard for whether they are contributing more to the information content or to errors in the result.

6. *Metadata*

As technology provides faster and more efficient ways to transmit and process spatial data, data producers and users are realizing the potential value of exchanging and sharing spatial data. The ability to use existing spatial data is important to organizations that are trying to share data and to increase benefits from their data collections. This ability depends not only on being able to find data, but also on understanding the characteristics and quality of the data. Metadata, 'data about data,' provide information such as the characteristics of a data set, the history of a data set, and organizations to contact to obtain a copy of a data set. Standardized metadata elements provide a means to document data sets within an organization, to contribute to catalogs of data that help persons find and use existing data, and to help users understand the contents of data sets that they receive from others. Metadata support activities include determining existing data, determining the appropriate data set for a particular use, providing information to access data sets, and providing information to transfer data sets for processing and use.

While the benefits of metadata are manifest, several impediments hinder uniform adoption and use. These center on two topics: agreement on what metadata elements to collect, and the level of effort required to collect whatever metadata is required. Obviously the two items are linked. From the user perspective, detailed metadata is highly desirable. More information will help the user determine the suitability of a given data set. From the data producer's perspective,

metadata costs money; metadata elements should be constrained to a cost-effective set. Significantly more resources may be required to collect metadata about 'legacy' data holdings than data sets collected using techniques that capture the metadata as a part of the entire data-collection process.

Agreement on standardized terminology and definitions would not only provide benefits in the automation of the collection of metadata, but would also be exceedingly valuable in searching data catalogues. Several metadata 'standards' are in widespread use around the world. In general they have data elements that have been selected to provide information about four topics:

Availability—data needed to determine the sets of data that exist for a geographic location;

Fitness for use—data needed to determine if a set of data meets a specified need;

Access—data needed to acquire an identified set of data; and

Transfer—data needed to process and use a set of data.

These elements form a continuum where a user cascades through a pyramid of choices when determining what data are available, evaluating the fitness of data for use, accessing the data, and transferring and receiving the data. The exact nature of these data elements continues to be the subject of much debate and discussion.

A collection of metadata records combined with data management and search tools forms a data catalogue. The architecture of these data catalogues can vary from tightly held internal data indexes to widely accessible distributed catalogs spread across the Internet. Establishing a data catalog can be a major project. Among the items that need to be accomplished are to:

(a) determine which programs or individuals produce, manage, or disseminate data that are to be included in the catalog;

(b) identify what geospatial data an organization holds, where data are located, and their condition;

(c) identify priorities for documenting previously collected or produced data based on demand, geographic extent, uniqueness, or other criteria to be determined by the organization;

(d) create the metadata for new spatial data;

(e) ensure that the metadata comply with applicable standards, to the extent possible for the organization;

(f) provide training and technical assistance to metadata producers, quality-assurance personnel, and end users;

(g) update and maintain metadata as necessary;

(h) specify, acquire, and manage the hardware, software, and telecommunications services so that the metadata are electronically accessible;

(i) determine how to link or cross-reference spatial data and metadata to ensure consistency, maintainability, easy query or search, and easy access; and

(j) respond to questions about or orders for spatial data.

Clearly the catalog function can go far beyond the basic listing of content. Extensions that allow for direct ordering or download of data, user comment or feedback, as well as requests for new data collections are all possible. Metadata and data catalogs are the means by which data users can more economically find, share, and use spatial data.

Spatial Data Infrastructure

1. The Context

The nature of Geographical Information Systems (GIS) is that the basic principles are simple, sometimes apparently even trivial—but the rate of change in all aspects of the field is great and good practice is sometimes fiercely demanding intellectually and in other ways. This article reflects that situation; the continuously evolving characteristics of GIS and Spatial Data Infrastructure make this a snapshot of the situation in the early part of the twenty-first century (see *Geographic Information Systems*).

The history of GIS has been summarized by Coppock and Rhind 1991) and Foresman (1997). What began as a hugely expensive—and thus rare—mainframe computer tool for inventory and mapping purposes in the mid-1960s blossomed in the 1990s. The statistics suggest that there are now about two million users of GIS worldwide and this figure is growing at about 20 percent per annum. Many of the active users of GIS are carrying out tasks on behalf of large numbers of citizens, notably through the work of governments. In addition, there are many everyday users of services that include GIS elements, sometimes without this being obvious (e.g., in many Internet searches).

The annual commercial revenues generated from sales of GIS software are now over $1 billion worl-

Figure 1
Attendance at the annual ESRI User conference since 1981—a surrogate for interest in GIS as a whole.
Source: Environmental Systems Research Institute

dwide. Typically this leverages a ratio of about 1:5 in terms of expenditures on hardware, staff training, data collection, and operations. Thus the total annual GIS expenditure is now likely—insofar as it can be estimated—to be of the order of $15 to $20 billion. This figure is supported by estimates of expenditure by known users e.g., cadastral and mapping agencies. The great bulk of the software revenues are earned by a small number of US-based firms but other GIS expenditures are typically more local. One surrogate for the growth of GIS is the number of people attending conferences: attendances at the most popular GIS software conference have grown from 23 in 1981 to over 10,000 in 2001 (Fig. 1). All this is not surprising for the range of applications of GIS is now truly extraordinarily huge (Longley et al. 2001). GIS has thus moved in 30 years from an esoteric side issue, based on the creation of software by academics and government, to a fully fledged global business and scientific endeavor.

2. *The Problem*

That said, views of what GIS is and why it is significant expanded greatly in the late 1990s. Issues such as the reliability of results from GIS-based analyses of multiple data sets, the impact of the technology on privacy, debates on public policies on access to information and its ownership, plus the international interactions of national policies, all involved and influenced thinking on GIS. The result was to re-engineer GIS as a science and as a political, managerial, and business issue as well as a technological one. This has a series of consequences, such as calling into question the existing, surprisingly homogeneous, GIS educational infrastructure existing in over 2,000 universities worldwide (Longley et al. 2001). Paradoxically, it has also led to a recognition that the 'island-like state' of GIS in respects other than education needs to be addressed: to date, most applications and uses of GIS have been project- based.

If GIS is to become totally ubiquitous—a reasonable aim given the ubiquity of use of geographical information in most decision making—then a number of major problems have to be overcome. These have been summarized by the US Federal Geographic Data Committee (1997) as follows:

> In the United States, geographic data collection is a multi-billion-dollar business. In many cases, however, data are duplicated. For a given piece of geography, such as a state or a watershed, there may be many organizations and individuals collecting the same data. Networked telecommunications technologies, in theory, permit data to be shared, but sharing data is difficult. Data created for one application may not be easily translated into another application. The problems are not just technical—institutions are not accustomed to working together. The best data may be collected

> on the local level, but they are unavailable to state and federal government planners. State governments and federal agencies may not be willing to share data with one another or with local governments. If sharing data among organizations were easier, millions could be saved annually, and governments and businesses could become more efficient and effective.
> Public access to data is also a concern. Many government agencies have public access mandates. Private companies and some state and local governments see public access as a way to generate a revenue stream or to recover the costs of data collection. While geographic data have been successfully provided to the public through the Internet, current approaches suffer from invisibility. In an ocean of unrelated and poorly organized digital flotsam, the occasional site offering valuable geographic data to the public cannot easily be found. Once found, digital data may be incomplete or incompatible, but the user may not know this because many data sets are poorly documented. The lack of metadata or information on the "who, what, when, where, why, and how" of databases inhibits one's ability to find and use data, and consequently, makes data sharing among organizations harder … If finding and sharing geographic data were easier and more widespread, the economic benefits to the nation could be enormous.

This statement actually understates the scale of the problems encountered in typical GIS projects or programs. These normally involve dealing with the assembly of data from multiple sources and coping with scarce staff skills, 'state of the art' technology, and frequently contested outcomes. Making effective and safe use of data encoded by different people to different levels of resolution and accuracy, collected at different times and without certification of quality, is self-evidently non-trivial. These are some of the problems that Spatial Data Infrastructures are designed to resolve.

3. *What is a Spatial Data Infrastructure?*

It seems (Table 1) that Spatial Data Infrastructures (SDIs) are already commonplace. Harris (1997) and Masser (1998) have described various policy aspects relating to Geographic Information and to the early stages of SDIs but the situation is constantly evolving. The use of terminology, however, conceals many different entities and states of development. In Australia the local manifestation is termed 'the Australian Spatial Data Structure;' in Canada 'the Canadian Geospatial Data Infrastructure;' in the Asia-Pacific group there is 'the Permanent Committee for GIS Infrastructure in Asia and the Pacific;' and in the UK it is the 'National Geospatial Data Infrastructure.' SDIs are not necessarily national: a number of US states have set one up and a global version is under discussion.

Table 1
Countries which have assembled or are assembling National Spatial Data Infrastructures as of mid-2000. Source: Henry Tom, Oracle Corporation

Argentina	Hungary	Northern Ireland
Australia	India	Norway
Canada	Indonesia	Pakistan
Colombia	Japan	Poland
Cyprus	Kiribati	Russian Federation
Finland	Macau	South Africa
France	Malaysia	Sweden
Germany	Mexico	United Kingdom
Greece	Netherlands	USA
	New Zealand	

The most commonly used terms in this arena are 'spatial data,' 'geospatial data,' and 'geographic(al) information.' The phraseologies can be regarded as synonymous in some uses but not in others (see, for instance, Longley et al.'s (2001) discussions of data, information, evidence, and knowledge). Broadly speaking, 'spatial data' is the most widely used term except in Europe where 'Geographic Information (GI)' is widely used.

Formal definitions of SDIs vary significantly around the world. Two definitions of the US National Spatial Data Infrastructure (NSDI) are shown below, together with that of the putative Global Spatial Data Infrastructure (GSDI):

> [The National Spatial Data Infrastructure is] 'the comprehensive and coordinated environment for the production, management, dissemination, and use of geospatial data. [It subsumes] the totality of the policies, technology, institutions, data and individuals that were producing and using geospatial data or GI within the United States.' Source: 1993 and 1994 reports of the Mapping Science Committee (MSC) of the United States National Research Council
> [NSDI is] 'the technology, policies, standards, and human resources necessary to acquire, process, store, distribute, and improve utilization of geospatial data.' Source: Presidential Executive Order #12906: 1994
> The GSDI is the broad policy, organizational, technical and financial arrangements necessary to support global access to geographic information.' Source: Steering Committee of the Global Spatial Data Infrastructure (see http://www.gsdi.org)

The differences in these are subtle but important. For instance, the financial underpinnings of NSDIs were largely ignored in the early years, as were the commercial and private sector contributions. Many originally saw the entire NSDI enterprise being driven by new technologies, especially Geographical Information Systems; others saw the key issues as the information production process. The progressive acceptance of Geographical Information Science has now broadened the generally accepted concept of NSDIs to include a stronger research and education agenda. In the USA in particular, the NSDI was originally driven by federal government agencies and the Federal Geographic Data Committee in particular; this has led to much debate on how to create leadership in an enterprise that can or should not—according to Internet enthusiasts—be led.

4. The US Experience with an SDI

The President's Executive Order and the FGDC identified three primary areas to promote development of the NSDI. The first was the development of standards, the second improvement of access to and sharing of data by developing a National Geospatial Data Clearinghouse, and the third was the development of the National Digital Geospatial Data Framework. All of these efforts were to be carried out through partnerships among federal, state, and local agencies, the private and academic sectors, and non-profit organizations. Executive Orders in the USA are only enforceable in regard to federal agencies: such cross-sectoral adherence can only be achieved by influence and the leverage through federal funding.

The Federal Geographic Data Committee operates as a bureaucracy through a series of subcommittees based on different themes of geospatial data (e.g., soils, transportation, cadastral), each chaired by a different federal agency. Figure 2 illustrates the original subcommittees and which federal agency led each one. Several working groups have also been formed to address issues on which there is a desire among agencies to coordinate and which cross subcommittee interests (e.g., Clearinghouse, Standards, Natural Resource Inventories).

4.1 Standards

Many of these groups have developed standards for data collection and content, classifications, data presentation, and data management to facilitate data sharing. For example, the Standards Working Group developed the metadata standard, which was formally adopted by the FGDC in mid-1994 and has since been adapted in the light of international and other national developments. All of the FGDC-developed standards undergo an extensive public review process. This includes nationally advertised comment and testing phases plus solicitation of comments from state and

Figure 2

Figure 3
Growth in use of the US NSDI Clearinghouse. Source: Henry Tom, Oracle Corporation

local government agencies, private sector firms, and professional societies. The most recent NSDI standards at the time of writing (late 2000) are for utility data content, hydrography, geological maps, and a profile (i.e., a subset) of the shoreline metadata standard. The Executive Order mandated that all federal agencies must use all FGDC-adopted standards.

4.2 The Clearinghouse

The second activity area is intended to facilitate access to data, minimize duplication, and assist partnerships for data production where common needs exist. This has been done by helping to advertise the availability of data through development of a National Geospatial Data Clearinghouse. The strategy is that agencies producing Geographical Information describe its existence with metadata. They then serve those metadata on the Internet in such a way that they can be accessed by commonly used Internet search and query tools. The FGDC-adopted metadata standard describes the content and characteristics of geospatial data sets. President Clinton's Executive Order stipulated that agencies make these metadata accessible electronically. This has been rendered practicable by the development of metadata-creating software within GIS by the larger vendors. As a result of all this, nearly all federal agencies—as well as most States and numerous local jurisdictions—have become active users of the Internet for disseminating geospatial data. This model does not necessarily assume that GI will be distributed for free. Obtaining some of the data sets requires the payment of a fee; others are free. The Clearinghouse can also be used to help find partners for database development by advertising interest in or needs for GI. The growth in use of the Clearinghouse is shown in Fig. 3.

4.3 The Geographical Framework

The third NSDI activity area is the conceptualization and development of a US digital geographical (or geospatial) framework data set. Framework data are those which underpin all GIS operations, providing the geographical context and structure within which spatially manifested processes operate and on which other ('area coverage') data are assembled. There are two main reasons why a spatial framework is essential in almost all GIS operations. The framework provides both spatial context and spatial structure. In dealing with a satellite image, for example, the incorporation of place names facilitates linkage to the real world; moreover, the framework may be used to rectify distortions in, or subset and reorientate, the imagery. The second reason for the importance of the framework is that geographic information is typically collected by many different agencies, usually within the boundaries of national territories; and most of these agencies have historically collected data primarily to suit their own local purposes. Thus, if the benefits of added value are to be obtained from data

integration within a GIS, there must be a mechanism (or spatial 'key') to register the different data sets together in their correct relative positions and, beyond this, to ensure that the component objects within each data set are properly related. In general, only the geographical framework can provide this ubiquitous data linkage key through the use of coordinates or implicit geographical coding.

What constitutes the framework varies in different countries. In the USA, the Federal Geographic Data Committee (FGDC 1995a) has defined the information content of the US framework as consisting of:

- geodetic control
- digital orthoimagery
- elevation data
- transportation
- hydrography
- the geography of governmental units; and public land cadastral information.

Similar definitions—including place names—would in practice occur in many countries. Most typically, the framework is manifested in user terms through topographic mapping—the 'topographic template'-—which may contain all this information but partly in implicit form (e.g., geodetic control).

Hence the US framework was intended to form the foundation for the collection of other data, minimize data redundancy, and facilitate the integration and use of geospatial data. It should be pointed out that the USA is generally less well endowed in relation to a consistent geographical framework than are many other nations. The federal nature and physical extent of the country has ensured a multilevel and inconsistent hierarchy of geographical information is produced by the federal, state, and local governments, with local updating and tailoring by agencies and private sector bodies. This contrasts with Britain and many other countries where a single, consistent national framework has long been in existence and is consistently maintained up to date. The disadvantages of a multiplicity of frameworks are evident: the creation of multiple but different framework data sets will guarantee the creation of artifacts in any computer analysis using combinations of data sets related to each of the frameworks. Putting a value on such externalities is difficult, especially since the costs are visited on those at the end of supply chains and are often only discovered long after the data have led to mistaken conclusions.

Given the huge number of players involved, getting agreement on a multipurpose framework has been difficult in the USA. The Executive Order directed the FGDC to develop a plan for completing initial implementation of the framework by the year 2000 but this has proved impossible. A popular, partial solution has been to create one-meter resolution geometrically correct orthophotomaps in place of a conventional digital map framework. Attractions of this approach are that it could be automated to a great degree and could also be financed jointly by states and the federal government and implemented via the private sector.

The collaboration to create or refine the national NSDI has led to various tensions. These have occurred between federal agencies, between them and the states and local governments, and—to a more limited extent because of their more modest involvement until the late 1990s—with the private sector. These tensions arise partly because the NSDI permits the questioning of traditional, legacy roles for government bodies: for instance, the concept of assembling national databases by sewing together detailed ones held by states directly undermines the traditional role of some federal agencies. In addition, the NSDI has made public some latent demands which have ramifications for budget holders: in many cases the beneficiaries of spending are not those called on to divert resources from other activities.

Most recently, a US national report on NSDI pointed out the consequences of seeking a private/public sector partnership in developing the National Spatial Data Infrastructure. These consequences include an obvious requirement for the private sector to generate profits from trading in information and in financing infrastructure. These would necessitate, it was argued, a more cohesive and industry-friendly policy on information ownership and massive investment by government to convert its data into more coherent, consistent, and object-oriented form—which could then be marketed. Partnerships of this kind—as opposed to normal contractual arrangements with the private sector working for the government—are difficult to make work.

5. *The Global Spatial Data Infrastructure*

Most GI has been collected, assembled, and used hitherto in a national context. Yet there is a growing number of requirements for pan-national, even global data. For instance, Agenda 21 was designed to facilitate sustainable development. The manifesto was agreed in Rio in 1992 at the 'Earth Summit' and was supported by some 175 of the governments of the world. It is noteworthy that eight chapters of the Agenda 21 plan dealt with the need to provide geographic information. In particular, Chapter 40 aimed at decreasing the gap in availability, quality, standardization, and accessibility of data between nations. This was reinforced by the Special Session of the United Nations General Assembly on the Implementation of Agenda 21 held in June 1997. The report of this session includes specific mention of the need for global mapping, stressing the importance of public access to information and international cooperation in making it available.

The Global Spatial Data Infrastructure (GSDI) is an attempt to enhance the availability and accessibility

of global GI. It is the result of a voluntary coming together of national mapping agencies and a variety of other individuals and bodies. The organization has sought to define and facilitate creation of a GSDI by learning from national experiences. As part of this process, it funded a scoping study carried out by Australian consultants. They outlined in early 2000 their conceptual view of how the inputs to decision-making were linked to an SDI and the potential benefits that would arise from having one. They pointed out however that proof of the reality of the predicted benefits was difficult to find. The fundamental question for any GSDI business case is: what exactly is the product that governments and other agencies will be asked to fund? The consultants said bluntly that 'The broad definitions of GSDI are not sufficiently operational (or practical) to build a clear business case around.' They went on to raise some key questions which they recognized as being difficult to answer but had to be tackled to give credibility to a formal business case for GSDI. These included:

- Is GSDI a real global SDI or a federation of national or regional SDI?
- Is GSDI really about encouraging developing countries (or at least those that do not currently place emphasis on geospatial data to do so)? In this case, the product may be a suite of policy recommendations and technical assistance approaches that development agencies can apply in their client countries.
- Is GSDI a process, a general framework, or is it a particular product such as a world map or a comprehensive database?
- Who are the stakeholders?
- What about the demand side of GSDI? How do you isolate demand which arises from decision-making processes?

Given all this—and not surprisingly in view of the lack of any global government and the complications in building a national, let alone pan-national NSDI—progress on a GSDI has been slow to date. The primary reason is not inadequate technology but the requirement to clarify real need, obtain sources of finance, and secure political support.

6. *Spatial Data Infrastructures and the Social Sciences*

The diversity of multiple strands in the social sciences revealed by this encyclopedia complicate any brief attempt to link the book's subject matter to GIS and SDIs. This relationship is, however, manifestly in existence. Examples of factors which underpin the multiple and sometimes subtle relationships include:

- The increasingly 'taken for granted' nature of the role of GIS in supporting tactical (and sometimes strategic) decision making worldwide
- The growth of problem-oriented approaches within government as well as in business. These necessitate
  crossing traditional disciplinary boundaries and using information drawn from many sources e.g., relating to the natural environment as well as the social sciences—with all the ownership, epistemological, and other problems that entails
- The methodological implications of conflating information on people, places, institutions, and policies which have different conceptual bases and other characteristics
- Policy conflicts between different nations or other governed units such as US states (e.g., on the 'proper' role of the state as in the free distribution or charging for information)
- Institutional and interinstitutional politics and financing struggles within government (still the largest sources of Geographical Information). This can be encapsulated in the 'who leads' question which is difficult to answer given the permeation of SDI and GIS through many activities and responsibilities in different sectors.
- The interrelationship of the state and business. This is more complex than in many other cases for governments are both providers (in some case competitive with the private sector) and consumers of Geographic Information. The supply of some GI is a natural monopoly. There is a geography to this business/government relationship which is much more complex than national information policies would suggest (Longley et al. 2001).
- The legal issues involved in SDIs and GIS relate to liability, privacy (e.g. Curry 1999 and Longley et al. 2001), and 'fair dealing' as well as information ownership and protection. Again, there is a geography of the law related to SDIs.

In summary, SDIs are posited on worthy aims. But they raise fundamental theoretical and practical questions of the role of the state and of intersectoral and organizational partnerships on a scale hitherto unknown in many social sciences. Success in creating SDIs may both benefit and disadvantage the individual (e.g., in providing better and cheaper access to information but also in undermining privacy). It is also not clear how to assess success in an environment where competition and partnerships within governments and between them and the private sector are both inevitable. SDIs also raise a series of practical managerial questions. Ultimately, they impact on the lives and work of everyone. As a consequence of all of the above, SDIs provide a fertile laboratory for the social sciences.

Spatial Decision Support Systems

People frequently make choices that involve evaluating geographic position or geographic context. Whether selecting routes, making service areas, or defining environmental hazardous areas, they use 'multiple spatial criteria' in making such choices and apply them to complex geographic data. In social science, such complex decision-making problems are often called 'ill-structured' and a set of theories, methods, and techniques has been developed for a wide variety of problem-solving contexts. It has become common to link these together in computer software that operates on spatial data. They are called spatial decision support systems and are increasingly being used in both business and public sectors today.

1. Spatial Decision Support for Ill-structured Problems

A number of problems may occur when making decisions for ill-structured problems. First, it may not be clear to the decision maker how much of the attainment of one spatial criterion should be sacrificed in order to attain a given amount of another. The decision maker often wants to explore alternative solutions and to reach a decision about the best solution only after extensive exploration of the spatial and the attribute solution space. That is, their preferences for a particular solution may be influenced by what can be attained in a particular context. Although they may have preferences for abstract entities, the implementation of these preferences is mediated by knowing what can be attained in the given context. Decision support systems are designed to facilitate the exploration of these spaces and thus to assist decision makers in their search for the best solutions to their problems.

A second problem is that the spatial databases containing relevant information may not be complete either with respect to all the variables that are relevant or to the accuracy with which they are measured. During the process of searching for a solution, decision-makers will sometimes want to add their unique spatial knowledge about an area or decide to search for additional facts about a location or area before making a decision.

A third problem is that though decision makers may want to view the results of models of processes, they may choose not to accept these results over concerns about their validity for the given situation. All three problems lead many decision makers to ask for computer-based, interactive, support systems with which to explore their problem and search for a solution.

1.1 Solution Spaces in SDSS

The solutions to all SDSS problems exist in both geographic and attribute space. As the geographic space of the solution to any problem changes, so its attribute space changes too. For example, in making districts from which voters will elect representatives, the geographic solution space is the map of the boundaries of the constituencies and the areas they contain. The corresponding attribute space describes the numbers of eligible voters in each district, their

party affiliations, their past voting record, and any attribute that a politician may view as relating to their likely voting behavior on a range of relevant issues in an upcoming election. Such attributes might be their ethnicity, income, age structure, religious preferences, etc. Thus, in an exercise to re-draw electoral districts following a decennial census, any participant in the process may want to see how any changes in the boundaries are accompanied by changes in any or all of these attributes. A system for simultaneously computing alternative regionalizations of territory would constitute a spatial decision support system for electoral redistricting. In this example, 'regionalizing' is the spatial function for which the support system is developed. Defined characteristics of the areas and the constraints for their definition specified by a particular political system would be the attributes for which the SDSS would be developed.

2. *Types of SDSS*

Different types of SDSS can be defined according to how geographic and attribute spaces are generated. In some SDSS, these spaces are generated interactively by the user. The capabilities of the SDSS then consist of the tools for manipulating the geographic information and reporting the characteristic attributes of the outcomes. Consequently, the simplest SDSS incorporate the capacity to convey information from the geographic to the attribute space or from the attribute space to the geographic space. These are key capabilities of geographic information systems (GIS).

GIS are simple spatial decision support systems. They permit users to query locations and learn about attributes at the locations. They also permit the definition of attributes—often following database queries such as sort or find—and then to see their geographic locations quickly. Good examples can be found in Birkin et al. 1996. Crossland et al. (1995) determined the efficacy of using GIS as SDSS for making location decisions. In an experiment, the students with access to GIS made better and quicker decisions with the SDSS than those without it.

The term SDSS is often reserved for systems that combine the functions of GIS with multicriteria decision analysis and optimizing models. These are developed for problem contexts that involve not only the manipulation of geographic information in GIS, but also the generation of preferences, the modeling of choices, and the search for locations or areas that best meet a user's defined needs. For such problems, GIS need to be integrated with spatial models. Integration is accomplished by visualization of related geographic and attribute spaces and by linking the analysis systems so that users can move easily between them using a unified user-interface (Densham 1994).

All SDSS link together a set of fundamental elements described below (see Fig. 1).

2.1 *Preference, Choice and Multicriteria Decision Models*

Many spatial decisions involve correct anticipation of how people will make selections from alternative locations when presented with any given set of alternatives. Subjective analysis of maps of existing or hypothetical future alternatives does not lead to accurate predictions of how many people will select one alternative over another. For this purpose spatial interaction or spatial choice models have been developed. When added to GIS with appropriate measures of the variables that affect choice, these models can provide invaluable assistance to people charged with making decisions about future facility locations, for example. These 'choice models' (Timmermans et al. 1984) examine the social and economic characteristics of small areas, and then, based on results from samples of the population, estimate how many of each population group will go to one facility and how many to another. When repeated for each small area, (Goodchild 1984) the sum of all the estimates is the aggregate estimate of the use of each facility.

In some cases, instead of modeling the choices of individuals, the user of the SDSS directly participates in the choice evaluation process. Jankowski and Ewart (1996), for example, used the spatial query capability of GIS to select plausible locations for rural health practitioners within an area. Their SDSS asked users to compare pairs of locations on given criteria, and then, using a multicriteria evaluation technique, to rank order the locations for this purpose. The GIS displayed the locations of the highest ranked alternatives.

2.2 *Location Optimizing Algorithms*

Many decision-makers want to select locations to optimize some defined outcome. A large literature describes models for finding optimal locations, routes, etc. SDSS often integrate such models with GIS so that, from a common user interface, the user can assemble the spatial data, solve the problem using a model selected from the interface, and then display the result. Ghosh and Rushton (1987) describe the evolution of location-allocation models from tools to find optimal locations for well-defined objectives to tools that can be incorporated in flexible analysis systems. In such systems, decision makers explore alternative location patterns and use optimizing algorithms to compute alternatives that they can evaluate against criteria of interest, some of which are highly qualitative in character.

Other SDSS are designed to select geographic routes for the delivery of goods or services (Keenan 1998). These are often used in a GIS environment supported by inputs from mobile units that are monitored by global positioning systems (GPS) that report their

Figure 1
Fundamental elements of spatial decision support systems

locations at regular intervals to headquarters. This information is used in subsequent spatial assignment tasks.

The principal spatial task of some SDSS is to form regions (Densham and Rushton1996). Strapp and Keller (1996) developed a spatial decision support system to support the consolidation of agricultural land in the Czech Republic. Their link with GIS permitted the dynamic computation of spatial relationships between small pieces of territory and the farmsteads into which they are grouped at any point in the region formation process. Because of the ill-structured nature of this problem, they designed a spatial decision support system to permit users to work interactively with provisional regions to improve upon them.

2.3 Group Decision Support Systems

Spatial decisions are often made by groups of people, involving them in collaborative efforts. Nyerges and Jankowski (1997) discuss using adaptive structuration theory in a GIS environment to assist these efforts for situations in which groups are involved in public land planning controversies such as hazardous waste clean-up and habitat redevelopment.

Some SDSS incorporate methods for reconciling different views. Couclelis and Monmonier (1995) discuss this problem and offer a computer-supported system to help promote the resolution of NIMBY-type ('not in my back yard') planning controversies. Their system uses GIS capabilities to present spatial details of the planning situation but uses the concept of the graphic script as a device for encouraging dialogue and reconciliation of opposing views. Armstrong (1993) describes how computer supported cooperative work (CSCW) computing environments can enhance SDSS by enabling group members to observe, manipulate, and evaluate alternative plans collectively and then provide mechanisms for conflict resolution.

3. Knowledge-based SDSS

In many situations, the assistance required by users of an SDSS lies in the knowledge of experts who are not

available in person. Much of current research in SDSS entails capturing the knowledge of experts and incorporating it in the analysis system so that this knowledge becomes available at the appropriate time to the user. An early paper by Armstrong et al. (1990) outlined this approach. Examples of such systems are beginning to appear (Leung et al. 1997). In fully developed knowledge-based SDSS, many of the activities of the user-interface are bypassed (see Fig. 1) and are automated in the knowledge base. Some of the knowledge there is about the algorithms and their links to the decision task. Other knowledge is substantive knowledge about the processes that need to be modeled.

4. Implementations of SDSS

Many examples of prototype implementations of SDSS can be found in the academic literature. Commercial SDSS applications are usually domain-specific and are being developed to support decision making for specific problems that are complex, yet occur with sufficient frequency to support the overhead cost of developing and testing SDSS developed for the purpose. In many countries, following each census, there is a flourish of political redistricting activities. Increasingly, decision makers rely on SDSS for this task.

5. Conclusions

Currently, most SDSS are tailored for specific problem domains. Users often will not recognize that SDSS in quite different application domains have similar architectures and combine similar elements. The applications use the attribute language of the domain, even though the spatial data inputs, manipulations, and outcomes may be identical. SDSS represent the integration of ideas, methods, and techniques from many of the social, behavioral, and management sciences. Their usefulness in the policy and planning sciences is based on the degree to which they successfully incorporate the findings and approaches of these sciences. Their focus on the spatial and the geographic leads to a very important link with the evolving field of geographic information science. The rapid development of national spatial data infrastructures provides a rich and expanding database to which attribute information can be attached.

SDSS, at their inception, were a derivative science that built upon the successful development of models of behavioral, social, and political processes. However, with the expanding use of SDSS in a wide variety of decision situations, theories and models of these processes will have to account for the use of SDSS. When normal decision-making patterns involve SDSS use, they will become an important element in social science theories and models to explain decisions in these areas. This evolution from the use of social and behavioral models as exogenous units in SDSS to their incorporation as endogenous units is an important development in the social sciences. This development will mark the more explicit incorporation of geographic variables in social science theory and method.

Spatial Equity

Although most social scientists may not know the term 'spatial equity,' almost everyone experiences it in everyday life. 'Spatial' implies that most of the experienced world, physical and social, takes up room; this has important social consequences. Elements of the natural and social world always have a location in space or a place, just as they do in time. Phenomena also have relationships of distance, spatial interaction and accessibility with one another, and these attributes shape the causes and consequences of things. 'Space' has structure, that is, institutions and relationships which constrain what and who can be where—in other words, everything and everyone's place on the landscape.

'Equity' is a social construct by individuals, or groups or societies, as to the degrees and kinds of inequalities that are acceptable or 'fair' or are unacceptable and 'unfair.' Thus, the measure of equity is inescapably bound up with the individual's or group's position with respect to the basic human dilemma of individual and collective rights and responsibilities. There is no measure of where 'fair' ends and 'unfair' begins; society redefines the line as needed according to custom and law. Classic works include Perin's *Everything in its Place* (1977), Rawls' *A Theory of Justice* (1971) and Harvey's *Social Justice and the City* (1973). The latter was recently commemorated in Merrifield and Swyngedouw's *The Urbanization of Injustice* (1997). On Rawl, see also Clark (1985).

1. *The Meaning of Spatial Equity*

Webster defines equity as 'a legal system which supplements statutes or laws to correct, if necessary, its failure to account for what is morally just and fair.'

Societies may deal with questions of equity and fairness in the justice system or via regulations and legislated standards. Thus a 13-year-old may not claim an equity issue in not being allowed to drive, but a healthy 80-year-old can.

The very fact of space implies that the notion of spatial equality (that all parts of space are of the same quality or value) is without meaning; every bit of space is different from every other. For this reason, equity is of heightened importance and difficult to obtain. In economic theory an efficient equilibrium should be equitable as well. Structurally, monopoly and inheritance, for example, lead to inefficient and inequitable outcomes. But space itself may make a structurally efficient pattern geographically inequitable. Consider a common situation of an uneven distribution of people, far denser on one side of a jurisdiction than the other. The most efficient, travel-minimizing location for a public facility will be strongly pulled to the densest core, leaving those in the low density edge in a highly unequal position (Morrill 1973).

The physical environment is incredibly diverse, and utterly unequal from place to place and over time in its utility or value to human production, residence, exchange or enjoyment. For physical, cultural, historic, and political reasons, individuals, groups, corporations, institutions, and societies are similarly diverse, and highly unequal in physical and mental capacity, experience, and mobilization of resources. They are profoundly unequal in their power to structure the landscape, to alter the environment, or to control more valuable locations.

Individuals, groups and societies are continually aware of their unequal positions in space, which often leads to perceptions of unfairness on the part of the less territorially advantaged (those on the 'wrong side of the tracks'), and on the part of moralists, ethicists, and liberals offended by or concerned with territorial inequality.

1.1 *Spatial Equity and Social Inequality*

Inequality of power and of rewards itself may lead to resentment and a profound sense of unfairness of the social system. At the societal level, the equity issue is the social system itself, and the battles are more structural than spatial, for examples, calls for socialism or communism as the solution for unequal power and wealth, or battles over minimum wages and tax rates. An exception is perhaps the demand for political self-determination of colonies—struggles that were more territorial and cultural than structural.

But within a nation and social system, as in the USA, although there may be many who want to change the system, the majority of US citizens, for example, accept the competitive and individual system and understand that unequal power and wealth are inherent to the system, that the rich and powerful can and will preempt the 'best places.' Thus a class-segregated society as such is not a spatial equity issue. After all, that poor person may win the lottery! Rather, issues of spatial equity arise when people feel unfairly treated, although they're playing within the rules of the game; when they feel that the rich and powerful manipulate the law itself to get more than the share their competitiveness and wealth warrant. An example is the conviction of poverty area residents that since they pay taxes, too, the potholes on their streets should have no lower priority than the potholes on the streets of the rich.

There are many examples of spatial inequality that raise equity issues. Starting at the global scale are historical colonialism and imperialism and contemporary dependency theory, hypothesizing that unfair power relations exploit and impoverish the Third World. Less technologically advanced cultures distrust

and fear the power of Western and especially of US culture. Smith (1977, 1994) provides extensive treatment of inequality from the global to the local scale. See also Knox (1975).

Within nations, prominent bases for raising issues of equity include (a) regional inequality, the sense of exploitation of the periphery by the core, or of poor regions by rich regions; (b) unequal access to public facilities and resources; (c) unequal or unfair treatment of areas because of their poverty, wealth or power; (d) spatial manifestations of the sports analogy that a competitive society should have a 'level playing field;' and (e) spatial aspects of unequal treatment of categories of people, because of race, ethnicity, language, religion, lifestyle, and gender.

1.2 Regional Inequality

Within the European Union, a dominant part of the budget and a large amount of research and rhetoric are devoted to the issue of lagging regions, built on the perception that it is somehow 'unfair' that some regions are prosperous and growing while others are poor and languishing; that it shows the failure of the system, rather than of the region. In US economic history, class struggles often seemed secondary to the resentment of the south and west against the hegemony of the northeast. In a generally private economy, the US has a long tradition of regional redistribution via public programs; for example, the Reclamation Act subsidizing irrigation development in the West, federal defense outlays and massive highway programs, TVA and the Bonneville Power Administration, and the Regional Development Commissions, were all designed to improve the competitive position of 'disadvantaged' parts of the country (Johnston 1980). Harrington's classic *The Other America* (1962) raised the nation's consciousness of poverty and helped lead to the War on Poverty.

Efficient market decisions frequently take the form of the closure of factories and consequent community decline, leading to forced out-migration. In these cases, 'pure market' solutions implying the 'shipment' of the surplus labor to growing regions confront the immense nonmarket value of places to their long-term residents, and a strong sense of unfairness arises, that the decline is not the fault of local people (Clark 1983). Societies often institute a variety of programs to reduce the social and economic costs, as through subsidies, community purchase of the closed plant, tax forgiveness, or retraining and relocation assistance.

The same principle is applied at the local level through federal or local programs such as slum clearance, public housing, and 'enterprise or empowerment zones,' reflecting a political consensus that the landscape had become unfairly unequal, presumably because of forces beyond local control.

1.3 Voting and Representation

In the USA, perceptions of unfairness in representation led to a series of Supreme Court decisions outlawing malapportionment (unequal population per district) and racial gerrymandering which disenfranchised minorities (initial decisions ruled against 'diluting' and 'packing' minority voters, but later rulings forbade gerrymandering to maximize minority representation). Ironically representation in the US Senate intentionally violated the equal population principle, since every state has two senators, but this inequality was defended on grounds of avoiding unfair domination of smaller by larger states.

1.4 Overcoming the 'Unfairness' of Nature

As communities develop and compete with other places, perceptions of being treated 'unfairly by nature' may arise. At the international scale, such perceptions may be used to justify invasions and wars. Within countries, governments at all levels spend huge sums to overcome natural limits, so they may 'compete on that more level playing field.' Examples are bridges, tunnels, and artificial harbors, built to improve the accessibility of a place to national and global markets.

1.5 Access to Public Facilities and Resources

This is the arena for which the word equity is most likely to be invoked, and for which legal remedies may be sought, on grounds of 'equal protection' under law (Pinch 1985). In the USA, until as recently as the 1960s it was the perception and probably the reality that weaker, poorer places among a set of jurisdictions, and weaker and poorer areas within a jurisdiction, were unequally and unfairly treated. Examples of inequitable access to public services and facilities entail the maintenance and quality of utilities and infrastructure, like roads; the location and quality of parks, playgrounds and pools, or of libraries; and the timeliness of police response calls, as if action were a function not of citizenship but of wealth—which it was. As a consequence of a series of court decisions over many years, cities have become far more attentive to more equal treatment across all parts of their jurisdictions, although huge historic inequities remain.

The construction and operation of public transportation systems have similarly been subject to scrutiny, as to the costs and benefits of subsidies to different parts of a region; poor, more transit-dependent districts no longer meekly accept inferior service and equipment. In most of the USA school districts are a distinct set of governments. District populations are astoundingly unequal in income, and districts in tax bases. In many but not all states, courts

have interpreted state constitutions to mean that all students should have 'equal access' to education, wherever they live. This has resulted in substantial redistribution of resources from richer to poorer districts, as well as to the subsidy of 'remote but necessary' small schools in very isolated communities.

1.6 The Location of Undesirable Facilities: Environmental Racism

A different issue of equity arises as to the differential ability of stronger and richer or weaker and poorer jurisdictions or parts of cities to ward off undesirable private and public activities. Less advantaged places and areas widely perceive that they have long been and remain dumping grounds for unattractive and even damaging facilities—prisons, halfway houses, incinerators and landfills, and services to the 'less desirable' folks (drug addicts, alcoholics, the homeless); adult shops and theaters, and polluting and noisy factories. If the obnoxious facilities or activities are in segregated racial minority areas, charges of 'environmental racism' may be made.

Poorer and minority areas perceive also that they are treated as tolerance zones for illicit activities and inadequate law enforcement. More generally, these areas are characterized by loss of jobs, retailing and services, and middle-class housing, leading to spatial mismatch between a declining inner city and more affluent suburbs. In more liberal cities and states, a consensus may arise for some degree of 'sharing' of the 'burden' of housing the less affluent, as through requirements for 'fair shares' of subsidized affordable housing, even in suburbs. In a very few metropolitan areas, where extreme political fragmentation results in highly inequitable resources for jurisdictions, a sense of injustice and unfairness has resulted in a degree of tax-base sharing, as for police and sewerage services.

1.7 Urban Inequality: Unequal treatment of categories of people

Many books focus on spatial inequality in US and European cities, e.g. Badcock (1984), Gottdiener (1985) and Katznelson (1981). An influential segment of the intellectual and planning community advocates fairly radical efforts to break down the high degree of racial and class segregation, as through stronger zoning control of settlement. The failed programs of mandatory bussing for school desegregation were similarly based on a sense of injustice and on the premise that mixing in classrooms would lead to mixing in neighborhoods. As with schools, current efforts toward class mixing seem unlikely to be a match for the stronger societal forces for segregation. Although men and women are usually residentially integrated, the history of gender inequality resulted in unequal access to opportunities and resources, and in insecure built environments. And because of this history the very subject of inequitably gendered landscapes has only recently been studied (Pratt and Hanson 1994).

2. Reactions to Spatial Inequity

As most of these examples show, the achievement of greater spatial equity seems limited to those aspects of everyday life in which public resources or facilities are involved. Social intervention in the form of redistribution of resources toward weaker places and areas seems to occur when a social consensus of 'market failure' arises—that the 'playing field' has become too uneven, within the prevailing social order. Within the social system, it proves easier also to address inequities in some arenas of life than in others. Not surprisingly it is less threatening to those on top, usually the holders of wealth, to accept equalizing measures with respect to political participation and voting and social dimensions (race, language and gender, although these remain highly contested), and even, if rarely, as to urban housing, than with respect to the truly key economic arena of income, taxes and inheritance.

In the USA, issues of equity and redistribution were fought mainly at the national level for most of the post-world war period. Since the mid-1980s and national shifts toward the right—that is, toward greater individual than collective responsibility—the arena of action has moved to local and state levels, where coalitions of activist groups have sometimes been able to gain enough power to enact redistributive plans unimaginable at the national level, for example, high minimum wages, rent controls, or mandates for affordable housing, in a process that might be called 'pluralist democracy' (see also *Postmodern Urbanism*). In other areas and arenas conservative coalitions stress faith in the market, privileging its efficiency over concerns for equity. Indeed, the concepts of efficiency and equity are the very symbols of differing ideological stances toward inequality. The treatment of equity (including this discussion) is usually based on a liberal assumption of people's similarity in needs and values—ideas going back at least to John Stuart Mill. The new politics of identity and difference may complicate the meaning and evaluation of equity (Keith and Pile 1993, Young 1990).

2.1 The Analysis of Spatial Equity

Maps, and now GIS (geographic information systems) have proven highly effective in revealing the structure of inequality in the landscape—patterns of segre-

gation, poverty, concentration of pollution, and unequal access, and have proven essential to convince legislative bodies and courts to address equity issues. A variety of both statistical and mathematical models have been used to measure inequality and its costs, and to assess the impacts of policy changes. Awareness of the human costs of spatial inequality may be increased through more ethnographic studies of the situation of individual households.

Spatial Interaction

The study of spatial interaction has been carried on actively for many years in the field of geography, with its emphasis on the spatial aspects of cities and regions. Spatial interaction studies in geography may be divided into those dealing with spatial structure and those dealing with attempts to understand and model these structures. Spatial structure includes the study of: linkages the connections between centers; nodes, the centers themselves; hinterlands, the tributary area surrounding the nodes; and hierarchies, the systems composed of hinterlands, nodes, and linkages. Each of these will be examined briefly, with a particular emphasis on Chicago, as an example of a large, centrally located focus of spatial interaction. Then, some models of spatial interaction will be discussed as examples of attempts to describe and explain the structural systems of linkages, nodes, hinterlands, and hierarchies.

1. Structural Systems of Spatial Interaction

1.1 Linkages and Nodes

Linkages are a basic part of spatial interaction and may be studied at several different geographic scales. At the local scale, dense and complex networks of commuting linkages surround large metropolitan centers connecting city and suburban residential areas to employment areas. In the case of Chicago, certain corridors have been traced out by the flow of commuting traffic. These corridors developed initially in connection with commuter railroads and were later massively reinforced and ultimately replaced by expressways which both compete with and complement the rail linkages. Shopping and recreational flows form quite different sets of linkages with a more dispersed and multicentered pattern. In Chicago and other large metropolitan centers, beltways in the form of high-capacity peripheral expressways encircling the city have become important additional linkages connecting suburbs and connecting with the major radial corridors leading into the central city.

At the national scale, certain primary corridors have developed in the network of linkages. Chicago is at the western end of a major corridor extending through the Midwest to connect with the Megalopolis corridor extending from Washington to Boston. In air transportation, quite a different national pattern of linkages has developed, dominated by the traffic flows between large cities so that Chicago's strongest linkages are with New York and Los Angeles rather than with nearby cities.

Nodes within networks represent another structural aspect of spatial interaction study. The relative im-

portance of a node is determined by the size and nature of its linkages. At the local level important nodes are located along the major radial corridors and near the beltways. Nodes located in areas where beltways intersect radials have particularly high accessibility to the rest of the metropolitan area.

At the national level, the development of nodality has been closely linked to technological change. Chicago's national-scale nodality in the railroad era was unmatched by any other large US city. As the US highway system and the Interstate Highway System emerged, however, Chicago's nodality was no greater than that of a number of other large metropolitan areas. With the coming of high-speed, high-capacity jet airline service in the 1960s, Chicago again served as major focal point, ranking with New York and Los Angeles in number of high-density linkages. When national communication networks are considered, however, a different pattern of spatial interaction emerges. For television, entertainment, and publishing, there is a strong focus on the New York and Los Angeles nodes.

1.2 Hinterlands and Hierarchies

Spatial interaction has also been studied in terms of hinterlands and hierarchies. Systems of linkages and nodes give rise to groups of tributary areas, or hinterlands which, in turn, may be organized into hierarchical networks. Some of the earliest geographic studies of spatial interaction dealt with the delimitation of local hinterlands. These could be based on commuting, retail market areas, social trips, recreational trips, newspaper circulation, or shipments of goods. Chicago's large metropolitan area, which is mainly defined by its commuting linkages, also contains within it a number of small cities each with its own commuting and retail hinterlands. The result is a complex, fine-grained hierarchical structure of central places.

At the national scale, Chicago itself is embedded into several hierarchical systems. In air passenger traffic, for example, New York has become the single most dominant center. By the 1990s, it was the leading passenger generator not only for a group of adjacent cities but also for such large more distant cities as Chicago, Atlanta, and Los Angeles. In hierarchical fashion, each of these centers dominates its own surrounding hinterland. In terms of scheduled airline traffic as opposed to air-passenger origin and destination, a hierarchical hub-and-spoke system has developed. Short-haul connections for a particular airline focus on a single hub where passengers transfer to connecting flights to other hub centers.

Communications networks, such as those developed in the film and television industries, have a clearly bipolar structure focused on New York and Los Angeles. Other large metropolitan centers, such as Chicago, occupy far less central positions in the system. The rise of the Internet is in the process of creating still a different structure of spatial interaction. To date, the system has been a dispersed one in which it is difficult to detect major nodes such as those marking hierarchical or bipolar systems.

At the global scale, the early pattern of world trade routes focused on Britain and a number of strategically located ports has given way to an extensive system focused on major world cities such as London, New York, and Tokyo. There is also some evidence of a hub-and-spoke system, with the major world cities serving as regional centers, distributing international traffic to their surrounding areas. London serves European cities; New York, US cities; Miami, Latin American cities; and Tokyo, Hong Kong, and Singapore serve Asian cities.

2. Spatial Interaction Models

Models have ranged from the descriptive through the explanatory, predictive, and normative. Useful descriptions of the comparative accessibility of given networks, or of given nodes within a network, have been provided by graph-theoretic models. Hubs may be identified, and the differing accessibility of industrial cities may be measured and compared. Such measures, both for nodes and for entire networks, permit planners to evaluate the effects of proposed new linkages on nodal and network accessibility.

More explanatory models evolved from earlier descriptive efforts as attempts were made to identify some of the underlying forces shaping systems of spatial interaction. There is a large literature dealing with the observed tendency for interaction between any two cities to increase as the distance between them decreases. This relationship was first described as a gravity model: directly proportional to the product of the two cities' populations and inversely proportional to the distance between them. It soon became apparent, however, that spatial interaction influenced by many other factors. Distance had different effects for different kinds of interaction. Highway traffic, for example, was much more sensitive to distance than was air traffic. Other characteristics of cities such as per-capita income, economic complementarity, and community of interest had to be considered. The spatial structure of the regions surrounding the cities was also found to have effects in the form of intervening opportunities for spatial interaction and of the proximity of competing origins or destination cities. As the explanatory models continued to ramify, they evolved into a series of traffic demand equations incorporating a number of variables that had been shown empirically to affect spatial interactions.

Intra-urban spatial interaction, that is, the flow of traffic within large cities, has come in for special attention in recent years. Initially, aggregate explana-

tory models were used by planners and engineers as a basis for predicting and improving urban transportation. These models were codified and used in large traffic surveys and analyses. Cities were divided up into analysis zones and detailed surveys were carried out. Demand equations were used to estimate trip generation by analysis zones and the trips were then allocated to existing transport network facilities and used as the basis for future planning. Later, these aggregate models generally were replaced by models designed to facilitate an understanding of individual travel behavior. Data were collected and analyzed at an individual or household level rather than at an aggregate traffic-zone level. These behavioral studies addressed questions of travel choice at an individual level. How did such attributes as comfort, reliability, safety, waiting time, or privacy related to time and cost? How did the attributes interact with such travels characteristics as time and cost? What trade-offs were involved, as travelers would choose between such present or planned types of service as auto, bus, express bus, park-n-ride, car pools, high-occupancy traffic lanes, light rail, and others?

Spatial interaction was also modeled in a normative fashion. The most efficient patterns of linkages between a given set of supply nodes and a given set of demand nodes could be ascertained with programming models. Constraints could then be introduced to account for such things as bottlenecks, capacity limitations, or particular market characteristics. Also, if it were desirable to maximize profits rather than minimize transport, a more complex set of economic functions would be used at the various cities. In addition to optimal linkage patterns, programming models have been used to identify optimal hinterland or tributary area patterns. An optimal set of school districts, for example, can be obtained by minimizing the travel times of a given set of schools with varying capacities. Similar studies have been made for tributary areas of supermarkets, rural hospitals, and others.

Normative models have also been used for purposes other than the establishment of an optimal system of linkages or hinterlands. Sensitivity analysis permits the planner to view the consequences of a number of alternative proposed changes in the transport facilities. Each proposed change can be run through the model and the minimum costs identified. For example, in a school-district case, decisions as to the optimum location for adding or eliminating a school could be aided by running the model for each alternative. Trade-offs could then be evaluated. The cost in increased travel time of certain socially desirable alternatives, such as adding to the ethnic or racial diversity of each school, could be ascertained and evaluated in the light of other possible policy alternatives.

Thus, there is a gradation from descriptive models to explanatory, predictive, and normative models, all of which may provide improved understanding of spatial interaction as it is expressed in structural systems of linkages, nodes, hinterlands, and hierarchies.

Spatial Interaction Models

1. Definitions and Uses

Spatial interaction is the general term for any movement of people, goods, or information over space that results from a decision-making process. Specific examples include movements such as migration, shopping trips, commuting, trips for recreational purposes, trips for educational purposes, freight flows, the spatial pattern of telephone calls, emails and world-wide web connections, of the use of healthcare facilities. Consequently, spatial interaction is a very broad topic, and spatial interaction models have a wide range of

applications (see also *Spatial Interaction*). Olsson (1970, p. 233) states:

> The concept of spatial interaction is central for everyone concerned with theoretical geography and regional science … Under the umbrella of spatial interaction and distance decay, it has been possible to accommodate most model work in transportation, migration, commuting, and diffusion, as well as significant parts of location theory.

Spatial interaction *models* are mathematical descriptions of spatial flows (see *Mathematical Models in Geography*). The models serve two purposes. One is to predict flows where they are unknown. For example, spatial interaction models have been used to predict the impact on traffic patterns of a new development (O'Kelly 1986), to predict the impact a new store will have on trade at existing stores (Fotheringham and O'Kelly 1989), and to predict the optimal spatial arrangement of healthcare facilities (Mayhew et al. 1986). The other is to yield information on the determinants of the flow system being analyzed. For example, spatial interaction models are commonly used to determine the influence of various store attributes on the choice of stores by consumers (Fotheringham and Trew 1993) or to examine the characteristics of places which affect in and out migration (Boyle et al. 1998, Flowerdew and Salt 1979).

Some questions that can be answered with the judicious use of spatial interaction models include:

(a) Is there sufficient demand between two cities to justify direct air service and what frequency of air service will be sufficient to meet the demand?

(b) Where is the optimal location for a new supermarket within a metropolitan area?

(c) What will the effect on traffic patterns be of building a new bridge or tunnel across a river?

(d) What can a store do to attract new customers—what features of the store are most likely to attract or deter customers?

(e) Are migrants becoming less constrained by distance over time?

(f) What influence does a political or administrative boundary have on students' choices of a university?

The remainder of this article examines some of the basic elements of spatial interaction modeling. It then describes four common types of spatial interaction models and outlines a typical application of each type of model. Brief discussions of model calibration and local forms of spatial interaction models are then given followed by a description of the various underlying theoretical structures that have been proposed to substantiate spatial interaction models.

2. *The Basic Elements of Spatial Interaction Models*

The starting point for spatial interaction modeling is a matrix of flows between a set of origins, each of which is usually labeled i, and a set of destinations, each of which is usually labeled j. The task is to represent the number of trips between any i and j, T_{ij}, as a function of origin characteristics, destination characteristics, and the separation between origins and destinations.

Hence spatial interaction models contain four basic elements:

(a) a measurement of the spatial interaction

(b) a measurement of the propulsiveness of each origin (that is, a measure of how many flows begin at each origin)

(c) a measurement of the attractiveness of each destination (that is, how many flows terminate at each destination)

(d) a measurement of the spatial separation between origins and destinations.

Each of these elements can be measured in different ways depending on the type of spatial interaction being modeled. Usually, distances between origins and destinations are used to measure spatial separation although cost and time can also be used. Regardless of how spatial separation is measured, it is often the most important determinant of spatial interaction patterns: individuals tend to be highly constrained by space for most types of spatial interactions. However, spatial separation is not the only determinant of spatial interaction patterns. For example, while an individual is likely to patronize a supermarket close to home, it may not always be the supermarket *closest* to home that is the most attractive: a supermarket farther away but offering a wider range of products or cheaper prices might be more attractive. This trade-off between proximity and other destination attributes is the essence of spatial interaction modeling.

Sometimes, the number of trips leaving each origin or the number of trips terminating at each destination is known from surveys or from some other exogenous source. In such cases, this information is used directly in the model. When such information is not known, the model has to contain surrogates of origin propulsiveness or destination attractiveness or both. Table 1 gives some ways in which origin propulsiveness and destination attractiveness might be measured for different types of spatial interaction. Different forms of spatial interaction model arise from having different amounts of information on the number of trips leaving each origin and terminating at each destination. These different types of spatial interaction model and how they arise are now described.

3. *A 'Family' of Spatial Interaction Models*

It was established above that in order to predict the volume of interaction between places, it is necessary to have three types of information about those places: a measure of origin propulsiveness, a measure of destination attractiveness, and a measure of spatial separation. The last is readily available as distances

Table 1
Possible measures of origin propulsiveness and destination attractiveness

Type of spatial interaction	Origin propulsiveness	Destination attractiveness
Shopping trips	Population Household income	Store size Number of parking spaces Variety of products Price levels
Commuting flows	Population Household income Car ownership rate	Number of jobs
Migration	Population Crime rate Unemployment rate Wage rate	Population Crime rate Unemployment rate Wage rate Climate

between locations can easily be calculated, especially if the locations are stored digitally. This produces four possible situations in which different levels of information are available on origin propulsiveness and destination attractiveness. In turn, these situations give rise to four different forms of spatial interaction model which are collectively referred to as a 'family of spatial interaction models.' (Fotheringham and Dignan 1984) demonstrate that they are actually four extreme points on a continuum of spatial interaction models.

3.1 The Unconstrained Model

Suppose a measure of spatial separation is available but there is no information on how many trips originate at each origin and how many trips terminate at each destination. These latter two values need to be estimated within the spatial interaction model by surrogate variables such as those described in Table 1. The appropriate spatial interaction model in such a situation is known as an unconstrained model with the following general form:

$$T_{ij} = k\, V_{i1}^{\alpha 1}\, V_{i2}^{\alpha 2} \ldots V_{ip}^{\alpha p}\, W_{j1}^{\lambda 1}\, W_{j2}^{\lambda 2} \ldots W_{jq}^{\lambda q}\, d_{ij}^{\beta} \quad (1)$$

where T_{ij} is the number of trips that begin at origin i and end at destination j, V_i represents an origin attribute that is a surrogate for the number of trips beginning at i, W_j represents a destination attribute that is a surrogate for the number of trips ending at j, and d_{ij} represents the spatial separation (assumed here to be measured by distance) between origin i and destination j.

The number of origin and destination variables included in the model depends on the type of spatial interaction being modeled and the information available. Here the number of origin variables is denoted by p and the number of destination variables is denoted by q. In some situations there might only be one origin attribute and one destination attribute in the model. The parameters α, λ, and β reflect the influence of each of the exogenous variables in the model on the volume of interaction and the values are obtained in the calibration of the model (see below). For example, if V_{i1} were population, it would be expected that $\alpha 1$ would be positive: as the population of an origin increased, a greater volume of interaction would emanate from it, everything else being equal.

Similarly, β would normally be negative: as the distance between any two places increases, the volume of interaction between them decreases, everything else being equal. The exact rate at which interaction decreases or 'decays' as distance increases, is a matter for empirical evaluation. One of the fascinating aspects about spatial interaction modeling is the ability to estimate these parameters in different systems and to compare spatial behavior in different systems and over time. For instance, the value of the distance-decay parameter, β, has been shown to vary across different economic systems, over time, by income group, and by gender (Southworth 1983). Generally, the deterrence of distance for interaction is less in more developed economies and there is a gradual reduction in distance-decay over time as transportation facilities improve and as knowledge about different locations increases. Finally, the parameter k in the model is a scale factor that simply balances the units on both sides of the equation and is of no great behavioral importance.

3.2 The Production-constrained Model

Suppose data on spatial separation *and* on the numbers of trips emanating from each origin are available but there are no data on the number of trips that terminate at each destination. The appropriate spatial

interaction model for this situation is known as a production-constrained model and it has the form:

$$T_{ij} = O_i \frac{W_{j1}^{\lambda 1} W_{j2}^{\lambda 2} \ldots W_{jq}^{\lambda q} d_{ij}^{\beta}}{\sum_j W_{j1}^{\lambda 1} W_{j2}^{\lambda 2} \ldots W_{jq}^{\lambda q} d_{ij}^{\beta}} \quad (2)$$

where O_i is the total number of trips beginning at origin i and it replaces the surrogate origin propulsiveness variables in the unconstrained version. The model essentially distributes the number of trips from an origin in proportion to the relative attractiveness of each destination as measured by the numerator of Eqn. (2). The denominator acts as a constraint on the predicted trips so that

$$\sum_j T_{ij}^* = O_i \text{ for every origin} \quad (3)$$

where T_{ij}^* is the predicted value of T_{ij} from the model. The model is sometimes represented as:

$$T_{ij} = A_i O_i W_{j1}^{\lambda 1} W_{j2}^{\lambda 2} \ldots W_{jq}^{\lambda q} d_{ij}^{\beta} \quad (4)$$

where

$$A_i = [\sum_j W_{j1}^{\lambda 1} W_{j2}^{\lambda 2} \ldots W_{jq}^{\lambda q} d_{ij}^{\beta}]^{-1} \quad (5)$$

Production-constrained forms of spatial interaction models are encountered very frequently, particularly in retailing where estimates of the number of trips leaving each origin can be obtained from census population data. The models are used to discover the characteristics of stores that attract consumers and to predict the proportion of people in each residential neighborhood shopping at each store. Once such a model is calibrated, it can be used to estimate a new store's potential market and its impact on the sales at existing stores. The model can be used to estimate sales at a variety of possible locations to aid in the optimal location of a store. It can also help retailers decide on the optimal strategy to attract more customers to a store. For example, would more customers be attracted to a store if the number of parking spaces were doubled or if price levels were reduced slightly?

3.3 The Attraction-constrained Model

Suppose data on spatial separation and on the numbers of trips terminating at each destination are available but there are no data on the number of trips beginning at each origin. In this case, an attraction-constrained spatial interaction model is the most appropriate form because it uses the known inflow totals into each destination and a set of surrogate variables to represent the total number of trips beginning in each origin. The model has the general form:

$$T_{ij} = D_j \frac{V_{i1}^{\alpha 1} V_{i2}^{\alpha 2} \ldots V_{ip}^{\alpha p} d_{ij}^{\beta}}{\sum_j V_{i1}^{\alpha 1} V_{i2}^{\alpha 2} \ldots V_{ip}^{\alpha p} d_{ij}^{\beta}} \quad (6)$$

where D_j represents the total number of trips terminating at destination j and this replaces the destination attractiveness surrogates in the unconstrained model.

The attraction-constrained model is the complement of the production-constrained model. In this case the model allocates the number of trips terminating at a destination across the various origins in proportion to the relative propulsiveness of each origin as measured by the numerator of Eqn. (6). The denominator again acts as a constraint on the predicted trips but in this case, the constraint is on the number of predicted trips into each destination so that

$$\sum_i T_{ij}^* = D_j \text{ for every destination} \quad (7)$$

where T_{ij}^* again represents the predicted value of T_{ij} from the model. The model can also be represented as:

$$T_{ij} = B_j D_j V_{i1}^{\alpha 1} V_{i2}^{\alpha 2} \ldots V_{ip}^{\alpha p} d_{ij}^{\beta} \quad (8)$$

where

$$B_j = [\sum_i V_{i1}^{\alpha 1} V_{i2}^{\alpha 2} \ldots V_{ip}^{\alpha p} d_{ij}^{\beta}]^{-1} \quad (9)$$

The terms A_i and B_j in the production-constrained and attraction-constrained models are sometimes referred to as 'balancing factors' since they constrain the row and column totals, respectively, of the predicted flow matrix.

Attraction-constrained spatial interaction models are encountered less frequently than production-constrained models but they can be used to estimate the demand for housing in different residential neighborhoods due to the location of a new enterprise. They can also be used to analyze geographic patterns in student enrollments where the total number of students attending a university is known. The attraction-constrained model can then be used to determine the characteristics of places that affect the number of students attending from different origins. The model can also be used in a normative way to derive 'expected' numbers of students enrolling from each origin (the predicted trips from the model) and to compare these expected values with the actual enrollments. This comparison can help identify areas from which the university is drawing more students than expected, given the characteristics of these areas, and areas where it is drawing fewer than expected. The latter could be targeted to increase enrollments. Obviously, this type of application could easily be extended to retailing or any other area where there is competition to attract individuals.

3.4 The Production-attraction Constrained Model (or Doubly Constrained Model)

Suppose data are available on spatial separation, the total number of trips beginning at each origin, *and* the total number of trips terminating at each destination. The appropriate spatial interaction model is then the production-attraction constrained, or doubly constrained, model. This has the form:

$$T_{ij} = A_i\, O_i\, B_j\, D_j\, d_{ij}^{\beta} \tag{10}$$

where

$$A_i = [\textstyle\sum_j B_j\, D_j\, d_{ij}^{\beta}]^{-1} \tag{11}$$

and

$$B_j = [\textstyle\sum_j A_i\, O_i\, d_{ij}^{\beta}]^{-1} \tag{12}$$

The A_i and B_j terms have to be estimated iteratively and they ensure that the constraints in Eqns. (3) and (7) are met.

The doubly constrained model allocates trips to the cells of the flow matrix (the origin-destination links) given row and column totals. It does this solely on the basis of the distance between origins and destinations. Its use has mainly been confined to transportation applications where the total numbers of commuters leaving each residential neighborhood are known and the total numbers of employment opportunities in each destination are also known. What is unknown, and can be predicted from the model, is the distribution of trips between origins and destinations.

4. A Note on Model Calibration

Although a detailed discussion of the nature and methods of calibrating spatial interaction models is beyond the scope of this article, it is worth mentioning very briefly how the parameters in a spatial interaction model might be estimated. For a fuller discussion of the calibration of spatial interaction models, the reader is referred to Fotheringham and O'Kelly (1989).

In order to use a spatial interaction model to answer questions such as those posed in Sect. 1, it is necessary to obtain values for the model's parameters. If the purpose of the model is to obtain information on the way either origin or destination characteristics affect spatial interaction patterns, the model must be calibrated with some known flow data. This is done by finding the values of the parameters that maximize some criterion, such as the accuracy with which the model replicates the known flow pattern. Parameter values that are far from their 'true' values will tend to produce very poor estimates of the flows, while parameters close to their 'true' values will tend to produce more accurate estimates. It is sometimes useful to determine how sensitive a model's predictions are to variations in the parameters used to derive the predictions.

If flow data are not available, model calibration as described above is impossible and 'educated guesses' have to be made for parameter values. This could be done, for example, by surveying the results of previous calibrations of similar models. However, in practice this is fraught with difficulties and should be avoided where possible as it is rare to find exactly the same spatial interaction model with the same combinations of explanatory variables being used in different applications. Also, it appears that the parameters of spatial interaction models are quite context dependent (Meyer and Eagle 1982).

5. Local Forms of Spatial Interaction Models

The forms of spatial interaction models described above are referred to as 'global' models because they provide a single set of parameter estimates for the whole flow system being analyzed. For instance, in each of the above models, a single estimate of distance-decay is obtained when the model is calibrated. In most circumstances, it would be useful to obtain more detailed information on the flow system and to obtain separate distance-decay parameter estimates for each origin in the system or for each destination. This is quite easy to achieve by calibrating what are known as origin-specific models and destination-specific models. An origin-specific form of the production-constrained model given in Eqn. (4) is:

$$T_{ij} = A_i\, O_i\, W_{j1}^{\lambda 1(i)}\, W_{j2}^{\lambda 2(i)} \ldots W_{jq}^{\lambda q(i)}\, d_{ij}^{\beta(i)} \tag{13}$$

where

$$A_i = [\textstyle\sum_j W_{j1}^{\lambda 1(i)}\, W_{j2}^{\lambda 2(i)} \ldots W_{jq}^{\lambda q(i)}\, d_{ij}^{\beta(i)}]^{-1} \tag{14}$$

In this model, each parameter is specific to origin i so that the spatial distribution of a parameter can be mapped to examine any spatial patterns in the behavior represented by that parameter. Interestingly, there is a long history of estimated origin-specific distance-decay parameters exhibiting spatial patterns in which centrally located origins have less negative parameter estimates than peripheral ones (Fotheringham 1981). The interpretation of such a pattern has provoked intense debate at times, but it appears that the distribution is due to a mis-specification bias which can easily be eliminated by the addition of a variable measuring the proximity of a destination to all the other destinations (Fotheringham et al. 2000, chap. 9). The models that result are termed 'competing destinations models' and have been shown to remove the previously observed spatial pattern of origin-specific, distance-decay parameters. Fotheringham and O'Kelly 1989). It is interesting to note that the mis-

specification of spatial interaction models became evident only when local forms of the models were calibrated.

For completeness, a destination-specific form of the attraction-constrained model in Eqn. (8) is:

$$T_{ij} = B_j D_j V_{i1}^{\alpha 1(j)} V_{i2}^{\alpha 2(j)} \ldots V_{ip}^{\alpha p(j)} d_{ij}^{\beta(j)} \qquad (15)$$

where

$$B_j = [\textstyle\sum_i V_{i1}^{\alpha 1(j)} V_{i2}^{\alpha 2(j)} \ldots V_{ip}^{\alpha p(j)} d_{ij}^{\beta(j)}]^{-1} \qquad (16)$$

In this model, parameters are obtained that are specific to each destination *j*.

6. *Theoretical Foundations of Spatial Interaction Models*

Although spatial interaction models generally perform well empirically and are generally assumed to be reasonable statements of spatial behavior, the models have been criticized for not having a sound theoretical base. The 'Holy Grail' of spatial interaction modeling has therefore been to provide a commonly acceptable theoretical derivation of spatial interaction models. Four main frameworks have been postulated for this purpose and in chronological order these are: (a) spatial interaction as *social physics*; (b) spatial interaction as *statistical mechanics*; (c) spatial interaction as *aspatial information processing*; and (d) spatial interaction as *spatial information processing*. It is not the place to describe each of these theoretical frameworks in detail (see Fotheringham et al. 2000, chap. 9, for such a description). However, a very brief discussion is given to demonstrate the progress that has been made in this area and how the modeling framework has moved far away from its original reliance on an analogy to laws of physical gravitation.

Attempts at understanding regularities in patterns of spatial flows began with the observation that the movement of people between cities was analogous to the gravitational attraction between solid bodies. That is, greater numbers of migrants were observed to move between larger cities than smaller ones, *ceteris paribus*, and between cities that were closer together than between cities that were farther apart, *ceteris paribus*. This led to the proposal of a simple mathematical model to predict migration flows between origins and destinations based on the Newtonian gravity model. However, there was no theoretical justification for this form of model until Wilson derived the family of spatial interaction models from entropy-maximizing principles (Wilson 1967). However, this framework, although a catalyst for a great volume of research in spatial interaction modeling, was behaviorally difficult to justify and was superseded by McFadden's random utility maximizing principle (1974). This linked spatial interaction modeling with the process of spatial choice (see *Spatial Choice Models*) although the spatial choice process it depended on was developed for aspatial choice processes and did not always fit well into a spatial context (Fotheringham and O'Kelly 1989). Consequently, the latest theoretical framework in which spatial interaction models have been embedded is that of *spatial* information processing (Fotheringham et al. 2000, chap. 9 1992). This has led to the development of the new forms of spatial interaction models mentioned in Sect. 4 termed 'competing destinations models'.

Spatial interaction models are the products of a spatial theoretical framework that incorporates concepts from economics, such as random utility maximization, and psychology, such as spatial cognition and information processing (see *Spatial Cognition*; *Behavioral Geography*). However, the models describe the constraints of space on important aspects of human behavior and hence are quintessentially geographic.

Spatial Labor Markets

Everyone has seen headlines that report declining or increasing unemployment. If the articles that ensue do not report the unemployment data for distinct regions, the headlines are misleading. The idea that processes leading to unemployment are similar in all regions may be assumed, but it is not tenable. The labor market of a state cannot be thought of as a uniform entity; rather it comprises different spatial entities called spatial labor markets. The concept of a spatial labor market reflects the realities that mobility incurs costs, that information about a national labor market is not equally available everywhere and that people are not always willing to give up their home in order to take up a job where they are needed.

1. *Definition*

A spatial labor market is defined as an imaginary and sometimes also actual meeting place for the supply of and demand for labor. Thus, a spatial labor market is both a spatial entity and a mediation agency for paid work. Or, put another way: a spatial labor market is always both a territorial entity and a social institution that serves to distribute labor across the labor supply.

The dual nature of a spatial labor market can still be seen in many markets that emerge from time to time, as well as in more permanent markets. Markets are both actual meeting places for those offering and seeking goods and institutions that serve to set prices and distribute goods separated from the local and regional context.

2. *How a Spatial Labor Market Works*

From a functional point of view a spatial labor market thus corresponds to the general model of labor markets limited by the spatial range over which supply and demand can intersect and try to satisfy their requirements. It is the friction of distance that creates local and regional labor markets by limiting the spatial range over which supply and demand can intersect.

Nevertheless, the components and the mechanism of the spatial labor market corresponds to that of the nonspatial model. The labor supply offers its readiness to work and its qualifications while seeking to achieve high wages, job security, and career expectations. The labor demand, i.e., business people, entrepreneurs, public bodies, and representatives of all kinds of associations, seek this readiness to work and specific qualifications and endeavor on grounds of costs to pay low wages in return, while promising job security and career expectations only to certain employees. This searching process is accompanied on both 'sides' by organizations that have, through collective agreements, created the framework conditions which markedly shorten the individual negotiation process. For most workers the room for individual negotiations is narrowly restricted by wage agreements arrived at by collective bargaining, minimum wages, and labor laws.

The extent of labor supply and demand is not fixed. The number of people looking for work and in demand depends on many factors. On the supply side, the number of employable people of working age (usually between 15 and 60 years of age) is determined by the size of the population living in the region and its age structure, regardless of whether the people thus defined as 'employable' are in fact seeking work. The number of employable persons is increased directly by permanent, temporary, and pendular migration and natural population trends (fertility and mortality).

The proportion of employable people actually seeking work (workforce), and thus calculable as part of the labor supply, varies greatly. Factors determining whether people are seeking work include educational and professional qualifications, family status, gender, the regional infrastructure, and sociocultural norms. The proportion of people seeking work can be measured by the participation rate. This is obtained by dividing the number of persons employed (or unemployed) by the number of population. Finally, those seeking work offer their labor for a particular period of time, which is dependent on personal preferences and legal norms. In multiplying the labor supply by the period of work offered, it is possible to calculate the total volume of labor offered.

Set against this is the volume of labor demand. This can be calculated from the number of jobs available in a region. This is heavily dependent on the economic situation with an increase in the demand for goods and services tending to lead to an increase in the demand for labor, unless production is increased by new ways of organizing work and technical advances, which lead to a leveling-off in the volume of labor demand. The volume of labor demand is also dependent on the working hours, with a reduction and constant degrees of flexibility in the framework times clearly tending to an increase in demand.

The extent of the supply of and demand for labor is not fixed. On a spatial labor market the volume of labor supply and demand can fluctuate more strongly

Figure 1
Supply and demand at the labor market (after Fassmann and Meusburger 1997)

than on a national labor market. As well as those mentioned above, other factors that come into play are the effects of the varied accessibility of the spatial labor market. Thus, the construction of roads and of rail-borne means of mass transport can affect the accessibility of a spatial labor market and, thus, the labor supply, just as the establishment or transfer of a firm can increase or decrease the demand (Fig. 1).

3. Size and Demarcation of a Spatial Labor Market

There is a consensus that a spatial labor market is based on distance which creates local and regional markets and leads to geographical subdivisions of a nonspatial labor market. To this extent the definition is clear. But it is still not clear how large a spatial labor market is and by what yardsticks and criteria it is demarcated. Two different demarcation approaches are possible.

The first approach involves using given administrative units (or aggregation of administrative units). This means that spatial labor markets can be limited by administrative boundaries. If one asks what is the labor market situation in Munich the answer will contain information on unemployment and employment in the administrative area of the city regardless of the fact that the functional area is much broader. The same is true if, for example, the labor market of old industrial areas, the rural labor market or the urban labor market is in the center of interest. The space is always a homogeneous and not a functional unit.

This contrasts with the prominent position of the functional integration that is found in the second approach to the demarcation of labor markets. The demarcation of a regional labor market depends on the commuter field (Eckey et al. 1990) and thus the accessibility and integration of a labor market center with its own hinterland. This is a common method for defining regional labor markets in the literature and considered the 'best' approach. Self-contained labor market areas, functionally demarcated on the basis of commuter data, would be an ideal model for taking stock of regional labour markets (Bröcker 1988).

Both approaches—the spatial labor market as an administrative (homogeneous) unit respective a functional unit—are overlooking important points. Theoretical and empirical research came to the conclusion that the idea of demarcation of a spatial labor market which is valid for all societal groups and for all times is wrong (Peck 1989, Hanson and Pratt 1995, Fassmann and Meusburger 1997). Spatial labor markets are always time-specific and constructed. Spatial labor markets do not exist as *a priori* territorial entities which require only a suitable analysis to discover, but are socially-constructed spatial entities depending on gender, occupation, and sociocultural norms. The functional labor markets for the male population is significantly different to that of the female, the societal acceptance of commuting to work on a daily or weekly basis over long distances varies from country to country and region to region. An administrative boundary can also change, just like the catchment area of a central location. The transport infrastructure is as significant in the formation of spatial labor markets as are company location decisions and the effect of institutions. The establishment of a large new company or the closure of an existing one can—depending on the analytical criteria— alter decisively the flow of commuters. Similarly, the opening up of previously closed borders and currency fluctuations can quickly redirect commuter flows in border regions. Labor market regions thus defined must therefore be re-examined every few years and possibly redemarcated.

The following is a further principal argument against the method of functional demarcation of a labor market region by the flow of commuters. Commuter data always underestimate the real extent of a regional labor market because commuter data are based on figures for the actual places of residence and work. The fact that someone lives in the commuter catchment area and looks for a job there does not mean, of course, that the person concerned has always lived there. It is equally possible that they migrated from a long distance in order to take up a job. The demarcation of a spatial labor market on the basis of commuter data is not, however, based on the actual place of residence and ignores previous migration. This is of major significance in assessing the extent of a regional labor market.

Another problem in defining a spatial labor market by using commuting data lies in the suggested precision that is, however, not guaranteed. Especially at the margins of a spatial labor market, it is not clear if a small spatial unit belongs to one or the other spatial labor market. For example, when 20 percent of the workforce commutes into one center and 20 percent into another, the classification ceases to be clear.

A continuing and as yet unsolved problem, however, is still the question of the size of a region integrated as a result of spatial interactions. Depending on the research question and the purpose chosen, there exist local, regional, and national labor market centers with corresponding catchment areas. A national labor market can be broken down into regional labor markets and the latter can be further split up into 'subregional' or local labor markets. Precise bound-

aries demarcating where a local labor market becomes a regional one and the yardsticks suitable for defining the regional labor market are lacking. Those that believe that universally-valid demarcation criteria exist are, however, mistaken.

4. Empirical Findings

The difficult question of demarcation should not obstruct the main finding here. Those that would like to distance themselves from the abstract model of the labor market of the economy and move towards a more realistic position are unavoidably approaching the model of a spatial labor market because labor markets are always spatial phenomena and research cannot therefore avoid taking the spatial dimension into consideration.

In any case, empirical surveys have drawn attention to the systematic differences between specific regional labor markets and different types of spatial labor markets. As an example of that one can ask how spatial labor markets are changing when comparing large metropolises, with the medium-sized centers and the rural areas. Some results will be presented (Fassmannn 1993, Fassmann and Meusburger 1997). Analogous to and very closely connected with the idea of central place theory is the distribution of highly qualified and leading positions in the secondary and tertiary sectors. Large towns offer the highest-ranking central services and connected with them a specific range of jobs. Public sector institutions such as ministries, the highest courts, museums, universities, and the head offices of major companies, together with all the service industries connected with them, are located in the respective 'primate cities' of the national network of cities. This phenomenon is being strengthened by the decline of manufacturing jobs. Industrial cities are being transformed into information and services centers with a consequent change in the demand for labor (Table 1).

The wide and attractive range of jobs offered in metropolises has led to a marked increase in employment. In metropolises the proportion of those seeking and taking up work is higher than on other labor markets. Women in particular are attracted by the demand from service industry companies. They benefit particularly from the expansion of the tertiary and quaternary sectors and the transfer and reduction of manufacturing jobs.

With the decline in manufacturing jobs and the dominance by now of highly qualified tertiary and quaternary jobs in central locations, the labor markets of large towns and cities experience an increase in well-paid and highly-qualified workers. Their purchasing power and consumer behavior stimulate the growth of less qualified service industry jobs at the other end of the labor market. Laundries, restaurants, and retail shops with long opening hours make new lifestyles possible and family structures that are growing in number. These phenomena are not found to the same extent in all towns and cities, and depend on the political regulation of the labor market and on the accessibility of cheap and mostly immigrant labor. The tendency appears to be in this direction, however, and was also dealt with thoroughly in the discussion of global cities (Sassen 1994).

The generally attractive range of jobs in large towns does not prevent high unemployment but, paradoxically, contributes to it. Unlike on the labor markets of small towns, old industrial areas, and rural areas the attractive supply of jobs leads to immi-

Table 1
Geographical features of labor markets in relation to the settlement system

Features	Rural areas	Central places	Metropoles
Size of labour	Severe job shortage negative commuter flow	Job surplus balanced commuter flow	Large job surplus positive commuter flow
Unemployment	Moderate to small and seasonal peaks	Tremendous spatial variation (old industrial areas vs. new growth centers)	Relatively high but more polarized
Structure of labour, supply and demand	Low demand, concentration on a few sectors	Varying demand, according to structure of central locations	Varying and polarized demand in manufacturing and services sectors
	Moderate labor supply; especially low female supply	Structure-specific labor supply	High labour supply; through women and immigrants
	Low labor qualifications (industrial labourers, agriculture)	Medium-level qualifications; skilled workers; middle-level white-collar staff	Polarises qualification (specialists and lowly-qualified service workers)

Source: Fassmann 1993

gration, commuter migration, and to high levels of employability among the population which persists even in times of temporary unemployment. Unemployment does not lead to employable people retreating into the reserve army. They continue to actively seek work, but are registered as unemployed.

Characteristic of the urban labor market, therefore, is the wide range of opportunities. For both the highly-qualified and the low-qualified immigrants and natives, men and women, old and young, the cities offer the best chance of finding work. In addition to this, moreover, the chances of changing jobs, of mobility, and social promotion are also greater. In short, the urban-labor market is a career-labor market. To achieve certain positions on the labor market it is almost essential to commute or to move to the urban centers. The 'reward' for this is a labor market open-ended at the top. If there were any truth in the myth that everybody could reach every social stratum, this would apply in the first instance to the urban labor market. As one goes further down the settlement structure to smaller and medium-sized towns, the structural features of the labor market change characteristically.

The number of high-ranking services declines, together with the proportion of highly-qualified and leadership jobs. The employment spectrum becomes narrower and is restricted to a middle-ranking sector. In particular, in those industrial towns not yet affected by internationalization and company transfers, traditional skilled jobs dominate the job structure at the middle level. Compared with the polarized job spectrum of the large towns, that of the small and medium-sized towns is markedly more homogeneous, with fewer highly-qualified jobs but also fewer jobs for the lowly-qualified in the industrial trade and service sectors.

It is women who are affected primarily by the increasing concentration in the number and quality of jobs. They are less often in work and more often drop out of paid work at certain stages of their lives (e.g., after marriage or after childbirth). One result is that they reduce the labor supply and prevent a marked rise in unemployment although there is tremendous variation in this phenomenon across countries. The tendency of leaving the labor market after marriage or after childbirth varies according to sociocultural norms and stages of modernization. A further step down the settlement hierarchy finally leads one to the rural area, which no longer offers any central services for the surrounding area. As a result, the job spectrum is further restricted to just a few sectors: agriculture, the construction industry, tourism, and industrial jobs in wood processing, the production of building materials, textiles, and food. On the whole these tend to be unskilled and poorly paid jobs. Only a small proportion of the population of working age has a job on the local labor market. The locations lack the conditions for higher-ranking and highly qualified jobs. Service industry companies and modern industrial companies that amount to more than just extended workbenches require transport links and the advantages of an agglomeration.

The lack of jobs does not, as might be expected in theory, lead to a constantly high level of unemployment but, on the contrary, to average and in some regions even markedly low levels of unemployment. Part of the labor supply withdraws from the labor market and at first does not even try to find paid work. Women, who cannot undertake long commuter journeys or any journeys at all, because of the lack of childcare facilities, give up looking for work. This decision is easier when wage levels are low and compare unfavorably with the costs of commuting and childcare. In addition women take on minor and part-time activities or withdraw into unpaid housework.

Those wishing to have a career and attend a higher level school or university and then look for a suitable job at the end of their educational training must commute or leave the area, because in rural areas qualified jobs are in short supply. The establishment of school centers in rural areas has changed this situation only to a limited extent and sometimes has even been counterproductive. Those graduates not finding a job teaching in their hometown have to move or be satisfied with a job below their qualifications. Establishing school centers without creating new jobs has therefore often led to an erosion of qualifications in rural areas and can thus to be seen as a failure of regional policy.

5. *Conclusion*

The demarcation and analyses of spatial labor markets leads to a differentiated and more realistic picture of the dynamic and structures of a national labor market. Trends observed in recent years on the labor market differ fundamentally from those on the labor markets in metropolises, old industrial areas, rural areas, peripheral border areas, and in the suburbs. In each case there are considerable differences regarding those population groups which were unemployed, and to what extent, and which groups found work or were forced out of active life into the silent reserve army. This draws attention to the need for a regional labor market policy that takes account of the specific causes of unemployment, underemployment and wage differentials among regions, while seeking solutions that are spatially acceptable.

Spatial Memory Loss of Normal Aging: Animal Models and Neural Mechanisms

This article will consider the effects of normal, age-related changes on certain forms of memory. The term 'normal aging' is used to refer to developmental processes that are expected to occur in organisms near the end of their lifespan. Alzheimer's disease and other neuropathological conditions in humans, for example, are not 'normal' or inevitable parts of the aging process, and thus are not considered here. The focus here will be on the identification of brain changes responsible for age-related learning and memory changes, which can be understood by examining any number of mammalian species. The motivation for this approach is ultimately the development of methods that can attenuate age-associated cognitive decline, thereby improving life quality of the elderly.

1. *The Hippocampus as a Model Brain Structure in which to Study Age-related Memory Deficits*

The way in which new events are learned and remembered changes over the lifespan. A great deal of research on learning and memory has focused on the hippocampus (Fig. 1), a structure implicated in these processes (see *Memory and Aging, Neural Basis of*). O'Keefe and Nadel (1978) proposed that the hippocampus functions as a cognitive map, and, in all mammals studied to date, optimal functioning of this structure is required for acquisition of the spatial knowledge required for effective navigation. The hippocampus is likely to participate in more than just spatial memory, but its role in spatial memory is emphasized here to constrain the topic of review (Squire 1992). It is certainly the case that in either humans or rats, extensive hippocampal damage prevents formation of new spatial maps that allow accurate large-scale navigation. It is these types of observations that suggest that the computation the hippocampal system performs is likely to be conserved across mammals.

Figure 1
Coronal section through the rat hippocampus showing CA1 and CA3 pyramidal cell layers as well as the granule cell layer of the fascia dentata (FD)

1.1 *Changes in Navigational Behaviors in Normal Aging*

The acquisition of new spatial information is defective in old humans, old monkeys, and old rats. For example, Newman and Kaszniak (2000) tested healthy younger and older adults' ability to accurately locate a pole in relation to multiple cues present in a large tent-like environment. The older adults were not as accurate as were younger adults in placing the pole in the correct position, suggesting a difference in spatial knowledge between groups. Rapp et al. (1997) tested young and old monkeys in an eight-choice foraging task in which reward could be obtained only once at any location by the monkey. When the spatial memory demands of the task were made more difficult by imposing greater delays between choices, older monkeys became increasingly impaired. For rats, the circular platform task has been used to test spatial navigation ability. The object of the task is to navigate to the one place where it is possible to enter a dark chamber away from the brightly-lit open surface of the platform. The

consistent finding is that old rats do not remember this preferred dark chamber location from day to day as well as do younger rats (Barnes 1979). Taken together, the observations suggest that older mammals remember spatial information less accurately than do their young counterparts, and most often these spatial memory problems can be separated from other age-related sensory changes that might have a negative impact on performance.

2. *Changes in Hippocampal Connectivity and Functional Responsiveness*

Because normal aging results in hippocampal-dependent memory changes, changes in hippocampal structure and function over the lifespan might also be expected. In general, however, there appears to be rather little change in cell numbers, and only rather subtle and region-specific changes in cell function.

2.1 *Preservation of Hippocampal Cell Numbers and Function*

In contrast with some earlier anatomical studies, modern stereological cell counting methods have revealed no significant numerical differences in the major cell types within the hippocampus across the lifespan of humans (West 1993), monkeys, or rats. Similarly, studies of basic cellular neurophysiology suggest that the biophysical properties of hippocampal cells are largely preserved across the lifespan. This includes measurements such as membrane potential, cell input resistance, action potential heights, and membrane time constants measured *in vitro*, as well as average spontaneous cell firing rates measured in the awake, behaving state. Thus, normal aging does not result in widespread cell loss, or deterioration in cell viability and function (Barnes 1994).

Figure 2
Schematic of age-related changes in granule cells of the fascia dentata (FD) and pyramidal cells in CA1 of rat hippocampus. Old rats show fewer axon collaterals and synapses, but those synapses that remain are more powerful in FD. In CA1 old rats show fewer synapses, but no change in synaptic strength

2.2 *Specific Age-related Hippocampal Structural and Functional Changes*

The age-related changes that do occur appear to be in connectivity and functional responsiveness, and the pattern of change is specific to the region examined. For example, from anatomy we know that there are fewer synaptic contacts from the main source of input to granule cells of the hippocampus (Fig. 1) from the entorhinal cortex (Geinisman et al. 1995, Fig. 2). From electrophysiology we know that there is pruning of these axons; however, the synaptic contacts that remain in old rats are more powerful (Barnes 1994, Fig. 2). This change in synaptic strength appears to help keep the probability of granule cell output relatively constant, in spite of the extensive deafferentation, and suggests a compensatory process at this synapse during aging. By contrast, in adjacent hippocampal regions to the granule cells (CA3 and CA1 in Fig. 1) there is no pruning of CA3 pyramidal cell axons that project to the pyramidal cells of CA1 (Fig. 2). The anatomy and physiology suggest that there are, however, fewer functional contacts per axonal branch in old rats. Interestingly, the efficacy of these individual synaptic contacts in CA1 does not change with age (Fig. 2), suggesting that functional compensation is not an obligatory process in response to age-related deteriorative change (Barnes 1994), but occurs selectively at only certain connections.

3. *How Does Aging Affect the Plasticity Characteristics of the Hippocampus?*

The changes in connectivity and cellular function during aging discussed above could impact the way in which information is stored in the hippocampal network. Hebb (1949) was among the earliest to propose that synaptic modification must take place during the acquisition and storage of associative memories. Modification of this type was described at the perforant path—granule cell synapse in the hippocampus by Bliss and Lomo (1973) and McNaughton et al. (1978) verified that it was, indeed, an associative process. Since that time an enormous body of empirical work has arisen describing the physiology, pharmacology, and molecular biology underlying this process known as long-term potentia-

tion (or LTP). Although there is no direct proof that LTP induced artificially at synapses in the brain reflects the process the nervous system normally uses to store information, there is a wide range of evidence consistent with this hypothesis. Thus, it has been important to examine the effect of normal aging on this process.

3.1 Hippocampal Plasticity Deficits in Aging

Although LTP can be robustly induced at synapses in the aging hippocampus (Landfield et al. 1977), such modification is more difficult to achieve in older rats. The factors contributing to these age-related changes include synapse sparsity, reduced glutamate receptor numbers, and reduced temporal summation of incoming input. Even if equivalent LTP induction levels are achieved, LTP can *decay* faster in old rats (Barnes 1979). Furthermore, processes that decrease synaptic efficacy, such as LTP reversal and long-term depression, are *more* effective in older animals (Norris et al. 1996) Importantly, the decay rate of LTP in hippocampus of rats correlates with spatial memory accuracy on the circular platform task, that is, old rats with the fastest decaying LTP also show the poorest retention of spatial information. These data suggest that the most promising candidate mechanism for information storage in the nervous system is compromised in old rats. Furthermore, the data suggest that if we understood the mechanism of faster decay of LTP, one might better understand why older animals show faster forgetting. In fact, a number of laboratories are investigating pharmacological interventions for extending LTP decay rates, in an effort to modify forgetting rates in aging.

4. How Do Changes in Plasticity Mechanisms Impact the Information Processing Characteristics of Hippocamal Ensembles?

It has recently become possible to record significant numbers of single hippocampal cells simultaneously when rats are awake, and free to behave (Wilson and McNaughton 1993). With this type of electrophysiological recording, the firing patterns of ensembles of cells are monitored without the use of artificial stimulation. Rather, cell firing occurs in response to the animal's behavior and sensory input, and thus provides a complementary window for viewing experience-dependent changes in brain function. Single cells in the hippocampus increase their firing rates when an animal is in a particular place within an environment, which is why O'Keefe first called these cells *place cells* (O'Keefe and Dostrovsky 1971). The area of space over which a given cell fires is called the cell's *place field*, and the firing pattern of many cells over a given environment is hypothesized to represent a cognitive map of that environment (O'Keefe and Nadel 1978). In fact, it is possible to reconstruct the animal's location, simply from knowing the pattern of hippocampal cell activity (Wilson and McNaughton 1993). These place field distributions are commonly referred to as *maps*. With repeated exposure to an environment, it is hypothesized that these maps can become stabilized and bound to features of the environment as a consequence of LTP at the synapses conveying external sensory information to the hippocampus. Such binding could help ensure accurate map retrieval. Two main findings from age comparisons using ensemble recording methods are discussed below, both suggesting ways in which faulty LTP mechanisms may impact the information processing characteristics of hippocampal ensembles.

4.1 Experience-dependent Place Field Expansion Deficits in Aging

There is a plastic change in the pattern of place cell discharge characteristics that occurs as a consequence of experience, strongly suggesting that synaptic modification is taking place in the system. This empirical observation was predicted by theoretical considerations of route learning, the fundamental idea for which goes back to Hebb's ideas on phase sequences, or linked cell assemblies. The LTP mechanism has an intrinsic asymmetry that predicts that an expansion of place fields should occur with repeated traversal of a given route. Such place field expansion, and a shift in the center of mass of place fields towards the origin of a route, has been verified experimentally (Mehta et al. 1997). Moreover, glutamate receptor blockade that blocks LTP induction also blocks this experience-dependent place field expansion effect. Because LTP mechanisms are disrupted in old rats, it was predicted that normal aging may alter place field expansion. This was confirmed by Shen et al. (1997) who showed that the expansion of place field size that occurs in young rats after a few traversals of a route is much less robust in old rats. The deficit in experience-dependent place field expansion in old rats is consistent with the likelihood of a failure of effective LTP mechanisms in these old animals.

4.2 Map Retrieval Deficits in Aging

Another example of how deficits in hippocampal synaptic plasticity may impact spatial cognition can be illustrated by a comparison of hippocampal map retrieval in young and old rats. When ensembles of hippocampal cells are recorded in young rats, different place cells fire selectively in the environment through which the rat moves. If the young rat is removed from a familiar environment, and then brought back later to

Figure 3
The firing of different hippocampal cells are shown in different colors, only a few of the simultaneously recorded cells are plotted for clarity. This illustrates hippocampal map retrieval accuracy on a triangular maze in a young rat on two different recording sessions, and a map retrieval error between sessions in an old rat

the same room, the same place field distribution, or same map, is retrieved at this later time (Fig. 3). On about two thirds of occasions when old rats are removed and returned to the same familiar room, they retrieve the same map, just like young rats. About one third of the time, however, a different place field distribution appears, as though the old rat had failed to retrieve the original map (Fig. 3). Thus, possibly because of a deficient binding to environmental cues or weak associative connections within the map itself, when old rats come back to the same situation a completely different pattern of cell activity can emerge (Barnes et al. 1997). This may well be associated with a place recognition failure. In addition to the map retrieval deficits described above, Tanila et al. (1997) have also shown that memory-impaired old rats do not create new maps as readily as do young rats when features are changed in an environment. Thus, it seems possible that altered LTP-like plasticity mechanisms may be partly responsible for the greater tendency of old organisms to become lost.

5. *Conclusions*

At the cellular level, normal aging leads to changes in hippocampal connectivity and plasticity mechanisms that are specific to different subregions, but leaves many biophysical parameters of neurons relatively unaffected. At the system level, aging also leads to changes in hippocampal network dynamics that result in nonlinear failures in information retrieval. These age-related changes in brain structure and function are likely to contribute to moderate, but clear changes in spatial learning and memory observed during normal aging.

Spatial Mismatch

Spatial mismatch describes a broad set of geographical barriers to employment that stem from a disparity, or mismatch, between where people live and where appropriate job opportunities are located. A more specific form of spatial mismatch, the *spatial mismatch*

hypothesis (SMH), argues that the combined effects of residential segregation and economic restructuring limit geographical access to employment opportunities for black, inner-city residents. This article emphasizes geographical dimensions of the SMH, highlighting the changing spatial distributions of residences and job opportunities in cities, the measurement of geographical separation between the two, the sociospatial processes that underpin spatial mismatch, and policy implications.

Spatial mismatch is a historically specific concept that emerged in the 1960s amid widespread concern about racial discrimination and urban poverty. Although he never used the term 'spatial mismatch,' John Kain (1968) introduced the concept in analyzing the combined effects of residential segregation in housing markets and the postwar suburbanization of jobs on black unemployment. Poor geographical access to jobs, especially jobs in manufacturing, was said 'to reduce employment opportunities of Negroes who are already handicapped by employer discrimination and low levels of education' (p. 196). Although some subsequent researchers have defined spatial mismatch in narrow geographical terms, as long distances to jobs or small numbers of locally available jobs, Kain's research was notable in exploring the intersections between spatial and social barriers to employment. He considered how transportation access, employer discrimination, skills, and social networks affect workers' access to employment. These themes continue to the present in the SMH literature.

Kain's research stimulated discussion and debate during the early 1970s. After that, the field languished for a decade until William Julius Wilson's research on the urban underclass brought spatial mismatch back to the forefront (Wilson 1987). Since then the SMH has attracted research attention in a wide range of social science disciplines.

1. *Evidence of Spatial Mismatch*

The great appeal of the SMH is that it connects two prominent features of postwar American cities: the strong segregation of residential areas by race and ethnicity and the movement of jobs, especially jobs in manufacturing, to the suburbs and overseas. But do these processes necessarily result in spatial mismatch? Many central cities are losing employment, but they are also losing population (Stoll 1999). Thus, the balance of jobs to resident workers has remained relatively constant. Although the SMH emphasizes city–suburban differences, finer-grained patterns of residential and work location are much more relevant to job access. Cities and suburbs are not homogeneous; within each, African-Americans and other minorities are concentrated in a few areas.

Research using diverse indicators of geographical access to employment, in a variety of US cities, finds support for the SMH at the localized, intra-urban scale. Within central cities, black neighborhoods generally have a lower ratio of jobs to resident workers than do white neighborhoods, though the findings are highly sensitive to the geographical areas considered (Holzer 1991). A better approach is to examine the availability of jobs within a reasonable commuting radius. Research in cities like Chicago and San Francisco finds that blacks are less likely to work in their local neighborhoods than are comparable whites, and that the density of job opportunities is lower in and near predominately black neighborhoods (Ihlanfeldt and Sjoquist 1998).

In the 1990s researchers have started to combine the power of geographic information systems with detailed urban databases to compute new measures of employment accessibility (Ong and Blumenberg 1998). Transportation routes and physical and social barriers to movement can be layered together to describe the influences on travel and interaction patterns.

Spatial mismatch is also apparent in commuting times and flows. African-American workers have longer commute times on average than do comparable white workers, and the differences persist after controlling for wages, mode of transportation and personal and household characteristics (McLafferty and Preston 1996). Black workers are also more likely to have 'constrained' work trips that involve long travel times to low-wage jobs (Johnston-Anumonwo 1997). The propensity to work in one's local neighborhood—local working—is also low in black neighborhoods (Immergluck 1998). Spatial mismatch, then, is evident in long work trips to jobs that provide little economic return.

Although the time and cost of commuting are important in their own right, they have several limitations as measures of spatial mismatch. By definition, the measures are only based on a selected group, namely, employed workers. This 'selection bias' implies that commuting indicators may not accurately represent geographical barriers to employment for the unemployed (Cooke and Ross 1999). One way to address this problem is to analyse changes through time as people and jobs move away from central city locations. Case studies reveal that when firms move to the suburbs, black workers are more likely to quit and less likely to relocate in order to gain access to a new suburban work site than are comparable white workers (Ihlanfeldt and Sjoquist 1998). Black workers are more fixed in their residential locations, indicating the long-lasting effects of racial segregation and discrimination.

There are also problems in interpreting commuting patterns. Do long work trips reflect individual choices to travel further for high-wage, high-quality employment, or do geographical constraints compel long work trips? Many commuting decisions result from a complex mix of choice and constraints, as people juggle personal and family needs within the spatial and

social bounds of daily life (Gilbert 1998, Hanson and Pratt 1995). These choices and constraints vary between men and women, highlighting the importance of gender in the SMH.

Attention is turning to the role of place in spatial mismatch and the important variations in spatial mismatch within and among cities (Holloway 1998). In the USA, spatial mismatch is primarily a large-city phenomenon that is most evident in cities like New York, Chicago, Atlanta, and Los Angeles. It is also more apparent in the 'rustbelt' cities of the Northeast and Midwest where economic restructuring and suburbanization are in full force (Ihlanfeldt and Sjoquist 1998). Little has been written about spatial mismatch in racially and ethnically diverse cities outside the USA, although there are hints of mismatch in cities like London and Berlin where ethnic minority populations cluster in areas of limited job opportunity.

2. *Spatial Mismatch and Labor Market Processes*

Spatial mismatch is rooted in the social, economic, and spatial processes that shape urban labor markets. These influence where people and firms locate, the channeling of workers into certain types of occupations, workers' ability to search for and commute to job opportunities, and firms' willingness to hire workers. Connecting spatial mismatch to employment outcomes requires an understanding of labor market processes, as well as an understanding of the changing geographical patterns of firms and people.

Urban labor markets are strongly differentiated according to gender, race, ethnicity, and class. This labor market segmentation concentrates blacks and Latinos in a narrow set of occupations, and the particular occupations vary with gender. Historically black men worked as laborers, in transportation, manufacturing, and certain service occupations, whereas black women were concentrated in domestic service. Although these occupations have changed over time, there continues to be strong segmentation by race and gender. Segmentation implies that groups of workers face different sets of potential job opportunities that are unevenly distributed within metropolitan areas. Thus, the spatial mismatch may vary by gender, race, or class. Researchers have only begun to tease out the interactions between segmentation and spatial mismatch (Wyly 1996). For example, despite their different occupations, black men and women face similar spatial mismatch barriers in urban labor markets (McLafferty and Preston 1996).

Some labor market segmentation results from differences in education and skills that coincide, in some cases, with racial and ethnic divisions. The skills mismatch refers to the gap between the education and skill levels of inner-city residents and the requirements of available jobs. The transformation from a goods-producing to a service-producing economy is causing a loss of low-skill, manufacturing jobs from central cities, while the emerging 'information economy' demands a highly educated workforce. Poverty, poor quality schools, and social dislocations limit educational achievement in the inner city, resulting in the skills mismatch. The spatial and skills mismatches position workers and jobs in intersecting social and geographical spaces to limit employment opportunities for innercity residents.

Transportation is a crucial factor in spatial mismatch, influencing the ease and cost of overcoming distance in traveling to work. American cities are built around the automobile, the most flexible mode of transportation and the one that offers access to the widest geographical range of job opportunities. In contrast, travel by public transit is slow and limited to fixed routes and schedules. For inner-city residents, the hub and spoke design of most mass transit systems is poorly structured for travel to suburban job centers. Because blacks and Latinos have low rates of car ownership and licensing, they are much more dependent on public transit than are their white counterparts. Transit dependence affects all aspects of employment including job search and access to suburban jobs, and it is the single most important determinant of minority workers' long commute times. Some argue that this 'automobile mismatch' is a more serious problem than the spatial mismatch (Taylor and Ong 1995).

The process of spatial job search is also important to the SMH. People often search for jobs near their homes. As distance from the home increases, information about nearby job opportunities decreases and the costs of job search rise. Research indicates that blacks' and Latinos' job search patterns are centered upon their homes, and they tend to search in fewer areas and areas with weaker employment growth than do comparable whites (Stoll and Raphael 2000). Social networks play a key part in spatial job search. Racial and ethnic minorities rely heavily on family and friends for finding employment. For low-income, low-skill workers this may lead to job search in areas of low job growth and poor quality jobs, thus aggravating the spatial mismatch.

3. *Impacts of Spatial Mismatch*

Spatial mismatch affects peoples' lives in diverse ways. The SMH emphasizes the effects on poverty and unemployment and low incomes, but the empirical record is mixed. Perhaps the strongest support for the SMH comes from research on minority youth. For this group, unemployment is strongly correlated with

the average travel time to the types of jobs that youth normally hold and youths' proximity to areas of employment growth (Ihlanfeldt 1992). Minority youth who face long travel times or distances to areas of employment opportunity are much more likely to be unemployed. Looking beyond youth, research among vulnerable populations such as welfare recipients reveals that unemployment is highly sensitive to the concentration of low-wage jobs nearby (Ong and Blumenberg 1998). A 1998 review of the spatial mismatch literature concludes that the vast majority of recent studies support the SMH, and 'the lack of geographical access to employment is an important factor in explaining labor market outcomes' (Ihlanfeldt and Sjoquist 1998, p. 881).

Others follow Ellwood (1986) in arguing that 'race, not space' (p. 181) is the main determinant of poor labor market outcomes. Racial discrimination permeates urban labor markets in the United States, reducing minority employment irrespective of geographical access to jobs. Racial discrimination is often rooted in place, as firms avoid hiring workers from inner-city, minority communities, or use far-flung, racially-biased social networks in attracting employees (Kasinitz and Rosenberg 1996). Critics of the SMH point to examples where high unemployment and dense job opportunities exist side by side. The challenge in examining 'race versus space' is that the two are deeply intertwined: Race *is* space in the USA. Kain (1968) recognized this in the original formulation of the SMH, noting the impacts of racial discrimination by employers and discrimination in housing markets on geographical access to employment. Attempts at disentangling the effects of race and space find that both have large and significant effects on employment outcomes (Stoll 1999).

The implications of spatial mismatch beyond labor markets are discussed in Wilson's path-breaking work on the urban underclass (Wilson 1987, Wilson 1996). Wilson starts with spatial mismatch and economic restructuring and weaves a rich tapestry that includes the effects on male unemployment, marriage, household structure, and the implications for an array of social issues such as crime, migration, local institutions, and educational achievement. As jobs move away and incomes decline, the ties that bind communities, households, and institutions start to disintegrate. Spatial mismatch is not the only cause of these changes, but it is an important piece of the puzzle.

4. *Spatial Mismatch and Urban Policy*

Despite differences of opinion about the SMH, it has played an important role in urban policy formulation for several decades. Policies to address spatial mismatch involve efforts to bring people and jobs closer together or to improve the connections between them. Three general types of policy have been suggested. First, 'economic development' policies aim at creating jobs in inner-city areas. These place-based policies include public works programs and the provision of subsidies, training programs, and infrastructure to attract new industries to inner-city areas. The policies go by various names—the current incarnation is 'enterprise zones'—and they have had limited success. Many have failed to generate sustained, long-term employment because they did not alter the profitability of inner-city locations and benefits leaked out from inner-city neighborhoods to other areas.

Second, 'dispersal' policies aim at facilitating the movement of people to job-rich suburban areas. These strategies focus on the housing market and include the vigorous enforcement of fair housing laws, the development of public housing in suburban areas, and the provision of subsidies to help inner-city residents move to the suburbs. A good example of the latter is the Gautreaux program in Chicago, which offered housing subsidies to residents of public housing who wanted to move to the suburbs. A careful comparison of movers and stayers showed significant gains in employment for those who moved to the suburbs (Popkin et al. 1993).

Third, 'mobility' strategies emphasize improving inner-city residents' access to suburban job opportunities, rather than changing the locations of jobs or residences. Included here are improvements in public transit to facilitate reverse commuting, creation of car pools and van pools, employer-sponsored transportation from inner-city areas to job sites, and efforts to improve car ownership among the poor. Such policies have immediate and obvious benefits; however, they have never been implemented on a large scale. Also, the most effective mix of policies varies among cities depending on the density of urban development and the availability of transportation infrastructure.

After decades of experimentation, most analysts agree on the need for multipronged approaches that are sensitive to the particularities of place and context. Furthermore, there is general agreement that spatial mismatch cannot be isolated from the constellation of forces that affect poverty and unemployment. Breaking down the barriers of racial discrimination in job and housing markets, and improving health, housing, and education in disadvantaged communities could make spatial mismatch irrelevant in the long run.

Looking ahead, the historical specificity of the SMH highlights the fact that spatial mismatch is not a characteristic of particular locations but of particular places where people are disadvantaged based on a combination of race, ethnicity, class, and poor geographical access to work. Changing patterns of urban development, including the gentrification of inner-city neighborhoods, the growth of poverty in the suburbs, and evolving patterns of employment opportunity

mean that spatial mismatch is perpetually recast. Today's suburbs may become tomorrow's 'inner cities' as urbanization redefines spatial mismatch.

Spatial Optimization Models

The concept of spatial optimization is quite simple. This topic involves identifying how land use and activities should be allocated and arranged spatially in order to optimize efficiency or some other measure of goodness. For example, how should fire protection resources be distributed across a city in order to maximize protection? How do we design a system of reserve lands that can ensure the survival of an endangered species? How should an area be divided into school attendance zones? These are but a few examples of spatial design problems. For each type of design problem there can be numerous if not an infinite number of alternative configurations or solutions. Optimization involves the attempt to identify the best of the alternatives. Simply put, spatial optimization is the science of optimal arrangement. The use of spatial optimization is growing due to the existence of better spatial data, the emergence of powerful geographic information systems, decreasing costs of computation, and better computer graphics and solution algorithms.

At first we might think that such a topic is futuristic, cutting edge. Actually, spatial optimization is a geographical problem that is as old as mankind. For example, hunters and gatherers had to decide how to allocate their efforts in collecting foodstuffs, moving encampments, etc. Such societies needed to be efficient in order to survive. Anthropologists and geographers have used optimization to analyze the efficiency of these early societies (see, for example, Van Reidhead (1979), Keene (1979), Church and Bell (1988)). Even the ancient Chinese art of Feng Shui deals with the arrangement of activities in order to be in a harmonious state. Just as we are interested in how spatial arrangements evolved in the past, we are equally interested in how future patterns of activities should be designed. For example, just where should that new store be located? Where should a dealer

provide service facilities for their products? How should a network of warehouses be designed and operated in order to supply a number of retail locations? Such questions are but the tip of the 'iceberg' of possible spatial location/allocation problems.

As with all geographic problems, the temporal domain is important. For example, between 1990 and 1998 Broward County, FL, located 15 new schools and operated up to 2,000 portable classrooms in order to cope with a growing school population. This means that school boundaries have been frequently adjusted and school capacities are often expanded with portable classrooms in order to cope with increasing enrollment. One of the major objectives in planning new schools and creating attendance areas is to plan an expansion that involves the least disruption of students and school reassignments (Lemberg and Church 2000). In a different example, to meet the fluctuations in daily emergency '911' call demand in San Diego County, CA, American Medical Response operates between two and 24 ambulances during each day. Posting ambulances at various locations and dispatching them over time is a complicated logistical/spatial optimization problem. Rest assured that the patterns of deployment vary over the day in order to reduce response times, but just where should such posts be located to get the most service out of a limited number of vehicles? Since it costs over $500,000 per year to keep an ambulance in operation, it is important to find an efficient service plan.

Geographic scale is an equally important issue in spatial optimization. There are typically three basic scales in spatial optimization problems: micro, meso, and macro. The macroscaled problem involves the highest level or area size (i.e., smallest map scale). At such a level, we might ask: 'in which cities should we have factories or warehouses?' We generally use no specific site information in making such a selection. Interactions between customers and facilities are modeled at an aggregated level. The objective is to identify those areas in which it makes the most sense to open a facility or activity. Such a decision might be considered 'strategic.' If we have a strategic plan to locate a regional warehouse in Reno, NV, the 'meso' level question is 'where in Reno should it be.' Such a problem would involve identifying the best available site, considering a wide range of criteria. This is a type of 'tactical' decision making and is often performed to support a strategic decision. Once we have a site or a place the microscaled problem involves carving up that space and allocating it into specific activities. For example, we may allocate store space to specific retail items or a shop floor to machine tools. Even malls are arranged spatially in order to take advantage of anchor stores and walking patterns (Bean et al. 1988). How people use such facilities and interact with their environment is an especially important aspect of this problem (Underhill 1999). In the industrial engineering literature, this type of problem is often referred to as a layout problem. Microscaled problems are akin to an 'operational level' problem.

1. *Historical Roots of Spatial Optimization*

Efficient land use activity was first discussed by Von Thunen (1842) when he described how agricultural activities including wood lots should be optimally arranged around an isolated village. Primary industries such as forestry now use spatial optimization to identify how each stand (tree type and age class) is to be managed over time. These management plans include the building of roads, the provision of environmental standards, and the return on investment (Church et al. 1998). In Chile, forest companies optimize nearly every feature of their industry, including the scheduling and routing of vehicles for log transport (so that logs arrive when just needed at loading facilities such as ports), the placement of harvest towers and cable ways for steep slope harvesting, and the minimization of land devoted to unproductive elements (e.g., roads). The US Forest Service has utilized a spatial optimization model called Forplan (and its successor SPECTRUM) for the last three decades in developing management plans (Kent et al. 1990) for virtually every national forest in the US.

Alfred Weber proposed one of the earliest industrial location models in 1908 (Wesolowsky 1993). As a simple example, he described the location of a manufacturing point between two localized raw materials and a market. He considered that the three points could be plotted on a Cartesian plane as shown in Fig. 1. Transport distances between the points were assumed to be Euclidean. Weber discussed how, under certain assumptions, the ideal location was the one that minimized transport costs of the raw materials to the manufacturing point and the product to market. Weber showed how this model could be solved geometrically for certain problems. The first optimal solution for the more generalized Weber model involving many markets and raw materials was developed in 1937 by Weisfeld and reinvented by Kuhn and Kuenne and Cooper in the 1960s (Wesolowsky 1993). Cooper subsequently proposed an extended model involving the location of multiple facilities. The multifacility Weber problem can now be solved optimally for only those problems involving less than 100 points.

In 1933 Walter Christaller (1966) wrote: 'Just as there are laws which determine the life of the economy, there are special economic-geographic laws determining the arrangement of towns.' Christaller attempted to find the laws that determined the number, size, and distribution of towns in a region of Southern Germany. Since that time geographers, archaeologists, and anthropologists have searched for Christaller's central place patterns in other regions and in other

Figure 1
The classic Weber location triangle

applications, and have developed spatial optimization models that solve for the optimal spatial arrangement of towns and markets (Kuby 1989, Storbeck 1990). Virtually all early location theories have some type of spatial optimization counterpart today.

2. *Selected Examples of Spatial Optimization*

A large number of spatial design/arrangement/allocation problems have been approached using some form of optimization modeling. Techniques used to solve optimization models are typically found in the operations research (OR) literature. The field of OR traces its roots to World War Two and the need to solve large scale military logistics problems. One of the first OR models that was developed and can be solved optimally was the classical transportation problem. This problem involves a distributed set of supply points (called sources) and a distributed set of demand locations (called sinks). Each source has a finite capacity to supply a good and each destination has a specified amount of demand for that good that needs to be met. Between each unique pair of one source and one sink we can identify the most efficient route and

Table 1
Examples of spatial optimization problems

Problem name	Problem definition	General reference
Corridor location problem	Across a landscape, identify the optimal route for a right-of-way for a facility such as a pipeline, highway, or power transmission line that connects an origin and destination	Smith et al. 1989 Goodchild 1977 Lombard and Church 1993
Vehicle routing problem	Optimally route a vehicle from a starting point to visit a number of pre-specified locations and then return to the starting point.	Bodin 1990 Weigel and Cao 1999
Classical transportation problem	Allocate limited supplies at different locations to a number of spatially distributed demand points in such a manner as to minimize transportation costs of serving all demand	Yeates 1963 Camm et al. 1997
Simple plant location problem	Locate a set of facilities and allocate their supplies to demand points in such a manner as to minimize facility and transportation costs	Love et al. 1988
p-Median location problem	Locate p-facilities so that the total weighted distance of serving all demand is minimized	ReVelle and Swain 1970
Maximal covering location problem	Locate p-facilities so that the largest proportion of demand is covered or served within some maximal distance or time	Church and ReVelle 1974 Schilling et al. 1993
p-Hub location problem	Locate p-transportation hubs and allocate demand to specific hubs in such a manner as to minimize total transportation costs	O'Kelly and Miller 1994
Site configuration/design problem	Identify the best set of parcels or land units that optimizes costs and meets shape, contiguity, size, and suitability constraints	Wright et al. 1983 Cova and Church 2000
Districting problem	Partition spatial units into a set of districts that optimize one or more criteria; examples, school districts, political districts, etc.	Woodall et al. 1980 Lemberg and Church 2000
Spatial allocation problem	Allocate specific activities to defined spatial units	Hof and Bevers 1998

the cost to ship one unit of that good between the source-sink pair. The objective of the classical transportation problem is to allocate the supplies to the demands so that the total transport cost is minimized and the demand at each sink is met. Garrison (1959) was the first geographer to discuss the utility of the transportation problem as a model to analyze spatial structure. Yeates (1963) and others have since used this spatial optimization model to analyze efficiency of an existing arrangement or to develop an optimal transportation plan.

Table 1 gives a representative sample of spatial optimization problems that can be found in the literature, including the classical transportation problem. The list includes vehicle routing, districting, transportation, facility location, site search, and space allocation. For each of the 10 problems listed, the name, definition, and a few references are given. For each of these generic problems, a number of models have been developed. The references cite the original work, a review, or a recent work that contains an up-to-date list of references. All of the problems listed in

Table 1, with the exception of the corridor location problem and the classical transportation problem, have a problem complexity that is called NP (Non-deterministic Polynomial). The class NP refers to a set of problems for which there exists virtually no chance that procedures will be found which can solve all problems optimally within a reasonable computational time on a computer. One of the reasons for this is that these problems require the use of integer programming, an area of optimization that can be both computational intensive and limited in terms of the size of an individual application that can be solved optimally.

Because of this fact, it is common to see that different techniques are used for solving specific models and that heuristics are needed for most moderate to large sized problems. Heuristics are specialized solution procedures that are designed to approach problem solving using either a set of rules or some search strategy. An example of a heuristic is given in the next section.

3. *A Detailed View of a Spatial Optimization Problem*

Hakimi (1965) proposed a network location model called the p-median problem. Consider the network depicted in Fig. 2. Each node is connected to other nodes by arcs of given distances. Without any loss of generality, consider that each node represents a potential facility site as well as a point of demand. The measure of demand is represented as a demand weight (in units of people, tons, trips, or some other measure of need to be supplied by a facility). Assume that each demand will be supplied or served by their closest facility. The transportation cost is assumed to be directly proportional to the weight of a demand multiplied by the distance to the closest facility (note: this is the same assumption used in the Weber model). The p-median problem involves selecting the locations of p-facilities so that the total weighted-distance for all demand is minimized. Hakimi proved that at least one optimal solution to the p-median problem consists entirely of nodes of the network. Thus, the search for an optimal configuration can be limited to just the nodes of the network.

Figure 2
An example road network

Searching for the best nodal configuration, and hence an optimal configuration, seems simple. Why not enumerate all of the possible facility patterns, and pick the configuration with the lowest weighted-distance? Unfortunately, it isn't that simple. Consider, for example, that we wish to locate 10 facilities on a network of 100 nodes. Such an enumeration would involve generating and evaluating the following number of combinations

$$\left\{ \begin{matrix} 100 \\ 10 \end{matrix} \right\} = \frac{100!}{5!(100-5)!}$$

$$= \frac{100*99*98*97*96*95*94*\ldots..*1}{10*9*8*\ldots..*1*90*89*88*\ldots..*1}$$

or

$$\frac{100*99*98*97*96\ldots*91}{10*9*8*7*\ldots.*1} \cong 17{,}300{,}000{,}000{,}000$$

configurations
or alternatives

If a very fast computer could analyze 1,000 solutions each second, it would take 548 such computers working simultaneously to finish the task in a year. Thus, for many problems enumeration is impossible. In such cases, it is reasonable to consider optimization. ReVelle and Swain (1970) proposed the first optimal approach to solving the p-median problem. The basis of their approach is to formulate the p-median model as an integer-programming problem.

Consider a connected transportation network comprised of n nodes and at least $n-1$ arcs (note: it requires at least $n-1$ arcs to be connected). An example of a 12-node network is given in Fig. 2. In this review we will consider the most general form of the p-median problem where each node represents both a place of demand and a potential facility site. Given any pair of nodes on the network, a shortest path exists between the pair of nodes, and the distance of that path is easily calculated by a variety of efficient techniques. Consider the following notation

n = the number of nodes in the network

Table 2
Optimization model

Objective function:	$\sum_{i=1}^{n}\sum_{j=1}^{n} a_i d_{ij} x_{ij}$	
Subject to:		
(1) Each demand must be served by either placing a facility at its node or by assigning to a facility elsewhere	$\sum_{j=1}^{n} x_{ij} = 1$	or each node i
(2) Assignment is possible to only open facilities	$x_{ij} \leqslant x_{jj}$	for each node i and j where $i \neq j$
(3) Exactly p-Facilities are located	$\sum_{j=1}^{n} x_{jj} = p$	
(4) Integer restrictions on variables	$x_{ij} = 0, 1$	for each node i and j

Table 3
Optimization model: modified second constraint

(2) Assignments are possible to a facility, only if it has been selected	$\sum_{i=1}^{n} x_{ij} \leqslant n x_{jj}$	For each node j

i, j = indices used to reference nodes,
where the nodes are numbered from 1 to n

a_i = the amount of demand at node i

d_{ij} = the distance from node i to node j

$$x_{ij} = \begin{cases} 1, \text{ if demand at node } i \text{ assigns to a facility at node } j \\ 0, \text{ otherwise} \end{cases}$$

$$x_{jj} = \begin{cases} 1, \text{ if node } j \text{ self assigns indicating that a facility is located at node } j \\ 0, \text{ otherwise} \end{cases}$$

Using the above notation, we can define the optimization model in Table 2 (ReVelle and Swain 1970).

The model in Table 2 can be solved by the use of integer programming techniques, most notably, linear programming with branch and bound (LP/BB). In a relatively high percentage of problems, the optimal linear programming solution is integer optimal as well and the branch and bound routine is not used. This property is called 'integer friendly.' Since branch and bound algorithms may take considerable computational time to resolve noninteger solutions, finding an optimal integer optima without BB usually means relatively fast computational times for a given problem size. Unfortunately, the above model is large in terms of the number or variables and constraints (n^2 and n^2+1 respectively). Consequently there is a limit as to how large a problem can be solved by this specific model formulation and LP/BB.

It is possible to formulate the p-median problem with a slightly different constraint set. Consider the following form of the second constraint (Table 3): the constraints that restrict demand assignments to only those nodes selected for a facility have been aggregated into one constraint for each facility. Consequently, this second model is more compact in that it contains only $2n+1$ constraints rather than n^2+1 constraints. As models are typically easier to solve when they have fewer constraints, this would at first seem to be an improvement. Unfortunately, this second model form is not 'integer friendly' and consequently the use of LP/BB typically relies on the BB algorithm and resulting solution times can be very large. The lesson here is that there are always alternate ways in which to formulate any given spatial optimization model, and the difficulty in solving a given problem can be in part due to the mathematical form of the problem.

There are practical limits, however, as to the size of a problem that can be solved optimally. For large problems it is simply not possible to find an optimal solution with certainty. Because of this there has been a great reliance on heuristic solution procedures. Heuristics are often designed to exploit some type of search strategy. For example one of the best known methods for solving the p-median problem is the 'swap' heuristic of Teitz and Bart (Church and Sorensen 1996). The 'swap' heuristic starts with a randomly generated solution. Given this starting solution, consider a candidate node as a possible replacement site for each of the currently selected nodes. If any swap involving this candidate node yields an improvement, the best swap with that candidate is made, creating a new and improved solution. Swaps are tested until no improvements can be made involving any node of the network. Repeating this procedure a few times has a good chance of finding a good, if not optimal solution. Other strategies are based upon 'survival-of-the-fittest' genetic algorithms, simulated annealing and statistical mechanics, Monte Carlo sampling, etc. All heuristics are rated for their capabilities in finding good solutions.

4. *Research Needs in Spatial Optimization*

Research in spatial optimization has expanded over the years. This expansion is due in part to increasing computational power and availability of computers,

better general purpose commercial products like GIS and optimization software, fourth generation computer language tools like visual studio and C++, and high resolution color monitors. Some spatial optimization models are now a part of general purpose GIS software. There are, however, a number of research directions that must be taken in order for such modeling tools to be commonly available. To make this a reality, research is needed in the following areas:

(a) develop better and more capable solution algorithms and heuristics. This is especially important in improving the capability to solve large problems of the simple plant location problem where the facilities have finite capacities;

(b) expand existing models and develop more comprehensive spatial optimization models, especially in ecological reserve design and land use planning;

(c) develop methods to better estimate the impact of data error and its propagation on model results. This is especially important since all geographic data sets of realistic size contain error;

(d) expand data model definitions to better link spatial optimization models with GIS. One application of considerable importance is the optimal location of cellular phone towers;

(e) develop better visualization methods along with graphical interface approaches that can support collaborative decision making processes;

(f) explore methods of data aggregation so that it may be possible to construct small problem representations that are easier to solve, but still retain all of the important problem characteristics.

Many industries and government agencies have been pushed to become more efficient. Increasing productivity has become a mantra of stockholder and citizen alike. In many settings new spatial optimization models are being proposed to help increase efficiency, promote equity, reduce environmental damages, and reduce energy needs. For example, new spatial/temporal optimization models that are being used for emergency ambulance operations can create plans that improve service response without additional investment or keep service levels constant and cut costs. The economic incentive to improve services and reduce costs will expand the application base that is already very large.

Spatial Pattern, Analysis of

Spatial data consist of measurements or observations (data values) taken at specific locations (data sites) in a geographic space. Typically, such data are presented visually in the form of a map, although they may also be represented in other analog forms such as aerial photographs and remotely sensed images. Since most processes operate over both space and time, such representations may be considered as cross-sectional snapshots of reality. The relative locations of the data values in the geographic space define a spatial pattern. Spatial pattern analysis involves describing and explaining such patterns. In general, this is done by comparing characteristics of an empirical pattern with those of null models representative of spatial randomness (i.e., no discernible spatial order). Once identified, the distinctive characteristics of the empirical pattern can be used as evidence to gain a better understanding of the processes which generated the pattern. A classic example of this is provided by the nineteenth-century physician John Snow who identified the cause of a cholera epidemic in London by observing that deaths were concentrated around a particular public water pump.

Methods of spatial pattern analysis can be classified in terms of the kinds of spatial data analyzed. Three types of spatial data are usually recognized: point data; geostatistical data; and lattice data. For each type, further classification can be achieved by considering if the data values are qualitative (categorical) or quantitative, and if they are univariate or multivariate. In addition, spatial pattern analysis originated in distinct academic communities. Point pattern techniques were developed in plant ecology, economic geography, and epidemiology; geostatistics in mining engineering and geology; and lattice data methods in econometrics. As a result, there are literally hundreds of different spatial pattern analysis techniques and almost as many texts describing them. Consequently, this essay will emphasize conceptual issues common to all techniques and illustrate them by outlining a widely used procedure for analyzing univariate, quantitative spatial data of each type. To simplify the presentation, it is assumed that the behavior of the process responsible for the pattern being analyzed is the same throughout the area under study. This condition is known as 'stationarity.' For more comprehensive treatments of spatial pattern analysis see Upton and Fingleton (1985), Cressie (1993), and Bailey and Gatrell (1995).

1. Point Data

Here the data sites consist of a finite number of point locations which themselves are the object of interest (e.g., the towns shown in Fig. 1). More formally, let $(\mathbf{s}_1, \mathbf{s}_2, \ldots, \mathbf{s}_n)$, where $\mathbf{s}_i = (s_{i1}, s_{i2})$, be the locations of n events in a bounded study region A of size $|A|$. Such patterns are typically analyzed by examining characteristics of either the number of events in subareas of A or interevent distances $\|\mathbf{s}_i - \mathbf{s}_j\|$. The most popular method of analysis, K function analysis, developed by the statistician Brian Ripley (Ripley 1981), combines a consideration of both characteristics. The procedure analyses the average number of events that lie within a distance h of a randomly chosen event. For a given empirical pattern, the K function, $K(h)$, may be estimated using

$$\hat{K}(h) = \hat{\lambda}^{-1} \sum_{i=1}^{n} \sum_{j=1}^{n} w(\mathbf{s}_i, \mathbf{s}_j)^{-1} I(\|\mathbf{s}_i - \mathbf{s}_j\| \leqslant h)/n$$
$$h > 0,\ i \neq j$$

Figure 1
Bus service centers in south-central England, 1955

Figure 2
Observed and expected $\hat{L}(h)$ for bus service centers shown in Fig. 1.

where $\hat{\lambda} = n/|A|$ is an estimate of λ, the intensity (mean number of points per unit area) of the point process, $I(\cdot)$ is the number of events $\mathbf{s}_j$ within distance h of all events $\mathbf{s}_i$, and $w(\mathbf{s}_i, \mathbf{s}_j)$ is a correction for edge effects. The last is required since a disk, radius h, may extend outside the boundary of A. Usually, $w(\mathbf{s}_i, \mathbf{s}_j)$ is set equal to the proportion of the circumference of a circle centered at $\mathbf{s}_i$, passing through $\mathbf{s}_j$, that is inside A.

In order to evaluate $\hat{K}(h)$, it is compared to $K(h)$ which would result if the events were located independently in a completely homogeneous environment. Such a pattern is known as complete spatial randomness (CSR). More formally, CSR is the realization of a homogeneous planar Poisson process. This process has two conditions: every location in the study region has an equal chance of receiving an event (uniformity); and the selection of a location for an event in no way influences the selection of locations for any other events (independence). Under CSR,

$$K(h) = \pi h^2$$

To facilitate the comparison with CSR, the statistic $L(h)$ is often used in place of $K(h)$, where

$$L(h) = \sqrt{\frac{K(h)}{n}} - h$$

The expected value of $L(h)$ under CSR is 0. When the events in an empirical pattern are more dispersed over A than they would be in CSR (spatial segregation), the estimated value of $L(h)$, $\hat{L}(h)$, tends to be negative, whereas if the events are more clustered than expected under CSR (spatial clustering), $\hat{L}(h)$ tends to be positive. A test of the statistical significance of the difference between an empirical pattern and CSR can be made using a Monte Carlo simulation procedure. This involves simulating a set of x CSR patterns each with the same number of events as the empirical pattern in a study area identical to that of the empirical pattern. A confidence envelope is then defined by the extreme maximum and minimum values of $\hat{L}(h)$ for the x simulations. If $\hat{L}(h)$ for the empirical pattern extends outside of the confidence envelope, the null hypothesis of CSR is rejected (at a $1/(x+1)$ significance level) in favor of one of segregation or clustering, depending on the direction of the departure.

To illustrate the use of this technique, consider Fig. 1. This shows the locations of 74 central places in south-central England which provided bus services to surrounding rural areas in the 1950s. Figure 2 shows $\hat{L}(h)$ for this pattern together with a confidence envelope for CSR (based on 99 simulations). Note that for small values of h (approximately two miles or less), $\hat{L}(h)$ is negative and extends outside the CSR envelope. This indicates that the bus service centers have an inhibitive effect on each other since they are significantly more dispersed (at the 99 percent confidence level) than would be expected if they were independent.

2. *Geostatistical Data*

Geostatistical data consist of a set of n data sites, $(\mathbf{s}_1, \mathbf{s}_2, \ldots, \mathbf{s}_n)$, in a bounded study region A, at which the values, $(y_1, y_2, \ldots, y_n)$, of some spatially continuous variable Y have been measured, i.e., the data are assumed to represent sample observations from a surface defined by $(\mathbf{s}, y)$ (e.g., the snowfall data in Fig. 3). Geostatistical data can be analyzed by examining characteristics of the association between pairs of data values as some function of their relative location (e.g., the distance separating them). The most commonly used procedure, the semi-variogram, $\gamma(h)$, focuses on the variance of the data values. For empirical data, the semi-variogram is estimated for equidistant classes h using the sample semi-variogram

$$\hat{\gamma}(h) = \frac{1}{2n_h} \sum_{\|\mathbf{s}_i - \mathbf{s}_j\| = h} (y_i - y_{i+h})^2$$

where the summation is over all pairs of data sites separated by distance h, and n_h is the number of such pairs. In practice, if the data sites are irregularly spaced in A (as in Fig. 3), there may only be one pair of data sites for which $\|\mathbf{s}_i - \mathbf{s}_j\| = h$. In this case, a distance interval $h \pm \Delta$ can be used in place of h. The maximum value of $\hat{\gamma}(h)$ is often referred to as the 'sill' and the distance at which this occurs is known as the 'range.' The range defines the distance at which the data values cease to be related. In theory, $\gamma(h) = 0$ when $h = 0$, since the underlying surface is assumed to be continuous in A. However, in empirical data it is sometimes seen that as $h \to 0$, $\hat{\gamma}(h) \to c_0 > 0$. This is known as the 'nugget effect' and is considered to represent the inherent error induced by measurement errors and by micro-scale environmental variability. If there is no spatial dependence in the data, the sample variogram will consist of just a nugget effect, i.e., it is

Figure 3
Thirty year averages (1961–90) of annual snowfall in centimeters at meteorological stations in western Canada, latitude 48.75–60 degrees north, longitude 94–119.5 degrees west. To simplify visualization of the data, the individual values are grouped into three classes.

Figure 4
Empirical semi-variogram (crosses) and model semi-variogram (line) for snowfall data in Fig. 3.

horizontal. One of several parametric models can be fitted to the sample semi-variogram to provide a smooth, continuous description of the variance structure in the data. Such models can be used to predict the values of Y for non-sampled locations using a procedure called 'kriging' (Cressie 1993). Figure 4 shows the sample semi-variogram for the data mapped in Fig. 3. For this data the value of the sill is 2,100, reached at a range of 480 kilometers, and there is no nugget effect. An exponential model of the form

$$\gamma(h) = \sigma^2(1 - \exp^{-3h/r})$$

where σ^2 is the sill and r is the range has been fitted to the empirical data. The analysis indicates that while there is a clear spatial dependence in snowfall values at distances of up to about 500 kilometers, this is very marked for distances of up to 200 kilometers.

3. *Lattice Data*

In lattice data, the values, $(y_1, y_2, \ldots, y_n)$ of some variable Y are recorded for each member of a set of n areal units $(a_1, a_2, \ldots, a_n)$ which, taken collectively, cover the study region A, i.e., $a_1 \cup a_2 \cup \ldots \cup a_n = A$. The set of data values is considered to represent one possible realization of a spatial process operating over A. Lattice data are analyzed by examining characteristics of the association between pairs of data values as some function of their spatial association. This is referred to as 'spatial autocorrelation.' Since the data sites are areas, there are many different ways in which the spatial association w_{ij} between any two data sites a_i, a_j may be modeled. By far the most frequently used method is to set $w_{ij} = 1$ if a_i, a_j share a common boundary, and $w_{ij} = 0$, if they do not.

Moran's I, the most widely used measure of spatial autocorrelation, is given by

$$I = \left(\frac{n}{\sum_{i=1}^{n} \sum_{j=1}^{n} w_{ij}} \right)_{i \neq j} \times \left(\frac{\sum_{i=1}^{n} \sum_{j=1}^{n} w_{ij}(y_i - \bar{y})(y_j - \bar{y})}{\sum_{i=1}^{n} (y_i - \bar{y})^2} \right)$$

where: $\bar{y} = \frac{1}{n}\sum_{i=1}^{n} y_i$. The first term on the right-hand side of this equation is a normalizing factor, so that the range of I is approximately $-1 \leqslant I \leqslant 1$. The expected value of Moran's I under the assumption of inde-

Figure 5
Percentage of census tract population with German mother tongue (Kitchener-Waterloo 1996)

pendence in the spatial pattern of values of Y (no spatial autocorrelation) is

$$\mathrm{E}(I) = -\frac{1}{n-1}$$

and the variance is

$$Var(I) = \left(\frac{n^2 S_1 - nS_2 + 3W^2}{W^2(n^2-1)} \right) - \frac{1}{(n-1)^2}$$

where

$$W = \sum_{i=1}^{n}\sum_{j=1}^{n} w_{ij}; \quad S_1 = \frac{\sum_{i=1}^{n}\sum_{j=1}^{n}(w_{ij}+w_{ji})^2}{2};$$

$$S_2 = \sum_{i=1}^{n}(w_{i.}+w_{.j})^2; \quad w_{i.} = \sum_{j=1}^{n} w_{ij}; \quad w_{.j} = \sum_{i=1}^{n} w_{ij}.$$

An observed value of I which is larger than its expectation under the assumption of spatial independence indicates positive spatial autocorrelation (i.e., similar values of y, are found in spatial juxtaposition). In contrast, negative spatial autocorrelation occurs when neighboring values of y_i are mutually dissimilar, indicated by an observed value of Moran's I which is smaller than its expectation. For data sets of $n \geqslant 50$, I is approximately normally distributed so that the standard score

$$z = \frac{I - E(I)}{\sqrt{Var(I)}}$$

may be used to determine if the empirical pattern displays significant spatial autocorrelation.

As an example of this approach, consider Fig. 5 which shows the percentage of the 1996 population whose mother tongue was German for each census tract in the twin cities of Kitchener-Waterloo in Ontario, Canada. For this data set, $n = 56$, $\mathrm{E}(I) = -0.018$ and $\mathrm{Var}(I) = 0.0057$. While the observed value of $I = 0.115$ suggests that there is a tendency for census tracts with similar proportions of German speakers to cluster in space, the standard score of $z = 1.77$ indicates that the pattern of spatial association is not significantly different (at the 95 percent confidence level) from that which could arise by chance (i.e., no spatial autocorrelation).

The measurement of spatial autocorrelation can be extended to higher-order spatial neighbors where the spatially associated areas are $(k-1)$ intervening areas apart. A plot of the values of I for different spatial lags k, the spatial correlogram, is useful for detecting scale variations in the spatial pattern (Upton and Fingleton 1985).

4. *Changing Emphases and Recent Developments in Spatial Pattern Analysis*

Most recent developments in spatial pattern analysis have come in response to changes in two areas. The first involves characteristics of the typical spatial data set to be analyzed. Proliferation of automated monitoring devices, such as orbiting earth satellites, has meant that large (i.e., hundreds of thousands or more data sites) and often frequently updated data sets have become increasingly available. The second change is in computing; in particular, increases in computing power and memory capacity, coupled with cheaper hardware costs. One result of this is the appearance of more sophisticated geographical information systems capable of visualizing spatial data in a variety of ways.

The need to analyze large data sets has resulted in an increasing emphasis on spatial data exploration which, in turn, has led to a shift away from global methods of spatial pattern analysis to local ones (Getis and Ord 1996). While global methods attempt to summarize the entire spatial data set, local methods focus on searching for localized patterns within the data set by such means as identifying atypical locations (spatial outliers), clusters of abnormally high (hot spots) or low (cold spots) data values, and the presence of different patterns in sub-areas (spatial regimes). Since it is possible to generate a local statistic for each data site, the results of such analyses are best appreciated using some form of visualization (Hearnshaw and Unwin 1994).

For local statistics, the null models of spatial randomness, such as that of CSR described in Sect. 1, used to evaluate global statistics may not be appropriate. Instead, null hypotheses which take into account some form of pre-specified spatial structure

may be more appropriate. These may include, for example, allowing for some degree of significant spatial autocorrelation in the overall pattern or permitting the characteristics of the causal process to vary over subareas within the study area. Alternatively, a null hypothesis might be specified to evaluate if events cluster around one or more focal locations (e.g., disease incidences around toxic waste sites). While the characteristics of the simpler null models can be derived analytically, this is often not possible for the newer models, resulting in their properties being estimated from repeated simulations of the model processes.

Frequent updating of data sets has spurred an interest in real time surveillance of spatial patterns. This involves analyzing new data, as it becomes available, to detect any significant changes that have occurred in the characteristics of an existing spatial pattern (Rogerson 1997).

Since all of these innovations in spatial pattern analysis impose heavy computational demands, they have only become practical with the developments in computing previously noted. Indeed, in some situations it is possible that the amount of collected data may exceed human analytical ability. This has stimulated interest in the creation of automated procedures for spatial pattern analysis (Openshaw 1998). In particular, a new research field called spatial data mining, which integrates aspects of machine learning, database systems, data visualization, information theory and spatial statistics, has evolved with the aim of developing efficient methods for identifying the characteristics of very large spatial data sets.

Spatial Sampling

Sampling is undertaken in order to estimate an attribute of a variable of interest in a population. Sampling is used instead of undertaking a complete census for many reasons. For example undertaking a complete census may be impossible because the population is very, perhaps infinitely, large or it may be impractical because of expense. Some census data, for example household employment data in the UK, is only made available as a 10 percent sample from the 100 percent enumeration partly to help preserve confidentiality but also because the data requires manual coding which is expensive. In many situations a census is unnecessary because a value for the attribute is only required, or can only be measured, up to some predetermined level of precision and a sample size can be specified that will achieve that level of precision. Sampling is also undertaken to improve the accuracy of census data because some methods of recording are known to produce undercounts (e.g., in the case of crimes, not all events are reported to the police) and some methods of enumeration miss certain groups in the population (e.g., the homeless in the case of national censuses).

The term spatial sampling is used to describe the activity of sampling when the population is spatially or geographically distributed. All the individuals in the population have a georeference or geocode that identifies their location with respect to some local or global frame of reference. The population might be a surface of land-use values or ground-level air pollution values. In this case the population is the set of all points in the region and is infinitely large. The population might be the set of all households in a city in which case the population, whilst not infinite, is nonetheless very large. The population might refer to spatial aggregates. For example the population of households might be bundled into census units so that the population is the set of such units for which aggregate quantities are of interest.

Spatial sampling is usually undertaken by recording the data value at a point location such as a position on a line or a surface or recording some aggregate quantity for a polygon such as a pixel, a quadrat, or a census tract. In some spatial sampling a household is treated as a point (is the head of household unemployed?) in others as an area-based quantity (number of persons per room).

Designing a spatial sample to estimate an attribute involves selection of the required sample size (n) and

specification of the sample locations $(s_1,\ldots, s_n)$. The latter is called the sampling plan. The sampled data $\mathbf{z} = \{z(s_1),\ldots, z(s_n)\}$ is used to estimate the attribute which might be a 'nonspatial' attribute such as the mean value of the variable **Z,** or the proportion of the population with a given set of values on Z or the maximum value of Z. The attribute might be a 'spatial' attribute such as the autocorrelation function, semivariogram, or a map of the variable constructed using optimal interpolation. It is necessary to choose an appropriate estimator of the quantity and specify a measure of closeness (with respect to the attribute) that the sampling design seeks to minimize. A measure of closeness might for example be the sampling variance.

There may be other issues that affect spatial sampling designs. There may, for reasons associated with cost constraints, be a trade off that needs to be recognized between on the one hand the greater levels of precision obtainable by increasing the sample size versus the costs associated with collecting larger volumes of data. Samples designed to deliver acceptable levels of sampling error for a national survey won't achieve equivalent levels at smaller state or county-level scales without a larger sample and without stratification. Hence there needs to be some assessment of the benefits of having information at the smaller scale set against the costs of a larger sample. One solution to this problem, that can be used where some estimate is available at the local level, is to adapt methods based on 'borrowing strength.' National surveys yield precise estimates of national rates, but these are biased estimators of local area rates because local areas have different rates. Estimators that 'borrow strength' combine these two sources of information by using weights that reflect the relative precision of the two estimators (Ghosh and Rao 1994, Longford 1999). In disease mapping, 'borrowing strength' methods have been further adapted so that instead of borrowing strength from the national (or 'region wide') estimate, it is only borrowed from the geographically adjacent region (Elliott et. al. 1992).

There may be particular problems of accessibility to particular sample areas as well as the collection costs associated with adopting a dispersed distribution of sampling locations versus a more clustered distribution. Other issues may also need to be considered such as whether the sample design is required to undertake long term monitoring and whether there are to be several measured attributes recorded at each site so that some compromise is required between the different estimators (Haining 1990). The form of the sampling problem may be to decide how best to add to, or conversely rationalize an existing sampling network where there may be costs associated with any reconfiguration (Arbia and Lafratta 1997).

There are situations where some spatial object such as a polygon or a line is to be estimated, in which case the sample design is selected in order to estimate or represent characteristics of the object—such as the area of a polygon or the location of a line. In geographic information system databases the representation and resolution of boundary lines between polygons is the outcome of a sampling process. The precision with which any boundary or shape can be represented is a function of the spacing of the sample points (Griffith 1989).

1. Design and Model Based Approaches to Spatial Sampling

Suppose a region R is divided into a population of N units, where N might be very large. In the design-based approach it is assumed that $z(s_i)$ is the value of Z observed at the point s_i which is one of the N points in R. The value of Z at each of the N units is considered fixed. We let m(R) denote the mean of the population of these N values. The problem is to estimate the parameter m(R) and in the design-based approach Z is observed at n sample points where these sites have been selected according to some sampling plan where units have a known probability of being selected. Repeated sampling according to this scheme generates a distribution of values of the vector **z**. This distribution together with an estimator of m(R) defines a (design-based) sampling strategy. This estimator is used to make inferences about m(R) because, as it is based on **z**, it too will have a distribution of values under repeated sampling.

The model-based approach assumes an underlying random process with an assumed probability distribution that is generating the observed set of values in the N units of R. (See *Spatial Autocorrelation*; *Spatial Statistics*.) So the value $z(s_i)$ is the value of a random variable–it is only one of a distribution of values that could have been realized at location s_i. It is usual to specify properties of the model generating the N data values including the first order (mean, μ) and second order (variance-covariance, Σ) properties. Now m(R) is not a parameter but a random variable because it is a function of N random variables. To make clear the distinction this mean will be labeled as M(R) in the model-based case. It could also be of interest to estimate parameters such as the mean, μ, of the underlying model.

In the model-based approach the estimator of μ and the estimator (strictly speaking the predictor) of M(R) both incorporate the spatial model generating the data explicitly in order to produce good estimates (e.g., Haining 1988, Cressie 1991). For example, the best linear unbiased predictor of M(R) is of the form:

$$\sum_{i=1}^{n} a(i)\, z(s_i) \tag{1}$$

where the $\{a(i)\}$ depend on the model and are chosen to minimize the mean square prediction error. In this approach the sampling plan is of secondary interest.

By contrast in the design-based approach, the sample mean (a(i) = 1/n in Eqn. (1)) is used to estimate m(R) having been shown to have good properties (Bellhouse 1977). Attention focuses here on the sampling plan in order to identify which one will have the lowest sampling variance or sampling error. The advantage of this approach is that the estimator is easy to compute and it does not depend on specifying the underlying model. The model-based approach assumes a hypothetical super-population of possible (but unrealized) maps. The design-based approach is only concerned with the here and now of what has occurred. Perhaps more importantly from a conceptual perspective, the model-based approach can be used to estimate the parameters of the underlying signal (the parameters of the map generator, like μ) rather than the particular (noisy) map. For example, in relative risk estimation (also called disease mapping), it is a quantity like μ rather than M(R) that is usually of interest (Elliott et al. 1992).

2. *Sampling Plans*

There are a number of different ways to select the sites to be sampled. The main classes of sampling plan are random, stratified random, and systematic (Ripley 1981). We consider each of these in turn before turning to some other schemes.

In the case of random-sampling the n sample sites are selected so that each member of the population has an equal and independent chance of selection. Figure 1(a) shows a random sampling plan on a surface where each point on the surface had an equal chance of being selected. As has been commented before, a random sample often gives the appearance of some clustering in the distribution of selected sites. Figure 1(b) shows a stratified random sampling plan on the same surface that has been divided into nine strata. Within each stratum, one sample site has been selected according to the rule for a random sampling plan but more than one could be selected. Figure 1(c) shows one type of systematic sampling—the centric systematic sampling plan. The region has been divided into square strata and the central point in the strata selected. This method of sampling contains no randomization. However, randomization can be introduced by for example, randomizing on the location of the first sample point (the random start method). The other $(n-1)$ sample points occupy the same relative locations in the remaining $(n-1)$ strata. There are a number of variants of the systematic sampling scheme (Koop 1990). Stratified random and systematic sampling both raise questions about the size and shape of the strata to use. Shapes such as the hexagon or the triangle could be used for the strata. An understanding of the process generating the quantities of interest may help in designing these parameters of the sampling plan (Cressie 1991). A pilot survey may be important

Figure 1

(a)

(b)

Figure 2

in helping to decide on the size of the strata and hence what density of points are needed.

In addition to these sampling plans there are others that may be appropriate in particular circumstances although there are sometimes special problems associated with computing sampling variances and hence interpreting results. Cluster sampling involves grouping the population into clusters (Lyberg and Cassell). These clusters are often defined in such ways that subsets of individuals comprising the population are spatially close together within any one cluster. These clusters are sampled and then the sample is drawn by selecting, usually at random, individuals from within the selected clusters. This sampling method is often cheaper and administratively easier to implement. Kahn and Sempos (1989) give the example of a health survey involving a large number of economically similar but geographically dispersed villages. Instead of drawing the sample of size n from all the villages (which could involve visiting a large number incurring considerable time and travel costs), a subsample of villages is drawn and the sample of size n is drawn from within this subset of villages.

Nested sampling may be used where variation in the quantity of interest is associated with different spatial scales–for example, different administrative tiers of a political system. Nested sampling may be employed, again to help keep down the time and cost of the

sampling exercise. The area is subdivided at the first (highest) tier of the system and units are chosen at random (similar to cluster sampling). Then these selected areas are subdivided at the second tier and these in turn are sampled—and so on until the lowest tier is reached. Within the selected areas at the lowest tier, individuals are sampled (Fig. 2(a)). As can be seen from Fig. 2(a) this method does not control for distance between the sample points so that if scales of variation vary continuously (rather than in terms of discrete hierarchical levels) as might be likely to arise with a surface of values, then this method of sampling may obscure the different scales of variation. Fixed interval point sampling as illustrated in Fig. 2(b) avoids this problem. The distance between sample points is fixed at those intervals the investigator wishes to study closely (Oliver and Webster 1986).

3. *Spatial Variation and Sampling Plans*

Spatial autocorrelation is the term used to describe the presence of systematic spatial variation in a variable and positive spatial autocorrelation, which is most often encountered in practical situations, is the tendency for areas or sites that are close together to have similar values. The presence of spatial autocorrelation in a population to be sampled has important implications for the sampling variance of the estimator. It is however necessary to distinguish between estimating surface properties in the case of the design-based approach (for example, estimating $m(R)$) and estimating underlying parameters in the case of the model based approach (for example estimating μ). We consider the design-based approach first.

If the purpose is to estimate $m(R)$ then the presence of positive spatial autocorrelation implies that each sample point carries information not only about its own sample site but also some information about neighboring site values. In the case of random sampling, the sampling variance of the sample means (as the estimator of $m(R)$) for any given sample size will be lower than that arising in the case of a population of independent individuals (Griffith et al. 1994). However, this does raise the question as to whether other sampling plans might do better.

Consider the three sampling plans described in Fig. 1. If the surface of values is positively spatially autocorrelated one of the problems with random sampling is that because adjacent values will be similar there will be information redundancy in the case of those sample points that happen to be close together. It is also evident from Fig. 1(a) that the random sampling plan leaves areas unsampled. Both these problems with the random sampling plan are reduced to some extent by the introduction of strata, but as is clear in Fig. 1(b) there are still some sample points that are close together resulting in information redundancy, and there are still some areas of the map not sampled—albeit smaller in extent. Systematic sampling, especially using the centric or the random start methods reduces both effects. Intuitively we therefore expect that for given sample size n, systematic sampling ought to produce estimates with lower sampling variances of a quantity such as m(R). This, by and large, proves to be the case because separating the sample sites improves the information content of the sample. However, while the gains of moving from random to either stratified random or systematic sampling are considerable, the gains of systematic sampling over stratified random sampling are generally much smaller and seem to depend quite critically on the specific form of the underlying spatial autocorrelation (Ripley 1981, Matern 1986, Dunn and Harrison 1993).

The sampling variance is estimated in the case of random sampling using:

$$\sum_{i=1}^{n} [z(s_i) - \bar{Z})]^2 / (n-1) \tag{2}$$

where

$$\bar{Z} = \frac{1}{n} \sum_{i=1}^{n} z(s_i)$$

Equation (2) provides an unbiased estimator in this case and Ripley (1981) discusses related methods for estimating the sampling variance under stratified random and systematic sampling.

The presence of spatial autocorrelation has implications for the other sampling plans. In the case of cluster sampling a critical factor is between-cluster and within-cluster variation. If the clusters are just random assemblages of individuals in the population then cluster sampling (with random selection of individuals from within each cluster) ought not to produce sampling variances any greater than say random sampling. If all the clusters differ greatly then selecting a sample of them will not lead to good population estimates. If clusters have internal positive spatial autocorrelation (so that they are more homogeneous than the population as a whole) then cluster-sampling variance is likely to be bigger than (simple) random sampling. In the case of (hierarchical) nested sampling, if the population shows spatial autocorrelation then, again there will be information redundancy because some sample sites are close together. This effect may be somewhat less of a problem in the case of fixed interval point sampling as a result of keeping sample sites apart.

In the model-based approach, if the purpose is to estimate μ (of a spatially autocorrelated model) using the sample mean, then this estimator's sampling variance is inflated relative to its sampling variance under the assumption of a population that is independent. If Eqn. (2) is used as the estimator of

the sampling variance it can severely underestimate the true sampling variance of the sample mean. Although the sample mean is an unbiased estimator of μ, the best linear unbiased estimator (BLUE) is usually preferred although it requires the correct specification of the underlying spatial model (see Eqn. (1)). As noted above the choice of sampling plan tends to be of secondary interest in this area of analysis but careful specification of the required sample size is needed if parameters are to be estimated to the desired level of precision (Haining 1988).

In addition to undertaking sampling to estimate non-spatial properties of an attribute, sampling may be needed in order to estimate spatial properties (the correlogram or semi-variogram) or to construct maps based on optimal interpolation. Evidence suggests that particularly for optimal interpolation and for constructing contour maps for a variable, centric systematic sampling grids are best with a density chosen to achieve required levels of precision and with a rectangular grid selected for practical reasons (Webster and Burgess 1981). Interpolation error will vary across the map as a function of the density of sample points and the effect of the survey boundary. If anisotropy is present (directional differences in the autocorrelation structure) then both alignment and grid specification for the systematic sampling will need to be adjusted (McBratney et al. 1981).

Spatial Search Models

Spatial search is recognized as an important construct within behavioral geography because it is the preliminary, information acquisition phase of most locational decision processes. Spatial search is the task of identifying and investigating spatially distributed choice alternatives that serve as the basis for a locational decision. Spatial search processes range from purely mechanical, space covering procedures characteristic of remote sensing methods through complex, multi-stage searches drawing on indirect information sources as well as direct experience—the search for a new residence or a new place of employment, for example. No less important is the ongoing acquisition of geographic information which occurs as people move about their environment, consciously and unconsciously creating a practical knowledge base which they draw upon to inform the myriad locational decisions made during the normal course of a day—way finding and shopping decisions, for example (for a detailed review of the spatial search literature and for further references see Golledge and Stimson 1997).

Whether searching for a new place to live or shopping for a new pair of shoes, the set of locations visited during the search process describes a search pattern with predictable spatial characteristics and

important locational consequences. Four spatial regularities in the search patterns are particularly important: search patterns are limited in geographic scope and search effort is spatially persistent; the search patterns reflect the underlying spatial distribution of choice alternatives within the geographically limited search domain; the search pattern reflects the spatial biases in the information sources used to identify potential choice alternatives; and the search pattern is oriented around key locations or anchor points in the decision-maker's activity space. By implication, the spatial regularities and biases observed in residential mobility patterns, local labor mobility patterns, and in shopping patterns are reflections of systematic spatial regularities in the underlying search processes and in their associated search patterns.

Spatial search emerged as a major theoretical construct in behavioral geography in the 1960s as attention shifted from descriptive questions relating to the patterns of geographic activity to an interest in understanding the spatial choice and locational decision-making processes generating the geographic pattern. The early conceptualizations of the locational decision-making process by Wolpert (1965) and Brown and Moore (1970) emphasized the importance of understanding how search decisions affect both the probability of success and the geographic distribution of the locational alternatives included in the decision maker's choice set thereby affecting the location of the final choice. They argued that the first key decision in a locational decision process is the decision to begin active search for attractive alternatives. The decision to begin active search implies that: the decision maker is dissatisfied with the current situation; better alternatives are believed to exist within the decision maker's prospective search domain; and the expected returns to search are greater than the expected search costs. Subsequent work on the decision to begin the search process emphasizes the context dependent nature of the decision and the need to consider the prior knowledge and experience which the decision-maker brings to the spatial search decision.

Three search questions are triggered by the decision to begin a spatial search; the decision-maker must decide: which information sources should be used; where search effort should be focused; and when to terminate the search. Subsequent theoretical and empirical work on spatial search has been primarily concerned with the locational consequences of the decisions made in response to one or more of these three questions. Each of these questions has a geographic consequence and each decision is affected by the interaction between the locational preferences of the individual and the decision-making context.

The delineation of a geographically bounded search domain reflects the locational preferences of the decision-maker but is also closely tied to the choice of information source or sources used to identify search possibilities. The primary information source affecting the delineation of the search domain is the practical knowledge base that the individual brings to the search task. If an area is familiar to a person, search is more likely in that area; the search costs are likely to be lower as is the risk of making a bad choice. The search domain tends to be defined in terms of the individual's activity and the awareness space that varies in geographic scope depending upon the age, class, and ethnicity of the individual. Similar observations pertain for personalized information sources such as friends and relatives. Households relying on personalized sources of information are found to have much smaller search domains than individuals relying on impersonal sources such as newspapers and directories or professional sources such as real estate agents or employment agencies (Clark and Smith 1979).

In these instances, the search domain is dictated by the geographic reach of the information source. The role of information channels as sources of bias in the search process has received considerable attention in the racial segregation literature (Courant 1978). These investigations have focused specifically on racial steering and the potential role of real estate agents in creating racially homogeneous neighborhoods through selective filtering of housing information to black and white households. It is important to understand how geographic information is produced because whether systematic and mechanical or selective and subjective, spatial search processes produce representations of the external environment which are necessarily incomplete and potentially distorted both as a result of the geographically selective knowledge base and because information channels also selectively represent or filter the locational information available to the decision-maker. Most locational decisions and the search process leading up to the actual choice are bounded geographically in that the active investigation of choice alternatives is preceded by a decision to focus the search effort within a particular geographically delineated market. Once search begins within a particular market area, there is a strong tendency to continue searching within that same market area. Once the search for a new residence begins within a local housing market, for example, it is highly likely that search will continue within that same housing market. Similar patterns of spatial persistence are observed in job searches within local labor markets and in shopping decisions within local market areas. In other words, people continue to focus search effort within a targeted market area as a spatial satisfying strategy that discounts the potential acceptability of choice alternatives located outside the targeted market area. There is also evidence that area based search strategies continue to apply at more micro scales within the larger market area. In the case of residential search, for example, households tend to focus their search effort within specific community areas within

larger geographically defined housing markets (Huff 1986).

Decision makers decide where to focus their search effort based upon their locational preferences and upon what they know about the chances of being able to satisfy locational and nonlocational preferences by targeting search within a given area. Often there are pre-existing anchor points that have locational significance for the decision-maker and serve to focus or anchor the search effort (Golledge 1978). When households search for a new residence, for example, the job locations of the wage earners in the household and the location of the previous residence often serve as strong anchor points in the search process (Huff 1986). In the case of job search, the location of the residence often ties the search to a particular labor market and may result in a highly focused job search in the immediate proximity of the home (Hanson and Pratt 1988). In the case of search associated with shopping, home and work locations frequently are identified as key anchor points in the search process and at a more micro level, the strategic locations of anchor stores in shopping centers reflect an awareness of how these stores anchor the search behavior of shoppers within the mall.

How people decide when to conclude the search process has received a great deal of attention within the economics literature on job search (Lippman and McCall 1976). Conceptually, the answer to the stopping-rule question is quite simple: search will continue until the expected cost of further search exceeds the expected returns to further search. On the other hand, the empirical validation of stopping rule models has proven to be quite difficult. In the case of spatial search, both the expected costs and the expected returns to search are expected to vary from one geographic area to another (Smith et al. 1979) which implies that the length of search and the chance of successfully completing the search vary from one geographic area to another (Rogerson 1982).

Understanding the path dependent nature of the spatial search process is of vital importance with respect to the stopping rule question as well as the information use and the search location questions. In the stopping-rule case, the order in which choice alternatives are visited during the search process is found to affect the outcome of the search process. Different information sources with very different content and spatial coverage tend to be used during different phases of the search process. During the actual search process, the path dependencies often are spatial in nature. Spatial persistence in the decision to continue searching in the same area, the spatial clustering of choice alternatives visited during search highlight the existence of strong spatial dependencies in the search sequence. In the case of multi-purpose shopping behavior, spatial search often requires the resolution of both a routing or way finding problem and a stopping rule problem (Miller 1993).

Spatial Statistical Methods

Spatial statistics is characterized by modeling and data analysis for processes displaying spatially-indexed dependence structures. Adjustment for spatial dependence has long been mandated in many disciplines. The very nature of geography is spatial. F. Stephan (1934) noted 'Data of geographic units are tied together … in dealing with social data, we know that by virtue of their very *social* character, persons, groups, and their characteristics are interrelated and not independent.' In the context of agricultural field experiments, Fisher (1935) described the basic intuition underlying much of spatial statistics: 'After choosing the area we usually have no guidance beyond the widely verifiable fact that patches in close proximity are commonly more alike, as judged by the yield of crops, than those which are far apart.' Though Fisher developed randomized experimental designs to avoid modeling spatial dependence explicitly, agricultural applications are an important motivation for spatial statistics (Besag 1991).

In the early 1950s the South African mining engineer D. G. Krige pursued methods for the spatial interpolation of data with the intent of predicting the distribution of ore (e.g., gold) in space. G. Matheron

(France) extended that work, formalizing mining geostatistics, and coined the term 'kriging' to refer to a class of spatial prediction methods. In parallel, L. S. Gandin (Soviet Union) developed essentially the same procedures for applications in meteorology where they are known as *optimal interpolation* and *objective analysis*.

While basic geostatistical methods remain very useful, the methodology was limited in terms of (a) applicability, since the analyses were historically confined to linear models and (b) volume of data analyzed. Technological advances regarding both data collection methods and computation have led to expansion of applications and methods of spatial statistics. Specifically, image analysis is and will continue to be a critical research area. Example problems include satellite remote sensing of the Earth's environment and ecology, including humans and their behavior and impacts; analysis of astronomical images from optical, radio-wave, infrared, etc., instruments; magnetic resonance imagery; and computer vision. Methods for image restoration (filtering out noise), classification, and object identification are sought. Similarly, the development of geographic information systems is a watershed of geographically referenced data, though the efficient extraction of information from such massive datasets offers new statistical challenges.

Spatial statistics also includes modeling and analysis of mapped point processes, in which the locations of observations are themselves random. For example, observations may be the locations and characteristics of trees in a forest (Stoyan and Penttinen 2000), or positions and types of galaxies in space (Feigelson and Babu 1992). For applications in archaelogy, see Hodder and Orton (1976); see also Stoyan (1988). Finally, an introduction to spatial modeling of random objects can be found in Cressie (1993); see also Grenander (1993).

1. Perspectives and Comparisons

Let D denote a collection of sites or locations denoted by $\mathbf{s}$, distributed in space. (Formally, D is taken to be a subset of d-dimensional Euclidean space. This permits mathematical consideration of the differences and distances between sites). In geostatistics, D is a collection of sites on the surface of the Earth, indexed in two dimensions either by $\mathbf{s} = (\text{latitude, longitude})$ or by Cartesian coordinates $\mathbf{s} = (x, y)$, or in three dimensions with the addition of altitude or depth. In image analysis, $\mathbf{s}$ typically represents a pixel located on a discrete lattice. For each $\mathbf{s}$ in D, there exists some random quantity, $Z(\mathbf{s})$, of interest. The stochastic process $\{Z(\mathbf{s}):\mathbf{s} \in D\}$ is a random field or spatial random process. Z could be a continuous variable (e.g., temperature); a discrete variable (e.g., a binary variate indicating the presence or absence of some characteristic, or a multivalued discrete variable of gray levels, especially in image analysis); a mixed variable (e.g., rainfall may be zero with positive probability at a location, yet continuous, if some rain occurs). Z may also be a multivariate variable.

Goals in spatial statistical analyses include distributional modeling of spatial random processes; estimation and inference for aspects of the spatial model based on observational data; prediction at sites where observations are not available; and filtering or noise reduction. Two approaches to spatial process modeling dominate current practice. In the first, jointly or simultaneously specified models for the process $\{Z(\mathbf{s}):\mathbf{s} \in D\}$ are developed. For example, in much of geostatistics, the variable $Z(\mathbf{s})$ is decomposed into 'mean' plus 'error' components. A critical challenge is the development of joint distributional information for the errors across space. A second strategy is to build conditionally specified models by modeling local dependence structures. This track builds directly on the intuition that variables in close spatial proximity tend to be related. This is quantified by formulating distributional features of $Z(\mathbf{s})$, conditional on the rest of the Z process, to depend only on the values of Z at locations in neighborhood of $\mathbf{s}$.

Practical modeling often focuses on specification of conditional means and variances. Two important issues arise. First, to enable spatial prediction accompanied by meaningful measures of uncertainty, a conditionally specified model should correspond to a proper joint distributional model. To that end, conditionally specified Markov random fields are often used since there is a well-developed theory regarding the existence of implied joint models (e.g., Cressie 1993, Chap. 6). The second issue involves dealing with variables located near the boundary of D, since this region typically dictates local dependence structures that are by nature different from those in the interior of D. Indeed, boundary problems are among the issues that generally distinguish spatial statistics from other applied statistics areas.

While geostatistics and imaging appear to have developed separately, they share some common formulations and goals. However, modeling and analysis methods are responsive to the typical types of data available. Geostatistical settings often feature small to moderately sized datasets, and data that are irregularly distributed in space, leading to difficulties in model estimation. In many imaging problems datasets are relatively large and are often regularly distributed in space. One impact of this difference is that treatment of measurement error is more accessible and common in imaging compared to its haphazard treatment in classical geostatistics.

The primary goal, particularly in geostatistics, is spatial prediction: Based on a vector of n observations, $Z \equiv (Z(\mathbf{s}_1), \ldots, Z(\mathbf{s}_n))'$, we seek predictions of $Z(\mathbf{s}_0)$ where $\mathbf{s}_0$ is an arbitrary site in D. Depending upon the level of assumptions made, two essential principles guide the predictive analysis. First, in analyses based

on assumptions asserting only the trend and covariance structures, most predictions are derived as best linear unbiased predictions (BLUP). 'Best' refers to the property of having smallest prediction variance among all linear, unbiased predictors. In analyses which also include distributional assumptions, predictive analyses are based on the implied conditional distribution of $Z(\mathbf{s}_0)$ given the observed data Z. For example, assuming mean squared prediction error as the criterion for assessing the quality of prediction, the optimal predictor is $\hat{Z}(\mathbf{s}_0) = E(Z(\mathbf{s}_0) \mid Z)$; that is, the conditional mean of $Z(\mathbf{s}_0)$ given the data.

Both Bayesian and non-Bayesian viewpoints are applied in spatial statistics, though the use of these terms varies with the application areas. Since most strategies view the primary variable of interest Z as *random*, the principle that spatial prediction is based on the conditional distribution, or at least its moments, of the unobserved variables given the data is clearly tied to the Bayesian view in both interpretation and computational techniques. This is particularly evident in image analysis, where a potentially nonrandom, 'true image' is modeled as a realization of a stochastic spatial process (e.g., Geman and Geman 1984, Besag 1989). On the other hand, despite similar stochastic modeling of the primary variables of interest, the origins of geostatistics and spatial point process analysis appear to be primarily non-Bayesian in language and spirit.

In particular, early approaches to model fitting and parameter estimation were primarily non-Bayesian, though their interpretation as empirical Bayesian is quite natural. With the advent of powerful Bayesian computational strategies (i.e., Markov chain Monte Carlo), the Bayesian approach is undeniably on the rise in applications of all areas of spatial statistics. It offers opportunities for effective analyses in complex spatial problems, including multivariate and inhomogeneous datasets and data types, as well as highly nonlinear and non-Gaussian datasets, not readily amenable to competing viewpoints.

2. *Spatial Random Fields*

Assuming all quantities exist, let $\mu(\mathbf{s})$, $\mathbf{s} \in D$ be the mean (expected value) $\mu(\mathbf{s}) = E(Z(\mathbf{s}))$, and let $\mathrm{cov}(Z(\mathbf{s}), Z(\mathbf{s}'))$, defined for all pairs of sites $\mathbf{s}$ and $\mathbf{s}'$ in D, be the covariance function of the process. The process is (second-order or weakly) stationary if it has constant mean $\mu(\mathbf{s}) \equiv \mu$ and

$$\mathrm{cov}(Z(\mathbf{s}), Z(\mathbf{s}') = C(\mathbf{h}), \quad \text{for all } \mathbf{s} \in D,\ \mathbf{s}' \in D \quad (1)$$

where $\mathbf{h} = \mathbf{s} - \mathbf{s}'$. That is, the covariance between $Z(\mathbf{s})$ and $Z(\mathbf{s}')$ depends on the locations only through their difference. Note that this implies that the variance of $Z(\mathbf{s})$, $\sigma^2(\mathbf{s}) \equiv \sigma^2$, is constant. The function $C(\mathbf{h})$ is known as the *covariogram*. Strict or strong stationarity involves similar requirements applied to the joint distributions of $\{Z(\mathbf{s}):\mathbf{s} \in \mathscr{D}\}$ as opposed merely to first and second moments (Cressie 1993, Sect. 2.3).

Alternatively, again assuming that $\mu(\mathbf{s}) \equiv \mu$, the process is intrinsically stationary if

$$\mathrm{var}(Z(\mathbf{s}) - Z(\mathbf{s}')) = 2\gamma(\mathbf{h}), \quad \text{for all } \mathbf{s} \in D,\ \mathbf{s}' \in D \quad (2)$$

The function $2\gamma(\mathbf{h})$ is known as the *variogram*; $\gamma(\mathbf{h})$, is the *semivariogram*.

If the process is stationary, then calculation implies

$$0.5\ \mathrm{var}(Z(\mathbf{s}) - Z(\mathbf{s}')) = C(\mathbf{0}) - C(\mathbf{h}) = \gamma(\mathbf{h}) \quad (3)$$

Hence, stationarity implies intrinsic stationarity. However, variograms satisfying (2) may exist in some cases for which covariograms do not exist. For stationary processes, (3) allows one to view modeling covariograms and variograms as being equivalent, though some have argued that estimation based on data is enhanced for the variogram.

An intrinsically stationary process is isotropic if $\gamma(\mathbf{s} - \mathbf{s}') = \gamma(h)$ for all pairs of sites, where h is the distance between them. That is, the variogram depends only on the distance between sites (i.e., the length of the vector $\mathbf{h} = \mathbf{s} - \mathbf{s}'$), but not their relative directions. Anisotropy (the violation of isotropy) arises for processes that develop differentially in different directions of space (Cressie 1993, Sect. 2.3). For example, temperature values, or variables depending on temperature (e.g., type of agriculture, ecology, etc.), are moderated roughly by latitude. Hence, north–south covariance structures might well be different from their east–west counterparts. An example of an isotropic semivariogram is the exponential model:

$$\gamma(h) = \begin{cases} 0 & \text{if } h = 0 \\ \gamma_0 + \gamma_1(1 - e^{-h/a}) & \text{if } h > 0 \end{cases} \quad (4)$$

where $a > 0$. Note that as $h \to 0$, $\gamma(h) \to \gamma_0$, rather than 0. This discontinuous behavior, known as the *nugget effect*, occurs in a variety of commonly used semivariograms. Physically, γ_0 has been interpreted as arising from (a) very small-scale fluctuations in the Z process, and/or (b) measurement error. However, if the process modeled is a sufficiently smooth function of space, the only mathematically valid explanation for the nugget effect is measurement error.

The exponential covariogram corresponding to Eqn. (4) is

$$C(h) = \begin{cases} \gamma_0 + \gamma_1 & \text{if } h = 0 \\ \gamma_1 e^{-h/a}, & \text{if } h > 0 \end{cases} \quad (5)$$

Another covariogram sometimes used is the Gaussian model.

$$C(h) = \begin{cases} \gamma_0 + \gamma_1 & \text{if } h = 0 \\ \gamma_1 e^{-h^2/b}, & \text{if } h > 0 \end{cases} \tag{6}$$

where $b > 0$. (Use of the modifiers 'exponential' and 'Gaussian' accrues from similarities to the exponential and Gaussian probability density functions, rather than distributional assumptions for Z.) A very rich class of isotropic covariograms is the Matérn class, written here without a nugget for comparison:

$$C(h) = \frac{2\sigma^2}{\Gamma(\nu)}(h\sqrt{\nu}/a)^{\nu} K_{\nu}(2h\sqrt{\nu}/a) \tag{7}$$

where $\nu > 0$, σ^2 is the variance of $Z(\mathbf{s})$, $\Gamma(\cdot)$ is the usual gamma function, and $K_{\nu}(\cdot)$ is the modified Bessel function of the second kind.

3. Spatial Prediction

A standard spatial model takes the form

$$Z(\mathbf{s}) = \mu(\mathbf{s}) + \varepsilon(\mathbf{s}) \tag{8}$$

Where $\mu(\mathbf{s})$ is a spatial mean model and $\varepsilon(\mathbf{s})$ is a zero-mean spatial error process. Critical issues involve the choices of models regarding both the mean or trend (also known as drift) $\mu(\mathbf{s})$ and the error process $\{\varepsilon(\mathbf{s}): \mathbf{s} \in \mathscr{D}\}$. Such modeling is challenging in that both components explain aspects of the spatial structure present in Z. The conventional guideline is that the trend reflects large-scale spatial variation, while the error process explains residual small-scale spatial dependence. Implementation of this guideline and interpretation of results vary with the context as well as with the goals and knowledge of the analyst. As noted by Cressie (1993, p. 25), 'What is one person's (spatial) covariance structure may be another person's mean structure.' Also note that in modern statistical approaches, trend models based on both spatial location and covariates are recommended. Trend models can also be incorporated in conditionally specified models, either via conditionally specified mean models, or with globally specified mean models and conditionally specified error models.

3.1 The Basics of Kriging

Ordinary kriging asserts a constant trend model. Linear predictors take the form

$$\hat{Z}(\mathbf{s}_0) = \sum_{i=1}^{n} \lambda_i Z(\mathbf{s}_i) \tag{9}$$

The unbiasedness condition, $E(\hat{Z}(\mathrm{s}_0)) = \mu$ adds the side condition that $\sum_{n=1}^{n} \lambda_i = 1$. Minimization of the predictive variance (or mean squared prediction error)

$$E(Z(\mathbf{s}_0) - \hat{Z}(\mathbf{s}_0))^2$$

subject to the side condition yields simple formulas for the optimal values of the λ_i as appropriate functions of the covariance function. Alternatively, the formula can be written in terms of the variogram, enabling spatial prediction for processes that are intrinsically stationary (Cressie 1993, pp. 121–3). The achieved optimal value of the predictive variance is then used to measure the precision of the prediction.

The kriging formulas are derived under the assumption that the variogram or covariance function is known. Typically, data-based estimates of these functions are simply plugged into the kriging formulas. A variety of methods for estimation of the variogram (or covariogram) have been suggested. A simple procedure is to apply a method-of-moments notion: an empirical version of the semivariogram is

$$\hat{\gamma}(\mathbf{h}) = \frac{\sum_{n(\mathbf{h})} (Z(\mathbf{s}_i) - Z(\mathbf{s}_{i'}))^2}{\#n(\mathbf{h})} \tag{10}$$

where the sum is taken over those data points satisfying $\mathbf{s}_i - \mathbf{s}_{i'} = \mathbf{h}$ and $\#n(\mathbf{h})$ is the number of such pairs of data points. A simple estimate of the covariogram is

$$\hat{C}(\mathbf{h}) = \frac{\sum_{n(\mathbf{h})} (Z(\mathbf{s}_i) - \bar{Z})(Z(\mathbf{s}_{i'}) - \bar{Z})}{\#n(\mathbf{h})} \tag{11}$$

where $\bar{Z}$ is the simple mean of the observed values. However, since there are only n observations, these estimates cannot provide estimates for all $\mathbf{h}$. Practical estimates are typically constructed based on binning procedures. For example, under the additional assumption of isotropy, consider a collection of M non-overlapping intervals

$$I_m = [h_m - \delta_m, h_m + \delta_m]; \quad m = 1, \ldots, M$$

For each interval the above empirical sums and counts of pairs are taken over all pairs separated by distances in I_m. The resulting M values can then be smoothed to produce a function estimate.

The above estimates suffer from a variety of deficiencies, especially if the sample size n is small. A variety of alternatives have been suggested. One general approach is to parameterize the covariogram (or variogram), specifying it to be a member of some class (the Matérn class (7) is a popular choice). Methods for parameter estimation include least squares, weighted least squares, and maximum likelihood. A second avenue for estimation involves the use of nonparametric function estimation, especially

in the context of estimating the spectral representation of the covariogram. Also, robust estimates with respect to outlying observations have been developed. See Cressie (1993) and Stein (1999) for further discussion of classes of variograms and estimation procedures. Sampson and Guttorp (1992) consider estimation in the nonstationary case.

3.2 Trend Models and Their Estimation

Universal kriging refers to spatial prediction based on trend models of the form

$$\mu(\mathbf{s}) = \sum_{j=0}^{p} f_j(\mathbf{s})\beta_j \tag{12}$$

where the $f_j(\cdot)$ are $p+1$ specified functions of space and $\boldsymbol{\beta} = (\beta_0, \ldots, \beta_p)'$ is a vector of $p+1$ unknown parameters. In vector notation, let $\mathbf{f}(\mathbf{s}) = (f_p(\mathbf{s}), \ldots, f_p(\mathbf{s}))'$, so the model is written compactly as

$$\mu(\mathbf{s}) = \mathbf{f}'(\mathbf{s})\boldsymbol{\beta}$$

Ordinary kriging is included by assuming $f_0(\mathbf{s}) = 1$ and $p = 0$.

A common example is a quadratic trend surface model: Writing locations in Cartesian coordinates $\mathbf{s} = (x, y)$, assume that

$$\mu(\mathbf{s}) = \beta_0 + \beta_1 x + \beta_2 y + \beta_3 x^2 + \beta_4 xy + \beta_5 y^2$$

In addition to higher-order polynomial trends, nonpolynomial models, such as local polynomials have been considered (Venables and Ripley 1999). The use of splines is highly related; see Wahba (1990) and Cressie (1993, pp. 180–3).

Representation of the kriging model in matrix form provides a better understanding and enables parallels to familiar statistical linear regression modeling. The notation $\mathbf{X} \sim (\mathbf{m}, \mathbf{C})$ is read 'the random vector $\mathbf{X}$ has a multivariate distribution with mean $\mathbf{m}$ and covariance matrix $\mathbf{C}$.' The notation $\mathbf{X} \sim N(\mathbf{m}, \mathbf{C})$ adds the assumption that the distribution is multivariate normal. The standard universal kriging model is then

$$\begin{pmatrix} Z(\mathbf{s}_0) \\ \mathscr{Z} \end{pmatrix} = \begin{pmatrix} \mathbf{f}_0'\boldsymbol{\beta} \\ \mathbf{F}\boldsymbol{\beta} \end{pmatrix} + \begin{pmatrix} \varepsilon(\mathbf{s}_0) \\ \boldsymbol{\varepsilon} \end{pmatrix} \tag{13}$$

where

$$\begin{pmatrix} \varepsilon(\mathbf{s}_0) \\ \boldsymbol{\varepsilon} \end{pmatrix} \sim \left(\begin{pmatrix} 0 \\ \mathbf{0} \end{pmatrix}, \begin{pmatrix} \sigma^2(\mathbf{s}_0) & \boldsymbol{\sigma}' \\ \boldsymbol{\sigma} & \boldsymbol{\Sigma} \end{pmatrix} \right) \tag{14}$$

where $\boldsymbol{\sigma}$ is the $n \times 1$ vector of covariances between errors at site $\mathbf{s}_0$ and the observation sites; $\mathbf{F}$ is the $n \times (p+1)$ matrix dictated by the functions $f_p(\cdot)$ evaluated at the observation locations; and $\boldsymbol{\varepsilon}$ is the vector of errors at observation sites. These errors are assumed to have zero means and covariance matrix $\boldsymbol{\Sigma}$ whose entries are the covariances $\mathrm{cov}(\boldsymbol{\varepsilon}(\mathbf{s}_i), (\varepsilon(\mathbf{s}_{i'}))$ for pairs of data points.

Formulas for the optimal linear predictor or BLUP are readily derived (Cressie 1993, pp. 172–80):

$$\hat{Z}(\mathbf{s}_0) = \mathbf{f}'(\mathbf{s}_0)\boldsymbol{\beta} + \boldsymbol{\sigma}'\boldsymbol{\Sigma}^{-1}(\mathscr{Z} - \mathbf{F}\boldsymbol{\beta}) \tag{15}$$

These formulas depend on appropriate values of the covariance function and $\boldsymbol{\beta}$, requiring estimation of both quantities. Note that use of (15) does not require spatial stationarity of the error process, though it is often assumed in estimation.

Estimation of $\boldsymbol{\beta}$ is typically accomplished via generalized least squares. Since the observations follow the model

$$\mathscr{Z} = \mathbf{F}\boldsymbol{\beta} + \boldsymbol{\varepsilon} \tag{16}$$

The generalized least squares estimate of β is

$$\hat{\boldsymbol{\beta}} = (\mathbf{F}'\boldsymbol{\Sigma}^{-1}\mathbf{F})^{-1}\mathbf{F}\boldsymbol{\Sigma}^{-1}\mathscr{Z} \tag{17}$$

Estimation of the covariogram of the ε process proceeds as discussed earlier, though now the data used are the residuals from the fitted trend model: $\mathscr{Z} - \mathbf{F}\hat{\boldsymbol{\beta}}$. However, there is a clear difficulty. The very residuals needed to estimate the covariogram depend on the covariogram since $\hat{\boldsymbol{\beta}}$ is the function of $\boldsymbol{\Sigma}$. A variety of approaches to this problem have been suggested. One is to use some preliminary guess at $\boldsymbol{\Sigma}$ in (17), but base prediction formulas on the estimated covariogram of the resulting residuals. With the increase of readily available computation, the more modern approach iterates between generalized least squares estimation of $\boldsymbol{\beta}$ and covariogram estimation until some stability is achieved (Venables and Ripley 1999). Note that the extra uncertainty accruing from the use of data-based estimates of $\boldsymbol{\beta}$ and the covariance function is seldom accounted for in classical kriging.

Treatment of measurement error can be included in the modeling. Rather than observing $\mathscr{Z}$ directly, the observed data values, denoted by Y, may be modeled as $Y(\mathbf{s}_i) = Z(\mathbf{s}_i) + e(\mathbf{s}_i)$; $i = 1, \ldots, n$. Let $\mathscr{Y}$ denote the $n \times 1$ vector of observations. In matrix form we write

$$\mathscr{Y} \sim (\mathscr{Z}, \mathbf{D}_y) \tag{18}$$

where $\mathbf{D}_y$ is the covariance matrix of the measurement errors $\mathbf{e} = (e(\mathbf{s}_1), \ldots, e(\mathbf{s}_n))'$. A common, but not unequivocal, assumption is that $\mathbf{D}_y = \sigma_y^2\mathbf{I}$ (i.e., the measurement errors are mutually uncorrelated). Also, assume $\mathbf{e}$ is uncorrelated with $\mathscr{Z}$. If Z is a smooth function of space, σ_y^2 is a quantification of the nugget effect. To complete the formalization, interpret (18) as

a specification *conditional* on $\mathscr{Z}$. The model (16) for $\mathscr{Z}$ implies that the *unconditional* model for $\mathscr{Y}$ is

$$\mathscr{Y} \sim (\mathbf{F}\boldsymbol{\beta}, \boldsymbol{\Sigma} + \sigma_y^2 \mathbf{I}) \tag{19}$$

(Compare this covariance matrix to the piece-wise definitions of variograms in (5) and (6).) Without replicate observations at some of the observation locations, σ_y^2 is not directly estimable in classical kriging. Typically, estimates are obtained by extrapolation of covariogram estimates for small distances.

Note that the goals of the analysis now include not only prediction of $Z(\mathbf{s}_0)$, but also prediction of $\mathscr{Z}$. Predicting $\mathscr{Z}$ based on $\mathscr{Y}$ provides spatial smoothing, as opposed to spatial interpolation when σ_y^2 is assumed to be zero.

3.3 Multivariate Methods

In many applications, several variables may be of interest, suggesting the consideration of a random vector, $\mathbf{Z}(\mathbf{s}) = (Z_1(\mathbf{s}), \ldots, Z_K(\mathbf{s}))'$. In mining, the data might consist of measurements of amounts of K minerals at each observed site. In meteorology, data on temperature, pressure and precipitation are often collected. In satellite imaging, multichannel sensors collect intensities in various bandwidths.

The classical geostatistical treatment of multivariate spatial data is known as *cokriging*. The modeling strategy is a direct generalization of the univariate case. For each coordinate $Z_k(\mathbf{s})$ of $\mathbf{Z}(\mathbf{s})$, consider a mean or trend model (see (12))

$$\mu_k(\mathbf{s}) = \mathbf{f}_k'(\mathbf{s})\boldsymbol{\beta}_k, \quad k = 1, \ldots, K \tag{20}$$

Note that the spatial regression functions comprising the various $\mathbf{f}_k$ need not be the same for all k: indeed, the dimensions of the $\boldsymbol{\beta}_k$ may vary with k. The key second-order parameters are the covariance matrices,

$$\operatorname{cov}(\mathbf{Z}(\mathbf{s}), \mathbf{Z}(\mathbf{s}')) = \mathbf{C}(\mathbf{s}, \mathbf{s}'), \quad \mathbf{s} \in D, \mathbf{s}' \in D \tag{21}$$

The principles and basic formulas for best linear unbiased prediction remain essentially the same as for the univariate case. Since the notation is cumbersome, the reader is referred to Wackernagel (1995) for details.

Practical implementation of cokriging can be difficult. First, specification and subsequent estimation of $\mathbf{C}(\mathbf{s}, \mathbf{s}')$ is problematic, in that it involves specification not merely of K spatial covariance functions (one for each variable) but also $0.5K(K-1)$ cross-covariance functions, one for each pair Z_k, $Z_{k'}$, $k \neq k'$. The number of observations critically limits the ability to estimate the required covariance functions. Indeed, sample size typically mandates the need for extremely simple, often implausible, covariance models and/or a reduction in K. Further, the sampling pattern (e.g., observations of only some coordinates of $\mathbf{Z}$ at some sites) can moderate the ability to estimate parameters and predict.

An alternative modeling strategy is to build multivariate models hierarchically, namely as a sequence of conditional models. A precursor to this view from the geostatistics literature is kriging with external drift. For example, suppose that spatial prediction of near-surface ozone is of interest. It is well accepted that temperature is predictive for ozone. Hence, spatial prediction of ozone could be enhanced if appropriate temperature data were available and included in the model. An elementary approach is to view temperature as a (fixed) covariate and to include it in the formulation of a universal kriging model for ozone. Next, suppose temperature observations are unavailable at sites at which ozone predictions are sought. One could essentially form a kriging model for temperature, and rely on temperature predictions to produce ozone predictions. These notions can be made rigorous statistically. Specification of a complete spatial model for ozone conditional on temperature combined with a marginal spatial model for temperature does imply a joint model for both, as might be formed in a cokriging approach. However, the parameterizations of the models can be different. In particular, rather than direct specification and estimation of the cross-covariance function for ozone and temperature, one specifies a conditional mean relationship between the two. For further discussion and examples, see Royle and Berliner (1999).

4. Bayesian Spatial Statistics

4.1 Bayesian Geostatistics

Models for the Z process, such as the basic model (13) along with a measurement error stage as in (18) can readily be posed in the Bayesian framework. Process models for Z are viewed as priors; these priors may be specified simultaneously or conditionally. Specification of prior distributions on model parameters, such as the trend model coefficients $\boldsymbol{\beta}$, measurement error variance, and parameters of the modeled covariance function are also formulated. Predictive inference is then based on the posterior distribution of unknown quantities, given the data. (A general review of Bayesian analysis is given in Bernardo and Smith 1994.)

Direct analogs to conventional kriging often rely on multivariate normal distributions in both (13) and (18). This imposition of distributional assumptions has been criticized. However, neither standard kriging nor Bayesian analyses based on normal distribution assumptions are recommended for highly non-normal data and processes. The Bayesian approach readily offers valid measures of uncertainty (e.g., Le and Zidek 1992, Handcock and Stein 1993), unlike those arising from the 'plug-in' of estimates procedures dominating non-Bayesian kriging.

With the advent of Bayesian computing advances, non-normal models can be analyzed. For example,

settings in which the Z variable is discrete, such as in some imaging problems (Geman and Geman 1984) or is count data modeled as via Poisson or related distributions (Kaiser and Cressie 1997, Wolpert and Icktadt 1998), have been considered. See also Diggle et al. (1998).

4.2 Hierarchical Models

Hierarchical Bayesian models for collections of variables are combinations of component models or stages. This strategy is particularly useful in complex settings. Motivations for hierarchical modeling include:

(a) individual stages are often formulated more easily than is the full joint model directly;

(b) scientific understanding of the relationships among variables is often readily available for components of the model; and

(c) combining datasets consisting of very different types of data is often enhanced.

The first stage of a Bayesian hierarchical model is usually a measurement error model for the observations, analogous to (18). A variety of higher-level stages, interrelating spatial processes and model parameters, can then be formulated. Finally, a prior probability distribution for all model parameters is specified. See Royle et al. (1998) and Berliner (2000) for examples and discussion.

5. Spatial Point Processes

A spatial point process arises when the locations of events occur randomly in D. Basic data take the form $(\mathbf{s}_1, \ldots, \mathbf{s}_N)'$, where the number of locations, N is a random variable. The probability theory for point processes typically formulates a model for random points in $\mathscr{R}^2$. The model then implies a distribution for N, the number of events in the study region D, a bounded subset of $\mathscr{R}^2$, as well as the joint distribution of their locations. Generally, the treatment of edge effects then becomes a challenge (Ripley 1988, Chap. 2).

A standard point process model is the homogeneous Poisson spatial process with intensity λ: For any k and any selection of disjoint subsets $A_1, \ldots, A_k$ of $\mathscr{R}^2$, assume that the numbers of events, $N(A_i)$, $i = 1, \ldots, k$, are independent random variables each with probability

$$P(N(A_i) = n) = \frac{(\lambda|A_i|)^n}{n!} \exp(-\lambda|A_i|), \quad n = 0,1,\ldots \tag{22}$$

where $|A_i|$ is the area of A_i, $\int_{A_i} \mathbf{ds}$. Note that for any set A, the mean $E(N(A)) = \lambda|A|$. The Poisson process is viewed as completely spatially random, since counts in disjoint intervals are independent and the probabilities in (22) depend only on A_i through its area and not its shape or position. This model is often used as a null hypothesis. Rejection of the Poisson model suggests that the process has some spatially dependent structure, or dependence among separated regions. Numerous generalizations have been considered. The Poisson cluster process allows cluster locations to be distributed according to one Poisson spatial process, while events in clusters are distributed according to another Poisson model. Extensions to alternative measures on sets beyond simple area, including measures which vary in space leading inhomogeneous processes have been considered. A Cox process is generated as a Poisson process, but the measures associated with sets are themselves random.

As in geostatistics and related areas, selected moments of a spatial process play roles in both theory and data analysis. Define the intensity function of a point process as

$$\lambda(\mathbf{s}) = \lim_{|\mathbf{ds}| \to 0} \frac{P(N(\mathbf{ds}) > 0)}{|\mathbf{ds}|} \tag{23}$$

where $\mathbf{ds}$ is a small square centered at $\mathbf{s}$. If only one event may occur at a location, note that

$$\lambda(\mathbf{s}) = \lim_{|\mathbf{ds}| \to 0} \frac{E(N(\mathbf{ds}))}{|\mathbf{ds}|}$$

The second-order product density of a point process is

$$\lambda_2(\mathbf{s}, \mathbf{s}') = \lim_{|\mathbf{ds}| \to 0, |\mathbf{ds}'| \to 0} \frac{E(N(\mathbf{ds})N(\mathbf{ds}'))}{|\mathbf{ds}|\,|\mathbf{ds}'|} \tag{24}$$

If $\lambda_2(\mathbf{s}, \mathbf{s}')$ depends only on $\mathbf{h} = \mathbf{s} - \mathbf{s}'$, the process is stationary; if $\lambda_2(\mathbf{s}, \mathbf{s}')$ depends only on the distance h between the points, it is isotropic. In the isotropic case Ripley (1977) developed a theory for the K function,

$$K(h) = E(\text{number of other points within distance } h \text{ of an event})/\lambda \tag{25}$$

and its relationship to $\lambda_2(h)$. A Poisson process is isotropic with $K(h) = \pi h^2$.

The K function plays a critical role in theory, because it can be computed readily for a variety of important point processes, and in practice, because it can be estimated readily from data. Simple data-based estimates take the form

$$\hat{K}(h) = \frac{\sum_{i=1}^{N} \text{number of other points within distance } h \text{ of } \mathbf{s}_i}{\lambda N}$$

(λ is often estimated as $N/|D|$.) Note that this estimate is biased negatively, since events outside the data collection domain D are not included. The intuition behind the K function relates generally to statistical distance methods and specifically, nearest-neighbor methods. Distance methods involve statistics which are computed from the set of all distances between events, rather than the actual locations. Substantial theory regarding the distributions of distance-based statistics is available.

Extensions of point processes include marked point processes for which a (possibly multivariate) variable Z is associated with each event, leading to data of the form $Z \equiv (Z(\mathbf{s}_1), \ldots, Z(\mathbf{s}_N))'$. A related multivariate class of problems involves the modeling and data analysis for multiple point processes.

6. Spatial–Temporal Statistics

Very complex model structures may arise when both spatial dependences and temporal dependences, and their interactions, are present. Early attempts in this area often viewed time as if it were another spatial dimension, leading to relatively simple treatments of spatial–temporal data via spatial methods. However, the special role of time (i.e., the direction of its flow) often renders such approaches ineffective. Alternatively, the Kalman filter adapted to space–time problems has had wide application in the sciences. The basic method is analogous to kriging in temporal settings. Spatial–temporal statistics is at the forefront of current statistical research. See Kyriakidis and Journel (1999) for a review in geostatistics. For recent Bayesian approaches and references, see Wikle et al. (1998) and Wikle (2000).

Spatial-temporal Modeling

'Spatial Temporal Models' (STMs) portray the variation of phenomena over time and across space. In the sections that follow, first the STMs are defined. Then the 'canonical' and 'compartment' types of STMs are described. The construction of STMs is discussed next. A number of trends that have influenced the evolution of spatial temporal modeling are touched upon in a 'concluding comments' section.

1. Introduction

A mathematical model qualifies as a STM if at least some of its variables are referenced spatially and temporally. Spatial temporal referencing means that the values of these variables are linked to points or intervals in time and simultaneously to entities in geographical space such as points, or areal units, or arcs or nodes of a network. The STMs are likely to include also purely spatial and purely temporal variables. Examples of spatial variables are distances, directions, spatial coordinates, locational quotients, measures of spatial inequality, measures of phenomena that vary over space or index geographic environments, and spatial dummies. Examples of purely temporal variables are time and functions of time, dummies associated with time intervals and points in time, and measures of phenomena that vary over time or index temporal environments.

The STMs primarily are concerned with three classes of phenomena: spatial flows, spatial diffusion, and spatial temporal change. The latter includes spatial variation of growth rates (for instance, of product per capita), qualitative spatial change (for instance, in land use), and change in spatial distributions (for instance, of crime events or of settlements). A systematic introduction to the spatial temporal modeling of several classes of substantive phenomena can be found in Haggett et al. (1977).

In the social sciences, much of the conceptual work that precedes or is intertwined with mathematical modeling is based on notions from system theory. Books dealing with the nexus between spatial temporal modeling and spatial systems include Bennett and Chorley (1978), Bertuglia et al. (1987), Huggett (1980), and Klassen et al. (1979). The STMs figure prominently in the edited collections by Anselin and Florax (1995), Fischer and Getis (1997), Griffith and Mackinnon (1981), Griffith and Lea (1983), Griffith and Haining (1986), and Wrigley (1979).

The STMs encompass a huge body of knowledge crisscrossed by many substantive and analytical literatures. In order to convey a feel for spatial temporal modeling the two most common types of STMs were singled out for a brief treatment in the next two sections. A subsequent section discusses an approach to the construction of STMs. In the concluding comments some trends that have influenced the evolution of the STMs are touched upon.

2. Canonical STMs

'Canonical single equation STMs' are models consisting of an equation with spatially referenced rates of change over time as the dependent variable, and in which at least some of the independent variables are spatial or spatially referenced. The 'canonical multiple equations STMs' instead are systems of equations, some or all of which qualify as canonical single equation STMs. In the social sciences, the most common STMs are the ones here referred to as canonical.

Examples of canonical single equation STMs can be found everywhere in the social sciences. For instance, they are the backbone of the empirical literature on the determinants of economic growth. Consider as a specific 'case' the regression model in Barro (1997). It has growth rates of GDP per capita as the dependent variable, and GDP per capita, male schooling, fertility rates, a democracy index, inflation rates, and others as independent variables. Barro estimated it using a sample of 114 countries, and growth rates calculated from several time intervals. In fact, the STMs in which the dependent variable is the rate of change of variables such as income, unemployment, population, welfare rolls, crime rates, for countries, counties, or regions, and in which the independent variables include indices of relevant characteristics of these geographical entities, are ubiquitous. Also very common are models in which rates of change are functions of distances or of spatial coordinates.

An example of canonical multi-equation STMs is Greenwood's 1981 model of metropolitan growth and migrations. The model consists of 14 equations with 14 endogenous and 16 exogenous variables. It focuses on the rates of change of income per capita, unemployment, and migrations into or out-of metropolitan and nonmetropolitan areas. A number of multi-equation canonical STMs are described in Putman (1979).

3. Spatial Compartments STMs

'Compartment models' describe systems made of subsystems interconnected by flows (De Palma and Lefevre 1987). In a number of instances the dynamics of a system and of its subsystems and the flows among these are influenced by controls or from policy instruments (Bennett and Chorley 1978). The term 'spatial compartment models' refers to spatial systems with subsystems corresponding to geographical entities such as regions, countries, or urban centers. For

instance, a world system may consist of spatial compartments made of aggregates of countries ('regions'). A system may be defined in terms of one or more 'elements.' For instance, population may be the only element in a system, and a four-elements system may be defined in terms of population, product, capital, and technology.

An example of spatial compartment STMs is the one employed in a 1977 UN study of the future of the world economy (Leontief 1977). The model is of the inter-regional input–output type. It has 48 producing and consuming sectors and 15 regions. The regions are aggregates of countries. A sector inputs from other sectors, and outputs to other sectors. The goods produced by sectors are classified as 'domestic' or 'internationally traded.' The internationally traded goods are exported to or drawn from international sectoral pools, and each region exports/imports a fixed share of the aggregate world exports/imports of any given internationally traded commodity.

The model is made of a total of 2625 equations grouped into 15 regional sets. Each regional set describes the inter-relations within a region of production, consumption, imports, and exports, of goods and natural resources. Each set involves 269 variables, of which 229 are region specific, and the remaining 40 represent the imports/exports pools of internationally traded goods and the balance/imbalance of the regions' international financial transactions. Thus, the model contains more variables than equations. To solve it, enough variables are set to fixed values to render the number of the remaining variables equal to the number of the equations.

This model was used to produce eight development paths of the world economy from the base year 1970 through 1980 and 1990 to the year 2000. These paths are based primarily on combinations of low/medium/high population growth scenarios, and low/high GDP per capita growth scenarios. In short, the questions asked focus upon what the world economy has to be like in 1980, 1990, 2000, if the population and product per capita follow specified scenarios that unfold within realistic technical and physical constraints.

Spatial compartment STMs can be constructed by combining input output models with econometric models. A review of pertinent issues and literatures is contained in Rey (1998). In the 'computable general equilibrium models' the demand and supply functions of products and of factors of production are specified and estimated. In the spatial compartment variants of these models the mechanisms affecting the spatial flows of products and factors are also brought forth and the equations describing these mechanisms are specified and estimated. Regional computable general equilibrium modeling has been surveyed by Partridge and Rickman (1998). Isard et al. (1998) review applied inter-regional equilibrium modeling. A discussion of the theory and estimation of multicountry trade models is contained in the book by Deardorff and Stern (1986). This 'Michigan' model represents a massive undertaking, and was developed for the purpose of evaluating the impacts of changes in tariffs on international trade flows. Linked macroeconomic models are discussed in Ball (1973) and in Fair (1984).

A spatial compartments follow up to the 'Limits to Growth' model (Meadows et al. 1972) is described in Mesarovic and Pestel (1974a) and is documented in the six volumes edited by the same authors (1974b). Their work builds upon the 'Limits to Growth' thesis that if the current population growth, economic growth, pollution increases, and natural resources depletion continue, the world will face a number of catastrophes. However, Mesarovic and Pestel maintained that before the middle of the twenty-first century we shall be confronted by regional catastrophes rather than by a collapse of the world system. These catastrophes will materialize in different regions for different reasons and at different times, and will be profoundly felt throughout the entire world (Mesarovic and Pestel 1974a).

Most of the spatial compartment models referred to in this section are constructed to produce forecasts, simulations, or scenarios. It should be noted, however, that there are extensive literatures dealing with spatial compartment STMs constructed for the purpose of investigating systemic optima. Intertemporal linear and non linear programming models based on spatial compartments are discussed in Takayama and Judge (1971) and in Judge and Takayama (1973). Optimal control spatial compartments STMs are reviewed in Tan and Bennett (1984).

4. *STMs Generated by Expansions*

In many cases, STMs in the social sciences have been imported from nonsocial science disciplines. For instance, some of the diffusion models in geography and economics originated from their counterparts in physics and engineering (Banks 1994). In general, the analogies between very different phenomena may trigger interdisciplinary transfers of methodologies and models. The notions of systems and of system dynamics and the schools of thought linked to them have played a major role in the construction of classes of STMs based on cross-disciplinary analogies.

However, in many circumstances the need may arise to construct STMs from purely spatial or purely temporal models, or to extend existing STMs to encompass relevant contexts that are outside their original scope. An approach to the incremental construction of mathematical models that can be easily applied to building STMs is the 'expansion method' (Casetti 1997). In a nutshell, the expansion method involves widening the scope of a simpler 'initial model' by redefining some or all of its parameters into

functions of expansion variables or variates that index substantively relevant contexts of the model. The 'terminal model' thus produced encompasses both the initial model and a specification of its contextual variation.

To demonstrate the operation of the method, let us discuss its application by adding a time dimension to a purely spatial model of urban population densities. This demonstration is based on a variant of the model presented in Casetti (1973). The urban studies literature has identified two spatial patterns of urban population densities that are often referred to as 'density cones' and 'density craters.' In the cones, the population densities decline exponentially with distance from city centers. Instead, a density crater type of trend is characterized by urban population densities that increase at first and then decline as the distance from the city center increases.

Let D, s, and ε denote, respectively, the natural logarithm of urban population density, distance from a city center, and an error term. Let

$$D = \alpha_0 + \alpha_1 s + \alpha_2 s^2 + \varepsilon \tag{1}$$

be an initial model subsuming both a density cone and a density crater as special cases. In fact, for $\alpha_1 < 0$ and $\alpha_2 \leqslant 0$ this model corresponds to a density cone, while for $\alpha_1 > 0$ and $\alpha_2 < 0$ it yields a density crater.

The literature has also identified distinctive patterns of temporal change of these spatial trends. They include the rising and flattening of the density cones, the widening of the density craters, and the gradual transformation of cones into craters. In order to extend the initial purely spatial model (1) so that it will encompass the spatial temporal trends recognized by the literature, the α parameters in it are expanded by the stochastic expansion equations

$$\alpha_i = \alpha_{i0} + \alpha_{i1} t + \theta_i \quad i = 0,1,2 \tag{2}$$

where the θs are error terms. The terminal models

$$D = \alpha_{00} + \alpha_{01} t + \alpha_{10} s + \alpha_{11} st + \alpha_{20} s^2 + \alpha_{21} s^2 t + u \tag{3}$$

$$u = \varepsilon + \theta_0 + \theta_1 s + \theta_2 s^2 \tag{4}$$

are obtained by replacing the right hand sides of the expansion equations for the αs in the initial model. Upon estimation, these terminal models can be used to test for the occurrence of specific spatial temporal trends, and to portray these trends if they occur.

The model appearing in this demonstration is intended for estimation and for the testing of statistical hypotheses. It should be noted, though, that the expansion method can be used to construct STMs of any kind. Any model that has parameters can be expanded, irrespectively of whether it is deterministic, stochastic, or mixed, and irrespectively of whether it is intended for solving, estimating, or optimizing.

5. *Concluding Comments*

Most STMs in the social sciences came into existence during or after the 1930s, and have been influenced or shaped by trends that kept altering the landscape of the quantitative analytical social sciences during this time horizon. The comments that follow highlight some such trends and influences.

Mathematical models in general, and STMs in particular, have been acquiring an important role in government and private sector activities as aids to decision making, to planning, to policy development and evaluation, and for forecasting. In the process they have been driven to address the complexities of the real world to an ever-increasing degree. The tendency toward more complex models is especially apparent in the canonical and compartment STMs, and in turn the proliferation of these models is a reflection of their practical usefulness. The movement toward the 'computational' counterparts of STMs that originated as purely mathematical formalisms is another aspect of these tendencies.

Increasingly complex STMs have also played an important role in the precise articulation of the theories and conceptual frameworks that constitute a substantial component of the social sciences. In the more theoretical applications this complexification has been intertwined with conceptual and technical advances imported from mathematics and the non social sciences. The STMs with nonlinear dynamics, and the ones centering on optimal control techniques are cases in point.

The entire evolution of STMs and of mathematical modeling at large has been permeated by the growth of stochastic modeling, and by the penetration of stochastic elements into models born deterministic. For instance, deterministic canonical STMs have been converted into 'mixed' or stochastic models by the addition of stochastic errors and/or of temporally or spatially autoregressive terms. An adequate stochastic specification and its attendant statistical econometric testing have increasingly become a must for empirical analyses to be credible.

E. Casetti

Spatial Thinking in the Social Sciences, History of

The objects upon which social sciences work, either people or artefacts, take up some room and are located in specific places. Cognition implies the building and mobilization of spatial skills, like orientation. Social scientists are generally more interested in particular spatial categories like direction, distance, place, area, landscape, village, town, city than in space: the distribution of things and people, the behaviors and practices of everyday life, or the plans developed for the future deal with concrete geographical realities rather than the abstract idea of space. Even geography was traditionally more oriented towards places, regions, or zones than towards space: the idea of geography as a spatial discipline did not develop before the 1950s, and was soon criticized. Among the other social sciences, economics was the only one with a specialty branch in the field: spatial economics, which began to flourish in the 1820s. Among the cognitive sciences, the psychology of orientation developed before Jean Piaget described the stages of space construction by children. As a result, spatial thinking in the social sciences often appears split into different fields, *urban* studies, *rural* studies, *landscape* studies, the significance of the *regional approach* and of *place*, the idea of *environment*, the problem of *orientation*, etc.

Spatial thinking refers to five types of intellectual operations: (a) using geographical observations as a starting point for social analysis, (b) explaining, generally within a functional perspective, the role of different aspects of space in the life of social groups, (c) understanding the way people invest symbolic meanings in their environment, (d) wondering about the significance given to space in the definition of concepts like society, economics, culture, language, polity, etc.,

or (e) deciphering the ways in which the human mind deals with space and builds and uses spatial categories. The first family was present from the earliest developments of the social sciences. The second family flourished mainly in the late nineteenth and most of the twentieth centuries. The third family is more characteristic of the rise of phenomenological approaches, since the 1930s or 1940s. The fourth family is mainly linked to the development of critical perspectives on the social sciences since the 1970s. The development of an interest for space by the cognitive sciences remained until recently independent from the other approaches.

1. Spatial Distributions as a Point of Departure for Social Thinking

We are living in social systems and so deeply embedded into them that generally we think they are an expression of the natural order. In order to build a science of social realities, the social scientist has to introduce a distance between the object. Travel narratives and geographical descriptions played a central role in this operation. Montaigne started to ponder about the relativity of social institutions when reading about the American cannibals. From Jean Bodin to Montesquieu, the diversity of political and social institutions nurtured the reflexion on social and political life and was interpreted through a simple model, the influence of climate.

The first steps of economics were linked with geographic evidence: the role of transport in the distribution of economic activities, the complementarities between cities and rural areas, the economic circuit served as bases for the development of a more conceptual vision, which started with the analysis of market mechanisms by Turgot and Adam Smith's reflexion on the division of labor.

With the development of travels and the improvement of their accounts, geographical comparisons became more sophisticated: they allowed for the development of new disciplines, like ethnography. The change of scenery could be provided by travel through time as well as space. Immanuel Kant emphasized the similarities between history and geography: spatial and temporal distributions were the first features to confront social scientists in their study of the World. He opposed spatio-temporal descriptions to systematic analyses. Partly under the influence of Kant, the idea that geography was essentially a description of spatial distributions developed and remained alive well into the twentieth century.

It was during the first decades of the nineteenth century that spatial comparisons played their most important role in the development of science. It was true for the natural sciences—Charles Darwin developed his evolutionary theory when traveling on the *Beagle*. In the social sciences, Alexis de Tocqueville built his analysis of democracy by comparing the US, where it permeated all forms of social life, and Old Europe, where aristocratics were still influencial. Karl Marx explored the opposition between medieval cities and rural areas, the Asiatic social and economic organization, and the industrial revolution in Britain before building the notion of mode of production.

By the middle of the nineteenth century, the cartographic model was increasingly replaced by models each with a logic dictated by the dynamic, immediate, interactive phenomena under study: the new specialized disciplines broke their earlier links with spatial thinking.

2. The Functional Approach to the Relations Between Space, Social Life, and Thought

When social and behavioral sciences severed their former links with distributional approaches, they generally considered space as a neutral stand and ceased to use it as a significant factor for explaining what they observed. Many scholars thought, however, that space mattered: they had the idea that social life differed according to its physical setting, the fact that people lived in empty or overpopulated areas, and were more or less distant from each other. For Emile Durkheim the foundation of sociology lay in social morphology, but he was unable to provide a clear picture of it. The only way to take it into account was to adopt a functional perspective: space could be conceived either as a collection of environments or a set of distances (see *Functionalism, History of*).

2.1 Space as Environment

In the environmental perspective, the emphasis was given to the local connexions between people, artefacts, and place. The first environmental approaches were developed by the sensualist psychology of the eighteenth century. Man was a product of whatever his senses impressed upon his mind. His aptitudes and personality reflected his environment. If it was disorderly or unsound, social life had many reasons to be stressed. By the end of the eighteenth century, social scientists were well aware of the social and political implications of such a conception. Jeremy Bentham conceived his *Panopticon* in order to provide criminals with an environment which would teach them safer forms of behavior. More generally, the idea that to reform society, you had to change its material setting was central to the nineteenth century utopian socialism and still present in the conception of urbanism developed by the International Movement of Modern Architecture in the 1930s.

Johann Gottfried Herder was more sensitive to the harmony which developed between peoples and the country they lived in than to the sensual influence of

these surroundings on their mind and behavior. The early development of geography in Germany was linked to the combined influence of Kant (evident in Alexander von Humboldt's conception of geographical description) and Herder (who was closer to Carl Ritter). Such a conception was important for all the social sciences in Germany, since it was conducive to a keener interest in peoples than in individuals or social classes. For many German geographers, the harmony between a people and the land they lived in was expressed through its landscapes (see *Romanticism: Impact on Social Thought*).

The Herderian environmentalism was a literary and poetic one. Natural evolutionism had a more direct impact on the social sciences, since it was a scientific theory. The early forms of evolutionism as developed in the eighteenth and early nineteenth centuries had no direct impact on the then emerging social sciences. The publication of *The Origin of Species* occurred at a time when history and the idea of progress had become popular in the public opinion, and original forms of evolutionism had developed in sociology: hence the impact of its theses in the social sciences. For sensualist psychology or Herderian philosophy, the influence of things upon the human mind was a direct one. For scientific evolutionism, the relations were mediated through biological mechanisms (see *Evolutionism, Including Social Darwinism*).

Did environments shape completely the destiny of humankind and of any of its groups? Hot discussions developed between environmentalists and the scientists who believed in human liberty. In order to depict the relations between organisms and their environment, a new discipline, ecology, appeared. Named by Haeckel in 1872, its first scientific achievements occurred at the end of the nineteenth century; it became mature in the 1930s and 1940s. Geographers did not wait for the development of ecology to propose a new conception of their discipline: *Anthropogeographie*, or human geography, was named and shaped by Friedrich Ratzel in the 1880s and 1890s. For him and for the first human geographers in France, a strict environmentalism was an unbearable position, but physical constraints did exist and shaped at least partly human behavior and history: geographers pleaded for possibilism, which gave room to physical and biological constraints, but acknowledged the role of other variables.

By 1920, it had become evident that environmentalism was not a very fruitful way of conceiving the role of space in social functioning.

2.2 Space as Distance

Economics had developed another approach to analyze the role of space in the functioning of society. In the early nineteenth century, some economists were unhappy with the elimination of space from mainstream theory. Hence, the development of spatial economics as a sideline. It was centered on two problems: the uneven distribution of natural factors and the role of distance. The name of David Ricardo is associated with the first orientation and the ensuing theory of international specialization and trade. Johann Heinrich von Thünen explained how distances to the market determined farming specialization even in a perfectly uniform setting (1826–52). The progress of spatial economics was a slow one: people had to wait until Alfred Weber for a coherent theory of industrial location (1909), and Walter Christaller and August Lösch for an understanding of the location of service activities and the nature of urban networks (early 1930s).

At the end of the nineteenth and the beginning of the twentieth centuries, some anthropologists also considered distance as a major factor of cultural differentiation. It soon appeared that diffusionism could not serve as an overall explanatory theory. Diffusion was, however, a significant cultural process (see *Anthropology, History of*).

When geographers, tired from the hopelessly descriptive character of the possibilist approach, tried in the late 1950s and 1960s to develop a more systematic view of their scientific enterprise, many of them decided that geography should become a discipline of distances: they incorporated what spatial economics and anthropology could offer and went further through the emphasis they gave to communication processes. They used what a new scientific field, the study of communication, was developing.

The functional approach to social problems through the analysis of distance was fruitful. Its role in planning theory and practice was essential during the 1960s and 1970s. It allowed for the design of well organized cities or suburbs. It did not prevent, however, the development of urban pathologies. In order to understand them, other approaches to the role of space in social life had to be developed.

3. Space as Experience

Functional approaches were specific to the social sciences. They did not offer many possibilities to the cognitive sciences. The situation is different for those who try to analyze space as experience.

3.1 Environmental Psychology

The curiosity of psychologists for spatial problems was initially focused on the problems of orientation and place recognition. Their interest changed with the genetic approach developed by Jean Piaget: his problem was to understand the way in which children explored their environment and built behavioral

schemes and mental categories out of their experience and inborn capabilities.

The relations between man and environment are mediated through the senses: what are the specific contributions of sight, hearing, smell, touch, taste, and cynesthesic sensation to the individual experience of space? Michel Foucault, for instance, was fascinated by the place given to sight by Western civilizations and its role in social control.

Because of its emphasis on experimental methods, mainstream psychology ignored the social dimension of spatial learning and experience. They were brought back by phenomenologists, Gaston Bachelard or Maurice Merleau-Ponty, for instance. Environmental psychology introduced the theme of proxemics.

3.2 The Psychological, Moral, and Religious Significance of Space

Through phenomenology and proxemics, space started to be conceived as a necessary component of communication systems: hence the contribution of linguistics and semiotics to spatial thinking. Landscapes ceased to be analyzed in a functional perspective. They were conceived as supports for messages. People experience different forms of connivance with them.

A difference exists between analytical and symbolic communication: in the first case, the problem is to transfer complex sets of information from individuals to individuals; in the second one, it is to stir simultaneously many persons through a unique and short message. Symbolism appears in this way as a way of mastering distance. Hence, the interest of geographers for this form of communication.

Space has other social meanings. Normative thinking relies on perspectives from the outside: people have to imagine Beyonds, either within beings or things (when the way of immanence is chosen) or outside them, generally in another World (when the way of transcendance is selected). These choices are important since they introduce a qualitative differenciation of space: places where the Beyonds touch the surface of our World are loaded with sacrality, in contrast to the surrounding profane areas. The building of Utopias, the belief in the Golden Age, or in a Land without Evil are ways to use history or terrestrial space to build other types of Beyonds. The dreams they nurture are important in the shaping of rural or urban areas.

The new approaches to geography developed since the 1970s incorporate this interest in the human experience of space.

3.3 Social Experience as a Localized Experience

People cannot develop an experience of society outside specific places. The *Time Geography* developed by Torstein Hägerstrand stresses the fundamental diversity of spatial and social experiences developed by people along their life trajectories: it means that social experiences differ according to persons. In the field of communication, for instance, people participate to different intersubjectivity circles depending on the places they live or had lived.

Such an observation is fundamental for all the social sciences: it reminds that societies, cultures, polities, languages do not exist in a spaceless social realm. They differ from place to place, because of the existence of *locales*, as expressed by Anthony Giddens. The social sciences of today can no more ignore spatial thinking: it is one of the main lessons of the postmodernist epistemological revolution.

Spatially Explicit Analysis in Environmental Studies

Problems of the human–environment condition, including its change, are increasingly examined in terms of their spatial configuration and scale of analysis. It could be argued that much, if not all, of the field of geography studies these problems in this way, and there are numerous articles in this Encyclopedia dedicated to geographical problem solving and approaches. Spatial analysis of the human–environment condition (i.e., environmental and resources problems) has expanded beyond geography, however, becoming a multidisciplinary if not interdisciplinary

subfield of study. This multidisciplinary focus on spatially explicit problem solving, where the spatial aspect of the human behavior and/or the natural environment makes a crucial difference in the analysis and policy response to the problem, is treated here. Throughout, the emphasis is on geographical space (metric and relative distance), not on such social science concepts as 'social distance' (i.e., between social or economic classes), which are treated elsewhere.

1. Space in the Sciences

The natural sciences are further advanced than the social sciences in their theoretical developments of models of spatial processes. Landscape ecology and population biology are exemplary. In both of these fields, the spatial arrangement of the geophysical landscape, as well as flora and fauna on the landscape are the major focus of analysis. The advances in spatial analysis in the natural sciences, compared with the social sciences, are fairly straightforward to explain. There is a more developed physical theory of behavior over space, such as gravity and watershed impacts, or species interaction over space, than there are theories of spatial human behavior and individual preferences of spatial configuration. Also, until recently, there has been much more spatially explicit natural science data than social science data available for modeling and hypotheses testing, resulting in delayed response in the social sciences to spatially explicit problem solving (NRC 1997).

In geographical spatial models employed in the social sciences, space appears as a constraint on the system under consideration. For example, geographical space is reduced to distance in a transportation cost model of location. However, space cannot be considered only as a constraint or cost to be paid; it must also be considered in terms of spatial processes and must be modeled as such at the appropriate scale of analysis. In order to explain and predict these spatial processes, theoretical and empirical models must be developed to address where, when, and why these processes happen (Bockstael 1996).

The other social and behavioral sciences have lagged behind geography in developing theories and models of human behavior and choices over space. One of the main reasons for this lag is likely the paucity of disaggregate spatially explicit social science data. These data are necessary to test empirically the hypotheses derived from the theoretical constructs of individual human behavior. In addition to the increase in spatial data, the advances in geographical information systems (GIS) technology in availability and ease of use has increased the interest in spatial issues among the social sciences beyond geography. Also, as spatial data have become more available, so too have the statistical tools to use these data.

2. Topical Areas

Associated with the use of many renewable and nonrenewable natural resources are spatial effects, where the spatial location and configuration of the natural resource affects human behavior and consequences to the environment. Examples include stationary resources, such as energy resources, minerals, forestry; and nonstationary resources, such as fisheries and other wildlife, as well as the use of resources that can lead to spatial environmental problems. The specific examples that are focused on in this article include fisheries and other wildlife, forestry and urban land use, with an emphasis on the implications of where spatially explicit problem solving makes a critical difference in the analysis and policy response to the interaction between human systems and natural systems.

2.1 Fisheries and Wildlife Management

Historically, the primary focus of fisheries management models has been the common property feature of most fisheries, that is, not one person, industry or even country has control over the stock and location, and often, owing to mismanagement, this leads to open access problems resulting in overfishing and depletion of stocks. The policy responses to address these problems have included reduction in fishing season, and the development of tradable permits. Sanchirico and Wilen (1999) argue that these traditional models assume a spatially homogenous distribution of the resource, but if that is not case, then the policy implications concerning the associated human behavior will likely be incorrect. They have developed a model that includes the spatial configuration of the resource, focusing on patchy and heterogeneous distribution of the fish populations, especially the interconnections among and between patches. The main result is that by incorporating different forms of these dynamic spatial relationships, such important biological concepts as 'source' or 'sink' of the living resource can depend on both biological and socioeconomic parameters. Therefore, spatially differentiated management techniques, such as refuges or rotating harvesting zones that do not consider the spatial interaction of human behavior and the resource, could lead to suboptimal policies.

Similar to the spatial fishery models are spatial terrestrial wildlife models that analyze different wildlife management schemes. An example of the effects of the spatial interaction between beaver populations and forestry management is found in Bhat et al. (1996). As beaver populations move over space, management of the beavers on one property can have unintended spillovers on contiguous properties. By taking these interactions into account, the optimal beaver control strategies is derived for each location

and time period, leading to a more efficient management scheme than would be possible without taking into account the spatial dynamics of the system.

2.2 Forestry: Timber Management and Deforestation

The original emphasis of timber management forestry models was to maximize the value of the timber products deriving from a stand, and these stands were assumed to be spatially homogenous. These models assumed that the only benefit from the forest was the value of the timber, and that there were no off-site impacts from the growing forest or from timber harvesting. Swallow and colleagues (1997) argue that while these models are important, the lack of stand interactions in them can lead to faulty management and policy prescriptions, as the spatial relationships that lead to many ecosystem functions are ignored, such as the relationship between forest fragmentation and wildlife populations. By including these spatially explicit ecological interdependencies, Swallow and colleagues show that the optimal forestry management scheme can differ substantially from using a nonspatial modeling approach, including different harvesting periods for the different stands, and different amounts of the total benefits of recreation and forage availability to wildlife. Similarly, a spatially explicit cellular landscape ecology model that incorporates spatial ecological interdependencies derives the optimal spatial pattern of harvesting over time, a result that could not be obtained from a nonspatial approach (Hof et al. 1994). These results have important policy implications. For example, this approach can be used by public land managers who are managing the forest for multiple use and have to take into consideration nontimber outputs, such as wildlife, that are located on adjacent land that is not under their jurisdiction.

Tropical forest management issues have an important global policy context, owing to the linkages between tropical deforestation and the loss of biodiversity, and the decrease in carbon sequestration potential and those effects on global warming. The major uses of tropical forests include timber activities as in the temperate forest context, but to a greater degree than exists in temperate forests, they also include gathering of fuelwood, agroforestry and land clearing for cultivation. In a tropical forest management context, Albers (1996) develops a theoretical spatial model that incorporates the different potential land uses and their spatial interaction across plots. Tropical forest fragmentation and its spatial pattern have important effects on biodiversity and the ability of the forest to regenerate. The simulation model optimizes the pattern of land uses under different spatial and management scenarios, and investigates how these characteristics affect forest fragmentation and the associated ecological effects of the different scenarios. Albers concludes the interaction between land-use patterns and forest recovery generates flexibility in spatial planning for forest recovery that can generate income for land managers in the short run, while maintaining the option for large preserved areas in the long run.

For reasons not entirely clear, there has been much work on spatially explicit empirical modeling of tropical deforestation than in the temperate forestry (e.g., Mertens and Lambin 1997, Veldkamp and Fresco 1997). Included in these models are variables that can be derived from the satellite imagery and used with geographical information systems to create spatial variables, such as distance to roads and urban centers, as well as existing spatial geophysical data. As these models do not include any model of human behavior, the spatial pattern is not an outcome of a behavioral spatial process. The only possible simulations that can be performed are changes that are imposed on the explicit features of the landscape, therefore only simple policy analyses such as a moratorium on road-building or certain land uses can be performed. In contrast, models that develop an underlying structural model seeking to explain the human behavior that generates land-use patterns include Chomitz and Gray (1996) and Pfaff (1999). These models include advances by correctly including aggregate economic variables in a behavioral model. This makes these models policy-relevant, as behavioral responses to changes in policies can be predicted. However, spatially explicit tropical deforestation models have made advances in controlling for the spatial heterogeneity of the landscape, they all have a very simple spatial behavioral process, where distances to roads and markets are the main spatial elements linked with deforestation. More sophisticated spatial processes are needed for models of tropical deforestation where, in addition to distances to roads and markets, distances to neighboring land uses and the patterns of those neighboring land uses are considered in the probability of deforestation (e.g., Geoghegan et al. 2000).

2.3 Urban Land Use

The location, distribution and pattern of urban land uses and urban fringe development have major effects on the environment. It is the pattern of development that determines the amount and type of nonpoint source pollution into water bodies; loss of farmland and other open-space amenities; the amount of commuting with associated air pollution and congestion; as well as ecological effects, including hydrological disturbances and habitat fragmentation. There is a rich social science literature of spatial models of urban land use. The classic monocentric city model is an equilibrium model of urban spatial structure, where the distribution of land uses on a featureless plain

around a central business is a result of an equilibrium between the declining land price gradient and increasing transportation costs. In its simplest form, concentric rings of residential development around the urban center describe the resulting equilibrium pattern of land use and decreasing residential density as distance from the urban center increases. More sophisticated versions of the model have been developed, but nonetheless, the model's ability to explain observed land use patterns is weak. In comparing the model's predictions with actual land-use patterns, the model fails to explain the complexity of the spatial and temporal patterns of urban growth. This limitation is partly due to the treatment of space, which is assumed to be a 'featureless plain' and is reduced to a simple measure of distance from the urban center.

Some research has tried to overcome the 'featureless plain' assumption by including some of the heterogeneous landscape features that exist, for example, by focusing on how individuals value different landscape arrangements. In a study of individual preferences concerning agricultural land abandonment and subsequent spontaneous reforestation, Hunziker and Kienast (1999) use photographs of different stages of reforestation to elicit respondents' most preferred pattern of land uses and find that there are particular arrangements of the landscape that are preferred by individuals. In order to test the hypothesis that individuals value the pattern of land uses surrounding their homes, Geoghegan and colleagues (1997), have created spatial indices of land use fragmentation and diversity measured at different scales, and include these variables in a spatially explicit model of residential land values. Results demonstrate that individuals prefer to have a homogenous distribution of land use in the immediate area surrounding their homes, but a more heterogonous distribution of land uses on a larger scale.

The spatial interdependencies among land use, zoning regulations and on ecosystems are modeled in Bockstael and Bell (1997). A spatially explicit modeling approach is necessary in order to understand how these regulations affect development decisions across the landscape and in turn how the location of nutrients from point sources, such as sewer treatment plants, and nonpoint sources, for example, septic fields affect water quality. They find that differential zoning across regions deflects development from one region to another and that the amount of increased nitrogen loadings from a constant amount of new development varies from 4–12 percent, depending on the degree of difference across zoning regulations.

In the urban land-use models introduced above, the theoretical structure assumes a very simple concept of spatial human behavior—that individuals only respond to exogenously determined locations of landscape features. Other models allow for the potential spatial interactions among individuals. An approach that can be used to model this interaction explicitly is a cellular automata model, where behavior of a system is generated by a set of deterministic or probabilistic rules that determine the discrete state of a cell based on the states of neighboring cells. Despite the simplicity of the transition rules, these models, when simulated over many time periods, often yield complex and highly structured patterns. Researchers have used cellular automata models to analyze the process of urban growth (e.g. Clarke et al. 1997, White et al. 1997). In contrast to the standard urban economic models of urban structure introduced above, in which complex patterns are generated by imposing external conditions, these models demonstrate how complex structure arises internally from the interaction among individual cells. While these models fit the spatial process and the spatial evolution of urban land uses when compared with urban forms in the USA, because these models impose the land-use transition rules there is very little policy-relevant context to these models.

This limitation is overcome in a cellular automata approach used by Irwin and Bockstael (1999) to predict patterns of land use change in an urbanizing area, in which the transition probabilities are estimated as functions of a variety of exogenous variables and an interaction term that captures the effect of neighboring land use conversions. They then use a cellular automata model, with estimated parameters of land conversion, to demonstrate that a model in which there are spatial interactions between the land use decisions of individuals result in the evolution of a fragmented land-use pattern that is qualitatively much more similar to the observed pattern of development than the pattern that is predicted by models that ignore these spatial interactions. Models that include improved understanding of the spatial evolution of urban land use, when linked with a spatial ecosystem model, will be able to make much better predictions of the effects of government policies concerning land use on ecosystems.

3. *Conclusions*

In order to improve the understanding and modeling of spatially explicit human behavior in relationship to the environment, improved datasets, methods, and theory need to be developed (Irwin and Geoghegan 2000). All three of these issues are closely linked. As argued above, the historical paucity of spatially explicit social science data constrained spatial modeling of human behavior. As a result, interest in spatial issues in the social sciences, beyond the field of geography, has been sparse. But now that spatial social science data are becoming available, there has been a renewed interest in spatial issues. In a recent discussion of future research issues in natural resource and environmental economics, Deacon and colleagues (1998) comment, 'the spatial dimension of resource use may turn out to be as important as the exhaustively

studied temporal dimension in many contexts'—a conclusion that the regional and spatial science of the 1960s and 1970s argued previously. Therefore, having spatially explicit social science data should result in more sophisticated modeling of spatial human behavior and hypotheses testing. However, this necessitates improved empirical methods, such as those being developed within the field of spatial statistics and econometrics. A better understand of human behavior over space, coupled with better data and improved tools are necessary for advances in spatially explicit environmental problem solving.

Special Education in the United States: Legal History

People with disabilities in most parts of the world have often been excluded from many of the usual privileges and benefits of the societies in which they lived. This has been as true of schools as of any other social institution. Although the rhetoric of public education, in particular, has often emphasized equality of opportunity, the practice of education well into the twentieth century belied this rhetoric. A recent report on educational practices in China, for example, indicates that students with disabilities are routinely rejected by universities regardless of how intelligent or hard working they are. As a result, most of China's 20 million young people with physical disabilities stand

little chance of receiving a higher education (Mooney 2000).

Institutionalized inequalities in schools have been most evident in the ways that children of racial and ethnic minorities have been excluded from equitable learning opportunities, sometimes under the rationale that they could be provided a 'separate but equal' education. Less known is the history of exclusion of children with disabilities through legal and administrative practices. In 1893, a child was expelled from the Cambridge Public Schools in the USA because he was claimed to be 'weak in mind.' The expulsion was upheld by the Massachusetts Supreme Court (*Watson v. City of Cambridge* 1893).

The extent to which school decisions leading to the exclusion of children with disabilities were based on factors other than a child's academic ability is also illustrated by the wording of another court decision. In 1919, the Supreme Court of Wisconsin heard the case of a child with cerebral palsy who had the academic ability and physical capacity to be in school, but who drooled, had impaired speech, and had frequent facial muscle contractions. The court ruled that the child could be denied continuation in public school because he 'produces a depressing and nauseating effect upon the teachers and school children' (*Beattie v. State Board of Education*, *City of Antigo* 1919).

During the first half of the twentieth century, exclusion of children with disabilities from schooling was common and legal. A striking example of the justification given for segregated education for children with disabilities is the statement of the Superintendent of the Baltimore Public Schools in 1908. James Van Sickle said:

> If it were not for the fact that the presence of mentally defective children in a school room interfered with the proper training of the capable children, their (separate) education would appeal less powerfully … But the presence in a class of one or two mentally or morally defective children so absorbs the energies of the teacher and makes so imperative a claim upon her attention that she cannot under these circumstances properly instruct the number commonly enrolled in a class. School authorities must therefore, greatly reduce this number, employ many more teachers, and build many more school rooms to accommodate a given number of pupils, or else they must withdraw into small classes these unfortunates who impede the regular progress of normal children. The plan of segregation is now fairly well established in large cities, and superintendents and teachers are working on the problem of classification, so that they may make the best of this imperfect material (Van Sickle 1908, pp. 102-3).

The idea that children with disabilities have a right to an education, and that they should be educated in integrated settings, somewhat haltingly followed the racial integration implementation efforts that were put into motion following *Brown v. Board of Education* decision in the USA. Although there were increasing allocations of funds in the 1960s for training special education teachers and supporting special classes, these were usually incentive programs that school districts could choose to participate in, or not. The question of a right to an education for children with disabilities was not addressed for decades after the racial integration of schools was mandated.

In 1975, the interest and commitment in the US Congress to special education had evolved to the point that legislation was passed that provided the basic foundation for the right to education for students with disabilities that exists today. That legislation, entitled the Education of All Handicapped Children Act of 1975 (PL 94-142 1975), delineated that appropriate educational services be provided to all students with disabilities. It provided funding for the implementation of these services. It also mandated the manner in which these services should be planned and provided, and it included safeguards for students and their families.

The statement in the law that most directly addressed the issue of integrated education for students with disabilities is one that provides for what has come to be known as the least restrictive environment: 'Each public agency shall insure that special classes, separate schooling, or other removal of handicapped children from the regular educational environment occurs only when the nature or severity of the handicap is such that education in regular classes with the use of supplementary aids and services cannot be achieved satisfactorily' (*Public Law* 94-142 1975).

In 1986 the law was amended by PL 99-457. This legislation required a free appropriate education for preschool children aged three to five with disabilities. It also provided funding incentives to encourage the development of early intervention programs for infants and toddlers with disabilities, and those at risk of developing disabilities.

PL 94-142 was further amended in 1990. Among other modifications, this amendment changed the name of the existing law to the Individuals with Disabilities Education Act or, as it is now commonly called, IDEA. The IDEA included language that was very explicit in its call for including children with disabilities in regular school programs. It stated that schools must have a continuum of placements available in order to appropriately meet the needs of these students. It emphasized, however, that unless a child's individualized education program specifies some other necessary arrangement, the student must be educated in the school he or she would attend if he or she did not have a disability. Thus the IDEA reiterated the requirement that children with disabilities and those without disabilities be educated together to the maximum extent appropriate. The law also underscored the requirement that special classes, separate schooling, or other forms of segregation of students with disabilities occur only when the education of these students with the use of supplementary aids and

services cannot be achieved satisfactorily in regular classrooms (Individuals with Disabilities Education Act 1990).

1. The Institutionalizing of Special Education: A Conceptual History

It is ironic that PL 94-142 has been referred to as 'the mainstreaming law.' Mainstreaming, as both a concept and a term, has been used widely but defined very imprecisely. Like other educational terms, it has been used by professionals, parents, and politicians as if there were a common understanding of what was being communicated. In fact, that has often not been the case. Rather, the term has meant different things to different individuals and groups.

One early attempt to offer a model of mainstreaming outlined three elements that should characterize it: a continuum of services for students with disabilities, a reduction in the number of children 'pulled out' of regular classes, and increased provision of special services within regular classrooms rather than outside of those classrooms (Berry 1972).

The impetus for mainstreaming as it was defined by Berry, and as it was interpreted elsewhere under the term least restrictive environment, can perhaps be seen most clearly in Lloyd Dunn's 1968 article entitled 'Special Education for the Mildly Retarded: Is Much of It Justifiable?' In the article, Dunn called for special educators to consider carefully the efficacy research then available indicating that children with disabilities made greater academic progress in regular classrooms than in special classes. He urged special educators to resist 'being pressured into a continuing and expanding program (special classes) that we know now to be undesirable for many of the children we are dedicated to serve' (Dunn 1968, p. 5). He also argued that the labeling of children for placement in special classes led to a stigma that was very destructive to their self-concepts. Dunn asserted that 'removing a child from the regular grades for special education probably contributes significantly to his feelings of inferiority and problems of acceptance' (Dunn 1968, p. 9).

Following the publication of Dunn's article, there were others who called for the activating of Dunn's concerns in educational policy and practice. A 'zero reject model' was advocated that suggested that no child with mental retardation should be 'rejected' from a regular class and placed in a special class (Lilly 1970). The Council for Exceptional Children Policies Commission adopted a policy that specified that all students with disabilities 'should spend only as much time outside of regular classroom settings as is necessary to control learning variables' (Council for Exceptional Children Policies Commission 1973, p. 494).

Even though it was variously defined and understood, the concept of mainstreaming grew in importance and in its acceptance among professionals and the public during the 1970s and 1980s. However, the actual practice of mainstreaming was not, according to some critics, as common as the rhetoric that endorsed it. In 1986 a new call for the integration of children with disabilities into regular education programs was issued from the Assistant Secretary for Special Education and Rehabilitative Services of the US Department of Education. Secretary Madeline Will proposed what she called the Regular Education Initiative (REI). The REI proposed the restructuring of American education into a single system for the delivery of services to all children. Will argued that by merging special and regular education, a 'shared responsibility' would be created that would serve children without the stigma of diagnostic labels or segregated classrooms (Will 1986).

Will's proposal for the REI generated a great deal of controversy and concern in the special education profession. In 1987, for example, a group of leaders in the field met to assess the implications of the proposal. They praised the intent of Secretary Will's call for restructuring but cautioned that it 'is important to acknowledge that special education cannot seek institutional solutions to individual problems without changing the nature of the institution … school organization is what fundamentally must change' (Heller and Schilit 1987). This idea, that special education can change in fundamental ways only if the institution of the public school changes, is to be found repeatedly in the literature on special education reform that has been written in recent years (McLaughlin and Warren 1992).

The critics of the REI voiced strong concern over the implications of the proposal. Kauffman, for example, expressed fears that the special services needed by children with disabilities might be diluted or eliminated if the REI became a reality. He also argued that most regular classroom teachers do not have the training and/or the inclination to work with many of the students who are served by special education. In language reflective of his strong beliefs on this issue, Kauffman stated, 'The belief systems represented by the REI are a peculiar case in which both conservative ideology (for example, focus on excellence, federal disengagement) and liberal rhetoric (for example, nonlabeling, integration) are combined to support the diminution or dissolution of a support system for handicapped students' (Kauffman 1989, p. 273).

Supporters of the REI asserted that the response to Lloyd Dunn's challenge in 1968 to the efficacy of special classes had not been genuine or widespread. They questioned the essential validity of what had been tried and accomplished during the 1970s and 1980s in the name of mainstreaming. REI proponents maintained that only through a merger of special education into the regular education structure could all children be given the educational services they need without the stigma that had become associated with special education (Robinson 1990).

The interest in a merger of special and regular education as it was advocated by REI supporters proved, however, to be a one-dimensional interest. REI advocates were almost exclusively special educators. Ironically, regular education showed very little interest in the REI. This lack of interest in a merger of structures and efforts between regular and special education inspired an early critic to write: 'We have thrown a wedding and neglected to invite the bride. If this is an invitation to holy matrimony, it was clearly written by the groom (special education), for the groom, and the groom's family. In fact, the bride (general education) wasn't even asked. She was selected' (Lieberman 1985, p. 513).

2. *Inclusion and the Future of Special Education*

The most recent descriptor for the effort to create greater integration of children with disabilities into school programs is the term inclusion. For many educators, the term is viewed as a more positive description of efforts to include children with disabilities in genuine and comprehensive ways in the total life of schools. Whereas mainstreaming might have meant the same thing for many people, it could also be taken as having as its primary focus the physical presence of a child with disabilities in a regular classroom. Mainstreaming in this form could be only the appearance of integration. The REI was seen by some people, even some of its supporters, as meaning the dismantling of special education.

Inclusion, however, can mean that the goal of education for children with disabilities is the genuine involvement of each child in the total life of the school. Genuine inclusion means welcoming children with disabilities into the curriculum, environment, social interaction, and self-concept of the school.

Inclusion, of course, can (and already does) mean different things to different people. Some people interpret it to be just a new way of talking about mainstreaming. For others it may be seen as the REI with a new label. Some have even used the term inclusion as a banner for calling for 'full inclusion' or 'uncompromising inclusion,' meaning the abolishment of special education (Fuchs and Fuchs 1994).

Debates over the nuances and fine points of difference between mainstreaming, the REI, inclusion, full inclusion, and whatever the next term or concept may be are surely not reflective of the grassroots concerns of parents, teachers, and school leaders who are earnestly trying to do their best for children with disabilities. Coupled with the other vagaries and demands that are placed on parents and educators in our increasingly complex society, the confusion that exists over the rights and responsibilities of the various constituencies in the education arena must seem overwhelming.

The most sound basis for providing an inclusive education for students with disabilities in public schools must ultimately consist of the legislative foundations that create services for these students, and the interpretation that courts give to questions about this foundation.

The legislative foundation for inclusion in the USA, for example, is IDEA. It is clear that this statute stress two things: the policy of the least restrictive environment and the requirement that a continuum of services must be available so that an appropriate education may be provided to every child who has the need for special education. Court decisions about this foundation are a fitting topic for the close of this discussion of the institutional aspects of special education.

Although the cases and decisions of US courts concerning inclusion have varied, the principles derived from this litigation have been clear and compelling. Yell (1995) has shown that school districts must make every good-faith effort to maintain students with disabilities in general class placements with whatever appropriate aids and services might be needed to support a student in that environment. School districts that have not done so have consistently been found by courts to be in violation of the law. On the other hand, it is apparent from judicial review and decisions that some children may be so disruptive to general classrooms that these settings are not in their best interests or those of their nondisabled peers. The following suggestions to educators and others interested in the inclusion of children with disabilities in the total school environment are based on Yell's study (1995) of court decisions concerning the issue of the least restrictive environments for the education of students with disabilities:

(a) Determination of the LRE (least restrictive environment) must be based on the individual needs of the child.

(b) Good-faith efforts must be made to keep students in integrated settings. The beginning assumption should always be that a student belongs in a general classroom. Exceptions may be made to this assumption based on individual needs.

(c) A complete continuum of alternative placements and services must be available.

(d) In making LRE/inclusion decisions, the needs of the student's peers should be considered.

(e) When students are placed appropriately in more restrictive settings, they must still be integrated into general classes and other school activities to the maximum extent feasible and beneficial to the student.

(f) The LRE/inclusion decision-making process must be thoroughly documented.

The achievement of an individualized and appropriate educational program for any student is a dynamic process. Decisions regarding the most effective blend of special services and inclusive practice must be continually reviewed and changed in the best interests of the student.

Specialization and Recombination of Specialties in the Social Sciences

Specialization is an old phenomenon, observed as early as Auguste Comte. Recombination of specialties is also an old trend: Robert Merton noticed it in the early 1960s: 'the interstices between specialties become gradually filled with new cross-disciplinary specialties' (Merton 1963, p. 253). The multiplication of scientific activities and the growing complexity of knowledge have brought a division of labor, visible in increasing expertise in all domains. The history of scientific advancement is a history of concatenated specialization. In spite of this evidence, 'even since the social sciences began to develop, scholars have repeatedly expressed apprehension about the increasing fragmentation of knowledge through specialization' (Smelser 1967, p. 38).

Fragmentation and specialization are the two faces of the same coin. This double process is a condition of scientific advancement. The term 'discipline' is inherited from the vocabulary of the nineteenth century and is understood as a branch of instruction for the transmission of knowledge and as a convenient mapping of academic administration. In all universities, teaching, recruitment, promotion, peer review, and financing are still organized along disciplinary lines, but the great scientific laboratories and the most creative research centers are anchored on specialties, which in many cases cross the borders of formal disciplines, or are located at the interstices between disciplines. In the sociology of science the term 'discipline' is defined as a 'cluster of specialties' (Crane and Small 1992, p. 198), the specialty being the main source of academic recognition and of professional legitimation (Zuckerman 1988, p. 539).

In the natural sciences, specialization is celebrated as a mark of competence. Each contemporary natural science from astronomy to zoology is a conglomerate of dozens of specialties. Only in some social sciences, particularly in sociology, political science, psychology, and anthropology, does one hear complaints and lamentations about the fragmentation of the discipline into specialties. The word 'crisis' appears in the title of many books and articles about the identity and the contours of these disciplines (Horowitz 1993, S. Turner and J. Turner 1990). In reality, such 'crises' are symptoms of growth and expansion.

1. Specialization

Analysis means breaking things into parts. All sciences have made progress, from the sixteenth century on, by internal differentiation and cross-stimulation among emergent specialties. Each specialty developed a patrimony of knowledge. With the growth of these patrimonies specialization became a necessity. Increasing specialization has led to the creation of subdisciplines. A specialty requires a high qualification in a delimited domain. The process of specialization has tended to disjoin activities which had previously been united, and to separate scholars belonging to the same formal discipline, but who are interested in different fields. Specialties are considered as parts of a larger discipline but 'the modern scholar normally does not attempt to

master his discipline in its entirety. Instead he limits his attention to one field, or perhaps two' (Somit and Tanenhaus 1964, p. 49). Each formal discipline gradually becomes unknown in its entirety. No theory can any longer encompass the whole territory of a discipline. Talcott Parsons was the last sociologist to attempt such a theory. As a discipline grows, its practitioners become specialized and must neglect other areas of the discipline. It is for this reason that scissiparity, the amoeba-like division of a discipline into two, is a common process of fragmentation. Specialization provides researchers with methods so that they need not develop them anew. Refinements in methods are more easily transmitted among specialists. Specialization within disciplines is visible in national and international professional meetings. Everyone who has participated at a gathering of several thousand people has noticed the absence of coherence: 20–30 panels may run simultaneously, most of them mobilizing only a handful of people. The plenary sessions attract only a small minority, with most participants uninterested in issues encompassing the entire discipline.

Disciplines fragment along substantive, epistemological, methodological, theoretical, and ideological lines. To those in the field, the theoretical and ideological divisions are likely to seem more important than to others. Ralph Turner gives a description of this process in sociology, based on his experience as Editor of an important journal: 'In the 1930s and 1940s the aspiration to be a general sociologist was still realistic. There was a sufficiently common body of core concepts and a small enough body of accumulated research in most fields of sociology that a scholar might make significant contributions to several, and speak authoritatively about the field in general. It is difficult to imagine the genius necessary for such accomplishments today' (R. Turner 1991, p. 70).

The division of disciplines into specialties should be distinguished from their fragmentation into schools and sects. The term school refers to a group of scholars 'who stress a particular aspect'. The proponents of a school are emotionally committed to their approach. A school is simultaneously a subdivision of a field and a species of cult or sect (Smelser 1967, pp. 6–7). While the multiplication of specialties is related to the maturation of the discipline, 'the presence of numerous schools in a discipline generally betokens a relative scientific immaturity' (Smelser 1967, pp. 6–7). The same diagnosis is formulated by Gabriel Almond who, by crossing two dimensions, an ideological one and a methodological one, described four types of schools in political science (Almond 1990, p. 15). These types are not determined by the process of specialization.

Various authors stress the importance of the patrimony's expansion for subsequent fragmentation. As disciplines grow, they fragment and most parts become the patrimonies of individual subfields; a rare few are passed down in the patrimony of several formal disciplines and become the classics. For Randall Collins, the increasing specialization in sociology could be explained by the growth in scale in the profession during the late twentieth century: 'How does one make oneself visible when the sheer number of competitors increases? The field differentiates into various specialties. Instead of seeking recognition in the larger field, one opts for a smaller arena within which the discourse and the search for originality and for allies can go on' (Collins 1986, p. 1340). A process of differentiation without integration is visible across disciplinary borders. Specialists 'seem scarcely to recognize the names of the eminent practitioners in specialties other than their own' (Collins 1986, p. 1340).

Another scholar who emphasizes the importance of specialties in the organization of scientific communities is Harriet Zuckerman: 'Much historical and sociological evidence suggests that specialties have been prime audiences for many scientists: they are the explicit and tacit audiences—the reference groups—to which they address their work, just as they are the prime sources of wherewithal and rewards for that work' (Zuckerman 1988, p. 539). As in some cathedrals, there are more ceremonies in the chapels than under the principal nave.

2. *Specialties Versus Disciplines*

Analyzing the relationships between specialties *within* disciplines and between specialties *across* disciplines, two kinds of disciplines can be perceived: 'restricted disciplines, such as most physical sciences, which would be expected to exhibit a high degree of linkage between different research areas within the discipline, but less linkage to other disciplines,' and unrestricted sciences, such as most social sciences, which would be likely to exhibit relatively diffuse links among research areas both within and outside the disciplines (Crane and Small 1992, p. 200).

Depending on the definition we adopt, there are in the social sciences between 12 and 15 formal disciplines, but dozens of specialties, sectors, fields, and subfields. In sociology, for instance, there are some 50 specialties, as indicated by the list of research committees of the International Sociological Association. There are as many in the International Political Science Association. Most of these groups cooperate to a limited extent within their respective discipline.

There is more communication between specialties belonging to different disciplines than between specialties within the same discipline. Sociometric studies show that many specialists are more in touch with colleagues who belong officially to other disciplines than with colleagues in their own discipline. The 'invisible college' described by Robert Merton and other sociologists of science is an eminently interdisciplinary institution because it ensures communication

not only from one university to another and across all national borders, but also, and above all, between specialists attached administratively to different disciplines. The networks of cross-disciplinary influence are such that they are obliterating the old classification of the social sciences.

The division of disciplines into subfields tends to be institutionalized, as can be seen in the organization of large departments in many American and European universities. Another good indication of the fragmentation of the discipline is the increasing number of specialized journals. In the last two decades several hundred specialized journals in English relevant to social sciences have been launched. Most of these new journals cross the borders of two or three disciplines. Some other new journals have appeared in French and German. European unification has had an impact on the development of cross-national journals focusing on special fields. Specialization has consequences on the role of national professional associations and on the general journals. The size of specialties varies greatly: Egyptology and biosociology are small specialties; socialization and clientelism are very large. A segment which drifts away from the main body of the discipline has to reach a certain critical size before being recognized. Some of them enjoy a relative autonomy within the discipline.

A distinction has to be drawn between specialization within a formal discipline and specialization at the intersection of several monodisciplinary subfields. The latter can occur only after the former has become fully developed.

3. *Recombination of Specialties Across Disciplines*

Specialization within disciplines, accompanied by their fragmentation, is the first process. Recombination of specialties across disciplinary borders is the second. In the history of science a twofold process can be seen: on the one hand, a fragmentation of formal disciplines and, on the other, a cross-disciplinary recombination of the specialties resulting from fragmentation. The new field may become independent, like social psychology, or may continue to claim a dual allegiance, like historical sociology. In the latter case, librarians are not sure whether to place a work in the category of history or of sociology.

Such a recombination has been called hybridization (Dogan and Pahre 1990, p. 63). A hybrid is a combination of two branches of knowledge. Jean Piaget suggested a different analogy: genetic recombination (Piaget 1970, p. 524). The reasons for hybridization are clear enough: specialization leaves gaps between disciplines; specialties fill the gaps between two existing fields. Many of the new specialties are to a large degree hybrid specialties. The phenomenon is even more obvious in the natural sciences, e.g., in the awards of the Nobel prizes.

Some scholars recommend an 'interdisciplinary' approach. Such a recommendation is not realistic because it overlooks the process of specialization. Research enlisting several disciplines involves in fact a combination of segments of disciplines, of specialties, and not whole disciplines. The fruitful point of contact is established between sectors, and not along disciplinary boundaries. Considering the trends in the social sciences, the word 'interdisciplinarity' appears inadequate since it carries a hint of superficiality and dilettantism, and consequently should be avoided and replaced by hybridization of specialties. Different disciplines may proceed from different foci to examine the same phenomenon. This implies a division of territories between disciplines. In contrast, hybridization implies an overlapping of segments of disciplines, a recombination of knowledge in new specialized fields. Innovation in each discipline depends largely on exchanges with other fields belonging to other disciplines.

When old fields grow they accumulate such a mass of material in their patrimony that they split up. Each fragment of the discipline then confronts the fragments of other fields across disciplinary boundaries, losing contact with its siblings in the old discipline. A sociologist specialized in urbanization has less in common with a sociologist studying elite recruitment than with a geographer interested in the distribution of cities; the sociologist studying social stratification has more in common with his colleague in economics analyzing income inequality than he does with a fellow sociologist specialized in organizations; psychologists studying child development are much more likely to be interested in developmental physiology or in the literature on language acquisition than they are in other branches of psychology. A political scientist researching political socialization reads more sociological literature on the agents of socialization (family, church, school, street-corner society, cultural pluralism, etc.) than literature in political science on the Supreme Court, legislative processes, party leadership, or the recruitment of higher civil servants. Those working on the subfield of international relations in the nuclear age have little recourse to the classical literature in political science, but rather to economics, technology, military strategy, diplomatic history, game theory, nuclear physics, and engineering.

Most hybrid specialties and domains recognize their genealogical roots: political economy, political sociology, social geography, historical sociology, genetic demography, psycholinguistics, social anthropology, social ecology, biogeography, and many others. Some hybrid sciences do not indicate their filiation in their name: cognitive science, paleoarcheology. Eight social sciences also have roots in the natural sciences: demography, geography, psychology, anthropology, linguistics, archeology, criminology, and cognitive

science. The hybrid specialties branch out in turn giving rise, at the second generation, to an even larger number of hybrids.

Recombination of specialties appears in the borrowing of concepts, theories and methods (Dogan 1996). Concepts are vehicles for communication between specialties belonging formally to different disciplines. Concepts are not equally important in all specialties. For instance, alienation is more frequently used in social psychology than in political economy, segregation more in urban studies than in comparative politics, and charisma more in political sociology than in social ecology.

There are very few general theories accepted by the majority of scholars in any discipline; the best known theories are specialized theories: they are what Robert Merton calls middle-range theories, which do not encompass an entire discipline, but only a part of it. A specialized theory can cross several disciplines with a minimal effort of adaptation. For instance 'rational choice'—considered by some as a theory and by others as a school or sect—is, except for some stylistic features, basically the same in political science, in sociology, and in economics. The theory of methodological individualism does not change on moving from one discipline to another. Two to three dozen theories peregrinate freely among formal disciplines. The high interdisciplinary mobility of specialized theories and of specialized concepts, and also of research methods, gives some centripetal orientation to the wide range of social sciences. The cross-disciplinary diffusion of concepts and theories is in fact a diffusion among specialties belonging to different disciplines.

Methodology divides some disciplines as much as ideologies, and at the same time builds bridges between specialties across the disciplinary borders. The scholars who practice factor analysis understand each other well no matter what their official disciplinary affiliation, but most of them encounter some difficulties in communicating, *within* their discipline, with their colleagues who do not practice quantitative methods. In some departments methodological controversies generate factions, which may or may not coincide with divisions between specialties.

The citation patterns in academic publications permit us to measure empirically the degree of coherence of a discipline, the relations between specialties within disciplines, and the interferences of disciplines. If specialists in a given subdiscipline tend to cite mostly, or exclusively, specialists of the same subdiscipline, and if relatively few authors cite across the borders of their subdiscipline, then the formal discipline presents a low degree of internal coherence. In this case the real loci of research are the specialties. If, on the contrary, a significant proportion of authors cross the borders of specialties, then the discipline as a whole appears more or less as an integrated territory (Dogan 1997). Political scientists have borrowed in the 1930s from law, in the 1950s from sociology and law, and in the 1970s from sociology, philosophy, economics, history, and psychology. According to Craig Calhoun, 'Sociology is neither the most open nor the most insular of social sciences' (Calhoun 1992, p. 143). A study of patterns of citation during the period 1936–75 has found that sociologists cited 58 percent of the time articles in sociology journals, political scientists cited 41 percent of the time scholars from their own discipline, anthropologists referred 51 percent of the time to their colleagues, psychologists 73 percent to their own kin, and 79 percent of the economists did the same (Rigney and Barnes 1980, p. 117). In each social science a significant proportion of theoretical, methodological, and substantive communication has been with other disciplines, the most open being, in the late twentieth century, political science and the most autarchic economics.

In an analysis of journals identified as belonging to sociology and economics, a significant shift has been found from sociology to 'interdisciplinary sociology' and from economics to 'interdisciplinary economics,' between 1972 and 1987. The criteria for trade between disciplines was the proportion of citing references in journals of the respective discipline (Crane and Small 1992, pp. 204–5). An analysis by the same authors in terms of clusters of references shows a clear increase in interdisciplinary relationships.

Most social scientists are specialists contributing primarily to their own subdiscipline. For instance, the *Handbook of Sociology* edited by Neil Smelser (1988) is divided into major specialties, without an overarching structure. Smelser is aware of this heterogeneity. Noting that Talcott Parsons had 'exaggerated the internal unity of the discipline,' which 'if applied today would appear almost ludicrous' (p. 12), he writes: 'there appears to be no present evidence of an overarching effort at theoretical synthesis … and little reason to belief that such an effort is on the horizon,' adding that 'we have by now gone too far down the road of specialization and diversification' (p. 12). The ship of sociology is already built with watertight compartments. If the borders between specialties *within* disciplines are hermetic, in exchange, paradoxically enough, the frontiers between formal disciplines are open.

A distinction is needed between interdisciplinary amalgamation and hybridization by recombination of specialties belonging to different disciplines. A 'unified social science' was visible only in the early phase of the development of social sciences, when disciplines were not yet differentiated. Hybridization of specialties came much later, after the maturation of the process of internal fragmentation of disciplines. The word interdisciplinary is appropriate only for a certain phase of social sciences at the beginning of the twentieth century; it becomes misleading when it is used to describe contemporary trends, because at the end of the twentieth century only specialties are overlapping, not entire disciplines.

Some may confound recombination and synthesis. A synthesis brings a new interpretation, a personal or stylistic achievement. The difference is most clear in history. Arnold J. Toynbee's theory of history and Hobsbawn's *The Age of Empire* are syntheses. Fernand Braudel's *The Mediterranean World* is a recombination of segments of social sciences, largely history and geography. Perry Anderson's *Lineages of the Absolutist State* is largely synthesis, whereas Karl Wittfogel's *Oriental Despotism* is largely recombination.The recombinations are varied. Child development includes developmental physiology, language acquisition, and socialization. Indo-European studies encompass segments of historical linguistics, archeology, prehistory, and botany. Scholars in criminology come from subfields in law, sociology of deviance, social psychology, endocrinology, urban studies, social economics, and ethnopolitics. The study of artificial intelligence encompasses formal logic from philosophy, grammar and syntax from linguistics, and computer programming from computer science. Folklore studies includes sectors from historical linguistics, cultural anthropology, social history, and comparative literature.

In one generation the number of social scientists has increased 10-fold. Their status in the profession depends mostly on their contribution to knowledge, and much less on their performance as teachers. As teachers they are generalists, as researchers, specialists. A strong feeling of diminishing marginal returns is perceived among the mass of social scientists. This phenomenon of saturation and overcrowding has been called the 'paradox of density': the tendency of densely populated disciplines to produce less innovation per head in spite of the greater effort applied in these overcrowded domains (Dogan and Pahre 1990, p. 32). What is perceived by some scholars as 'dispersion' and 'disintegration' should be considered as manifestations of the growth of specialties, resulting in the weakening of the saturated disciplinary core, a process engendered by centrifugal and autonomous tendencies of the specialties across disciplines. The recombination of specialties across disciplines requires a remodeling of the intellectual map of the behavioral social sciences.

M. Dogan

Species and Speciation

At first glance, 'species' should be a relatively easy term to define: a group of organisms sharing a common biological lineage. Yet biologists have argued over the details of the definition since around 1900. This is in large part because the definition inevitably reflects concepts about processes resulting in the formation of species (or speciation), which lie at the heart of Darwinian evolution. Those speciation processes also underlie observed patterns of biodiversity in both space and time.

1. Species Concepts

Species concepts proposed since around 1950 may be broadly grouped into three categories: typological (based on shared traits), biological (based on breeding habits), and evolutionary (based on lineage) concepts. In the first case, the goal is usually a definition that follows taxonomic practice in species descriptions. The second and third categories reflect ideas about the speciation process.

1.1 Typological Species Concepts

Typological species concepts are based on the premise that a group of individuals of one 'type,' sharing a list of traits, constitute a species. This set of species concepts includes the phenetic species concept (Sokal and Crovello 1970) and the genotypic cluster definition (Mallet 1995). In these cases, species are individuals sharing well-defined clusters of traits, with few to no individuals with intermediate traits. Some versions of what are usually referred to as phylogenetic species concepts (e.g., Cracraft 1983) also fall into the typological category, as species are defined by clusters of shared traits, although individuals are also grouped by population or lineage (for asexual organisms).

Traits may be genotypes or phenotypes; that is, the genes possessed by an organism or the characters resulting from the expression of those genes. However, as its name implies, the genotypic cluster definition focuses on genotypes. Phenotypic traits are commonly measured as length, width, etc., of some body part, or as proteins separated and visualized on a gel. Genotypic traits tend to be quantified as DNA or RNA base sequences. For example, bacterial species that cannot be grown in the laboratory are often described based on their DNA differences and similarities.

Taxonomists routinely use these typological species concepts when they identify individual organisms to species. The definitions have the advantage that they can be applied to almost any organism, dead or alive, fossil or recent. All one needs to be able to do is to make measurements of the phenotype and/or the genotype of the organism in question. However, this is also the disadvantage: one has to choose appropriate traits to measure, which will highlight the differences and similarities among individuals.

1.2 The Biological Species Concept and Its Relatives

The biological species concept states that species are populations of interbreeding organisms. This concept, strongly espoused by Mayr (1942), was dominant until the 1980s. It continues to be widely cited.

The initial formulation of the biological species concept focused on reproductive isolation and hence restriction of gene exchange between species. The inverse of inter-specific reproductive isolation, use of shared mate recognition and fertilization systems within a species, was later put forward by Paterson (1985). For example, two species of frogs could be discriminated upon based on their inability to produce viable offspring, or alternatively by shared mating calls and ability to produce viable offspring within each species.

Some relatively obvious difficulties arise in applying this species definition to individual cases. First, the requirement for interbreeding makes the application to asexual or clonal organisms impossible. Second, many populations are geographically separated and it is not known whether they could interbreed or not if they were brought together in the same place. Third, application to the fossil record is nearly impossible, as the probability of finding two fossil organisms interbreeding is exceedingly low, and even if that were to occur, the question of viable offspring remains. Nonetheless, the concept is useful as an embodiment of the necessity for restricted gene exchange between species.

1.3 The Evolutionary Species Concept and Its Relatives

Evolutionary species concepts place weight on defining species based on organisms' historical or evolutionary lineage. These concepts arose initially out of the recognition that species do occasionally interbreed. Interbreeding results in movement of genes from individuals of one species into the gene pool of another (introgression), but in some cases, species maintain their morphological and ecological distinctness even in the face of gene introgression. Definitions by Simpson (1951) and Wiley (1978) focused on species as lineages that have their own evolutionary histories and fates.

Most phylogenetic species concepts also fall under this heading. A species is defined as those organisms within a lineage between the initial splitting off of the species (cladogenesis) and either extinction of the lineage or further cladogenesis (e.g., Hennig 1966). The idea has been refined further to assert that such lineages must be monophyletic (derived from one common ancestor). However, the observation of gene introgression suggests that while individual traits in a species may be monophyletic, it is unlikely that all traits will be.

In practice, application of these species concepts requires knowledge of evolutionary history, which at present is obtained through comparisons of traits and constructions of cladograms (or genealogical trees) representing phylogenetic hypotheses. The data used are thus similar to that described in Sect. 1.1.

1.4 Pluralistic Views of the Species Concept

While broader conceptualizations of species may be unwieldy in terms of the data required to define a set of

individuals as a species, such concepts have been put forward as more realistic and defensible. Templeton (1989) offered a cohesion species concept, which defines species based on a combination of factors promoting genetic divergence between populations along with those promoting genetic similarity within populations, and includes factors that limit the spread of variation through genetic drift or natural selection. This concept combines biological species and recognition concepts outlined above with a more explicit incorporation of evolutionary processes. Identification of species starts with identification of an evolutionary lineage (as in evolutionary species concepts), followed by tests of reproductive isolation or mate recognition systems, and culminating with examination of the uniformity of selection regimes or ecological adaptations within groups.

1.5 Remaining Problems with Species Concepts

Most of these discussions of species assume that species are now formed as well-defined entities. This is clearly not the case for any of the definitions or concepts presented in Sects. 1.1–1.4. We can identify races and sub-species, which eventually may form species, using the typological approach; hybrid zones between species challenge the biological species approach; and gene introgression poses problems for monophyly. As a result, further refinement of the species concept is likely in the future.

2. Speciation Mechanisms

In practice, speciation occurs through formation of barriers to gene exchange between groups of organisms, concurrent with or followed by genetic differentiation of the groups.

2.1 Pre- and Post-zygotic Barriers to Gene Exchange

The barriers to gene flow are often lumped into two classes: pre-zygotic and post-zygotic mechanisms, named depending on whether they occur before or after the uniting of the gametes to form a zygote. Pre-zygotic mechanisms include all the factors associated with mate location, courtship, and mating, either behavioral or morphological. They also include the process of gamete union to form a zygote. Post-zygotic mechanisms include hybrid inviability or sterility. In general it is believed that even though post-zygotic mechanisms may initially isolate two species, selection should favor the development of pre-zygotic mechanisms whenever variation allowing that development occurs. This is because the investment by individuals in a hybrid offspring is higher if only post-zygotic mechanisms are in place.

2.2 Specific Barriers to Gene Exchange

Specific barriers to gene exchange include morphology, behavior, and genetic and cytoplasmic incompatibility. The first, morphology, has been well documented in a number of insect-pollinated plants. The location of the anthers (pollen bearing structures) relative to the nectaries combined with the body size and shape of the insects determines whether visiting insects actually brush against the anthers and hence transport pollen to other flowers.

Speciation may also involve behavioral divergence between two groups. Behavioral changes involved in speciation are usually associated with courtship and mating rituals. For example, species' differences in mating calls occur in frogs and crickets. Pheromones, or chemicals use to communicate between individuals, may also change. Moths, butterflies, and flies, for instance, use pheromones as integral parts of mate attraction or courtship. The chemical composition of the pheromone mix is generally species-specific. Species may also be isolated by differences in the timing of courtship and mating either within the year or within the day. Seventeen year and 13 year cicadas are an extreme example of such temporal isolation. These cicadas develop underground, emerging as adults to mate at the end of a 17 or 13 year lifespan, depending on the species. Each of three species of 17 year cicadas in the USA has a corresponding very similar 13 year cicada species. Yet, 17 and 13 year cicadas will only overlap as adults once every 221 years. Finally, species may be effectively isolated if they have different courtship or mating locations. The fruit fly, *Rhagoletis pomonella*, is a classic example. Courtship and mating occur on the fruit tree species where the female will later lay eggs. Initially in USA, hawthorn fruits were used; a new race of the fly moved onto apple in the nineteenth century, and then onto sour cherry in the mid-twentieth century. *Rhagoletis* races on each of these hosts respond to specific odors and color, shape and size cues, effectively isolating them (summarized in Bush 1998).

Genetic incompatibility between species arises in several ways. For example, egg and sperm, or pollen and stigma can possess surface proteins that prevent either fusion of the egg and sperm into a zygote, or pollen tube growth allowing fertilization of the plant ovum. A modification of these incompatibilities is seen in patterns of sperm or pollen precedence within a species, which limit gene exchange and could precede speciation (Howard 1999). Alternatively, once a hybrid zygote is formed, it may have low viability or be sterile. Mating between a horse and a donkey, for example, produces mules, which are sterile. Thus genes from the hybrid mating are not transferred beyond one generation. Empirically, the sex for which survival or fertility is more affected by hybridization tends to be the heterogametic sex (or the sex possessing dissimilar sex chromosomes, commonly called 'x' and

'y' chromosomes), in a phenomenon labeled 'Haldane's Rule' (Haldane 1922). This suggests that genes affecting hybrid sterility might be localized to the sex chromosomes. However, the genetics underlying hybrid sterility have been explored in *Drosophila*, which does show stronger male than female sterility in hybrid crosses. Genes affecting either male or female sterility are spread throughout the genome, and the number involved in male sterility alone sometimes exceeds 100 genes (summarized by Wu and Hollocher 1998).

Genetic barriers may also arise through changes in the number of chromosomes in new species (Ramsey and Schemske 1998). This is particularly common in plants. Gametes (in this case, pollen and ova) generally have a single copy of each chromosome (termed haploid), uniting to give a zygote with two copies of each chromosome (termed diploid). In the case of hybrids between two species, each of the two copies will come from different species, and gamete formation may be impeded because the cells cannot properly divide. Occasionally, however, errors in cell division occur, and diploid gametes are produced. If these form within hybrid individuals, then the resulting tetraploid zygote is completely fertile, as it now contains a complete set of the chromosomes from each of the original parent species. Subsequent gamete formation can proceed normally and the offspring are interfertile, but cannot mate successfully with the parental species. Such polyploidy has been demonstrated for example in the history of both agricultural tobacco and wheat. Other sorts of errors can produce individuals with other chromosome copy numbers; anything greater than diploid is generally called polyploid. No matter what their origin, if polyploid individuals are viable, the gametes they produce cannot usually produce viable offspring by uniting with gametes from their diploid parents.

Cytoplasmic incompatibility occurs when factors in the cytoplasm of the two gametes are not compatible, resulting in the death of the zygote. *Wolbachia* bacteria in insects, which are passed with the cytoplasm from mother to offspring, are one example. Currently, it is believed that males infected with *Wolbachia* produce sperm which must be 'rescued' by a factor in eggs produced by females that are also infected, before viable zygotes are produced. Whether this mechanism has been involved in speciation in the past, or is 'simply' a factor enhancing reproductive isolation at present is not yet established (see Werren 1998 for a review).

2.3 *Differentiation: Selection and Chance*

Both the development of reproductive isolation and the differentiation of other characters identifying organisms as members of a species could be influenced by selection or by genetic drift. In the former case, adaptation to a particular set of environmental conditions drives speciation. In the latter case, chance events, such as the genetic diversity present in individuals that become geographically isolated, or that happens to be included when a polyploid individual is formed, influence the results of speciation. The relative influence of these two forces has been the subject of debate; like many polarized debates in biology, most cases probably fall along the continuum between the two ends.

3. *Biogeography of the Speciation Process*

Evolutionary biologists have historically categorized speciation based on the geographic relationship of the newly evolved species. This classification reflects differences of opinion as to the relative role of geography in reducing gene exchange between putative species. Nonetheless, the actual evolutionary processes underlying speciation may be the same in each of these types of speciation.

3.1 *Allopatric Speciation*

'Allopatric' derives from 'allo' meaning 'separate' and 'patria' meaning 'country.' Allopatric speciation is thus speciation that occurs through geographic isolation of two populations or groups of populations. In this scenario, a population is split by some geographic barrier, such as a mountain range or river for terrestrial organisms, or a land mass for aquatic organisms. Over time, individuals in populations on each side of the barrier differentiate. This may be due to a founder effect, in which only part of the genetic variability originally present is represented in a new population; to chance loss of genetic variation through accidents of who happens to reproduce or not; or to adaptation to environmental differences on each side of the barrier. This differentiation between the divided populations is extensive enough to include the evolution of differences in reproductive biology, such that when the two populations are re-united by the removal of the barrier, they are no longer able to inter-breed and are viewed as separate species.

Support for the allopatric speciation model increased with the discovery of continental drift and plate tectonics, and the subsequent increased understanding of geologic history. Such continental rearrangement at a deep time level, and geographic changes associated with Pleistocene ice ages in more recent times, provide the geographic variation needed for allopatric speciation. Enhanced understanding of geologic events also provided the opportunity to test expected distributions of species under allopatric speciation through the study of vicariance biogeography, or the geographic distribution of species as a result of subdivision of ancestral species' ranges.

Allopatric speciation has been the dominant geographic model for speciation processes since around 1950, although other models are currently gaining support. This dominance derived from the argument

that development of genetic isolation would most likely occur if incipient species were physically isolated from each other for a time period, allowing the evolution of reproductive isolating mechanisms.

3.2 Parapatric Speciation

'Parapatric' derives from 'para' meaning 'near' and 'patria' meaning 'country.' Parapatric speciation thus occurs when a smaller population is isolated, usually at the periphery of a larger group, and becomes differentiated to the point of becoming a new species. Gene flow may remain possible between the two populations during the speciation process, and hybrid zones may be observed at the interface between the two populations as a result.

The best-known example of incipient parapatric speciation occurs in populations of the grass *Agrostis tenuis* which span mine tailings and normal soils. Individuals that are tolerant to heavy metals, a heritable trait, survive well on contaminated soil, but poorly on non-contaminated soil. The reverse occurs for intolerant populations. Gene flow occurs between sub-populations on and off mine tailings, but hybridization is inhibited by slight differences in flowering time between the two locations (McNeilly and Antonovics 1968, McNeilly and Bradshaw 1968).

3.3 Sympatric Speciation

'Sympatric' derives from 'sym' meaning 'together with' and 'patria' meaning 'country.' Sympatric speciation thus refers to speciation occurring within a single population. Because of the lack of geographic isolation, sympatric speciation was historically regarded by many biologists as being impossible. However, evidence is accumulating that sympatric speciation does indeed occur.

The most obvious mechanism that can result in sympatric speciation is speciation through polyploidy (Ramsey and Schemske 1998). A chance doubling of the chromosome number can lead to reproductive isolation through zygote inviability, without a preceding need for geographic isolation. Given that about half of all flowering plants are polyploid, this form of speciation may have played a large role in their formation.

Hybridization between two species, followed by rapid changes in the hybrid to enhance reproductive isolation from the parents has been held up as a form of sympatric speciation, particularly in plants. While the number of solid examples of this speciation mechanism are few, it does occur (Dowling and Secor 1997, Rieseberg 1997).

Genetic introgression through mechanisms other than hybridization, or genetic rearrangements ('jumping genes') are a potential source of variability within a population that could lead to speciation, but are essentially unexplored at present.

Small shifts in the ecological niche of individuals within a population are also argued to result in a form of sympatric speciation. The host races of *Rhagoletis* described above are a case in point. Another example is the radiation of species of cichlid fish within small crater lakes in Cameroon (Schliewen et al. 1994). Genetic analysis indicates that the species in each lake derive form a single ancestor. Although species differ slightly in habitat preference, the lakes are small enough that the different fish species are sympatric. In order for this mechanism to be effective, natural and sexual selection would need to act in the same direction. For example, if individuals diverge in resource use, and individuals with similar resource use prefer each other as mates, resource use races will evolve, which may eventually become full species. Note that this form of speciation has conceptual affinities both to the biological species concept (reproductive isolation) and to the recognition species concept (species cohesion).

4. Space: Patterns of Biodiversity Resulting From Speciation

The different modes of speciation outlined above each result in a different spatial pattern of biodiversity. Hybrid zones between newly formed species are the predicted outcome of allopatric speciation, if the geographically isolated populations have not developed full reproductive isolation prior to removal of the geographic barrier. Further, the establishment of a geographic barrier is expected to divide ancestral populations of many species within the flora and fauna of a region. Removal of that barrier and recontact of newly divergent flora and fauna can result in multiple individual hybrid zones that overlap, or suture zones. Such suture zones mark boundaries between regional floral and faunal assemblages. Remington (1968) outlined six major suture zones and a number of minor suture zones in the Nearctic region, including a compendium of known hybridizing pairs of species within each suture zone and an analysis of the likely geographic barriers whose removal resulted in the now-observable suture zone pattern.

Ring species also result from the interaction of speciation with a geographic barrier, but with a twist. As populations of a species expand into new areas, moving around a geographic barrier, they can form a ring around that barrier. While the immediately adjacent populations at each point around the ring interbreed, the terminal populations are reproductively isolated and cannot interbreed. Ring species thus can be thought of as a result of geographically extended parapatric speciation. Irwin et al. (2001) present an outstanding example of a ring species in the case of the greenish warbler (*Phylloscopus trochi-*

loides), whose six sub-species circle the Tibetan Plateau. The sub-species that are sympatric at the ends of the ring in central Siberia do not interbreed. The structure of songs involved in mate choice have diverged due to selection pressures favoring increased song complexity as the species expanded from the southwest around on the eastern and western sides of the plateau, eventually contacting again north of the plateau. Interestingly, there is now a gap in the ring in central China, which is probably due to habitat destruction by humans. The recentness of this gap has not allowed time for song divergence across the gap, but one could predict speciation across the gap in the future.

Sympatric speciation can generate a different pattern of biodiversity, hot spots of endemic species. Endemic species have very localized distributions, being found in one (usually small) area. Such species are not necessarily rare; the localized populations may be quite large. The cichlid fish species assemblages found in the crater lakes of Cameroon and cited above, along with the much richer cichlid diversity in the rift lakes of east Africa, are classic examples of hot spots of endemic species. In Lake Victoria, for example, over 300 species are found, of which very few are found anywhere else.

Overall biogeographic patterns of diversity within a region should therefore reflect the relative dominance of allopatric, parapatric, and sympatric speciation in shaping the flora and fauna. However, these biogeographic patterns are all too easily disturbed by human activities, which include habitat destruction resulting in species extinction and species transport resulting in new mixing of floras and faunas. This disturbance lends urgency to attempts to understand the causes of biogeographic patterns at the beginning of the twenty-first century, before the evidence is muddied by human activity.

5. *Time: Speciation Speed*

Based on the mechanisms of speciation outlined in Sects. 2 and 3, it is clear that speciation takes variable amounts of time to occur. Speciation via polyploidy, for example, can be nearly instantaneous. Speciation via changes in sexual signals involved in mate choice may be a much more gradual event.

From a lineage perspective, there are two models of speciation rates. First, speciation may occur through gradual change within the lineage, such that over time species 'a' is transformed into species 'b.' Second, lineages may split by either budding off a new lineage while the ancestral lineage remains unchanged, or by branching into two new lineages with the loss of the ancestral lineage. Thus, in the first model, change is slow; in the second, speciation events are rapid and interspersed among periods of no change or stasis. The first model has been dubbed 'gradualism' and the second, 'punctuated equilibrium' (Eldridge and Gould 1972). Large debates about the relative importance of gradualism and punctuated equilibrium raged among paleontologists throughout the 1970s and 1980s. The debate had a bearing on the role of natural selection and adaptation in speciation, as contrasted with genetic drift or chance founder effects. Supporters of the gradualist position usually argued that natural selection is of overwhelming importance, while supporters of punctuated equilibrium, initially at least, postulated a strong role for founder effects resulting in sub-sampling of the variation present in an ancestral species in a newly geographically isolated population, enhancing the speed of evolution of new species in those isolated populations. Support for both gradualism and punctuation exists in the fossil record, making resolution of the debate difficult. In addition, the time scale of the fossil record is very coarse, making it difficult to determine exactly how saltatorial a lineage might be.

Spectral Analysis

Spectral analysis is one of several statistical techniques necessary for characterizing and analyzing sequenced data. Sequenced data are observations that have been taken in one, two, or three dimensional space, and/or time. Examples might be observations of population density along a road, or of rainfall over an area, or of daily births at a hospital. One important limitation is that the observations be equally spaced in order that the analysis proceed efficiently. Spectral analysis refers to the decomposition of a sequence into oscillations of different lengths or scales. By this process, the observations in what is called the data domain are converted into the spectral domain. The reasons for doing this are that: (a) some forms of manipulation are easier in the spectral domain; and (b) the revealed scales are necessary statistical descriptors of the data and may suggest important factors that affect or produce such data. The following will provide brief descriptions of: (a) Fourier analysis and its use in manipulating data that are assumed to be periodic; (b) relevant statistics; and (c) one approach to spectral analysis of nonperiodic data including an example.

1. Fourier or Harmonic Analysis

Here data are represented by y where the position in the sequence is labeled by j, i.e., $y[j]$, where j varies from 0 to $(n-1)$. Because trigonometric functions require radians for their calculation the label j is converted to radians with $2\pi j/n$. What Fourier showed in 1822 was that almost any equally spaced sequence $y[j]$ could be fitted exactly by a set of cosine and sine curves. In addition, since no information was lost, these could be returned to the original data. There was one important assumption, that the data were periodic, i.e., that they repeated themselves both forwards from $(n-1)$ and backwards from 0 indefinitely.

A sinusoidal curve,

$$y[j] = A[k]\cos\{(2\pi kj)/n - \Phi[k]\},$$

as displayed by curve (a) in Fig. 1 is characterized by its frequency label, k, its amplitude, $A[k]$, and phase, $\Phi[k]$. The frequency, k, is the number of complete oscillations that occur over the total observations, n. For curve (a) this is 2. For n observations k may have integer values of 0 to $+n/2$ (n even). Frequency may also be expressed in observational units as $f = k/n\Delta t$ where Δt is the interval between observations. In the example, if y is observed daily for a year, the oscillation at $k = 2$ has a frequency of $f = 2/(365 \times 1 \text{ day}) = 1/182.5$th of a cycle per day $= 2$ cycles per year. It also has a wavelength (peak to peak distance) of $1/f = 182.5$ days $= 1/2$ year. The highest frequency that may be calculated is $f_{\max} = 1/(2\Delta t)$. The amplitude, $A[2]$, of curve (a) is 0.5. This also provides the variance of the curve, which is half the square of its amplitude, $A^2[2]/2 = 0.125$. The phase $\Phi[k]$, when it is divided by k to give the phase shift, gives the distance of the first peak from the origin. In this case $\Phi[2]/2 = 0.46$. Curve (a) can also be represented by the sum of a simple cosine curve ($y[j] = a[k]\cos(2\pi kj)/n$) as displayed as curve (b) and a simple sine curve ($y[j] = b[k]\sin(2\pi kj)/n$) given by curve (c). From trigonometry we can show that $A[k] = (a^2[k] + b^2[k])^{1/2}$, and $\Phi[k] =$

Figure 1
Examples of (a) sinusoidal, (b) simple cosine, and (c) simple sine curves for periodic data

arctan($b[k]/a[k]$). The coefficients $a[k]$ and $b[k]$ may be obtained from

$$a[k] = \frac{2}{n}\sum_{j=0}^{n-1} y[j]\cos\left(\frac{2\pi kj}{n}\right), \tag{1}$$

$$b[k] = \frac{2}{n}\sum_{j=0}^{n-1} y[j]\sin\left(\frac{2\pi kj}{n}\right), \tag{2}$$

where, for $k = 0$ and for $k = n/2$ when n is even, only Eqn. (1) exists and the factor 2 is replaced by 1. $a[0]$ is the mean of the series. A real set of data will be represented by the sum of the whole range of possible frequencies,

$$y[j] = \sum_{k=0}^{n/2}\left[a[k]\cos\left(\frac{2\pi kj}{n}\right) + b[k]\sin\left(\frac{2\pi kj}{n}\right)\right]. \tag{3}$$

Note that there were n $y[j]$ and a total of n $a[k]$ and $b[k]$. Thus the information present in the data domain, $y[j]$, is equivalent to the information in the spectral domain, $a[k]$ and $b[k]$. It is just arranged differently. A variable arranged according to k is said to be the spectrum of that variable. As an example, Fig. 4 represents the spectrum of the percentage variance.

All of these formulas refer to one dimension (along a road or through time). Similar equations may be written for spatial observations. It is nothing more than a curve- or surface-fitting procedure, like fitting a polynomial to observed data. One problem to be considered is how well the beginning of the data match the end of the data. If the beginning and ending points have very different magnitudes, the periodic assumption causes a big jump at those points. As a result, many frequencies will be required to account for it and these amplitudes may overwhelm the amplitudes within the data. Consequently, it is advisable to smooth off the ends of the data so that they meet at approximately the same magnitude. By this technique some information about the beginning and the end will be unavoidably lost.

What the Fourier series fitting does is to estimate any truly periodic elements present. In addition, it permits analytical procedures to be applied to the data even if they are not periodic. Often manipulations that are complex in the data domain are very simple in the spectral domain. For example, the degree of slope and azimuth of slope is a simple process of differentiation of Eqn. (3). The amplitudes are calculated by the process previously described, each amplitude is multiplied by its respective frequency, and the new amplitudes converted back to the data domain where they produce slope and orientation (Rayner 1972). As another example, pattern recognition is a simple multiplication process in the spectral domain (Rayner 1971). Yet another use is in the description or summarization of shape. Manipulation of digitized shape data such as national or other boundaries, by these Fourier techniques can reduce the number of original observations to less than one third without significant loss of information (Moellering and Rayner 1982).

2. Statistical Description

One use of statistics is to summarize large amounts of data. For example, Fig. 2 displays one year of daily birth data at one hospital. A first step is usually to calculate its probability distribution. Under ideal conditions that distribution will approach the 'normal probability distribution' or 'Gaussian probability distribution' form. Then the mean (μ_1) and variance (σ^2 or μ_2) are all that are needed to describe the data. Fig. 3 shows the probability distribution of the birth data which have a mean of 8.7 and a variance of 9.5. Superimposed is the normal curve. If the distribution is 'skewed' higher moments than the second moment (variance) will be required. Multimodal distributions will have to be subject to additional processing. In cases where more than one set of observations are being compared or related, 'covariance' and 'regression' techniques are applied. The true or population

Figure 3
Probability distribution of birth data

characteristics of distributions are called 'parameters.' Since only samples of data are available, only estimates of these characteristics can be obtained. These estimates are called statistics and are usually denoted by 'hatted' symbols ($\hat{\sigma}^2$ or $\hat{\mu}_2$). The particular formula used to calculate a statistic is called an estimator so, for example, different variance estimators are produced by dividing the sums of squares of deviations from the mean either by n or by $(n-1)$, where n is the number of observations in the sample. Two important measures of the quality of an estimator are bias, which is the deviation of the mean magnitude of the estimate from the population magnitude, and the variance of the sample estimates. Unfortunately, estimators that have small bias typically have large variance, and vice versa. Another quality measure is consistency, in which both bias and variance should decrease as n increases. Spectral estimates are typically not consistent.

Statistical estimates are assumed to come from an ensemble of observations. That is, the sample is taken from all possible occurrences of the phenomenon. In fact, typically only one set of observations is available through time or in space. To be useful therefore, the data from the series must be assumed to be representative of the ensemble, the data are assumed to be ergodic data. This also assumes that the particular segment of time series is representative of the whole continuum. Then the statistics from the different segments should be equivalent. In other words, the data are said to be stationary data.

Now to return to the description of observations, if the data are independent and one observation is not affected by the previous or next one, the probability of observing a particular magnitude is dictated by the normal distribution and is not related to the sequence of magnitudes observed. Then the mean and variance are sufficient descriptors. When this assumption is not fulfilled (e.g., the population density one kilometer away from a high density within an urban area is also likely to be high and not given by the normal distribution), this influence may be specified by the autocovariance function (i.e., the covariance of each observation with its next neighbor, with its neighbor two observations away, with its neighbor three observations away, etc.),

$$yy[p] = \frac{1}{n-|p|} \sum_{j=0}^{n-1-|p|} y[j]y[j+p], \tag{4}$$

where p is the neighbor distance, which is often called the *lag*. The $y[j]$ are pre-processed to have a mean of zero. Because the possible number of summed pairs is reduced as the lag increases, there is a practical limit to p which is typically taken to be in the order of $n/10 = m$. Note that this is a symmetrical function around $p = 0$ having $2m$ terms, and it is not necessary to calculate for negative p. Eqn (4) produces a new set of numbers that typically have a maximum at $p = 0$, decline to zero, and then oscillate around zero. How may this function be interpreted? Because, like the original data, these numbers are not independent, that is not easy. However, if this sequence is transformed with an orthogonal function, the new sequence, which is independent, is interpretable. The function selected is the Fourier transform which is a limiting form of Fourier analysis. This produces a spectrum of the variance: an allocation of the variance into different scales, wavelengths of frequencies of fluctuations.

In Sect. 1 it was shown that harmonic analysis requires that the data be periodic. The autocovariance function, $yy[p]$, is truncated at $(m-1)$ and $-(m-1)$ and is certainly not periodic. The $yy[p]$ are really all that can be calculated from what may be seen through a blurred window of the original observations that theoretically extend from $-\infty$ to $+\infty$. How can this window be described, or what can be said about what is not seen? The oldest approach, also known as the classical approach (Priestley 1997), assumes that the ends of the series are smoothed off and the unseen $y[j]$ are zero. Alternative approaches have searched for other estimators which use knowledge of the data to obtain, for example, more realistic models of what is unseen. These use autoregression, moving average, and maximum entropy techniques, individually and in combination. They occupy a large amount of literature and all cannot be adequately summarized here where the classical technique will be used to illustrate the basic principles. For the other approaches reference should be made to books by Box and Jenkins (1976) and Kay (1988) which contains computer programs for empirical work.

3. *Classical Spectral Analysis*

As zeroes are added to the series, the number of frequencies that may be calculated is increased but their magnitudes are decreased. For example, if n is doubled the label for an equivalent frequency is doubled and its magnitude is halved. What this shows is that the individual amplitudes, which refer to integer k frequencies in harmonic analysis, become average amplitudes over a frequency band centered at k as $n \to \infty$. To distinguish them, the frequency counter is changed from k to f. The practical equations essentially stay the same but the interpretation changes. Also, now a and b are typically defined for two-sided functions with $a[f] = a[-f] = (1/2)a[k]$ and $b[f] = -b[-f] = (1/2)\ b[k]$, and Eqns. (1) and (2) become

$$a[f] = \frac{1}{n} \sum_{j=0}^{n-1} \left[y[j] \cos\left(\frac{2\pi kj}{n}\right) \right], \tag{5}$$

$$b[f] = \frac{1}{n} \sum_{j=0}^{n-1} \left[y[j] \sin\left(\frac{2\pi kj}{n}\right) \right]. \tag{6}$$

Figure 4
Spectrum of percentage variance of birth data

The calculation with the new interpretation of a and b is called a Fourier transform.

Because the autocovariance function is a symmetrical function only Eqn. (5) is required for its transformation,

$$YY[f] = \frac{1}{2m} \sum_{p=-(m-1)}^{m-1} \left[yy[p] \cos\left(\frac{2\pi kp}{m}\right)\right]. \qquad (7)$$

This still leaves the shape of the window to be taken into account. Various windows have been proposed. Their effect in the spectral domain is to perform a weighting average over adjacent frequencies, i.e.,

$$\text{ave}(YY[f_1]) = \sum_{-(m-1)}^{+(m-1)} YY[f]H[f_1 - f], \qquad (8)$$

where, for the 'hanning' window, $H[f]$ is equal to 1/4, 1/2, 1/4.

The above process is the same as a Fourier transform of the original $y[j]$ series that has had the mean removed, been windowed by the smoothing off of the ends, and had some zeroes added. Then, for the variance, the $(a^2[f] + b^2[f])$'s are summed over equally-sized groups of f values.

As an example of such an analysis the spectrum of the percentage variance of the birth data is given in Fig. 4 with $m = 40$ and $f = q/(2m\Delta t)$ where $0 \leqslant q \leqslant m$. One might expect the number of births to be random in time, in which case the spectrum should be flat (approximately constant variance over all frequencies). This is essentially what Fig. 4 reveals with one exception: a large peak at $q = 11$, at approximately one week wavelength. One may speculate on the cause.

The application of other techniques of spectral analysis, such as maximum likelihood, might tease out other interesting periods. The next step might be a regression analysis relating births to other factors. If the other factors are sequenced, then this calls for cross spectral analysis (Rayner 1971). It allocates the variance to other factors as a function of scale. It also provides an estimate at each frequency of any delay between births and the influencing factor. Of course, statistical techniques cannot assign a cause. They can only suggest interesting phenomena and apparent relationships for investigation by other means.

For more complex distributions, where higher statistical moments and products are required, higher order spectra, polyspectra, provide valuable insights (Rayner in press).

Speech Errors, Psychology of

The generation of spoken language is a complex task normally accomplished with high accuracy. Human beings are, on average, consummate 'talkers.' But, speakers do err occasionally, and in ways that reflect the mental processes underlying the act of speaking. That is the topic pursued here: What are the speech error patterns of normal language use, and what do they tell us about language processing?

Various departures from the ideal of perfectly articulated, fluent speech occur in ordinary conversation: hesitations, false starts, changes of mind in mid-sentence, and misarticulations. In this context, the term 'speech error' has come to be used in a semitechnical fashion to pick out particular errors

from the welter of everyday language. The focus is on fluently uttered forms in which some element or elements of the intended target utterance are missing, mis-selected or misordered. Errors of knowledge (i.e., those arising from ignorance of a word or of 'proper usage') and various nonfluencies are distinguished from speech error in this way of proceeding.

1. *A Methodological Note*

How is error data acquired? Several investigators have collected extensive records of errors heard during everyday language use. A classic such effort was that of Rudolf Merringer (Merringer and Meyer 1895) in the late nineteenth century. Cutler and Fay (1978) describe his methods in their introductory essay to a reissue of Merringer's work. The practices they describe are characteristic of later diary studies. Typically, a written record of an error is made soon after observation (normally, a few seconds to a few minutes), with annotations regarding pronunciation and setting. Such observation has the strong appeal of face validity for processes of language formulation. However, influences of perceptual filtering and memory distortion must be carefully weighed. It is clear that minor phonetic deviations may be missed, and only changes clearly discernable with respect to the speaker's target are well represented in such error corpora. See Cutler (1982) for detailed discussion of these and related issues.

Diary studies exist for several languages. It may be said with some assurance that whether the target language is Chinese, Dutch, English, German, Italian, Spanish, Turkish, or other, the same general types of phenomena arise. Specific language features may afford options for error —e.g., Chinese tone errors— not available in English or related languages. Nevertheless, the general behavior of errors involves similar mechanisms across languages. Discussion here focuses on English, with some commentary on representative language differences. Error examples are taken from papers in the bibliography.

2. *Types of Error*

In the popular literature, 'speech error' is synonomous with 'Spoonerisms', named after the Dean of New College, Oxford, Rev. W. A. Spooner (1844–1930), who was notorious for his misplacements of speech sounds, sometimes to extraordinary effect. For example, in lecturing a wayward student, he is alleged to have said: 'You have hissed all my mystery lectures. ... and tasted two worms' ('missed all my history lectures ... wasted two terms'). But Spoonerisms are special in several respects. They suggest that sound errors usually make words, and that they make a kind of wild and humorous sense. Neither condition is typical. Further, Spoonerisms primarily exploit sound error, and the relevant phenomena are much more general. No account of Rev. Spooner's performance is given here; for comment, see, e.g., Robbins (1966).

Notwithstanding the exclusion of Rev. Spooner's legacy, there is no denying the charm of suitably chosen errors as a way to display the hidden structure in language. The errors are intricate, and they illustrate essential features of language processing. Examples (a)–(n) are representative.

(a) '... sat down on a *s*ot *h*oddering iron' (... hot soldering ...)

(b) 'I won't hit the ba*rd* ha*ll*' (... ball hard)

(c) 'I have a case of l*ay* gr*o*de flu.' (... low grade ...)

(d) '... so I can start the s*tape*back up (... the tape ...)

(e) 'The curren*th* month is ... (The current ...)

(f) '..an anguage *l*acquisition device ... (... a language acquisition...)

(g) 'Is your *purr*y *kitt*ing' (... kitty purring)

(h) 'Make it so the *apple* has less *tree*s. (... so the tree has less apples.)

(i) 'She *sings* everything she *writes*. (... writes everything she sings)

(j) 'Bensinger takes to that left-field wall like *water* takes to *a duck*. (... like a duck takes to water)

(k) 'I've got whipped cream on my *mushroom*! (... on my mustache!)

(l) 'You put your *nose* ... your finger on it. (... put your finger on it)

(m) 'My! So that's the Porche *symblem*. (symbol/emblem)

(n) '*It doesn't care*. (It doesn't matter/I don't care)

A rough task analysis sets the stage for error interpretation. It is evident that systems for speaking include mechanisms that select from tens of thousands of available words just those appropriate to an intended message ('lexical retrieval'), mechanisms that integrate the words into sentence structures ('syntactic construction'), and mechanisms that orchestrate these decisions into control structures ('phonological and prosodic integration) that drive motor outputs. Psychological explanation must reconstruct this complex of mental events.

Descriptively, in examples (a)–(g), sounds move around in various ways—they are exchanged, anticipated, perseverated, and shifted. Important features of sound error include: Moved elements are *phonetically similar*, they correspond in *syllabic position*, and their immediate *phonetic environments are similar* (Boomer and Laver 1968, Dell 1984, Noteboom 1969, Caldognetti et al. 1987, del Viso et al. 1991, McKay 1970, Vousen et al. 2000). The fact that error likelihood is so strongly influenced by structural similarity suggests that errors arise, in part, out of mechanisms that associate independently specified processing elements (sounds, in this example) with a *planning framework* ('syllable or word frames', in this

instance). These errors and related phenomena indicate how sounds that make up words enter planning structures for sentences. In the task analysis, this reflects phonological and prosodic integration processes.

Examples (h)–(j) are 'word movement' errors. Some are of special interest because they reflect an analysis of words into stem and affix. In Example (h), 'apples' is decomposed into 'apple + s' —more abstractly ['apple' + plural marker]. The technical term in linguistic science for such a decomposition is *morphemic analysis*. Notice that the two types of morpheme (stem and affix) behave in very different ways. The stem moves, but the affix stays behind. One can also describe this error in terms of the notion of structural frame. By this hypothesis, the affix would be considered part of a phrasal frame that stem morphemes are assigned to as a sentence develops. This idea proves applicable to a wide range of error observations, and is strikingly manifest in languages with richly developed morphological structures. (Related facts are discussed in Sect. 3.4.) In the task analysis, these errors implicate syntactic integration.

Examples (k) and (l) provide another perspective on errors. Descriptively, these are *word substitutions*. Several points are relevant. First, (k) displays a phonetic similarity between target and intruding element; the phonetic similarities between 'mustache' and 'mushroom' are representative. Moreover, both words are nouns. Thus, the syntactic structure of the intended utterance is preserved. One may plausibly treat this as a failure—perhaps triggered by phonetic similarity—of mechanisms that retrieve elements from an inventory of word forms. But what about errors like (l)? Grammatical category is preserved, but phonetic similarity is not apparent. And, unlike (k), an obvious meaning relation holds between target and intrusion. Section 3.5 discusses this contrast. In the task analysis, these errors implicate lexical selection processes, and they encompass both form and meaning relations.

Examples 13 and 14 are *blend* errors. In morpheme, word, and phrase blends, two processing elements compete for a *single output slot*. Speakers are often aware of the competition, and can report experiencing it. The competing expressions are, with rare exception, of the same grammatical class and are semantically equivalent for the intended message. This phenomenon is a *prima facie* demonstration of some parallelism in sentence production. Such errors implicate lexical selection processes and aspects of phrasal and phonological composition.

3. *Interpretations of Error Phenomena*

Speech errors have many variants. The challenge is to explain their similarities and differences in ways that link them to accounts of production mechanisms at the necessary levels of representation (phrases, words, morphemes, syllables, sounds). A robust generalization across the error types is relevant: Like elements interact, i.e., sounds interact with sounds, words with words, and phrases with phrases. These interactions indicate vocabularies of 'units', and the error data shows they are linked in an architecture of processing stages discussed in Sects. 3.1–3.4.

3.1 *Accommodations in Error Processes*

Errors move elements of the intended utterance to 'new' positions. Because languages display many local dependencies of form, such displacements could violate these. But, typically they do not. Example (f) illustrates: '*a* language acquisition device' became '*an* anguage lacquisition device.' The indefinite article changed from 'a' to 'an', and so *accommodated* to the vowel onset ('anguage') created by the error. In Example (o), the bound morpheme deriving 'easily' from 'easy' shifts. But, the isolated stem 'easy' was correctly pronounced as /izi/ rather than with a reduced final vowel (as would have been appropriate had the affix remained in place).

(o) '... *easy enoughly* ...' (easily enough)

Many such variations triggered by changes in phonetic context appear in accommodations. By these observations, processes that fix the surface phonetic forms of words are ordered later than the error-generating structures: First, an abstract morphological and phonological representation is constructed, then regular processes flesh out its phonetic detail. This is a familiar notion in linguistics, and its expression in error phenomena is not greatly surprising (see Fromkin 1971). But, bear in mind that it could have turned out otherwise. The speaker of Example (f) might have said 'a anguage' but did not; the speaker of Example (o) might have said 'easuh enoughly', but did not; and so on. Error processes on this evidence are tightly bound to the structural systems that govern error-free speech.

3.2 *Other Evidence for Ordering of Processes: Sound Exchanges and Word Exchanges*

These error classes reveal syntactic and phonological planning structures. Sound interactions, and particularly exchanges as in (a)–(c), typically involve words *in the same phrase*. The relevant structure is prosodic (see Boomer and Laver 1968, Fromkin 1971, Garrett 1980). Prosodic grouping reflects syntax, but is also motivated by intonation and the phonological structure of the words chosen to express a given syntactic form. Treating the domain of sound exchange as prosodic may also explain some cross-language differences. For example, sound exchanges in English are predominantly between words, but in Spanish, within words (del Viso et al. 1992). The greater morphological complexity and length of Spanish words, as compared to English, would require exchanges be-

tween words to cross prosodic boundaries more often for the former than the latter.

Word and phrase exchanges sharply differ from sound exchanges. As Examples (i), (j), and (p)–(r) suggest, they arise for elements in distinct phrases that correspond in grammatical category.

(p) '... I left my *briefcase* in the *cigar*.' (... my cigar in the briefcase)

(q) 'What we want to do is train *its tongue* to move *the cat*.' (... the cat to move its tongue)

(r) 'As you *reap*, Roger, so shall you *sow*.' (As you sow ... so shall you reap)

Nouns exchange with nouns, verbs with verbs, adjectives with adjectives (Bierwisch 1970, Garrett 1975, Nooteboom 1967). On this evidence, operations at the point of error involve the grammatical roles of words (or minimal phrasal units). Sound exchanges differ in both respects. Recall also that sound exchanges implicate many detailed features of phonological structure; word exchanges are minimally so affected (see Dell and Reich 1981, del Viso et al. 1992). These differences in the role of phrasal domain, grammatical category, and phonological description reveal two processing systems. Syntactic constituents are built by a multiphrasal processor that does not represent the sound structure of its elements (word stems, morphemes, simple phrases); failures yield word and phrase exchanges. A subsequent process elaborates sound sequences for words within a phrase group; failures yield sound exchanges. Multiple phrasal units are present at the syntactic level, and a narrower planning window develops sound structures and pronunciation codes in prosodic groups.

3.3 Stranding Errors and Multiple Levels of Processing

The exchanges in Examples (g) and (h) decompose target words into their constituent morphemes and strand affixes. One finds stranding of a variety of productive structural markers, predominantly those of inflectional device (e.g., number, tense, and aspect markers, gerundives, comparatives). Evidence indicates that stranding arises at two points: within phrase (re prosodic groups for sound exchanges), and between phrase (re structures for word exchanges) (see Garrett 1993). These ideas extend the earlier discussion of accommodation. That discussion described it as a phonologically conditioned response to error movements. But, consider Examples (s) and (t).

(s) '··· that I would *hear* one if I *knew* it.' (...that I would know one if I heard it)

(t) '··· drei *Wochen* im *Tag* gearbeitet.' (drei Tage in der Woche gearbeitet).

Here there is accommodation, but, strikingly, it involves irregular forms of inflected words. In Example(s), the appropriate irregular verb forms for 'know' and 'hear' appear. The German example (Bierwisch 1970) shows several accommodations. Singular '*Woche*' takes plural marker 'en'; plural '*Tage*' has the singular form '*Tag*'. Further, German nouns bear grammatical gender: '*Woche*' is feminine, '*Tag*' is masculine. The articles required thus differ, and may interact with prepositions. Here, number and gender are appropriate, including interaction with the preposition ('*im*' is a contracted form of '*in dem*').

What accounts for this impressive range of accommodations? They are lexically dependent and so not derivable from phonological environments (as described in Sect. 3.2). In fact, lexically dependent accommodation is restricted to between phrase stranding exchanges for elements of corresponding grammatical category. In the account in Sect. 3.2, such errors occur at the level of abstract phrasal construction, prior to the phonological interpretation of content words. Development of the irregular forms follows from affiliation of the switched stems with stranded inflectional features.

3.4 Generalizing the Observations About Processing Frames

Stranding shows that inflectional elements are separately represented when stems are inserted into phrasal frames. This can be expressed by assuming that inflectional elements are parts of structural frameworks. If exchanges arise when lexical elements are misassigned to structural frames, it follows that parts of frames should not exchange. This expectation is borne out in error corpora; inflectional exchanges are rare (Garrett 1975, Stemberger 1984). Another class of observations (morpheme shifts), not discussed here, may also be connected to this picture (see Garrett 1980).

There is some basis for treating all functional elements both bound and free in this way. The claim is that functional elements (inflections, determiners, complementizers, etc.—the minor grammatical categories) are derivatives of structure and are thus recruited for incorporation into sentences by different mechanisms than those responsible for the selection of content items (nouns, verbs, prepositions, adjectives, adverbs—the major grammatical categories). This contrast has been discussed in the processing literature under the label of 'open class' and 'closed class' vocabularies. It might be construed as a distinction between those elements individually selected under conceptual control ('content elements') and those that are reflexes of the logic and syntax of the sentence (Levelt 1989, Bock and Levelt 1994). See Myers-Scotten and Jakes (2001), for a related account based on 'code-switching' (a bilingual language practice that fluently combines elements from two languages into a single utterance). Note, however, that some accounts of speech error link profiles for these vocabulary types to their relative frequency of occurrence in the language (Stemberger and McWhinney 1986, Dell 1991).

On this view, very high frequency rates, rather than structural roles, governs error behavior of functional elements.

3.5 *Lexical Selection Processes*: *Word Substitutions*

Word substitutions provide a data class distinct from movement error. These reflect failures in lexical retrieval; Examples (u)–(y) illustrate.

(u) 'Are you left-handed? No, I'm *amphibian*, no, *ambivalent*... arghh, ambidextrous!'

(v) 'If you can find a *garlic* around the house, I'll take it.' (gargle)

(w) 'All I want is something for my *shoulders*.' (elbows)

(x) 'He rode his bike to school *tomorrow*.' (yesterday)

(y) 'Yumm, are we having *lobsters* tonight?' (oysters)

A dissociation of errors with meaning similarities and those with form-based similarities is immediately apparent. Fay and Cutler (1977) in a seminal paper described these contrasts and proposed two selection processes, rooted respectively in content (semantic representations) and form (morphological and phonological representations). Depending on which process is compromised, errors should display quite different similarity metrics. Fay and Cutler's analysis, and subsequent studies, revealed multiple systematic form relations between target and error words that lacked a meaning relation—as Examples (k), (u), (v), while errors with meaning relations, as in Examples (m), (w), and (x), lack such phonological resemblances.

These substitutions also interact with sentence structure: Grammatical category correspondence between target and intrusion powerfully constrains word substitutions whether semantically or form driven. This links to the movement error analysis in Sects. 3.1–3.4. That analysis indicates staged processing in which phonologically uninterpreted elements are first associated with syntactic environments, followed by assignment of phonological representations to structural frameworks. Word substitution patterns fit into those processes. The distinction parallels the discussion of lemmas in *Speech Production, Psychology of*. Meaning-guided retrieval selects lexical representations (phonologically uninterpreted: lemmas) for input to the multiphrasal construction process that is the locus of word exchanges. Following this, word form retrieval (mapping from lemmas to word forms) provides inputs to the prosodic groups that are the locus of sound exchange errors.

The ordering is clear, but details of the sequencing less so. The differences between meaning and form-based substitutions have been a matter of sustained debate. A way to put this is to ask whether semantic selection is accomplished without feedback from form to meaning levels. Dell (1986) and others have argued that the process is to some degree interactive, and includes such feedback, yielding semantically related errors that also display a form relation, as illustrated in Example (y). Such errors are a minority, but occur with greater than chance likelihood. See Dell et al. (1997) for a recent review; and Levelt et al. (1999) for contrasting discussion.

4. *What Causes Error?*

Several causal factors have been identified. Broadly speaking, they are either 'noise' or 'competition' based. See Butterworth (1982) for a helpful exposition. He distinguishes causes of error in terms of 'sentence internal' and 'sentence external' processes, with emphasis on 'competing plans' as error sources.

Fluctuations in efficiency of the neural systems that underlie language processes could clearly cause error. But such accounts require explicit linkage to production mechanisms. This step is well represented in work by Dell (1986) and others using network models to simulate error patterns; see also Levelt et al. (1999). Error caused by competing sentence formulations is also readily identifiable in blends—as in Examples (m) and (n). These give strong evidence for multiple encoding paths within a sentence. It is easy to generalize such conditions to rationalize certain word substitutions and sound errors as well.

'Sentence external' processes provide additional sources of competing expressions. Such may be discourse-relevant variations on sentence form or discourse external representations for an independent line of thought. This latter may also include interaction of linguistic processing with attentional mechanisms that filter automatic responses to the environment. A 'filtering breakdown' may lead to incorporation of environmental material into speech (see e.g., Harley 1990).

Sigmund Freud (1901) is identified with accounts of errors motivated by thoughts related to unconscious wishes and desires. His account links those thoughts to the meaning of the words or phrases resulting from error. That requirement suggests that Freudian mechanisms are not a major factor in the generation of movement errors. A robust feature of virtually all such errors is their indifference to the meaning of error products (Bierwisch 1970). An alternative focus for Freud's claims may lie in editorial processes—i.e., accounts of self-monitoring and its relation to the mechanisms of sentence production (see Motley et al. 1982).

5. *The Broader Picture: Building Models of the Language Production Process*

Speech error analysis provides a rich source of information about the real-time processes that underlie human abilities to generate fluent, coherent, oral discourse. But, rich as it is, there are sharp limitations on its utility for certain questions about language

production. Issues of semantic and discourse structure are awkwardly represented or absent from error data, and multiple questions about the temporal relations of lexical and phrasal integration are undetermined by the patterns of naturally occurring speech error. At precisely this point one turns to experimental studies of production performance.

Bock (1987, 1990, 1995) and collaborators have used picture description tasks and related techniques to uncover detailed relations between sentence generation and the underlying conceptual structures that sentences encode. Models of lexical retrieval have been extensively investigated via picture naming and related paradigms (see *Speech Production, Psychology of*). A family of experiments that focuses on TOT (tip of the tongue) states provides complementary information on lexical staging for syntactic and phonological representations (see *Tip-of-the-tongue, Psychology of*). Studies using error induction techniques also provide points of contact with spontaneous error data. See Shattuck-Hufnagel (1987) for a comprehensive series of error induction studies relating sound error to lexical and phrasal structure, including stress factors. Work by Baars et al. (1975) led to a series of investigations showing lexical influences on the probability of sound exchanges. Some aspects of the experimentation point to monitoring processes as the source of such effects (see Levelt et al. 1999 for review). An extensive experimental literature on induced agreement errors has developed from original work by Bock and Miller (1991) on English number agreement, and has been applied to agreement issues in several additional languages (see, e.g., Vigliocco et al. 1999). See Bock and Levelt (1994) for a recent synthesis of several strands of production experimentation.

Speech Perception

It is a commonplace to have the impression that foreign languages are spoken much more rapidly than our own, and without silent periods between the words and sentences. Our own language, however, is perceived at a normal pace (or even too slowly at times) with clear periods of silence between the words and sentences. In fact, languages are spoken at approximately the same rate, and these experienced differences are solely due to the memory structures and psychological processes involved in speech perception. Thus we define speech perception as the process of imposing a meaningful perceptual experience on an otherwise meaningless speech input. The empirical and theoretical investigation of speech perception has blossomed into an active interdisciplinary endeavor, including the fields of psychophysics, neurophysiology, sensory perception, psycholinguistics, linguistics, artificial intelligence, and sociolinguistics.

1. *Psychophysics of Speech Perception*

In any domain of perception, one goal is to determine the stimulus properties responsible for perception and recognition of the objects in that domain (see *Psychophysics*). The study of speech perception promises to be even more challenging than other domains of perception because there appears to be a discrepancy between the stimulus and the perceiver's experience of it. For speech, we perceive mostly a discrete auditory message composed of words, phrases, and sentences. The stimulus input for this experience, however, is a continuous stream of sound (and facial and gestural movements in face-to-face communication) produced by the speech production process. Somehow, this continuous input is transformed into more or less a meaningful sequence of discrete events (see *Psychophysics*).

Although we have made great progress on this front, there is still active controversy over the ecological properties of the speech input that are actually functional in speech perception. One issue, revived by recent findings, is whether the functional properties in the signal are static or dynamic (changing with time). Traditionally, static cues (such as the location of formants (bands of energy in the acoustic signal related to vocal tract configuration), the distribution of spectral noise as in the onset of *saw* and *shawl*, and the mouth shape at the onset of a segment) have been shown to be effective in influencing speech perception. Dynamic cues such as the transition of energy between a consonant and the following vowel have also been shown to be important. For example, recent research has shown that the second formant (F2) transition defined as the change between the F2 value at the onset of a consonant–vowel (CV) transition and the F2 value in the middle of the following vowel is a reliable predictor of the place of articulation category (Sussman et al. 1998).

Controversy arises when research is carried out to argue for one type of cue rather than another. For example, investigators recently isolated short segments of the speech signal and reversed the order of the speech within each segment (Saberi and Perrott 1999). In this procedure, a sentence is divided into a sequence of successive segments of a fixed duration such as 50 ms. Each segment is time-reversed and these new segments are recombined in their original order, without smoothing the transition borders between the segments. In this fashion, the sentence could be described as between globally contiguous but locally time-reversed. The authors claimed that the speech was still intelligible when the reversed segments were relatively short (1/20th to 15th of a second). Their conclusion was that our perception of speech was demonstrated to be primarily dependent on higher-order dynamic properties rather than the short static cues normally assumed by most current theories. This type of study and logic follows a tradition of attempting to find a single explanation or influence of some psychological phenomenon. However, most successful research in psychology is better framed within the more general framework of *ceteris paribus* (all other aspects neutral). There is good evidence that perceivers exploit many different cues in speech perception, and attempting to isolate a single functionally sufficient cue is futile.

There is now a large body of evidence indicating that multiple sources of information are available to

support the perception, identification, and interpretation of spoken language. There is an ideal experimental paradigm that allows us to determine which of the many potentially functional cues are actually used by human observers, and how these cues are combined to achieve speech perception (Massaro 1998). The systematic variation of the properties of the speech signal and quantitative tests of models of speech perception allow the investigator to interpret the psychological validity of different cues. This paradigm has already proven to be effective in the study of audible, visible, and bimodal speech perception (Massaro 1998). Thus, this research strategy addresses how different sources of information are evaluated and integrated, and can identify the sources of information that are actually used.

2. *The Demise of Categorical Perception*

Too often, behavioral scientists allow their phenomenal impressions to spill over into their theoretical constructs. One experience in speech perception is that of categorical perception. Using synthetic speech, it is possible to make a continuum of different sounds varying in small steps between two alternatives. Listening to a synthetic speech continuum between /ba/ and /pa/ provides an impressive demonstration: students and colleagues usually agree that their percept changes qualitatively from one category to the other in a single step or two with very little fuzziness in-between. Consistent with this impression, there is no denying that we experience discrete categories in speech perception. This experience of discrete perception was developed as a description of the speech perception process and called categorical perception (CP), or the perceived equality of instances within a category. The CP of phonemes has been a central concept in the experimental and theoretical investigation of speech perception and has also spilled over into other domains such as face processing (Beale and Keil 1995, Etcoff and Mcgee 1992). CP was operationalized in terms of discrimination performance being limited by identification performance. Researchers at Haskins Laboratories (Liberman et al. 1957) used synthetic speech to generate a series of 14 consonant–vowel syllables going from /be/ to /de/ to /ge/ (/e/ as in gate). The onset frequency of the second formant transition of the initial consonant was changed in equal steps to produce the continuum. In the identification task, observers identified random presentations of the sounds as /b/, /d/, or /g/. The discrimination task used the ABX paradigm. Three stimuli were presented in the order ABX; A and B always differed and X was identical to either A or B. Observers were instructed to indicate whether X was equal to A or B. This judgment was supposedly based on auditory discrimination in that observers were instructed to use whatever auditory differences they could perceive.

The experiment was designed to test the hypothesis that listeners can discriminate the syllables only to the extent that they can recognize them as different phoneme categories. The CP hypothesis was quantified in order to predict discrimination performance from the identification judgments. The authors concluded that discrimination performance was fairly well predicted by identification. This rough correspondence between identification and discrimination has provided the major source of support for CP. There have been several notable limitations in these studies. Discrimination performance is consistently better than that predicted by identification, it is possible that participants are making their discrimination judgments on the basis of identification rather than on their auditory discrimination, and it is likely that any alternative theory would have described the results equally well (Massaro 1987).

In many areas of inquiry, a new experimental paradigm enlightens our understanding by helping to resolve theoretical controversies. For CP, rating experiments were used to determine if perceivers indeed have information about the degree of category membership. Rather than ask for categorical decisions, perceivers are asked to rate the stimulus along a continuum between two categories. A detailed quantitative analysis of the results indicated that perceivers have reliable information about the degree of category membership, contrary to the tenets of CP (Massaro and Cohen 1983). Although communication forces us to partition the inputs into discrete categories for understanding, this property in no way implies that speech perception is categorical. To retrieve a toy upon request, a child might have to decide between *ball* and *doll*; however, she can certainly have information about the degree to which each toy was requested.

Although CP has been discredited, it is often reinvented under new guises. Most recently, the perceptual-magnet effect (PME) has had a tremendous impact on the field, and has generated a great deal of research (Kuhl 1991). The critical idea is that the discriminability of a speech segment is inversely related to its category goodness. Ideal instances of a category are supposedly very difficult to distinguish from one another relative to poor instances of the category. If we understand that poor instances of one category will often tend to be at the boundary between two categories, then the PME is more or less a reformulation of prototypical CP. That is, discrimination is predicted to be more accurate between categories than within categories. In demonstrating its viability, the PME faces the same barriers that have been difficult to eliminate in CP research. In standard CP research, it is necessary to show how discrimination is directly predicted by identification performance. In the PME framework, it is also necessary to show how discrimination is directly predicted by a measure of category goodness. We can expect category goodness

to be related to identification performance. Good category instances will tend to be identified equivalently, whereas poor instances will likely be identified as instances of different categories. Lotto et al. (1998) found that discriminability was *not* poorer for vowels with high category goodness, in contrast to the predictions of the PME. The authors also observed that category goodness ratings were highly context sensitive, which is a problem for the PME. If category goodness is functional in discrimination, it should be relatively stable across different contexts.

Notwithstanding the three decades of misinterpreting the relationship between identification and discrimination of auditory speech, we must conclude that it is perceived continuously and not categorically. Recent research reveals conclusively that both visible and bimodal speech are perceived continuously (Massaro 1987, 1998). This observation pulls the carpet from under current views of language acquisition that attribute to the infant and child discrete speech categories (Eimas 1985, Gleitman and Wanner 1982). Most importantly, the case for the specialization of speech is weakened considerably because of the central role that the assumption of CP has played (Liberman and Mattingly 1985). Finally, several neural network theories such as single-layer perceptrons, recurrent network models, and interactive activation have been developed to predict CP (Damper 1994): its nonexistence poses great problems for these models.

Given the existence of multiple sources of information in speech perception, each perceived continuously, a new type of theory is needed. The theory must describe how each of the many sources of information is evaluated, how the many sources are combined or integrated, and how decisions are made. The development of a promising theory has evolved from sophisticated experimental designs and quantitative model testing to understand speech perception and pattern recognition more generally. A wide variety of results have been accurately described within the Fuzzy Logical Model of Perception (FLMP).

3. *The Fuzzy Logical Model of Perception (FLMP)*

The three processes involved in perceptual recognition are illustrated in Fig. 1 and include evaluation, integration, and decision. These processes make use of prototypes stored in long-term memory. The evaluation process transforms these sources of information into psychological values, which are then integrated to give an overall degree of support for each speech alternative. The decision operation maps the outputs of integration into some response alternative. The response can take the form of a discrete decision or a rating of the degree to which the alternative is likely. The assumptions central to the model are: (a) each source of information is evaluated to determine the continuous degree to which that source specifies various alternatives; (b) the sources of information are evaluated independently of one another; (c) the sources are integrated to provide an overall continuous degree of support for each alternative; and (d) perceptual identification and interpretation follows the relative degree of support among the alternatives. In the course of our research, we have found the FLMP to be a universal principle of perceptual cognitive performance that accurately models human pattern recognition. People are influenced by multiple sources of information in a diverse set of situations. In many cases, these sources of information are ambiguous and any particular source alone does not usually specify completely the appropriate interpretation.

Figure 1
Schematic representation of the three processes involved in perceptual recognition. The three processes are shown to proceed left to right in time to illustrate their necessarily successive but overlapping processing. These processes make use of prototypes stored in long-term memory. The sources of information are represented by upper-case letters. Auditory information is represented by A_i and visual information by V_j. The evaluation process transforms these sources of information into psychological values (indicated by lowercase letters a_i and v_j) These sources are then integrated to give an overall degree of support, s_k, for each speech alternative k. The decision operation maps the outputs of integration into some response alternative, R_k. The response can take the form of a discrete decision or a rating of the degree to which the alternative is likely

4. *Multimodal Speech Perception*

Speech perception has traditionally been viewed as a unimodal process, but in fact appears to be a prototypical case of multimodal perception. This is best seen in face-to-face communication. Experiments have revealed conclusively that our perception and understanding are influenced by a speaker's face and accompanying gestures, as well as the actual sound of the speech (Massaro 1998). Consider a simple syllable identification task. Synthetic visible speech and natural audible speech were used to generate the consonant–vowel (CV) syllables /ba/, /va/, /a/, and /da/. Using an expanded factorial design, the four syllables

Figure 2
Probability correct identification of the unimodal (AU = Auditory, VI = Visual) and bimodal (BI) consistent trials for the four test syllables

were presented auditorily, visually, and bimodally. Each syllable was presented alone in each modality for $4 \times 2 = 8$ unimodal trials. For the bimodal presentation, each audible syllable was presented with each visible syllable for a total of 4×4 or 16 unique trials. Thus, there were 24 types of trials. Twelve of the bimodal syllables had inconsistent auditory and visual information. The 20 participants in the experiment were instructed to watch and listen to the talking head and to indicate the syllable that was spoken.

Accuracy is given in Fig. 2 for unimodal and bimodal trials when the two syllables are consistent with one another. Performance was more accurate given two consistent sources of information than given either one presented alone. Consistent auditory information improved visual performance about as much as consistent visual information improved auditory performance. Given inconsistent information from the two sources, performance was poorer than observed in the unimodal conditions. These results show a large influence of both modalities on performance with a larger influence from the auditory than the visual source of information.

Although the results demonstrate that perceivers use both auditory and visible speech in perception, they do not indicate how the two sources are used together. There are many possible ways the two sources might be used. We first consider the predictions of the FLMP.

In a two-alternative task with /ba/ and /da/ alternatives, the degree of auditory support for /da/ can be represented by a_i, and the support for /ba/ by $(1–a_i)$. Similarly, the degree of visual support for /da/ can be represented by v_j, and the support for /ba/ by $(1–v_j)$. The probability of a response to the unimodal stimulus is simply equal to the feature value. For bimodal trials, the predicted probability of a response, $P(/\mathrm{da}/)$ is equal to

$$P(/\mathrm{da}/) = \frac{a_i v_j}{a_i v_j + (1-a_i)(1-v_j)} \qquad (1)$$

In previous work, the FLMP has been contrasted against several alternative models such as a weighted averaging model (WTAV), which is an inefficient algorithm for combining the auditory and visual sources. For bimodal trials, the predicted probability of a response, $P(/\mathrm{da}/)$ is equal to

$$P(/\mathrm{da}/) = \frac{w_1 a_1 + w_2 v_j}{w_1 + w_2} = w a_i + (1-w) v_j \qquad (2)$$

The WTAV predicts that two sources can never be more informative than one. In direct contrasts, the FLMP has consistently and significantly outperformed the WTAV (Massaro 1998).

More generally, research has shown that the results are well-described by the FLMP, an optimal integration of the two sources of information (Massaro and Stork 1998). A perceiver's recognition of an auditory-visual syllable reflects the contribution of both sound and sight. For example, if the ambiguous auditory sentence, *My bab pop me poo brive*, is paired with the visible sentence, *My gag kok me koo grive*, the perceiver is likely to hear, *My dad taught me to drive*. Two ambiguous sources of information are combined to create a meaningful interpretation (Massaro and Stork 1998).

Recent findings show that speech reading, or the ability to obtain speech information from the face, is not compromised by oblique views, partial obstruction or visual distance. Humans are fairly good at speech reading even if they are not looking directly at the talker's lips. Furthermore, accuracy is not dramatically reduced when the facial image is blurred (because of poor vision, for example), when the face is viewed from above, below, or in profile, or when there is a large distance between the talker and the viewer (Massaro 1998).

5. *Higher-order or Top-down Influences*

Consistent with the framework being developed, there is now a substantial body of research illustrating that speech perception is influenced by a variety of contextual sources of information. Bottom-up sources correspond to those sources that have a direct mapping between the sensory input and the representational unit in question. Top-down sources or contextual information come from constraints that are not directly mapped onto the unit in question. As an example, a bottom-up source would be the stimulus presentation of a test word after the presentation of a top-down source, a sentence context. A critical question for both integration and autonomous (modularity, models is how bottom-up and top-down sources of information work together to achieve word recognition. For example, an important question is how early can contextual information be integrated with acoustic-phonetic information. A large body of research shows that several bottom-up sources are

Figure 3
Observed (points) and FLMP's predictions (lines) of /g/ identifications for FT and S contexts as a function of the speech information of the initial consonant. Results from Pitt's (1995) Experiment 3a

evaluated in parallel and integrated to achieve recognition (Massaro 1987, 1994). An important question is whether top-down and bottom-up sources are processed in the same *manner*. A critical characteristic of autonomous models might be described as the language user's *inability* to integrate bottom-up and top-down information. An autonomous model must necessarily predict no perceptual integration of top-down with bottom-up information.

Pitt (1995) studied the joint influence of phonological information and lexical context in an experimental paradigm developed by Ganong (1980). A speech continuum is made between two alternatives, and the contextual information supports one alternative or the other. The initial consonant of the CVC syllable was varied in six steps between /g/ and /k/. The following context was either /Ift/ or /Is/. The context /Ift/ favors or supports initial /g/ because *gift* is a word whereas *kift* is not. Similarly, the context /Is/ favors or supports initial /k/ because *kiss* is a word whereas *giss* is not. Pitt improved on earlier studies by collecting enough observations to allow us to perform a subject-by-subject evaluation of the ability of specific models of language processing to account for the results. Previous tests of models using this task have been primarily dependent on group averages which may not be representative of the individuals that make the averages up.

The points in Fig. 3 give the observed results for each of the 12 subjects in the task. For most of the subjects, the individual results tend to resemble the average results reported by Pitt and earlier investigators. Ten of the 12 subjects were influenced by lexical context in the appropriate direction. Subject 1 gave an inverse context effect and Subject 7 was not influenced by context.

This FLMP was applied to the identification results of the 12 individual subjects in Pitt's Experiment 3a for which the greatest number of observations (104) were obtained for each data point for each subject. According to the FLMP, both the bottom-up information from the initial speech segment and the top-down context are evaluated and integrated. If s_i is the degree of support for the voiced alternative given by the initial segment and c_j is the support given by the following context, the total support for the voiced alternative i is given by

$$S(\text{voiced} \mid S_i C_j) = s_i \times c_j \tag{3}$$

The support for the voiceless alternative would be

$$S(\text{voiceless} \mid S_i C_j) = (1 - s_i) \times (1 - c_j) \tag{4}$$

The predicted probability of a voiced response is simply

$$P(\text{voiced} \mid S_i C_j) = \frac{S(\text{voiced} \mid S_i C_j)}{S(\text{voiced} \mid S_i C_j) + S(\text{voiceless} \mid S_i C_j)} \tag{5}$$

In producing predictions for the FLMP, it is necessary to estimate parameter values for each level of each

experimental factor. The initial consonant was varied along six steps between /g/ and /k/ and the following context was either /Ift/ or /Is/. Thus, there were six levels of bottom-up phonological information s_i and two contexts c_j. A free parameter is necessary for each level of bottom-up information but it is reasonable to assume that the contextual support given by /Is/ is one minus the lexical support given by /Ift/ so that only one value of c_j needs to be estimated. Thus, seven free parameters are used to predict the 12 independent points.

The lines in Fig. 3 also give the predictions of the FLMP. As can be seen in the figure, the model generally provides a good description of the results of this study. The root mean squared deviation (RMSD) between predicted and obtained is 0.017 on the average across all 12 independent fits. For the 10 subjects showing appropriate context effects, the RMSD ranges from 0.003 to 0.045 with a median of 0.007. Thus, for each of these individuals, the model captures the observed interaction between phonological information and lexical context: the effect of context was greater to the extent that the phonological information was ambiguous. This yields a pattern of curves in the shape of an American football, which is a trademark of the FLMP.

The model tests have established that perceivers integrate top-down and bottom-up information in language processing, as described by the FLMP. This result means that sensory information and context are integrated in the same manner as several sources of bottom-up information. These results pose problems for autonomous models of language processing.

Speech Production, Neural Basis of

1. *Brain Regions Involved in Speech Production*

Over a century ago, the French neurologist Paul Broca demonstrated that speech mechanisms could be localized in the human brain. He did this by interviewing a patient with a severe speech production disorder with output limited to the recurring utterance, '*tan*.' Upon the patient's death, Broca examined the brain and concluded that the patient's inability to speak was due to a lesion in the inferior part of the frontal lobe (Broca 1861b). A second patient also had severely reduced speech and was subsequently found to have a similar cortical lesion (Broca 1861a). Since the time of Broca, scientists have found that lesions to Broca's area alone are not enough to produce lasting speech deficits (e.g., Alexander et al., 1989; Dronkers et al. 2000; Mohr 1976). Many have attempted to diagram

and map additional areas that might also subserve speech and language functions. This chapter will focus on evidence related to brain mechanisms of speech production. Specifically, evidence will be reviewed from lesion studies, electrocortical stimulation, and functional neuroimaging, all of which are helping to elucidate the neural basis of the planning and execution of articulatory movements.

The involvement of these neural structures can best be understood in the framework of a working model that follows the utterance from its conception to its ultimate articulation. Numerous studies have confirmed that the temporal lobe is important for the translation of concepts into linguistic representations. Once the utterance has been linguistically formulated, it must be transferred to the speech mechanisms that will carry out its production. Articulation itself requires planning, initiation, modification, and execution. In addition to Broca's area, it has become clear that many areas are involved in these aspects of speech production. New research has suggested a role for the anterior insula in articulatory planning, the supplementary motor area for the initiation of sequential speech movements, the basal ganglia and the cerebellum in the modification of pitch, loudness and rate, and the primary motor face cortex and pre-motor cortex in the execution of articulatory movements. Each of these areas will be discussed below in terms of the lesion studies that have helped to identify them and the functional neuroimaging research that has corroborated these findings. This chapter will begin by discussing the structures that are believed to convey linguistic information to frontal lobe speech mechanisms from posterior language cortex and end with a description of those mechanisms that execute the articulatory plan.

Superior longitudinal and arcuate fasciculi. The arcuate fasciculus is a bundle of fibers that connects the temporal and frontal lobes. As it travels through the parietal lobe, it becomes part of the superior longitudinal fasciculus and incorporates parietal fibers as well. The arcuate fasciculus was identified by Norman Geschwind as the tract that could potentially connect Wernicke's language area to Broca's speech area as described in Wernicke's original model (see Geschwind 1970; Wernicke 1874). The Wernicke-Geschwind model predicts that disruption of this tract results in isolated repetition deficits. However, recently a more comprehensive disorder has been reported. Dronkers and colleagues found that lesions that sever the arcuate/superior longitudinal fasciculus result in a severe production deficit with a complete loss of propositional speech (see Dronkers et al. 2000). Only automatized utterances remain. These patients have lost more than just repetition skills—they are unable to transfer any information from temporal lobe language areas to anterior speech mechanisms.

Broca's two original patients were also noted to have this same production disorder, which Broca termed 'aphemia' (Broca 1861a; 1861b). Dronkers et al. (submitted) recently had the opportunity to scan the postmortem brains of Broca's two original patients. They found that deep lesions also existed in these brains, in addition to the lesions Broca noted in the inferior frontal lobe. These deep lesions involved the superior longitudinal fasciculus in both cases, suggesting that this lesion also played a role in these historic patients' production deficits.

Insular cortex. The insula is a region of neocortex hidden beneath the intersection of the frontal, parietal, and temporal lobes. In the past, the insula has been implicated only vaguely in speech production (e.g., Ojemann and Whitaker 1978; Tognola and Vignolo 1980). More recently, Dronkers (1996) linked lesions in a specific region of the insula to an inability to plan and coordinate the appropriate movements necessary for articulation. She found that all patients studied with this disorder, known as 'apraxia of speech,' had lesions in the superior tip of the precentral gyrus of the insula while those without speech apraxia did not. Dronkers concluded that this small portion of the insula is critical for coordinating articulatory movements.

In keeping with this conclusion, recent neuroimaging studies have reported activation in the insula with tasks such as articulation of single words, word reading, picture naming, and word generation (see Indefrey and Levelt 2000). Interestingly, the insula appears to be activated only when tasks involve articulation of non-repeated and phonologically complex words (e.g., Wise et al. 1999), but not when only automatic or simple articulatory patterns are produced (e.g. Murphy et al. 1997).

Supplementary motor cortex. The supplementary motor area is located in the superior frontal gyrus and extends medially between the hemispheres. Penfield and others described the participation of the supplementary motor area in speech by documenting the effects of electrocortical stimulation on this region in patients undergoing surgical removal of epileptic tissue (see Penfield and Roberts 1959). Stimulation to the supplementary motor area either caused patients to make involuntary vocalizations or interrupted their ability to speak.

Infarctions of the supplementary motor area often result in a transcortical motor aphasia (See Rapcsak and Rubens 1994 for a review). Spontaneous speech is initially dysfluent, but comprehension, repetition, and reading remain relatively intact. Similarly, complete excision of the supplementary motor area causes a transient aphasia with deficits in articulation that resolve quickly (Penfield and Roberts 1959).

A review of the lesion literature suggests that the supplementary motor area is involved in the initiation of sequential, voluntary movements, including those for speech (e.g., Ziegler et al. 1997). This also seems to be true for the right supplementary motor area, as demonstrated by several case studies as well as

functional imaging data (e.g., Indefrey and Levelt 2000; Laplane et al. 1977). Other functional neuroimaging tasks that elicit supplementary motor cortex activation include the control of breathing for speech and vocalization (Murphy et al. 1997) and automatic speech (e.g., reciting months of the year; Ackermann et al. 1998).

Basal ganglia. The basal ganglia are subcortical nuclei comprised of the caudate, putamen, and globus pallidus. These structures interact with the cortex and with a number of other subcortical structures in a series of feedback loops that help to maintain motor activity (see Love and Webb 1996). Lesions to the basal ganglia can result in several types of movement disorders including Parkinson's and Huntington's disease, which each have their own speech characteristics (Duffy 1995). Patients with Parkinson's disease (which results from a lack of dopaminergic innervation of the caudate/putamen) show hypokinetic speech with decreased intensity and little modulation of pitch or loudness. In contrast, patients with Huntington's disease (which results from a loss of GABAergic, inhibitory neurons in the caudate) exhibit hyperkinetic speech with erratic control of pitch and loudness. These data suggest a role for the basal ganglia in the modulation of articulation and phonation.

Similar disorders can be seen in patients with focal lesions in the basal ganglia. For example, Pickett et al. (1998) reported a case study of a patient with bilateral lesions in the putamen and caudate. Her speech was initially characterized as dysarthric and was very difficult to understand, with poor articulatory and phonatory control. Similarly, Fabbro and colleagues reported at least two cases in which lesions in the basal ganglia resulted in hypophonia and a reduction of speech initiation and output (Fabbro et al. 1996).

In functional neuroimaging studies, caudate activation has been noted in only a small number of speech production studies (see Indefrey and Levelt 2000), but this may be due to the fact that it is not generally treated as a region of interest in imaging studies of speech.

Cerebellum. The cerebellum has traditionally been thought to be involved in fine coordination of motor acts including speech. Evidence for this comes from patients with focal cerebellar lesions. Ataxic dysarthria following cerebellar injury is a motor speech disorder that appears to be due to a discoordination in muscular control of the speech apparatus, as opposed to loss of initiation or execution (Duffy 1995). Mutism has also been associated with midline lesions in the cerebellum, in both children and adults (Coplin et al. 1997). However, this mutism is often transient and can resolve into ataxic dysarthric speech.

A broader theory of cerebellar function suggests that the cerebellum acts as a timing mechanism. That is, the cerebellum's role in motor coordination (for speech and other coordinated motor acts) is based on a more general mechanism that allows for the precise temporal control of such movements (Ivry and Keele 1989). Consistent with this hypothesis, Gandour and Dardarananda (1984) and others have shown that cerebellar patients have abnormal voice onset time distributions, indicating a timing disorder.

In the late 1990s, the cerebellum was implicated in speech production as a store for verbal short-term memory. Silveri et al. (1998) studied a patient following right cerebellar hemispherectomy and found that the patient had poor verbal short-term memory due to an impaired phonological output buffer. Functional neuroimaging data have also suggested that the cerebellum may play a role in verbal short-term memory (Ivry and Fiez 2000).

The role of the cerebellum in speech is probably multi-faceted, based on the functional heterogeneity of the cerebellum in motor control. Functional neuroimaging studies may help to tease out the functions of the various subregions of the cerebellum and their roles in speech and language.

Broca's Area. Traditionally, the literature has emphasized Broca's area as a major structure for speech production. However, the function of Broca's area has been re-evaluated. Data from stroke patients and from neurosurgical excision have revealed that removal/injury to Broca's area results in a transient mutism that resolves in 3–6 weeks (Dronkers et al. 2000; Penfield and Roberts 1959). Also, focal lesions to Broca's area do not result in a persisting Broca's aphasia, and Broca's aphasia may result from lesions outside of Broca's area (Dronkers et al. 2000).

With the increasing acknowledgment of the contribution of other brain areas to speech production (discussed in this chapter), Broca's area is no longer considered to be as crucial to speech as once thought. Though clearly involved in articulation, Broca's area functions within a network of brain regions that support speech production. Indeed, neuroimaging studies have reported networks of activation that include Broca's area in tasks involving phonological encoding and articulation, such as picture naming, word generation, and reading (see Indefrey and Levelt 2000).

Motor face and pre-motor cortex. The muscles of the vocal mechanism are innervated by cranial nerves V, VII, IX, X, XI, and XII, which receive impulses from the cortex via the corticobulbar tract. The motor face area of primary motor cortex, as well as pre-motor cortex, are believed to be the source of these projections (Duffy 1995). Lesions to these areas result in a pure motor speech disorder with slow, effortful speech and impaired articulation but intact language (Alexander et al. 1989). Such lesions are presumed to disrupt the corticobulbar fibers that activate the cranial nerves necessary for speech.

Penfield and colleagues originally showed that a number of regions in primary motor and pre-motor cortex were involved in speech output, as electro-

cortical stimulation of these sites resulted in speech arrest (see Penfield and Roberts 1959). Similarly, Ojemann and Mateer (1979) showed that, in four cases, speech arrest followed stimulation of inferior motor and premotor regions in the left frontal cortex.

Activation of primary motor cortex has been reported in fMRI studies of speech production. Wildgruber et al. (1996) found that tongue movements elicited comparable right and left activation in the inferior region of the motor strip. Monotone recitation of the months of the year activated more left than right motor cortex, while singing activated more right than left motor cortex. Ackermann et al. (1998) also found left motor cortex activation for silent repetition of months of the year.

2. Conclusions

Much has been learned about the neural processes involved in speech based on studies that have examined the specific deficits associated with lesions in particular brain regions. While language mechanisms cluster in posterior neocortical areas, speech production is generally supported by anterior cortical regions. Broca's area, motor face area, supplementary motor area, and the insula all play important roles in aspects of speech production, as evidenced by the effects of lesions in these areas. The superior longitudinal fasciculus provides the mechanism by which language information is transferred to these anterior speech regions. The basal ganglia and cerebellum also assist in speech production through modulation, coordination, and timing of speech movements. Functional neuroimaging studies have corroborated these findings and have allowed the visualization of the networks involved in speech production on-line.

Speech Production, Psychology of

Speech production refers to the cognitive processes engaged in going from mind to mouth (Bock 1995), that is, the processes transforming a nonlinguistic conceptual structure representing a communicative intention into a linguistically well-formed utterance. Within cognitive psychology, research concerning speech production has taken various forms such as: research concerning the communicative aspect of speaking; research concerning the phonetics of the produced speech; and research concerning the details of the cognitive processing machinery that translates conceptual structures into well-formed linguistic utterances. We focus on the latter.

Native adult speakers produce on average two to three words per second. These words are retrieved from a lexicon of approximately 30,000 (productively used) words. This is no small feat: producing connected speech not only entails retrieving words from memory, but further entails combining this information into well-formed sentences. Considering the complexity of all the encoding processes involved, it is impressive that we produce speech at such a fast rate while at the same time remaining highly accurate in our production. Bock (1991) estimated that slips of the tongue occur in speech approximately every 1,000 words despite the ample opportunities for errors. In the following sections the cognitive processes subserving this ability will be discussed.

1. Methodological Issues

The prototypical empirical approach in cognitive psychology consists of systematically varying some properties of a stimulus (input), and to measure a corresponding behavior. Systematic relations between input and behavior are then used to infer the cognitive processes mediating between them. For example, researchers interested in language comprehension may systematically vary properties of a linguistic input such as the syntactic complexity of sentences or the frequency of words, and measure a corresponding behavior, such as reading times. Differences in the latter are taken as an indication of differences in the processes engaged in building an interpretation of a sentence (the output). Thus, the input is directly observable and completely accessible to systematic manipulation, while the output and the cognitive processes leading to it are inferred from the behavior.

The situation is different for research in speech production. The input (the conceptual structure to be expressed), is not directly observable and not readily accessible for experimental manipulation. By contrast, the output (i.e., the spoken utterance), is directly observable. Given this situation, research on speech production has started by focusing on properties of the behavior. Most prominent in this respect are analysis of speech errors, and of hesitations and pauses as they occur in spontaneous speech. These analyses motivated the general theoretical framework for speech production (Fig. 1) which is described in detail below. More recently researchers have started to make speech production accessible to standard experimental approaches from cognitive psychology (see Bock 1996).

Figure 1
Levels of processing in speech production. Left part refers to stored representations, right part refers to processes integrating these representations into well-formed linguistic utterances

2. Levels and Processes

Figure 1 provides an outline of the levels of processing involved in speech production. These levels are shared by most current psycholinguistic models (e.g., Dell 1986, Garrett 1988, Levelt 1989). *Conceptual prep-*

aration refers to the processes that transform thoughts into verbalizable messages. *Grammatical encoding* refers to the processes that turn the messages into syntactically well-formed skeletons for sentences. *Phonological encoding* refers to the processes that provide flesh to the syntactic skeletons, realizing the phonological content of the sentences. At these latter two processing levels, stored lexical information is retrieved from a long-term memory store, the mental lexicon. In particular, during grammatical encoding it is assumed that abstract lexical representations, specifying the syntactic properties of the words, but not their phonological content, are retrieved. During phonological encoding, word form information is retrieved. Finally, *articulation* refers to the processes that implement the phonetic content and turn it into motor commands for speech.

These processing levels were originally inferred from properties of speech errors (see *Speech Errors, Psychology of*). Speech errors can be analyzed with respect to the type of linguistic unit involved (words, morphemes, phonemes), and with respect to constraints that hold for errors concerning a given type of unit. For example, word exchanges (e.g., 'on the room to my door' instead of 'on the door to my room') are constrained by syntactic factors (like the syntactic category of the exchanged words) whereas phoneme exchanges (e.g., 'heft lemisphere' instead of 'left hemisphere') are constrained by phonological factors (like their position as onset, nucleus, or coda of a syllable). These and related results suggest a distinction between a processing level that is primarily concerned with syntactic processing (grammatical encoding), and another level primarily concerned with phonological processing (phonological encoding). The fact that phonemes are relevant units in speech errors also shows that the phonological form of a word is not stored and retrieved as a whole, but built from smaller units, namely the phonemes.

Planning of a sentence is not completed on one processing level and then sent to the subsequent level. For example, phonological encoding starts as soon as the syntactic structure of some part of a sentence has been determined, while the grammatical encoding of the remainder of the sentence continues. This piece-by-piece generation of a sentence is referred to as incremental production. Although there is no consensus on the size of the relevant planning units at the different processing levels, it is generally agreed upon that the size of the planning units becomes smaller as one moves from conceptual preparation through grammatical encoding to phonological encoding and articulation. Incrementality provides a natural account of fluency in speech production. Furthermore, incremental production reduces the burden of storage of intermediate results of the production process at each level.

Although there is general agreement on the levels of processing, theories differ with respect to how the flow of information between levels is characterized. According to modular views, each level of processing first produces a complete output representation for a given planning unit. Only then is this output representation passed onto the next level (e.g., Levelt 1989). According to interactive views, every processing stage can pass partial results to the next processing level, before the output representation at the higher level has been completely specified, and lower levels of processing can provide feedback to higher levels of processing. As a consequence, processes at the phonological level can affect processes at the grammatical level (e.g., Dell 1986). In the following sections, we discuss the different processing steps in more detail.

2.1 Conceptual Preparation

A first important goal of conceptual preparation is to establish which parts of the conceptually available information are going to be encoded, and in what order (see Levelt 1989, for an overview). A second goal is to convert the conceptual information into a format that is a suitable for the linguistic formulation processes. One important open issue concerning conceptual preparation is how to characterize the mapping between conceptual and grammatical encoding. First is the question of whether conceptual preparation takes language specific properties into account (see *Language and Thought: The Modern Whorfian Hypothesis*). Languages differ in which conceptual or formal properties need to be realized as a detail of the sentential form. For example, in English the word 'friend' does not carry information concerning the sex of the friend. In Spanish the corresponding word is differentially inflected for a man ('*amigo*') or a woman ('*amiga*'). In English, adjectives used as predicates (e.g., 'tall' in 'The friend of Luis is tall') do not agree in gender with the noun; in Spanish they do (e.g., '*El amigo de Luis es alto*' or '*La amiga de Luis es alta*'). Thus, in these two languages, conceptual information concerning natural gender must (Spanish) or need not (English) be conveyed by a sentence. Second is the question of whether conceptual information permeates the processes occurring during grammatical encoding beyond providing its input (Vigliocco and Franck 1999).

2.2 Grammatical Encoding

Grammatical encoding refers to the processes involved in developing a syntactically well-formed sentence. It comprises first, those processes that map the relationships among the participants in a conceptual representation (e.g., agent, patient, etc.) onto functional syntactic relations between the words of a sentence (e.g., subject, direct object, etc.). Next, on the basis of the resulting hierarchically organized syntactic frame for the sentence, the words in the sentence are linearized in a manner allowed by the language being

spoken. The first step is also referred to as *functional level processing*, the second as *positional level processing* (Garrett 1988). Distinguishing between building hierarchical and linear frames provides a solution to an important problem that the language production system faces. Speech production has to be incremental to allow for fluent utterances, but at the same time the resulting utterance has to obey language specific constraints that force the use of only certain word orders. Assuming incremental conceptualization, however, the order in which parts of a conceptual message are processed do not necessarily correspond to a word order allowed in the speaker's language. This problem can be solved by separating the construction of hierarchical structures from the serial ordering of the words. In this way, hierarchical structures can be built in an incremental manner as soon as lexical elements are available, these can then be mapped to permissible linearly ordered positions (Vigliocco and Nicol 1998). Evidence compatible with such a separation comes from studies showing that the linear position of words can be primed by the previous presentation of the same linear order, even if the hierarchical structure differs (Hartsuiker et al. 1999).

An important open question with respect to grammatical encoding concerns whether the encoding at this level can be influenced by feedback from phonological encoding (Bock 1986). Research on the process of computing number agreement between a sentence subject and a verb suggests that this grammatical process is sensitive to whether number information in the subject noun phrase is overtly realized in the phonological form of the noun, suggesting the possibility of feedback from phonological encoding to grammatical encoding (e.g., Vigliocco et al. 1995; but see Sect. 2.5 for an alternative interpretation of the results).

2.3 Phonological Encoding

Phonological encoding refers to the processes that are responsible for determining the phonological word forms and prosodic content of the sentence (e.g., Levelt 1999). First, the phonemes of words are retrieved from the mental lexicon, together with a metrical frame which specifies stress pattern and number of syllables in the word. Following this retrieval process, the resulting sequence of phonemes is syllabified according to a language specific set of syllabification rules. The domain of syllabification is assumed to be the phonological word which can but need not coincide with a lexical word. It should be noted that in this view, the syllabic structure of an utterance is computed on-line. The reason for this assumption is that the actual syllabification of a word in running speech depends on the context in which it appears. For example, the word 'deceive' in isolation is syllabified as 'de-ceive,' but in the context of the utterance 'deceive us,' the syllable structure becomes 'de-cei-veus.' This observation also provides a functional reason why the phonological form of a word is not stored and retrieved as one entity: such a representation would have to be broken up into its constituent parts whenever the stored syllabification of a word does not agree with its syllabification in the context of running speech. The representation formed by phonological encoding, a syllabified phonological code, forms the input for the articulatory processes which realize this code as overt speech. It is an open issue whether the transition from phonological encoding to articulation involves accessing a 'syllabary,' i.e., memory representations specifying the motor tasks that have to be performed to generate each syllable (Levelt 1999).

2.4 Lexical Access

Grammatical and phonological encoding make use of stored representations of words. Parallel to the distinction between grammatical encoding and phonological encoding, two levels of stored representation are distinguished. On one level, words are represented as abstract syntactic (and semantic) entities (technically also referred to as lemmas), and on the other level their phonological form is specified. Evidence for two levels of representation in the mental lexicon comes from tip-of-the-tongue (TOT) states (see *Tip-of-the-tongue, Psychology of*). It has been demonstrated repeatedly that speakers in a TOT state can report grammatical properties of a word (e.g., the grammatical gender of a noun) above chance level even when they are unable to access the phonological form of the word.

It is unresolved whether, within the lexicon, the flow of information from meaning to form can be characterized as discrete, cascading, or fully interactive. Discrete serial models of lexical access (e.g., Levelt 1999) assume that, first, on the basis of some fragment of a conceptual structure, a set of lemmas becomes activated. This set includes the target lemma as well as semantically related lemmas. Phonological encoding of the word is initiated only after the target lemma has been selected. Hence, the phonological forms of words which are semantically related to the target word should not become activated. Cascading models (e.g., Peterson and Savoy 1998) assume that every activated lemma sends some activation to its corresponding word form, even before the actual target lemma has been selected. Thus, also the phonological forms of semantic competitors of the target word should receive some activation. Finally, interactive models (e.g., Dell 1986) allow for feedback from the phonological level to the lemma level. Thus not only will the phonological forms of semantic competitors receive activation, but the phonological forms will also send activation back to all lemmas with similar phonological forms.

The question of whether the phonological forms of semantic competitors do receive activation, as pre-

dicted by cascading models and feedback models, or not, as predicted by discrete serial models, is still an empirically unresolved issue. Phonological activation of semantic competitors has been demonstrated for the case of near-synonyms like 'couch' and 'sofa' (e.g., Jescheniak and Schriefers 1998, Peterson and Savoy 1998) and has been interpreted in favor of cascading of activation. However, as the evidence is presently restricted to this specific semantic relation, it has been suggested that near-synonyms might be a special case (e.g., Levelt 1999).

Concerning the question whether there is feedback from lower levels to higher levels in lexical processing, the lexical bias effect has been cited as evidence for feedback. The lexical bias effect concerns the observation that phoneme errors lead to existing words rather than nonwords more often than would be expected by chance. This finding can be explained by feedback from the level of phonological segments to some higher level representing words as one integral unit (e.g., Dell 1986). According to discrete serial models, by contrast, the chance of incorrect selection of a phoneme should be independent of whether the resulting string of phonemes forms an existing word or not (but see Sect. 2.5).

2.5 Self-monitoring and Repair

Speakers not only produce speech, but also monitor their own speech output and this monitoring may occur on overt speech as well as on 'internal speech.' Assuming an internal monitor implies that not all misfunctions of the speech production system will become visible in the eventual output. Rather, some will be discovered and repaired before they are actually articulated. Such covert repairs can play an important role in the interpretation of speech error results. For example, the lexical bias effect in phoneme errors has also been explained as the result of a pre-articulatory covert repair mechanism. This covert repair mechanism might be more likely to detect and correct phoneme errors leading to nonwords than those leading to words before the resulting error is actually produced. Hence, the lexical bias effect would not imply feedback of activation from lower to higher levels. It should be noted that related arguments have been put forward with respect to other empirical findings which appear to speak against discrete serial models, like the potential influence of phonology on grammatical encoding processes. It is a matter for future investigation to design empirical tests that allow us to differentiate between feedback and monitoring explanations of the relevant empirical phenomena.

Speech Recognition and Production by Machines

The fields of speech recognition and speech production (text-to-speech or speech synthesis) have made great progress since the early 1990s. The technologies are now at the point of becoming commercially viable, and a number of products are currently available. Recent progress in both technologies has been charac-

terized by rapid incremental improvement rather than any theoretical breakthroughs. Both technologies are based on stochastic models and have benefited greatly from increased computing and data resources. This article will describe the techniques used for current state-of-the-art speech recognition and synthesis systems. It will give only a brief overview of the field. For further reading, see Jurafsky and Martin (2000) and Jelinek (1997).

1. Speech Recognition

This section will focus on large vocabulary continuous speech recognition (LVCSR), which is the most general form of the problem. There are other paradigms that are used to simplify the problem for some specific tasks. In isolated word recognition, as opposed to continuous recognition, the user is required to pause between words when speaking. This simplifies the problem by making it easier to find the word boundaries, so higher accuracies can be obtained. If the system only needs to detect a small set of words, and a small footprint is required, a technique called word spotting can be used. Word spotting attempts to find a small set of words in the input rather than trying to decode all of the speech. Both of these techniques can be viewed as special cases of LVCSR.

The general process of speech recognition is shown in Fig. 1. A signal processing component converts the analog speech signal into a sequence of discrete feature vectors. A decoding search process then matches internal acoustic models against the sequence of feature vectors to produce a sequence of words.

1.1 Signal Processing

While the exact signal processing configuration varies from system to system, the following description represents typical values. First, the analog signal is low-pass filtered with an 8 kHz cutoff and sampled at 16 kHz. A fast Fourier transform (FFT) is calculated using a 25 msec window, and the resulting amplitude spectrum is subjected to log compression. This log amplitude spectrum is then passed through another FFT resulting in a representation referred to as the cepstrum. Linear predictive coding (LPC) is used to calculate the coefficients for the cepstrum. In this scheme, each speech sample is represented as a linear combination of the N previous samples plus an additive term. The elements of the feature vector are the first N coefficients (for the linear combination) produced by the LPC calculation. A typical value for N is 12, and normally one feature vector is produced each 10 milliseconds.

1.2 The Matching Process

The most common form of speech recognition uses a maximum likelihood search. Given acoustic data A (as represented by the sequence of feature vectors), a maximum likelihood search attempts to find the word string W such that $P(W|A)$, the probability of the word sequence given the acoustic data, is maximized. This search evaluates hypotheses by applying Bayes Rule:

$$P(W|A) = \frac{P(A|W) \times P(W)}{P(A)}$$

where $P(A|W)$ is the probability of acoustic data A given word string W, $P(W)$ is the *a priori* probability of word string W, and $P(A)$ is the *a priori* probability of acoustic input A. $P(A|W)$ is estimated using acoustic models and $P(W)$ is estimated using language models. Typically, $P(A)$ is not estimated since it is difficult to estimate and it does not change the rank ordering of hypotheses since it is the same for all competing hypotheses.

1.3 Acoustic Models

Acoustic models are a stochastic mechanism for estimating $P(A|W)$, the probability of the observed acoustic feature sequence given a specified word sequence. The most common form of acoustic model

Figure 1
The speech recognition process

Figure 2
Hidden Markov models of speech units

used in speech recognition is the hidden Markov model (HMM). A hidden Markov model consists of a set of states S, a set of transition probabilities from each state to other states, and a set of observation probabilities for each state. This model is illustrated in Fig. 2. In order to apply the model to speech decoding, HMMs are associated with units of speech, such as phones, to model their acoustic realization. A word level model is generated by concatenating the HMMs for the phones comprising the word. In practice, more specific models are used which model phones in their left and right context. These models are referred to as triphones.

To create the models, the parameters of the HMMs, the transition and observation probabilities, must be estimated from training data. Recorded speech is transcribed, and the HMMs are aligned against the speech vectors using a procedure called the forward–backward algorithm. There is not a deterministic procedure for estimating the parameter values; rather an iterative procedure, Baum–Welch reestimation, is used to refine the parameters until a stopping criterion is achieved. While estimation of the transition probabilities is straightforward, estimation of the observation probabilities is less so since they are represented as a multidimensional space. For each state, the observation probability is the probability of observing the input feature vector given the state. There are two principal techniques for estimating the observation probabilities, Gaussian mixtures and neural networks.

In the Gaussian mixtures technique, the observation probability is estimated as a weighted sum of Gaussian probability density functions (PDFs). Every state has an associated set of multidimensional PDFs, each represented by a mean and covariance matrix. The feature vector is evaluated with respect to each of the distributions and the observation probability is a weighted sum of the values.

An alternate way of estimating the observation probabilities is to use neural networks to directly estimate the probability of the feature vectors. A recurrent neural network is associated with each Markov model state and gives the probability of the observation, given the state. These networks take a long time to train, but decode quickly.

1.4 Language Models

A language model is a stochastic mechanism for estimating $P(W)$, the *a priori* probability of a specified word sequence. $P(W)$ is normally decomposed to be applied in a left-to-right fashion. Using ! to represent the start of sentence, $P(W)$ is represented as:

$$P(W) = P(w_1|!) \times P(w_2|!w_1) \times P(w_3|!w_1w_2) \times \cdots \times P(w_n|!w_1w_2\ldots w_{n-1})$$

In this form, the probability of extending a sequence by the next word is conditioned on all the words in the sequence up to that point. In practice, it is not feasible to represent all possible histories, $!w_1w_2\ldots w_{n-1}$. The prevailing solution is to group all histories whose last $N-1$ words are the same, and thus to condition the probability of a word on the last $N-1$ words. These models are referred to as N-gram models. For $N = 3$,

Figure 3
The speech decoding search

referred to as a trigram, $P(w_n|!w_1w_2\ldots w_{n-1})$ is estimated as $P(w_n|w_{n-2}w_{n-1})$. N-gram models are also trained from training data and estimated as:

$$P(w_n|w_{n-2}, w_{n-1}) = \frac{C(w_{n-2}, w_{n-1}, w_n)}{C(w_{n-2}, w_{n-1})}$$

where $C(w_{n-2}, w_{n-1}, w_n)$ is the count of the number of times that the sequence w_{n-2}, w_{n-1}, w_n was observed in the training data.

1.5 The Decoding Search

The general structure of the acoustic decoding process is shown in Fig. 3. It uses a language model, a dictionary, and an inventory of acoustic models to decode speech input. The recognizer processes input from left to right. It generates a language model probability for each word in the lexicon, given the start of utterance and matches these words against the start of the input. The system pursues hypotheses in parallel and extends them forward by assigning language model probabilities that each word will extend each hypothesis and matching that word against the corresponding portion of the speech input. In order to match a word against the digitized speech input, the system looks the word up in its pronunciation dictionary to find the sequence of phones describing the word pronunciation. The phones in the dictionary are context-independent, that is, the representation does not change for a phone dependent on its context, the phones to its left and right. Since the acoustic realization of a phone depends very much on its phonetic context, context-dependent models are actually used. The context-independent phones in the pronunciation are mapped to context-dependent phones; that is, notation is added to reflect the context of the phone to the left and to the right of the phone used. These-context dependent phone units are referred to as triphones. The system has a pretrained inventory of HMM acoustic models for the triphones. The triphone models are concatenated together to form a word model, which is matched against the speech input.

A dynamic programming search, the Viterbi algorithm, is used to align the speech feature vectors with the HMM triphone models. This search produces the sequence of Markov states that has the highest probability of generating the observed feature vectors. In reality the search does not generate real probabilities for hypotheses, but scores intended to approximate probabilities. The score for a hypothesis is a weighted combination of the acoustic match score $P(A|W)$ and the language model score $P(W)$. The match process is a large stochastic search to match models for word sequences against the speech input. In principle, all possible sequences of words in the

vocabulary are matched against the speech input. An exhaustive search clearly is not computationally viable, so pruning must be applied. The language model scores are very valuable in helping prune the search to look for the more likely word sequences. Most often, beam pruning is used. Hypotheses with scores more than a threshold value worse than the current best score are pruned.

1.6 Performance

The performance of a speech recognition system depends on many factors:

The time–accuracy tradeoff—since the recognition process is a pruned search, it has a time vs. accuracy tradeoff. Less pruning allows the system to explore more hypotheses and thus achieve higher accuracy, but also requires more run time. Research systems may run in many times real time, but systems interacting with users must run in very near real time. Increases in machine power can therefore translate into increased recognition accuracy by allowing less pruning while still running in real time.

Amount of training data—since the acoustic and language model parameters are estimated from training data, the amount and appropriateness of the training data critically affect the quality of the model.

Degree to which usage conditions are represented in training data—the weakest feature of current recognition technology is its lack of robustness. The systems generally perform well as long as the usage conditions are represented well by the training data. As the conditions under which the systems are used move away from the data on which they were trained, the performance degrades rapidly. If a system were trained only on male voices, it would not work well for most females. If it were trained on native English speakers, it would not work well for someone with a German accent (or almost any other accent). If trained with a close talking microphone, it would not work well over a telephone. So-called speaker-independent systems just use a training database containing as many different speakers as possible to get a reasonably broad coverage of speaker variability.

The commercial dictation systems that are currently available generally require a short enrollment process where the user is required to speak some prompted sentences into the system. This is to allow the system to adapt its general models to the specific user and insure at least a small amount of appropriate training data. Currently, commercial dictation systems use about 30,000 words and report average word error rates of approximately 5 percent.

2. Speech Production

Currently, the various approaches to speech recognition can be grouped into three basic categories: articulator models, source-filter models, and concatenative synthesis. An excellent brief discussion of the details of these approaches can be found in Pellom (1998). This section will present only a short overview.

2.1 Articulator Model Synthesis

Articulator model-based systems attempt to explicitly model the physical aspects of the human speech production system. They produce detailed models of the articulators and the airflow in the vocal tract. These models are generally based on detailed measurements of human speech production. Models of this type are not widely used because it is difficult to get the sensor data and because the models are computationally intensive.

2.2 Source-filter Based Synthesis

Source-filter-based systems use an abstract model of the speech production system (Fant 1960). Speech production is modeled as an excitation source that is passed through a linear digital filter. The excitation source represents either voiced or unvoiced speech, and the filter models the effect produced by the vocal tract on the signal. Within the general class of source-filter models, there are two basic synthesis techniques: formant synthesis and linear predictive synthesis.

Formant synthesis models the vocal tract as a digital filter with resonators and antiresonators (Klatt 1980). These systems use a low-pass filtered periodic pulse train as a source for voiced signals and a random noise generator as an unvoiced source. A mixture of the two sources can also be used for speech units that have both voiced and unvoiced properties. Rules are created to specify the time varying values for the control parameters for the filter and excitation. This is the technique used by DECTalk (Bruckert et al. 1983), probably the most used commercial synthesis system. Linear predictive synthesis uses linear predictive coding to represent the output signal. Each speech sample is represented as a linear combination of the N previous samples plus an additive excitation term. As in formant synthesis, the excitation term uses a pulse train for a voiced signal and noise for un-voiced.

While the source-filter-based systems are capable of producing quite intelligible speech, they have a distinct mechanical sound, and would not be mistaken for a human. This quality arises from the simplifying assumptions made by the model and therefore is not easily remedied.

2.3 Concatenative Synthesis

In recent years, much research has been focused on techniques for concatenative synthesis (Taylor et al. 1998). This technique uses an inventory of prestored units that are derived from real recorded speech. A database of speech is recorded from a single speaker

and is segmented to create an inventory of speech units. These units are concatenated together to create the synthesized output. The speech units differ between systems. One popular unit is diphones, which consist of parts of two phones, including the transitions between them (Peterson et al. 1958). The beginning and end of the diphone are positioned to be in stationary portions of the two phones. This reduces the problem of smoothing the junctions of concatenated units. There are also a manageable number of units, at most 1600 (40×40). The actual number is somewhat smaller, since not all possible pairs of phones occur in English. Context dependent phones, clustered by acoustic similarity, are also used. A search algorithm is used to find the optimal sequence of units (Hunt and Black 1996).

An extension of the small unit concatenative synthesis technique is to use variable sized units for concatenation (Yi and Glass 1998). In this method, task-specific sentences, phrases, and words are recorded from a single speaker. A search process is used to concatenate the largest units available in generating the output. In some cases, an entire prerecorded sentence or prompt can be used. Much of the time phrase level and word level units will be used. If a novel word is encountered, it is synthesized by concatenating phone sized units. This technique sounds very natural if word sized or larger units are being concatenated. The problem with this approach is that good coverage with large units is only possible in limited domains, and a new database must be recorded for each new domain. Work is in progress to unify the small and variable unit approaches to give a more general system.

Speed Reading

Modern society requires individuals to process an increasing amount of written information on a daily basis. The rising stacks of to-be-read books, articles, and documents often induce people to turn toward the commercially available courses that claim to radically increase reading speed. Most of these speed-reading courses claim that reading speed can be increased to 1,000 words per minute (wpm) with improved comprehension. This rate is over three times normal reading speeds (200–300 wpm), and some speed readers have claimed to read up to 100,000 wpm. Typical speed-reading training involves instructing readers to focus on fewer sections of the printed material, to refrain from rereading words and from lip movement or inner speech, to attempt to perceive meanings at a glance, and simply to concentrate on reading faster. While there is an abundance of anecdotal claims from individuals who report that they are able to read at amazing rates, the scientific evidence is not as convincing. The empirical studies that have supported speed-reading claims have been fraught with methodological problems. Those studies that are better designed have generally found that speed reading considerably inhibits comprehension and is comparable to scanning or skimming. This article reviews the history of speed-reading, the validity of speed-reading claims, evidence that refutes speed-reading claims, and some potentially positive contributions of speed-reading methods.

1. Brief History of Speed-reading

Increased fascination with anecdotes of speed reading emerged in the late nineteenth century popular press. This interest led to the first known speed-reading course, which was offered at Syracuse University in 1925. After a brief hiatus during World War II, the use of machines became popular to increase reading speed by modifying readers' eye movements. Normal reading involves rapid, jerky eye movements, called *saccades*. Words are only perceived during *fixations* between saccades. Ordinarily, readers make forward saccades; however, backward saccades called *regressions* are also made to fixate previous words. The number of letters or words that are processed during a single fixation is called the *perceptual span* (see *Eye*

Movements in Reading). Poor readers tend to make more regressions, and more frequent fixations (see *Reading Skills*). Hence, speed-reading advocates assumed that reducing regressions and fixations (with increased perceptual spans) would improve reading rate and consequently, reading ability. The focus after World War II on using mechanical devices to change readers' eye movements emerged from the success of using tachistoscopes (machines that flash images at controlled rates on a screen) to train pilots to more quickly and accurately identify aircraft. Similarly, tachistoscopes were used to train readers to reduce the number of fixations and widen the perceptual span. The results from these methods were initially promising. However, it eventually became evident that the effects of training were temporary and did not generalize to normal reading situations.

In the late 1950s, Evelyn Wood popularized speed-reading with her hand-pacing method, which involved training the eyes to follow a zigzag motion down each page. Combined with other reading and learning techniques, she introduced Reading Dynamics in 1959, which ultimately led to Evelyn Wood Reading Dynamics Institutes worldwide. The variety of speed-reading courses increased in the 1960s along with an abundance of anecdotal claims of their success.

2. *The Validity of Speed-reading Claims*

Are there individuals who can read at 1,000 wpm, or faster, and still comprehend at least 75 percent of the information? With its increasing popularity in the 1960s, many researchers began to challenge the astounding claims made by speed-reading advocates. Although many individuals have claimed to possess this ability, the empirical evidence was scant. Two principle areas of debate emerged in the literature. The first area of debate concerns the possibility of modifying readers' eye movements and perceptual span. The second issue concerns the methodology employed by speed-reading studies. The empirical research in support of speed-reading has tended to be fraught with methodological weaknesses, generally with respect to the measurement of comprehension during speed-reading tests.

2.1 *Eye Movements*

Many speed-reading courses attempt to modify readers' eye movements by increasing the perceptual span and reducing the number of fixations and regressions. However, researchers have argued that eye anatomy constrains the perceptual span to approximately three words from the fixation point; and more specifically, 3–4 letter spaces to the left and 14 letter spaces to the right of the center of an advanced reader's fixation point (Rayner 1986). The physiological boundaries of the perceptual span imply that reading rates exceeding 600–800 wpm are physiologically impossible if the reader is attempting to read all of the words (Taylor 1965). For example, a rate of 10,000 wpm would allow about 2.5 seconds per page of text with 7–8 fixations. Thus, each fixation would have to include a span of 55 words, which is impossible.

In response, speed-reading advocates have claimed that it is unnecessary to read every word of a passage, and that readers can learn to fixate only important words or sentences. In support of that claim, research has indicated that speed-readers make inferences between parts of the text by using prior knowledge (Carver 1983). That is, knowledge allows readers to develop an understanding of the text, despite not having read all of the words. This process is more successful when readers have more knowledge about the text, but virtually impossible without relevant knowledge. Indeed, most speed-reading courses acknowledge that speed-reading is only effective for familiar material.

Nevertheless, there is no guarantee that knowledge-based inferences will be correct, and evidence does not support the assumption that speed-readers learn to read only the most important words or sentences of a passage (Just and Carpenter 1987).

Many speed-reading courses also encourage readers to eliminate the tendency to make regressive eye movements. However, research has shown that regressions are virtually unavoidable with unfamiliar or complex material, and are adaptive when the segments that are reread are relevant to the reader's goals. Moreover, the relationship between eye movements and reading efficiency remains controversial and there is no available evidence that eye movement training improves reading ability. Although speed-reading training may alter eye movement patterns, these patterns revert to normal when comprehension is emphasized.

2.2 *Comprehension*

The second area of debate has centered on the comprehension of rapidly read material. There is little doubt that readers can turn pages quickly and scan printed material. The question is whether speed-readers can do so and maintain comprehension of the information. Speed-reading advocates have claimed that comprehension is not only maintained but improved. Others have claimed that speed-reading results in large comprehension decrements. The answer to this debate has been clouded by methodological problems (Carver 1990).

Much of the evidence in support of speed-reading has been anecdotal. In these cases, neither documentation nor comparisons to normal readers are generally provided. In addition, many empirical studies of speed-reading are flawed because comprehension was not assessed, or comprehension and rate were measured on separate passages. Without correspond-

ing evidence of comprehension and reading rate, a speed-reader is apt to 'read' rapidly when rate is measured (with low comprehension of the material) and read more slowly when comprehension is tested.

A second weakness of speed-reading research has stemmed from the use of comprehension questions that can be answered with reasonable accuracy without reading the passage. Generally, passages used to measure reading rate cover relatively familiar information. Consequently, passage-independent questions that can be answered on the basis of reasoning or prior knowledge inflate estimates of reading comprehension. For example, Carver (1972) demonstrated that previous estimates of speed-readers' comprehension (see Wood 1963) dropped from 68 percent to 17 percent for fictional material after correcting for passage-independent questions. Hence, tests showing that speed-readers maintain comprehension may not account for questions that can be answered without reading the material.

Similarly, the common use of multiple-choice questions to assess comprehension allows readers to guess the correct answers among the alternatives. For example, if two readers answer 20 of 30 questions correctly, but one reader provides answers for only 20 (missing 0, but skipping 10) and the other provides answers for all 30 questions (missing 10), the latter reader is showing greater evidence of guessing. Without correcting for guessing (see Carver 1990), the readers seem statistically equivalent in terms of their comprehension levels. This issue is particularly important because speed-readers often answer more questions, and guess more, than normal readers.

An additional weakness of speed-reading research concerns practice effects on the tests. When the same test or similar tests are used to assess comprehension before and after speed-reading training, the speed-reader may improve from having completed the test previously and not from training. Likewise, similar tests during and after training can lead to improvement on the post-training tests. These testing problems are most important for studies lacking a control group.

In summary, typical shortcomings of speed-reading research include: the lack of a comprehension test for the material used to measure reading rate, the use of passage-independent comprehension questions, not correcting comprehension performance for guessing, and the lack of a control group to measure practice effects on the tests.

3. *Evidence that Refutes Speed-reading Claims*

The bulk of empirical research has led to the conclusion that reading rapidly and maintaining comprehension is not possible. For example, Homa (1983) assessed two graduates of the American Speed-reading Academy who had reported reading rates above 100,000 wpm. He administered two visual identification tasks (letters and words) and a comprehension task. The speed-readers performed comparably to six undergraduates on the visual identification tasks but showed a greater tendency to guess the answers than the undergraduates. The speed-readers averaged 15,000 and 30,000 wpm on the comprehension task, but clearly understood little of what they had read, even after three attempts with the same material and the same tests. Homa concluded, 'the only noteworthy skill exhibited by the two speed-readers was a remarkable dexterity in page-turning.'

Carver (1985) examined the reading rate and comprehension of four groups of superior readers: speed-readers, professionals, high-skilled college students, and people who scored exceptionally high on tests such as the SAT. Carver found that speed-readers were similar in ability to other superior readers, except that they typically chose to skim and accept the lowered comprehension at rates higher than 1,000 wpm. The evidence strongly suggested that reading rates exceeding 600 wpm, with adequate comprehension, were not possible.

Just and Carpenter (1987) compared the reading abilities of 11 graduates of a Reading Dynamics course, 12 skimmers, and 13 normal readers. On two passages, the speed-readers, skimmers, and normal readers averaged 700 wpm, 600 wpm, and 240 wpm, respectively. The speed-readers' and skimmers' accuracy on comprehension questions was comparable, though speed-readers more accurately answered questions concerning the gist of an easier *Reader's Digest* passage. Both groups showed consistent comprehension decrements (7–15 percent) compared to the normal readers. Just and Carpenter concluded that reading speed can increase, but not without sacrificing comprehension.

4. *Potential Advantages of Speed-reading*

Although reading rates exceeding 600 wpm clearly impede comprehension, research has also indicated that many individuals read more slowly than necessary and that moderate increases in reading rate may improve comprehension. In addition, skilled readers show greater flexibility and efficiency by adjusting reading rate to their purpose and to the difficulty or familiarity of the material. However, it is debatable whether readers can be trained to be more flexible and to focus solely on pertinent information. Nevertheless, knowing when to read rapidly is considered an important skill in most reading programs.

5. *Conclusion*

The available research leads to the conclusion that speed-reading does not allow the reader to adequately understand the reading material. A distinction should be made between speed-reading, which assumes that normal comprehension is maintained, and scanning

and skimming, which accept a considerable decline in comprehension levels. Many researchers claim that speed-reading is essentially skimming. Nevertheless, proponents of speed-reading remain steadfast in their claims that speed-reading is effective. Research to support these claims would have to carefully control comprehension measurements and show equivalent or improved understanding of material read at rates exceeding 1,000 wpm. At this juncture, however, evidence suggests that *you get what you read*, and reading takes time.

Spelling

In an alphabetic writing system, spelling refers to the norms or conventions by which the characters of the alphabet are arranged to form words. The term 'orthography' is also used to refer to a spelling system, especially within linguistics and literary studies.

The principle of alphabetic writing means that the characters used for writing correspond in some way, perhaps only roughly, to the individual phonemes of the language represented. In theory, it seems, spelling could be a simple matter of representing each phoneme by its corresponding alphabetic character. There are several reasons why this is not so, however.

(a) Spelling systems often, incorporate morphophonemic and/or grammatical information as well as phonological. They are rarely if ever simply representations of sounds.

(b) Spelling systems often are adaptations of spelling systems originally designed for other languages. This may result in some phonemic distinctions going unrepresented (or, conversely, subphonemic distinctions being indicated in spelling).

(c) The existence of a 'spelling system' implies a degree, often a high degree, of standardization. However, in every language, the written language represents an abstraction away from spoken varieties with potential variation along social, regional, and possibly other dimensions. There is always some mismatch between spoken words (even in a standard variety) and their written form.

(d) Over time, languages undergo grammatical and phonological change, but the spelling of the written language often remains conservative. Once established and conventionalized, a spelling system does not have to change at the same rate as the language it represents.

(e) Spelling systems, like other symbolic systems, are not purely a technical device but are subject to elaboration as part of the culture of their users. Spelling may communicate various kinds of social and ideological meaning as well as phonological information.

Thus, it is very rare for spelling systems to be wholly phonemic (or 'phonetic' as this term is often used outside linguistics); rather, they represent a complex of phonological, grammatical, historical and cultural information–only some of which may be apparent to their users on the occasion of use.

1. The Underlying Principles of Spelling Systems

Fundamental to spelling systems is an alphabetic principle, that is to say, that a finite, small number of symbols (typically less than 50) or 'letters of the alphabet' are used in combination to write linguistic units (morphemes or words). Alphabetic writing systems normally have discrete symbols to represent vowels and consonants (though some, like Arabic and Hebrew, do not represent vowels), and the alphabet typically has a fixed order (A, B, C, … etc.).

Closely associated with the alphabetic principle, at least historically, is the phonemic principle, which prescribes that there should be a correspondence between graphemes (letters or letter combinations) and phonemes of the language. While some words in some languages may be spelt more or less phonemically, it is rare for languages to be strictly phonemic in

their spelling systems. However, it is usual that, with a few exceptions, each letter in isolation has at least one phoneme of the language associated with it. In combination with other letters, it may keep its association with that phoneme or be associated with others. In English, for example, the ⟨c⟩ letter in isolation may be associated with /k/ or/s/ (although it cannot be pronounced without combining it with a vowel). In combination with ⟨h⟩ as ⟨ch⟩ it is associated with /k/ (as in 'ache') or /č/ as in cherry.

It is common for alphabetic spelling systems to observe a morphophonemic principle which preserves the spelling of specific morphemes even when they undergo conditioned phonological changes, Thus in English, the past tense ending is spelt ⟨ed⟩ even where, as in 'sailed,' it is pronounced [d], or, as in 'hoped,' it is pronounced [t]. Similarly, the unity of the German *Bild* [bIlt] 'picture' and *Bilder* [bildəR] 'pictures' is preserved by observing a morphonemic rather than a phonemic principle, as the latter would require the singular to be written as *Bilt*. As the change from /d/ to /t/ is predictable (because word-final plosives are always unvoiced) it is not reflected in the spelling.

An important cause of deviation from the phonemic principle in spelling systems is the operation of a historical principle, which in some cases might be called simply orthographic conservatism. The initial ⟨k⟩ in 'knee,' for example, has not been pronounced in most dialects of English for several centuries. Spelling systems are notoriously resistant to change, while phonological systems, by comparison, are not.

Another potential source of apparent inconsistencies is the etymological principle, typically applied to loan words from another language which shares the same alphabet. Thus in Dutch, the French loan-word *cadeau* ('gift') may be spelt ⟨*cadeau*⟩ (respecting the etymological principle) or ⟨*kado*⟩ which respects the phonemic principles inherent in the conventional spelling of native Dutch words. Likewise, considerations of etymology in English led to a class of words, coined on the basis of ancient Greek, in which /f/ is spelt as ⟨ph⟩: telephone, philosophy.

The historical principle and etymological principle together account for a phenomenon which is particularly apparent in English, though observable in many languages: the hybrid nature of the spelling system. English, though its inclusion of Anglo-Saxon, French, and Classical Greek and Latin words in the written language, with each set of lexis following the spelling tradition of the language in which it originated (the etymological principle) has become a hybrid system preserving (by the historical principle) a mixture of orthographic traditions, in particular the Anglo-Saxon and Norman French traditions (see Scragg 1974 for the history of English spelling). The longer the written tradition of a language, the more likely it is that the spelling system will be a hybrid showing the influence of different traditions. A further consequence of the hybrid nature of a spelling system like English is that it may become in part logographic, i.e., words which sound alike are distinguished by their 'shapes' or spellings (for example 'sole,' 'soul').

2. *Reading, Writing, and Spelling*

As pointed out by Augst (1986a, p. 26), 'no alphabetic script in the world is a representation of sounds and thus identical to a transcription.' Only the most naïve accounts of spelling see it simply as a matter of letters representing sounds. Many accounts, however, see spelling as a system of correspondences between phonemes (i.e., the potentially contrastive sound units of a language) and graphemes (written units, which could include single letters or letter combinations like ⟨sh⟩ in English representing the phoneme /š/). Such models assume that the processes of both reading and writing require access to the phonological level of representation of the word or morpheme. Augst suggests that a better model would be a trilateral sign, consisting of a representation of meaning, a phonemic schema and a graphemic schema. The reader could go directly from the graphemic schema (i.e., the written word on the page) to the meaning by recognizing the visual image, or vice versa in the case of writing. For words where the visual image was not familiar (or not familiar enough), the reader/writer would be able to access the phonemic schema—in lay terms, to 'sound out' the word by relying on the known correspondences between phonemes and graphemes. A common word like 'cat' might be read without accessing the phonemic schema, even though the phoneme-grapheme correspondence is exact; but an unusual word like 'tesla' might be read by matching graphemes to phonemes, and might be written 'phonetically' (and thus perhaps misspelt, e.g., 'tessler' or 'tezla' by a user who had heard the word but had not seen it in print.

The precise relationship between reading, writing, and spelling remains controversial. Which theoretical model is adopted clearly has consequences not just within linguistics, but for pedagogical theories as well, since in some countries pupils expend much time and effort to learn to spell (see Sect. 6).

3. *The Historical Origins of Spelling Systems*

The first written texts in a language are usually the work of writers who already know and use the written form of another language—one which already has a literate tradition. The conventions of writing are typically introduced from one culture to another through the mediation of a class of literate bilinguals. In terms of spelling, this means that the conventions associated with writing one language are transferred to a new language, for which they may or may not be well suited at the time. Spelling traditions therefore

tend to reflect social and historical movements and power relationships.

For example, the contemporary orthography of Manx (Sebba 1998a) reflects its origins in religious texts produced by a class of bilingual clergy who were the first writers of the language. More generally, as the vernaculars of Europe were transformed into written languages, the spelling conventions of Latin, in various forms, became part of the spelling traditions of the newly written languages.

During the era of imperial and colonial expansion, literacy was introduced to many languages using spelling systems based on the language of the colonial power. In many cases, the agents of literacy were missionaries or other clergy, or colonial administrators. Lepsius's (1863/1981) work set out to provide a 'standard alphabet' suitable for all languages, whereby the same symbol consistently represented the same sound (e.g., the symbol ⟨y⟩ for the [j] sound of English 'yes' and German *ja*). His work was the forerunner of phonemic orthographies introduced to many languages by trained linguists, both secular and missionary.

One issue debated by linguists providing 'new' orthographies for indigenous languages is whether such systems should reflect the spelling conventions of the local official language (e.g., Spanish in the case of language of Central America), enabling an easier transition to the dominant language of literacy—or more 'universal' principles, which may foster more independence for the language. See Barros (1995) for the history of this debate.

Languages with relatively short histories of literacy are often unfortunate enough to have several competing spelling systems, in spite of a dearth of printed literature. This may be the result of competing groups of missionaries (sometimes representing different linguistic philosophies or colonial powers) or competing political interests, or both (see Sect. 5).

4. *Spelling and Language Standardization*

The existence of a spelling system does not by itself imply standardization, but for languages which have gone down the road of grammatical and lexical standardization, the standardization of spelling seems to be an inevitable part of the process. In the histories of the main European languages of literacy, printers, publishers, and lexicographers have had a major part in this.

While English was successfully used as a written language for centuries even though the spelling system, was unstandardized, Stubbs (1980, pp. 44–5) points out how 'good spelling,' has become socially valued, while even the concept of a 'spelling mistake' in English is as recent as the last two centuries (Strang 1970, p. 107), following the publication of major dictionaries (*Johnson's*, in England, *Webster's*, in North America).

Publishers and printers have their own economic motives for wishing to standardize the forms of written words, and for English, had achieved this goal by about 1650, a century or so before spellings in private writing became standardised (Strang 1970, p. 107). It is not clear, however, whether the standardization of spelling produces gains in terms of reading efficiency. If reading is largely recognition of a visual image (see Sect. 2) then having just one image corresponding to each word might produce a gain in efficiency as fewer images will have to be stored and accessed. Standardization of spelling might then be expected to go hand in hand with mass literacy. This remains to be demonstrated however; and it does not fit with the fact that literacy in England was 'moderately widespread' in the two centuries before the industrial revolution (Strang 1970, p. 106), and then declined in percentage terms just as standardization approached completion.

Advocates of particular spelling systems (including the existing ones) rarely bother to justify the need for a standardized spelling. It is overwhelmingly taken for granted. This in itself is a good reason to ask why spelling standardization is necessary, and why such a high social value is put on being able to spell correctly.

5. *Spelling and Ideological Debate and Conflict*

Spelling systems, as a type of symbolic system, inevitably acquire social and cultural meanings which go far beyond their function as a means of representing a language. The circumstances of the introduction of a spelling system and the circumstances surrounding its use give rise to this cultural symbolism which may in turn lead to ideological contestation and conflict, with the spelling system as its focus. Some recent examples include the debate over an appropriate spelling system for Haitian Creole (Schieffelin and Doucet 1994), where a key issue was whether to use a 'gallicising' orthography, where certain letters had the same value as in French, or a more international one, where they did not. The choice between letters such as ⟨k⟩ and ⟨c⟩ was reinterpreted in the context of the debate by some protagonists as representing 'Anglo-Saxon imperialism' (⟨k⟩) vs. 'colonial subservience' (⟨c⟩).

A similar type of conflict exists in Galicia (Alvarez-Caccamo and Herrero Valeiro 1996), where the choice of orthography for Galician reflects a writer's view on whether Galician is a variety of Portuguese or an independent language. Those favoring 'reintegrationism' (with Portuguese) use mainly Portuguese spelling conventions; those favoring 'differentialism' use conventions closer to Spanish.

In less extreme cases, particular spelling systems may be unpopular because of their associations: for example, one orthography for Breton is disliked for its associations with Nazi collaborators during the World War II (McDonald 1989, p. 131ff).

Even where not codified, orthographic practices may represent ideological positions, especially a desire to differentiate. Thus Caribbean writers may write *kool*, *tuff* to distance Creole from English, although there is no significant pronunciation difference (Sebba 1998b). Within an Anarchist tradition in Spain, words such as *Okupación* ('Occupation (of buildings)') are spelt with ⟨k⟩ instead of ⟨c⟩ in graffiti, in defiance of the official spelling.

6. Spelling and Educational Policy

Most languages with a written tradition now have highly standardized spelling. Thus spelling is usually seen as one of the literacy skills which have to be acquired through formal schooling, with 'good spelling' taken as a sign that the writer is well educated. Education authorities differ, however, in the emphasis placed on the accomplishment of 'correct' spelling, as measured by the amount of school time devoted to it, and the penalties for failing to achieve the acquired standard. There are differences between Britain and the US, for example, in this respect, with Britain usually being seen as having a more tolerant attitude, though there have been recent policy changes. An insistence on 'correctness' in spelling and substantial penalties for underachieving are usually associated with political conservatism, with a more relaxed approach being seen as 'liberal,' in keeping with prescriptive approaches to other aspects of language.

In a few places, such as Norway, there are alternative spelling standards which take into account the dialectal preferences and competences of the local population (see Wiggen 1986). This is unusual; learners are much more likely to be subject to a national or supra-national spelling standard.

While there is almost universal acceptance of the notion that 'correct spelling' is a necessary educational outcome, for some languages there is a feeling that spelling is too difficult, and thus presents a barrier to educational achievement. This provides a major impetus for spelling reform, discussed in Sect. 7.

7. Spelling Reform

Spelling reform—usually meaning an adjustment to an existing system, rather than a root-and-branch rethink—is invariably controversial. Proposals for spelling reform are usually put forward when the current conventions are seen to be causing a 'problem'—typically an educational one. A commonly identified source of problems is language change, which results in the phonemic principle applying over a decreasing part of the lexicon; words where the spelling is out of step with the pronunciation are seen as causing difficulties for learners and leading to 'illiteracy.'

For English, the widespread perception of the spelling system as 'complex' and 'illogical' has led to many proposals for reform over the years, most of which have had no impact on actual spelling practices (see Carney 1994 for discussion). In England, the banner of spelling reform is carried by, among others, the *Simplified Spelling Society*. A few languages, such as Norwegian, have regular and fairly uncontentious reviews of spelling practices, carried out by a central authority. Other languages have implemented reforms, though seldom without resistance from the general public.

Recent examples of contentious reforms are those of Dutch (Jacobs 1997), Portuguese (Garcez 1995), and German, each of which required international negotiation. Reforms often founder as a result of conflicting interests: the general public (which nearly always seems to be opposed to changes), educationists (who are more likely to be in favor), publishers and lexicographers (who have a vested interest in certain types of change, which may produce increased demand from consumers), authors (who sometimes oppose change on the grounds that it will make earlier literary works unavailable to readers who do not know the pre-reform spelling), and national governments, who have to try to balance these opposing parties and promote their own interests. The outcome is often a set of reforms which satisfies no one, and the road to reform is often extremely rocky. The German reforms of the 1990s, for example, in spite of affecting only 0.05 percent of words in running text, have been subject to successful challenges in some regional courts, although these have been overturned by the Federal Constitutional Court (Johnson 2000).

Spencer, Herbert (1820–1903)

Herbert Spencer was born on April 27, 1820 in Derby, UK, and after a long and distinguished career as a major intellectual, he died on December 8, 1903 in Brighton, UK. During Spencer's childhood, he was privately tutored, first by his father and then, after the age of 13, by his uncle in Bath. Thus, Spencer received little formal education outside of his family, although his in-depth tutelage in mathematics and science was sufficient for him to contemplate as a relatively young man a grand Synthetic Philosophy in which a few general or 'first principles' (1862) could be used to explain the operative dynamics of physical science, biology (1864–67), psychology (1855), sociology (1874–96), and ethics (1892–98). He also was a moral crusader, writing important philosophical statements on such topics as education (1860) and social well-being (1850, 1892–98).

Spencer's sociology comes late in his career, beginning with a methodological treatise on sources of bias (Spencer 1873), continuing with an effort to systematically array cross-cultural and comparative data (Spencer 1873–34), and culminating with the use of data to illustrate the basic laws of sociology (Spencer 1898b [1874–96]). In this article, the goal is to see how Spencer's grand scheme developed and how it evolved into a profoundly important sociology [For a comprehensive listing of primary works by Spencer and of works on Spencer, see Perrin (1993)].

1. *Biographical Influences on Spencer's Sociology*

Several important aspects of Spencer's biography are important in examining his impact on social science. First, he never held an academic position, and hence, he did not have any students to carry forth his work after his death, although the wealth inherited from his uncle and from his book sales did allow him to commission other academics to perform research and, even after his death, to continue to completion the volumes of his *Descriptive Sociology* (Spencer 1873–34). Second, he lived an extremely spartan life, and yet at the same time, he interacted in London Clubs and various assemblies with the elite scientists and intellectuals of his time. Indeed, it is from these scholars—figures such as Thomas Huxley, Joseph Hooker, John Tyndall, and even Charles Darwin—that Spencer absorbed much of his knowledge about current discoveries in science. Third, Spencer was immensely popular in his time. His works generally came out in serial form in magazines and private subscriptions, later being packaged as whole books which sold more than 400,000 copies during Spencer's lifetime. Yet, despite his enormous popularity, Spencer was an enigma because he had no formal academic affiliation and because he lived a very private and, it appears, rather neurotic life punctuated by hypochondria. Yet, in all his works, several key influences are evident. Reading Thomas Malthus, Karl Erst von Baer, and Charles Darwin gave Spencer a view of the universe as evolving from simple to more complex through competition; extensive reading of the physical sciences gave Spencer a post-Newtonian conception of science, a view emphasizing that universal laws could explain all domains of the universe; and reading of Auguste Comte also gave Spencer a view of sociology as the search for general laws as well as a conception of social organisms as having structures devoted to meeting basic needs and of societal evolution as involving an increasing complexity of structures meeting these needs. Spencer (1968 [1864]) was, however, always rather defensive about perceptions of Comte's influence on him. Out of this mix of influences came Spencer's grand Synthetic Philosophy that was to unify physical science, psychology, biology, sociology, and ethics under first principles borrowed from the physics of Spencer's time.

2. *The Stigma of Spencer's Moral Philosophy*

Spencer's moral philosophy is one reason that his intellectual star began to fade in the early twentieth century. In his first major work, *Social Statics* (1850), almost a decade before Darwin published *On the Origin of Species*, Spencer coined the phrase 'the survival of the fittest' that was to haunt him for the rest of his career. The more general philosophy in this work simply argued that individuals should be free to pursue their happiness, as long as they do not abridge the rights of others to do the same, although there was a hard edge to this philosophy emphasizing that the less fit should not be supported by the state. Spencer (1904) complained bitterly in his autobiography about how he had become type cast as a result of this first book, but it is hard to feel sorry for him because he made the same 'libertarian' (in today's vocabulary) statements in his last work, *The Principles of Ethics*. For a discipline such as sociology, which is liberal in the twentieth century as opposed to the nineteenth century sense where freedom of the individual and lack of governmental activism are emphasized, this libertarian-sounding ideology has always worked to obscure the important contributions of Spencer to sociology.

3. *The 'First' or 'Cardinal' Principles*

Spencer's use of the physics of his time to formulate his 'cardinal principles' is now rather dated. Spencer postulated three basic principles: (a) the indestructibility of matter, (b) the continuity of motion in a given direction, and (c) the persistence of force behind movement of matter. From these general principles, three corollaries were derived: (d) the transferability of force from one type of matter and motion to another, (e) the tendency of motion to pass along the line of least resistance, and (f) the rhythmic nature of motion. From these principles, Spencer (1880[1862], p. 286) formulated his famous law of evolution as 'change from a less coherent form to a more coherent form, consequently on the dissipation of motion and integration of matter.' This law was presumed to apply to the evolution of celestial bodies, chemical compounds, organisms, and superorganic bodies (organization of organisms). Spencer was, therefore, the world's first general systems theorist.

The first or cardinal principles are less interesting than what Spencer did with them as he applied them to organic and superorganic evolution. In *Principles of Biology*, Spencer used the first principles to formulate the cornerstone of his biology and sociology: increasing size of an organic or superorganic mass requires an exponential differentiation of the structure necessary to support the larger mass. This principle is still used in biology, although its origins to Spencer are long forgotten; the principle is employed in sociology to study differentiation at all levels of social organization, with only a vague sense that this idea comes from Spencer. In many ways, this theoretical cornerstone of Spencer's Synthetic Philosophy actually comes more from his training and brief practice as an engineer than it does from his first principles; for within engineering it is well established that larger structures require more complex systems of support.

Spencer's star faded long ago in biology, and there is only a hint of his influence in education and philosophy today. Where Spencer still remains a figure deserving of at least mention, often in a somewhat derisive way, is in sociology. In order to appreciate what Spencer's legacy is today, we must review his contributions to sociology, where he still lives on as a marginal figure in sociology's pantheon of great masters that includes such giants as Karl Marx, Max Weber, Émile Durkheim, and George Herbert Mead.

4. *Spencer's Functionalism*

Spencer is famous for his 'organismic analogy' in which he lists in a more formal manner than Comte before him the parallel principles of organization between organic and superorganic bodies. But this analogy is often given too much emphasis in commentaries on Spencer because it hides a rather sophisticated functionalism. For Spencer, all superorganic systems composed of organic units must meet three basic requisites if they are to survive: (a) operation or (i) production of life-sustaining substances and (ii) reproduction of units; (b) regulation or coordination and control of units; and (c) distribution or movement of necessary information and substances among units. Populations which cannot meet these requisites will experience 'dissolution,' a notion first developed in *First Principles* (1880 [1862]). Thus, Spencer did not view evolution as an inevitable process of movement from simple to complex as populations sought to resolve problems of operation, regulation, and distribution; on the contrary, he recognized that societies often disintegrate. In this discussion of functional requisites, Spencer introduces two conceptions of 'selection.' On the one hand, Spencer argued that evolution of societies tends to increase complexity because, as societies come into conflict, the more complex and better organized generally will prevail, thereby ratcheting up the overall level of societal complexity. This argument is one of the first 'group selectionist' statements presented in either biology or the social sciences. On the other hand, there is another kind of selection which is at the core of all functionalist arguments. This selection occurs alongside Darwinian selection and revolves around problems and crises in production, reproduction, regulation, and distribution. When problems in any of these spheres emerge, they set into motion efforts to search for solutions by goal-seeking social units. Thus, social selection in superorganic systems is not blind because the very

units subject to selection can change their structure and thereby avoid being selected out. Spencer argues that most selection in sociocultural systems is of this second type, where problems of adaptation activate efforts to resolve crises with respect to production, reproduction, regulation, and distribution.

Since these requisites are the essential problems of survival in all superorganic systems, including both human and nonhuman societies, differentiation of structure during the course of evolution will revolve around these four axes. First will come differentiation of productive structures, followed by differentiation of reproductive units. This increased differentiation along these axes will generate selection pressures for their coordination and control, leading to the elaboration of political systems. As differentiation of operative and regulatory units occurs, new systems of distribution become necessary if dissolution is to be avoided. As these new systems of distribution emerge, e.g., markets, communication, and transportation infrastructures, they create new selection pressures for their regulation while at the same time providing positive feedback for further differentiation of production and, later, reproduction. Thus, movement of superorganic systems from simple to complex forms revolves around selection pressures along the axes of operation, regulation, and distribution as well as around the mutual feedforward and feedback effects of differentiation along one axis on the other axes. This kind of analysis is far more sophisticated than the typical commentary on functionalism acknowledges.

Spencer's substantive sociology also offers some very important models of system dynamics. One element of these models follows from the basic law: as a population grows, the increasing size generates escalated logistical loads for operation, regulation, and distribution which, in turn, set off selection pressures in the manner described above. Spencer's political sociology should be viewed in this context. For Spencer, once power is concentrated, this initial concentration will be used to gain even more regulatory control. As power becomes more concentrated, inequalities will escalate as those with power extract an ever-greater proportion of a population's resources. As inequalities increase, disintegrative pressures mount leading to the concentration of more power to suppress the potential conflict that always inheres in inequality; and as this process is iterated, system dissolution is likely. Geopolitics are also involved in these dynamics, in several senses. First, elites in the regulatory sector often engage in war to secure the resources of other populations which only increases the concentration of power and the scale and scope of inequalities. Second, such war-making efforts often distract subordinates in a system of inequality, at least for a time, from their true interests in changing the system of power generating inequality. Third, when power becomes too concentrated, resistance to this power inevitably increases, often leading to protest movements and other actions that lead to some deconcentration of power. Yet, the longer deconcentrated power lasts, problems of coordination and control escalate, creating selection pressures for reconsolidation of power. Societies thus cycle between concentrated profiles of power (what Spencer termed the 'militant') and deconcentrated power (what Spencer called 'industrial' profiles)—a line of analysis that predates Vilfredo Pareto's discussion of the circulation of elites.

5. *The Data Behind Spencer's Sociology*

These lines of argument have a very contemporary ring to them, and they can be found throughout Spencer's *Principles of Sociology*. Moreover, they are rather easily converted into laws or principles since this is how Spencer thought (see Turner 1985, for an effort to extract the principles from Spencer's work). One of the criticisms of Spencer's functionalism is that it is so speculative; while this may be so, Spencer also amassed enormous amounts of data to support his theoretical speculations. Indeed, the reason that Spencer's *Principles of Sociology* is such a long work is that it is filled with data. In fact, many scholars complained at its first publication in serial form and later as a three-volume book that the analytical ideas get lost in all the data. Thus, Spencer assembled data far in excess of almost any other sociologist in the history of the discipline. He hired professional academics to gather historical and ethnographic information, ordering it into categories that followed from his general functionalist scheme. There are many tragedies in the contemporary view of Spencer, but none is greater than the loss of what Spencer began in the 1860s and first published in 1873 as the inaugural volume of his *Descriptive Sociology* (the last volume was published in 1934).

Spencer was the first to execute what was later done by those assembling the Human Relations Area Files (HRAF) (e.g., Murdock 1953). Spencer recognized that in order to make generalizations about human societies, a large comparative database was necessary. But these data had to be arrayed so that they could be compared, leading Spencer to develop a category system for recording the data being assembled by professional academics. The result was the multivolume *Descriptive Sociology* (1873–34) which arrays data historically for those societies that have a written history and cross-sectionally for those less developed societies without a written history. The publication of these oversized volumes has been completely lost to modern social science, but if Spencer's lead had been followed by others in the nineteenth century, all social science would have a much firmer empirical base than is provided by HRAF. At the very time Spencer was assembling available information on 'primitive' societies, these societies were being changed or destroyed

by colonial forces, with the result that by the time anthropologists began to study them in detail in the 1930s, their pristine character had long been compromised. *Descriptive Sociology* could have been Spencer's greatest legacy, but like so much of his work, the contemporary world remains largely ignorant of his efforts to create a database for assessing the plausibility of his theories.

6. *What Might have Been, and What Can Still Be*

By the time of Spencer's death in 1903, his star had already begun to fade in intellectual circles. One reason for this decline can be attributed to Spencer as a lone scholar working outside of academia. Without students to carry on his work and without a school of thought institutionalized in academia, there was no one and no place to carry forward Spencerian sociology. Work still continued on *Descriptive Sociology* but this was much narrower in scope than Spencer's philosophy or even his sociology, and moreover, most of this work was contracted to scholars who were not committed to Spencer's grand scheme. So, when Talcott Parsons (1937) asked 'who now reads Spencer,' the answer was not very many scholars inside or outside of sociology. Spencer's star had fallen at the same time that evolutionary thinking came under attack in anthropology, and with no one to defend Spencer's sociology, he fell into obscurity. Yet, let us imagine for a moment what might have happened if Spencer had been defended by students or had established a school entrenched in academia like Durkheim's *année* school in France. In conducting this thought experiment, we can come to appreciate not only what might have been, but more fundamentally, what is still available in Spencer's legacy.

The first legacy would have been a Human Relations Area Files that came earlier, before colonialism completely destroyed indigenous populations. Moreover, sociology would have had a database that was comparative in several senses: the data would have been arrayed in common categories that are more sophisticated than George P. Murdock's (1953) HRAF; the data would have been both historical and ethnographic and would have allowed systematic comparisons of different types of societies at any point in time. Only in the last three decades has comparative-historical and ethnographic data been reintroduced back into sociology and, ironically, this reintroduction has been part of a movement to rekindle interest in the very evolutionary thinking that was used to discredit Spencer.

The second legacy is that the evolutionary paradigm would have survived and avoided the 50-year hiatus. Stage models have utility in sociological analysis, as has been demonstrated in the work of Gerhard Lenski (1966), Stephen K. Sanderson (1995), Jonathan Turner (1984, 1997), and others in recent years. Moreover, adopting Spencer's views on evolution would have avoided the view of evolution as inexorable, since dissolution would be a prominent point of analysis as would dialectical cycles within either evolution or dissolution.

A third legacy would have been a sophisticated functionalism that, unlike mid-twentieth century approaches, sought to articulate theoretical principles about the dynamics of social processes rather than simply cross-tabulate lists of functional requisites with lists of social processes. Functionalism fell into disuse not so much because it was dead wrong but because it was not done well. A reading of Spencer would have led the way to a functionalism that does not build conceptual schemes as much as highlight fundamental forces whose operative dynamics can be captured in theoretical principles.

A fourth legacy would have been a sociology that did not lose sight of its status as a science in which the goal is to generate theoretical principles that explain the operative dynamics of the social universe. Spencer's methodological treatise and his articulation of actual laws of human organization would have sustained the discipline better than Marx, Weber, Simmel, or Durkheim could, as various antiscience and excessively relativistic movements have come and gone for the whole of the twentieth century in sociology.

A fifth legacy would have been the actual substance of Spencerian sociology. Imagine if sociologists had mined *The Principles of Sociology* for insights into human organization with the same intensity as we have delved into Marx, Durkheim, Weber, or Mead. Spencer provided not only highly abstract theoretical principles but also many principles about the operation of stratification systems, polity, kinship, religion, economy, markets, ceremonies, professions, organizations, education, and many other key structures, and he documented these generalizations with copious amounts of historical, ethnographic, and for his time, contemporary data. The sociology of major institutions (e.g., family, education, religion,etc.) would be less parochial and descriptive than it is today because it would examine the dynamics of the institution with ethnographic as well as historical-comparative data organized by basic theoretical principles.

A sixth legacy would have been the continued connection between biology and sociology. This connection has only recently been revived along all the fronts found in Spencer's work. There is the ecological approach emphasizing Darwinian dynamics that Spencer saw before Darwin and that are now used to examine the relations between resources niches and a wide variety of social processes. Indeed, there is the revival of selection arguments in general (e.g., Runciman 1998), and moreover, an effort to move beyond Darwinian selection to considerations of group selection (e.g., Sober and Wilson 1998) and

Lamarckian processes so evident in Spencerian sociology (Turner 1995).

A seventh legacy is a political sociology that connects stratification processes within society to geopolitical dynamics in world systems. At the core of Spencer's sociology is a concern with power that is the equal of that to be found in either Marx or Weber. One of Spencer's main explanatory variables is how the concentration of power alters all other social processes, especially stratification and institutional systems, and his analysis of how war and commerce in the world system are implicated in power dynamics would not only have supplemented Marx and Weber but would have led to the emergence of world systems theory at the beginning rather than at the three-quarters mark of the twentieth century (e.g., Wallerstein 1974).

An eighth legacy is the emphasis on the fundamental relation between size, differentiation, and modes of integration. Much of this legacy was rediscovered in the mid-twentieth century in organizational studies on administrative intensity, but the basic dynamic operates at all levels of society. If sociologists had pursued Spencer's lead and focused in 1910 on this fundamental relationship in the social universe, not only would organizational studies been moved forward at an earlier point in history but also other social units might well have been analyzed for how these relations among size, differentiation, and integration play themselves out.

These eight lines of thinking that are part of Spencerian sociology were available to all sociologists by the early 1890s. In a sense we have squandered this incredible legacy, but it is not too late. The above thought experiment can be more than an intellectual exercise in the history of ideas. A reading of Spencer today can still inform sociology. There are gems of insight to be discovered and used to analyze societies in almost everything Spencer wrote. They simply sit there on library shelves, waiting to be used by scholars in the twenty-first century. There is probably little more to be gleaned from poring over the texts of others in sociology's early pantheon, but the neglect of Spencer for the whole of the twentieth century provides a rich resource for the twenty-first century.

Sperry, Roger Walcott (1913–94)

Roger W. Sperry, scientist, teacher, philosopher, and humanitarian was born in Hartford, Connecticut, USA on August 20, 1913. He was married to Norma Dupree in 1949; they had 2 children. He died on April 17, 1994.

The diversity of Sperry's interests is not only reflected in his distinguished academic career, but also in his avocations. In addition to his major contributions to our understanding of brain structure and function, he was an unusually talented artist, sculptor, and paleontologist. His multiple talents across many areas attracted a constant stream of graduate students, postdoctoral fellows, and visiting scientists to his Psychobiology Unit at Caltech for four decades.

Sperry's scientific contributions centered on four major areas, the first of which began in the early 1940s, while he was still a graduate student in Paul Weiss' laboratory at the University of Chicago. Paul Weiss, whose views dominated the field of neural development at the time, held that the leading tips of growing neurons solely responded to local mechanical stimuli, and were in no way influenced by distant chemical cues. His numerous tissue culture studies had essentially closed the door on any possibility of chemical influences on neuronal growth. Weiss also held that the normal function of the nervous system was in no way dependent upon the precise patterns of neuronal connections. One example of this, according to him, was that when motor nerves were transplanted into any foreign muscle, normal movements would eventually occur after a period of training.

Sperry, as was to become his custom, challenged these ideas, and designed a typically simple, but ingenious experiment to test whether or not specific nerve connections are critical for normal function. Using rats, he transplanted motor nerves from leg muscles of one side to muscles of the opposite side, then tested their movements after the new nerve-muscle connections were established. Function was found to be severely impaired, and no amount of training could correct it (Sperry 1945). These results also had important implications for humans. Neurosurgeons at the time were transplanting nerves in wounded war veterans in attempts to help them regain digit and limb movements, which had been lost as a result of war injuries. In spite of extensive post-surgical training, these transplants met with little success. During his military service with the Office of Scientific Research and Development (1942–45), Sperry, along with Weiss, showed that surgical transplantation of nerves to antagonistic muscle groups followed by intensive training simply did not work because transplanted nerves were inherently different from the nerves which normally innervated those muscles. This finding resulted in significant modifications of treatment procedures, thus saving a great deal of time, frustration, and money.

During this same period it was reported that if the optic nerve were sectioned in amphibians, optic axons would regenerate into the brain, and normal function would be restored. Sperry immediately recognized that this finding offered the perfect opportunity to test his ideas regarding functional specificity and the possible role of chemical influences on neuronal growth patterns. He first confirmed the above results (Sperry 1950), then once again designed a brilliantly simple study—the now classic eye rotation experiment in the frog—to test his ideas. A hungry frog will accurately strike out with its tongue to obtain a fly held in front of it. Sperry sectioned the optic nerves of normal frogs, and rotated the eyeballs by 180 degrees. After regeneration had taken place and connections were reestablished in that part of the brain which is known to receive visual fiber input (an area called the optic tectum), he tested the frog's ability to capture a fly. The premise was that if the retinal axons had regrown into their normal sites of termination (in spite of the fact that the eye had been left/right reversed and turned upside-down), the frog should misdirect its strike by 180 degrees in any direction. If, however, the regenerating optic fibers disregarded their original target sites and established new central connections corresponding to the rotated eyes, the frog would be capable of striking accurately at the target fly. The answer was unequivocal. When the fly was held 90 degrees to the frog's right, it struck out 90 degrees to its left—180 degrees out of phase. The same result was obtained for all directions—left, right, up, down. The strike was always 180 degrees off, and no amount of retraining could correct it. The conclusion from both of the above lines of evidence was clear: peripheral nerves cannot be 'forced' to establish connections with foreign muscles, and centrally regenerating nerves will reconnect to their original sites, in spite of radical alterations of their starting positions. A number of other rerouting studies were carried out, each of them supporting the basic premise, which Sperry termed 'the chemoaffinity hypothesis.' Briefly stated, the growth and development of a pre-patterned neural network is determined by a genetically controlled chemical code, and the 'hard-wired' nature of this network results in a specific, highly adaptive range of behavior which is unalterable by training. Other studies over the next 20 years, using neuroanatomical and neurophysiological approaches, provided confirmation of this hypothesis. Attardi and Sperry (1963) provided further, histological confirmation by showing that regenerating retinal axons in the goldfish would always regrow to their original terminal sites in the brain.

Two major theoretical papers were published by Sperry in the mid-1960s (see Voneida 1997, Sperry 1965a), in which he precisely described his chemoaffinity theory. In spite of numerous attempts over the next three decades to disprove the theory, it has prevailed with only slight variations and elaboration

of the basic premise. It was primarily this work, begun as a predoctoral student in 1938 and pursued through the early 1960s that resulted in his election to the National Academy of Sciences.

A second major area of Sperry's work deals with cortical organization related to higher cognitive function in mammals. He joined the renowned psychobiologist Karl Lashley at Harvard for his postdoctoral work, where he began a new series of studies on the role of electrical fields in neocortical function. He was not comfortable with the idea that electrical fields or waves acting in a volume conductor (the brain) are critical for neocortical processing. His first study to challenge this was published in the late 1940s (see Sperry 1947). Here he demonstrated that motor coordination in monkeys remained virtually unaffected after multiple transections of sensorimotor cortex. He later confirmed this by demonstrating that neither cortical cuts, the insertion of numerous short circuiting wires or insulating plates into the cortex had any adverse effect on cortical function. These studies demonstrated that perception is dependent upon vertically oriented afferent and efferent cortical axons, predating the discovery of vertically oriented cortical columns. Sperry's premise was based on his keen understanding of neuroanatomy and neurophysiology, including the work of Santiago Ramon y Cajal and Lorente' de No, both of whom had demonstrated the importance of radial cortical connections to cortical function.

Thus, in a few carefully conducted experiments, Sperry had once again upset two major theories of brain function, Gestalt electric field theory of perception and the reduplicated interference pattern hypothesis. Indeed, when the renowned neuroembryologist Viktor Hamburger presented Sperry with the Ralph Gerard Award from the Society of Neuroscience in 1979, he proclaimed, 'I know of nobody else who has disposed of cherished ideas of both his doctoral and his postdoctoral sponsor, both at that time the acknowledged leaders in their fields.'

Sperry's third major contribution relates to the function of neuronal connections between the two brain halves (called commissures), interhemispheric communication, and lateralization of cognitive abilities in humans. Most of this work was done at Caltech, where he served as Hixon Professor of Psychobiology from 1954 to 1994. It was these studies, carried out between the mid-1950s through the 1970s (see Sperry 1981), which resulted in the Nobel Prize in Physiology and Medicine (shared with Hubel and Wiesel) in 1981. The early studies, carried out by Sperry and his students at Caltech from the mid-1950s through to the 1960s, elegantly elucidated some of the major functions of interhemispheric connections in memory transfer and eye-hand coordination. Restriction of sensory input to one brain hemisphere in animals having undergone surgical separation of the two brain halves was shown to limit the learning of various tasks to the 'input' hemisphere; the opposite side was capable of learning, but remained naive to those tasks until trained. Learning curves for each brain half were virtually identical; it was as if two separate brains were housed within a single cranial vault. It was during this period that he also began his work on the lateralization of cerebral function in humans. Neurosurgeons Philip Vogel and Joseph Bogen had performed a surgical section of the major pathway connecting the two brain halves on a World War II veteran who was suffering from progressively worsening epileptic seizures. Working in collaboration with Vogel and Bogen, Sperry and his students began a series of tests directed at understanding the effects of this surgical hemispheric separation on human perception, speech, and motor control. The work involved comparisons of cognitive abilities between the two separated brain halves, demonstrating differences theretofore unrecognized.

For the next 20 years, the work of Sperry and his collaborators revolutionized our understanding of brain function. Prior to this time, the right hemisphere had been virtually neglected by neuroscientists. At best, it was felt to play only a minor role in human cognition, with all major cognitive functions emanating from the left, or dominant half. As a result of Sperry's research, the right hemisphere gained its long overdue recognition as a full partner to the left, playing a major role in holistic, parallel, and spatial abilities. The left brain half was found to be superior to the right in tasks involving analytical, sequential, and linguistic processing. Perhaps most importantly, however, Sperry demonstrated that the combined effects of bihemispheric activity amounted to much more than the simple additive effects of the 2 separate hemispheres, and led him into the area of his fourth and final major contribution; namely, the relationship between brain and mind, science and values.

Sperry began thinking and writing about the subjective aspects of brain function as early as the late 1950s. In 1959, for example, as part of the discussion at the Josiah Macy Conference on the Central Nervous System and Behavior, he stated that he had never been entirely satisfied with the behaviorists' interpretation of brain function in purely objective terms, with no reference whatsoever to subjective experience. He pointed out that this does not mean that we should abandon the objective approach; it simply means that we should also include subjective experience in our working models of the brain. Again, in his 1965 paper, *Merging Mind, Brain, and Human Values* (see Sperry 1965b), he reinforces this thesis in his declaration that conscious forces must be included in any model or description of brain function, stating that in this model, '… conscious mental psychic forces are recognized to be the crowning achievement of some five hundred million years or more of evolution.'

Sperry continued to think and write about the mind, consciousness, and their relationship to human values right up to the end of his life. He postulated that the

mind is an emergent property of brain function, and like most emergent properties, bears little resemblance to the hundreds of millions of neurons in the central nervous system. He emphasized that while the mind is not the *same* as the brain, it is *dependent* upon it. This point is an important one, for it separates Sperry's views from the philosophical concept of dualism. Thus brain and mind are by no means separate entities, but function rather as coexistant partners through the processes of emergence and downward causation, or feedback. Taken together, these two properties result in a continuous, highly dynamic process of change from one moment to the next, drawing constantly on previous experiences by way of learning and memory, whether they occurred in the distant past or only moments ago. He strongly argued against reductionism, which dominated psychological thinking during the first half of the twentieth century. He believed that reducing consciousness to its separate components obliterates the emergent properties of mind, with '*... all its great power and uniqueness*' (see Sperry 1993).

Sperry then elevated his concept of mind as an emergent property of brain activity to a global level, stating that:

> The new paradigm affirms that the world we live in is driven not solely by mindless physical forces but more crucially, by subjective human values. Human values become the underlying key to world change (see Voneida 1997).

He urged his scientific colleagues to use the very unique and powerful forces of mind and consciousness toward improving and preserving the quality of life on our planet, rather than the reverse. His urgent appeal finally began to be heard when his long-term friend and colleague, Professor Rita Levi-Montalcini, herself a Nobel Laureate, convened the International Conference of Human Duties at the University of Trieste in November, 1992, to discuss these ideas in greater detail. Regrettably, Sperry's illness prevented him from attending the first meeting, which included 10 Nobel Laureates and numerous others, representing such widespread disciplines as neurobiology, chemistry, physics, economics, and theology. This conference led to the formation of The International Council of Human Duties, which formulated 'The Declaration of Human Duties' in 1994. The document has been published (Trieste Declaration 1997) and forwarded to The United Nations, for its consideration as a corollary to the 'Declaration of Human Rights.'

Sperry's thinking about subjective experience, consciousness, the mind and human values were crystallized in his paper 'The Impact and Promise of the Cognitive Revolution' (Sperry 1993), delivered at the American Psychological Association's centennial meeting in 1993. It expressed his great hope and sincere belief that if we humans could simply be persuaded to put our collective minds together and to use the enormous emergent power that they are capable of generating, we might very well begin the new millennium by not only improving the quality of life on the planet, but also by significantly increasing our chances for survival.

Spirit Possession, Anthropology of

Since ancient times possession is a transcendental human experience that exists all over the world. Bourguignon (1973) found that in 90 percent of her sample of 488 societies, one or several forms of possession or, as she called it, altered state of conscience, existed. Even in Western societies, despite secularization, belief in spirits regains in importance due to new religious movements and the sweeping success of fundamentalist Christian churches. This

worldwide attractiveness asks for a rethinking of possession in relation to modernity and the disenchantment of the world.

1. Understanding Possession

The wide varieties of beliefs and cultural traditions make it difficult to define what possession is, and what it means for different people. A minimal classification is advanced by Boddy who defines spirit possession as 'the hold exerted over a human being by external forces or entities more powerful than she' (Boddy 1994, p. 407). In most possession cults these external forces are considered as spirits, god(s), or ancestor heroes. In Africa, possessing spirits are generically thought of as breath, air, or wind. Their individuality is produced in an interactive process, in which the medium, the afflicted person, and the public take part. Spirits may incarnate ancestors, cultural heroes, or former kings as well as specific ethnic or social groups, animals, material things, abstract principles, and even emotional states. They are refractions of social life and express the whole range of a society's cultural archive. Despite this objectification they are thought of as distinct personalities with special tastes for food, clothes, jewelry, colors, rhythms, and music.

The spirits' interaction with humans varies considerably. It is either conceived of as a form of communication through dreams, images, or voices and/or as a violent attack in which illness or misfortune is inflicted on an individual. During possession, humans are no longer themselves, but 'horses,' 'vessels,' or 'containers' of their spirits. They are not responsible for their acts or speeches, since they are dominated by forces alien to them. Lienhardt (1961) has called this mental stage passiones, a form of being acted upon, instead of being an actor. In order to determine the identity of the afflicting spirit, ritual performances are staged which serve as diagnosis and therapy at the same time. The process of initiation is more or less formal and in some cases dependent on public accountability. Complete unification with the spirit is achieved by way of trance or ecstasy which may be generated through music, dance, medicine, and drugs, or as Eliade (1951) has pointed out by way of archaic techniques, such as concentration, meditation, or rapture. Trance and ecstasy are used synonymously by many scholars. Others think they represent different bodily expressions of an altered state of consciousness. Trance, a sleep-like state and form of mental dissociation, may change into ecstasy: a form of frenzy, expressed in high pitched cries, hiccups, convulsive fits, speaking in tongues, or unknown languages, known as glossolalia. The identification with the spirit engenders a change in personhood and reverses former relations of subordination into relations of reciprocity. Spirits are accommodated and integrated into the medium's life and that of his/her family, since most rituals include wider kin. De Heusch (1962) called this process adorcism and differentiated it from exorcism that implies the removal of evil spirits or ghosts, which is typical of demonic possession.

2. Possession, Gender, and Empowerment

Possession is not a singular event but denotes a lifelong relationship whose meaning is culturally determined, socially transmitted, and individually learned and implemented. The great majority of the possessed are women. Their dominance in possession cults has been the object of many enquiries and the answers given have differed fundamentally. Lewis (1989) discussed possession as a means for subordinate women and (marginalized) men, to gain material benefits and improve their social status. Others have pointed out the close link between possession, femininity, and female identity that are playfully re-enacted, modified, or contested by transgressing moral boundaries. The heterosexual nature of most spirits rivals long established marriages and deconstructs male sexual hegemonies. It is this subversive nature of possession that is one reason for its ambivalent and ambiguous reputation.

Possession offers a wide range of opportunities for women and men to explore new identities, negotiate power relations between the sexes, and open up new spaces for social action. These are not limited to symbolic forms of behavior but refer to very mundane forms of praxis. Women and men competitively try to benefit from the professionalization and commercialization of healing which is more or less pronounced in different cults. They are engaged in ecological protection as 'guardians of the land' and exercise social and political power as cult leaders. Since colonial times spirit mediums are feared by colonial administrators as subversive, because they play(ed) eminent roles in wars of liberation and in the subsequent purification of war traumata. Due to the close association between possession, individual stress, and social change, possession cults are not limited to rural areas, but occur also in towns. In Malaysia female factory workers are struck by spirit possession (see Ong 1987) as a form of resistance against capitalist exploitation, while Kapferer describes exorcism in Sri Lanka as 'metacommunicative of the dynamics of class' (1991, p. 51). The transcending of class boundaries is also reported for Brazil and the Caribbean where middle-class people form a substantial number of cult members (Csordas 1987). In African towns a variety of possession cults compete for adherents belonging to all walks of life, including women as well as men. Although many cults are remarkably stable over time and extend over vast regions, a frequent redrawing of boundaries between town and village is quite typical.

3. Discourses on Possession

Since the beginning of the twentieth century the fascination with the subject on the part of scholars has generated a large body of literature. Whereas European case studies played an important role in earlier publications, examples from other continents began to dominate in the twentieth century. Due to the complexity of the subject all main theoretical debates are represented in the interpretations of spirit possession. Three of the most important approaches are:

3.1 Psychological Approaches

An important issue in early studies was the truth or falseness in the experience of possession that de Heusch (1962) classified as authentic or inauthentic possession. As a consequence, psychological interpretations loomed large from the very beginning, associating possession with multiple personalities and psychiatric symptoms. It was described as a form of pathology, due to personal stress or social change. Experiences of possession were predominantly discussed in metaphors of illness and healing which were dissociated from religious beliefs. Significant for this form of medicalization (Csordas 1987) was the neglect of its cultural and cosmological context. This reductionism was first challenged by more sophisticated case studies (Crapanzano and Garrison 1977, Obeyesekere 1981) which related psychological or psychoanalytical insights to the cultural construction of healing. A synthesis was achieved by Janzen (1992) who convincingly demonstrated that healing and religion are inseparable for the understanding of possession.

3.2 Sociological Approaches

Firth's (1964) distinction between spirit possession and spirit mediumship opened a sociological path for interpretation. He discussed spirit possession as a form of individual affliction whereas spirit mediumship was characterized 'as serving as an intermediary between spirit and men' (1964, p. 247). Beattie and Middleton (1969) elaborated this differentiation in their pioneering study on spirit mediums whose exercise of power they related to different forms of social organization. Arguing from a functionalist background they were concerned with the sociological and political functions of spirit mediumship and stressed its closeness to social change. Lewis (1989) took up their distinction and equated central possession cults with societies' main moral order being represented by men of social standing while peripheral possession cults were the domain of amoral spirits and powerless women. Being a weapon of the subordinate he described these cults as a 'thinly disguised protest movement directed against the dominant sex' (1989, p. 26). Another important discussion in his comparative sociology of ecstasy was his fervent pladoyer for the identification of spirit possession with shamanism. His arguments were directed against Eliade and de Heusch who had conceived the two as inverse processes. Whereas shamans rival with the gods and ascend to them, spirit mediums incarnate the spirits who descend and attack humans. Despite the impact of Lewis' book the instrumentalist portrayal of possession by most functionalists came increasingly under attack in the 1980s and led to another shift in methodology.

3.3 Hermeneutic Approaches

Due to the influence of Schütz and Geertz on anthropological theory during the 1980s, many authors favored a phenomenological or hermeneutic approach for a deeper understanding of the complexity of meanings acted out in these cults. Lambek who had earlier discussed curing ceremonies as performed 'texts' introduced a new topic by his ascription of possession as a means of knowledge (1993, p. 305f). He not only differentiated between objectified knowledge in Islam and embodied knowledge in possession, but also stressed the interdependence of objectification and embodiment for each type of knowledge. These dialectics explain, among other factors, as Boddy has pointed out, the counter-hegemonic praxis of possession without inhibiting the many forms of syncretism between the two. In her view possession beliefs constitute a metalanguage, 'a metaphoric construction on quotidian reality' (1989, p. 270). She describes how the world of humans is paralleled by the world of the spirits whose behavior, however, ridicules, satirizes or reinterprets human values. In an insightful analysis Leiris (1958) had already drawn attention to the playful and theatrical character of possession dances as arenas for negotiating identities. Fritz Kramer (1987) explored this venue further by interpreting 'performances of alien spirits as mimetic ethnographies' (Behrend and Luig 1999, p. 17). The distancing gaze on the other not only helps to recognize one's own self but also is a means of understanding past and present events. At the same time, this symbolic construction of the world is part of an ongoing appropriation of modernity that may be modified or even rejected through the intervention of the spirits. It is this creative aspect of the rituals of possession that allow for the regional or even international mediation of local practices that are to produce spirits of cosmopolitan nature. Spirit possession is thus in no way an archaic practice that runs counter to a disenchanted world, but rather acts as a metacommentary on its modernity.

Split Brain

Before the 1940s, the functions of the corpus callosum, estimated to have about 1,000 million axons, were unknown (Akelaitis 1944). Early in the 1950s, Roger Sperry at the University of Chicago, who was researching the anatomy of visual form perception in the cerebral cortex, proposed a surgical investigation that was to yield new insights into this tract and the brain systems of consciousness (Evarts 1990, pp. xix–xxi). Ronald Myers, a research student with Sperry, demonstrated by cutting the corpus callosum that a cat's visual experience was divided in two, and could be transferred by it between the hemispheres (Myers and Sperry 1953).

In the 1950s and 1960s Sperry's research group, now at the California Institute of Technology (Caltech), exploited what was now called the 'split brain' to study visual and tactile perceptions, memories and motor control in cats or monkeys (Sperry 1961). Studies with monkeys showed that, while ordinary pattern discrimination was completely split, less figurative visual experiences were not completely duplicated after split-brain surgery. This proved the importance of 'motor sets' or 'intentions to move' that 'anticipate' sensory information and that invoke undivided systems of the brain stem and cerebellum.

In 1962, the effects of commissurotomy, undertaken to arrest life-threatening epilepsy, were investigated in a human patient (Bogen 1985). Sperry directed psychological tests of consciousness, learning and various skills after the operation (Sperry 1967). Commissurotomy to treat multifocal epilepsy in other patients made it possible to test rational consciousness in the left and right hemispheres, their similarities and differences, their convergent influence over acts, ideas and feelings of the whole person, and the role of language (Sperry 1967, 1974, Sperry et al. 1969).

Commissurotomy research confirmed Sperry's theory of the causal potency of motor intentions, and of self-consistent conscious ideas and beliefs, and moral impulses (Sperry 1977, 1983). It stimulated the neuropsychological analysis of hemispheric differences unique to humans, and, by clarifying the special modes of processing in cortical territories, supported the 'cognitive revolution' of the 1960s (Sperry 1993). Sperry's research on the cognitive processes of the cerebral hemispheres of human beings gained him a Nobel prize in 1981 (Sperry 1982).

Since the classical period of split-brain research in the 1960s and 1970s, interest in hemispheric differences has flourished, and the cognitive processes, language processes and memory of commissurotomy patients have been studied in new, detailed ways. Nevertheless, the overall picture of cerebral functions has not significantly changed (Benson and Zaidel 1985, Nebes 1990, Trevarthen 1990a, Corballis 1991, Gazzaniga 1995). Though commissurotomy was effective in limiting seizures, the operation carries risks, and is now rarely performed.

1. *Split-brain Experiments with Animals*

Myers applied the stereo-microscope surgery developed by Sperry to cut the crossover of visual nerves in the optic chiasm under a cat's brain, so each eye would

Figure 1
Anatomy of the cerebral commissures. Saggital sections of the brains of cat, monkey (rhesus macaque) and human adult, showing the corpus callosum (c), anterior commissure (a) and optic chiasm (oc). The estimated numbers of nerve axons in the corpus callosum of each species is indicated. This illustrates the enormous expansion of cortical functions in human beings, and their bilateral integration through the corpus callosum

lead to only one cerebral hemisphere (Figs. 1 and 2). In 1953, he and Sperry reported the transfer of visual memory between the hemispheres in cats with the chiasm divided, and the abolition of this transfer when the corpus callosum was cut (Myers and Sperry 1953). Outside carefully controlled test situations, the animals moved normally.

Monkeys also experience independent visual perception and memory in the two brain halves after the optic chiasm and forebrain commissures (corpus callosum and anterior commissure) are cut (Fig. 1). Again, the operated animals retained normal coordination of movements and attention when free to orient, correcting for loss of awareness due to the surgery. Split-brain monkeys learn two, mutually contradictory, visual discrimination habits in the right and left half-brains, showing that they possess double and separate realms of consciousness (Trevarthen 1962, Sperry 1977). In the cat, each disconnected hemisphere directed movements of the whole body, but with monkeys, a hand on the same side as one seeing hemisphere was, at least in the immediate postsurgical period, less willing to respond and, if forced into action, was clumsy, as if blind. Crossed pathways linking each cortex to the opposite hand were superior for guiding fine, purposeful movements of the fingers. Related split-brain projects demonstrated shifts of attention between the two separated halves of the cortex and the effects of preparatory sets to move in particular ways. The results revealed the global design of the mammalian brain for awareness, learning, and voluntary action (Sperry 1961, Berlucchi 1990).

What a chiasm-callosum sectioned (split-brain) monkey sees and remembers, i.e., in which hemisphere visual perception and learning occurs when both hemispheres are presented stimuli, depends on which hand the animal chooses for response. This is evidence that intention can instruct experience, that activities of the neocortex are directed intrinsically by purposeful impulses generated in the brain as a whole, and not just by processing the input of stimulus information at the cortical level.

When a monkey learns a complex two-handed skill, the memory of how to move is located more in the hemisphere opposite the dominant hand, i.e., the hand that the individual spontaneously prefers to use for fine, consciously regulated manipulations. A split-brain monkey's visual awareness can be turned on or off in one side of the brain by changing which hand the animal uses to manipulate the test apparatus to gain a reward. When using the right hand the monkey becomes conscious on the left side of its cerebrum and is unable to see with the right cortex. This causes the monkey to be inattentive to things in the left half of its experience, and makes it likely to imagine things that did not exist there. This clarifies 'perceptual neglect,' and 'illusory completion,' phenomena known from clinical neuropsychological research with consciousness of patients who have lost function in parts of their cerebral cortex (Trevarthen 1990b).

Tests of vision in the divided brain led to the theory that the sensory systems are linked to a hierarchy of motor coordinative systems, which either gear body movements to the layout of the surrounding world, or direct the subject to select objects that have life-

Figure 2
Human brain showing asymmetric functions in the cerebral hemispheres. The hemispheres are separated after commissurotomy (the 'split-brain' operation). Above, the two hands in the visual field, with the subject's attention fixated on the tip of the paintbrush. (L = left half of visual field; R = right half of visual field; o.c. = optic chiasm)

relevant qualities. Two active visual systems were distinguished: wide-field and part-conscious *ambient vision* informs whole-body locomotion and orientation; *focal vision*, employing the foveae to see within only a few degrees of visual angle and with precise intermittent fixation of gaze, inspects detail and identifies objects (Trevarthen 1968). The former, involving many subcortical centers, as well as parts of the parietal cerebral cortex, acts as motivator and map-reader for attention in the latter, more conscious vision of shapes, colors and patterns. The split-brain operation divides focal vision because its essential processes are confined to the cortex, but leaves ambient vision largely intact.

2. *Human Commissurotomy Patients*

In 1960, Joseph Bogen, a Los Angeles neurosurgeon, saw a patient who was having progressive, life-threatening seizures as a result of head injuries sustained as a paratrooper. In the light of the research with monkeys, which showed that commissurotomy could leave essentially normal control of whole-body action and the distribution of awareness, it was decided that cutting the corpus callosum and other interhemispheric commissures, 'total commissurotomy,' would reduce the epilepsy. This operation was carried out in 1962, and the epilepsy improved significantly. Sperry and Bogen, with Michael Gazzaniga, began systematic psychological tests at Caltech on the effects on perception, speech, and motor control. Instead of relying on standard neurological procedures, original tests were devised based on principles learned from split-brain animals (Sperry 1967, 1974, Sperry et al. 1969). The first report, with clinical observations made by Bogen, described the resultant left–right division of human consciousness (Gazzaniga et al. 1962). Norman Geschwind and Edith Kaplan, in Boston, described comparable 'deconnection' phenomena in patients with lesions that interrupted cortico-cortical links (Geschwind and Kaplan 1962).

Tests confirmed that awareness of objects seen by either half of the brain (in left and right halves of the visual field), or felt in the left or right hand, was essentially normal, but, as in the earlier animal studies, when free orientation was prevented, the left and right mental realms were as separate as if in separate heads (Fig. 2). Only when the subject shifted visual fixation or passed an object from one hand to the other did the one hemisphere know what the other was perceiving. As with the monkeys, human commissurotomy subjects experienced unified ambient visual functions, but split focal vision (Trevarthen and Sperry 1973, Trevarthen 1990b).

Though both hemispheres were conscious, only the left could speak or write. Surprisingly, however, given that left hemisphere lesions can produce total aphasia, the right hemisphere, though speechless, could nevertheless comprehend speech (Gazzaniga and Sperry 1967, Zaidel 1990b). It picked up information quickly from utterances made by the left half-brain, could read common words flashed to the left visual field, and could follow verbal instructions. It was, however, conspicuously weak at calculating and in comprehending logical propositions. Jerre Levy showed that in the nonspeaking right hemisphere, classically referred to as the 'minor' hemisphere, mental faculties that imagine spatial relations and transformations in space were more highly developed than on the left 'dominant' side of the brain. Two different, complementary kinds of cognitive strategy, two kinds of consciousness, were demonstrated (Levy-Agresti and Sperry 1968) (Fig. 2).

The surgically separated left hemisphere commands fluent speech and can generate and retain phonological images of speech sounds. It performs serial logical propositions such as are expressed in spoken, gestural or written language, and it is adept at the kind of combinatorial and systematic logic required for formal mathematics or score-based musical thought. The right hemisphere, in contrast, has superior mastery of the immediate 'appositional' experience (Bogen 1969)—of forms by sight, sound, or touch—and,

according to recent research, of odors. It can remember these experiences better, can distinguish and remember faces better, has richer reactions to colors, and to affective tones of the voice and its prosodic quality. It perceives more easily resemblances in topological but not Euclidean geometry. Commissurotomy patients have a color anomia, an inability to name colors, because the disconnected right hemisphere has a superior but inarticulate ability to perceive color. There is evidence that an undivided brain-stem color vision defines a dichromatic distinction between blue space and the reddish-brown solids, part of the natural layering of the conscious mind to serve different forms of action in the world (Trevarthen and Sperry 1973). Tests with commissurotomy patients support findings with brain-damaged and normal subjects showing the right half of the brain to be involved in emotional communication and the mediation of direct social interactions. The main hemispheric differences are summarized in Sperry's Nobel Address (Sperry 1982).

Jerre Levy and Colwyn Trevarthen used 'stimulus chimeras,' pictures showing different half objects either side of the midline, to observe biases in cognitive activities of the hemispheres induced by what a commissurotomy patient intended to do, or by what he or she had been told to think about (Levy and Trevarthen 1976). They called the motive sets that were capable of turning on or off one or other hemispheric cognitive mechanism, sometimes independently of the different cognitive aptitudes on the two sides, 'metacontrol.' Similar habitual arousal biases in normal subjects cause individual differences in cognitive aptitudes.

3. *Theoretical and Philosophical Implications*

Commissurotomy research stimulated both the neuropsychological investigation of effects of unilateral brain injury, and tests of normal perceptual, cognitive, and motoric asymmetries. The findings have been invoked to explain why children with similar opportunities for learning may be different in educational performance, and why adults show different intellectual aptitudes and job preferences. It is likely that hemispheric biases in cognition and intellectual differences between persons are products of inherent styles in purposes and emotions, as well as of different experiences and opportunities for practice and for communication with others.

In the normal brain the hemispheres work in tight partnership. The intuitive response to experience and the evocation of imagery linked to phenomenal reality by metaphor, on the one hand, and verbal analysis and prescription of aesthetic judgments, on the other, are two natural brain systems that develop as complements in the making and communicating of language, technology and art. There are large differences between individuals. Findings with commissurotomy patients have been used to support theories of 'modular intelligence' derived from neuropsychological and cognitive science fields and attempts have been made to apply these theories to evolutionary changes in hominid behavior and the different kinds of cognitive processing inferred. However, such models of the mind are incomplete if they do not incorporate explanations of the motivations that generate both action and awareness, and the communicable emotions that evaluate them.

Cognitive operations resist efforts to locate them in parts of the brain. The skills, concepts and memories of language are stored over wide areas. Parallel-distributed processes contribute to the comprehension of language, as for facial recognition, spatial awareness and categorical understanding of objects, or for executive planning and motor sequencing. The development of cortical units involved in all these functions depends on associative cortico-cortical links, both within each hemisphere and through the corpus callosum. These supplement equally massive connections to and from cell populations beneath the cortex.

A majority of humans are 'right-handed,' and have been since Neolithic times, preferring to take conscious control in the right hand, especially for communicating by gesture and for carefully directing implements. About 15 percent prefer the left hand. Most of us tend to move the right half of our mouths more, or earlier, in speaking, and look right as we speak. These elaborated learned skills originate in asymmetries implanted in subcortical systems before birth.

It has been clear for more than 100 years that language functions are more strongly represented in the left hemisphere. Right hemisphere lesions selectively impair object and event recognition by sight or hearing and may have devastating effect on the capacity to recognize who another person is and what their emotion may be. Right posterior lesions can also weaken a person's discrimination of their own expression of feeling, and lower self-awareness generally. The cognitive and performance functions of the right half of the brain are important to a person's cultural life in a community, and to the acquisition of many skills that language may find hard to describe, and they serve to support the language-mediating functions in the left hemisphere.

There has been much speculation about how recurring asymmetries in works of art might be related to the anatomy of the brain, and our common brain asymmetry does appear to have been unknowingly exploited by many painters to generate aesthetic effects. There is a school of art teachers who draw on split-brain research to guide pupils to make stronger use of the right hemisphere, claiming that this generates more dynamic, coherent and aesthetically pleasing forms, and some require right-handers to sketch unthinkingly with their left hands. We have to learn how to talk about what is beautiful in art, and it is

inherently difficult to recall what we say. Language offers a powerful tool for introspecting, for planning actions and for manipulating information in 'phenomenal absence' from its source, but it is limited in representational imagination. It is particularly difficult to translate back from word to picture.

The work with commissurotomy patients convinced Sperry that brain-generated awareness and evaluation have a determining role over the experience obtained by learning. He concluded that science has to give consciousness an interactive, causal role in brain function. Subjective mental states explain conscious behavior and its changes, and determine what a person is and does. This view gives the higher 'macro,' mental, vital and social forces equal importance, in scientific explanations of life, with physics and chemistry. Sperry's thinking about human consciousness and the importance of values and emotion is summarized in *Nobel Prize Conversations* (Sperry et al. 1985).

C. Trevarthen

Sport and Exercise Psychology: Overview

Though the beginnings of sport psychological research can be traced back to the end of the nineteenth century it was not before the sixties that sport psychology emerged as an important and recognized academic and applied discipline (cf. Singer et al. 1993, ch. 1). The foundation of the International Society of Sport Psychology (ISSP) in 1965 and of several national organizations in Europe and in North America mark this period as the start of systematic scientific research and practice in sport psychology. Due to its increasing importance after World War II a systematic scientific research and support of elite sport gained significance. It became obvious that psychological processes were important aspects of athletic peak performance. Therefore, sport psychology was in this period mainly concerned with research on elite athletes and on performance enhancement in competitive sport. A distinction between the academic or research-oriented discipline of sport psychology and the discipline of applied sport psychology emerged in the 1980s, when not only the Association for the Advancement of Applied Sport Psychology (AAASP) was formed in 1985, but when also more and more books and journals were published worldwide that were dedicated to helping elite athletes reach their full potential. At the beginning of the twenty-first century it seems clear that academic and applied sport psychology are interdependent and profit from each other. Scientifically based methods of intervention are used in applied settings and research is stimulated by suggestions from practitioners.

During the 1980s another important development emerged. More and more researchers became involved in exercise psychology. In contrast to sport psychology that is focused on performance enhancement and competitive sports, exercise psychology is concerned with psychological aspects of primarily noncompetitive leisure, fitness, and health-oriented physical activity. This development can be nicely seen in the renaming of the *Journal of Sport Psychology*, first published in 1979, into the *Journal of Sport and Exercise Psychology* in 1988. Sport and exercise psychology, as it is called nowadays, deals with the psychological factors that influence sport performance and exercise behavior, including motor learning and motor development, as well as with the impact of sport and exercise on psychological growth and development, like personality, health, and well-being. The present overview will focus on individual, social, and motivational influences on sport and exercise behavior as well as on short- and long-term effects of sport and exercise. The topics of performance enhancement and of developmental sport psychology are dealt with in several other articles (see *Sport Psychology: Performance Enhancement*; *Developmental Sport Psychology*).

1. *Individual, Social, and Motivational Influences on Sport and Exercise Behavior*

1.1 *Individual Determinants of Sport and Exercise*

Research on personality differences in sport was greatly influenced by the paradigms of differential psychology. The trait approach was most popular until the 1970s. Numerous studies looked for differences in personality variables between athletes and nonathletes as well as between athletes of different performance levels. Talent detection via personality tests and performance enhancement due to personality training were the main impetus of this line of research. Taken together the results are rather inconclusive and show only correlational but no causal relationships. There were several methodological problems leading to these disappointing findings, like lacking adaptation to the sports context of the scales used and suboptimal research designs with respect to causal conclusions. Even the well-known finding from the 1960s showing a healthier personality profile of successful elite athletes than of nonathletes did not prove valid in the long run (Rowley et al. 1995). The interactional approach that followed is more promising and is still popular. Scales were developed within the sports context that differ between state and trait aspects of respective variables like, for instance, competitive anxiety, sport confidence, or cognitive strategies. Personality research in sport at the beginning of the twenty-first century is more concerned with either performance enhancement in sport or with effects of exercise on personality variables like, for instance, self-esteem (cf. Sect. 2.2).

1.2 *Social Processes in Sport and Exercise*

The beginnings of research on productivity in sport teams and about spectators' influence on performance can be traced back to the end of the nineteenth

century. Sport and exercise are often performed in groups or teams, and therefore social processes are deemed highly significant (Carron and Hausenblas 1998). Team cohesion, leadership, and aspects of group composition on individual and group outcomes are the most important topics. Whereas in the beginning cohesion was regarded as interpersonal attraction between team members, i.e., social cohesion, at the beginning of the twenty-first century cohesion in sport teams is conceptualized and assessed as social and task cohesion. The positive relationship of group cohesion and performance has been well-documented for sport teams and is mainly based on task cohesion. This relationship is quite robust, and exists irrespective of the group task. For example, highly cohesive handball, rowing, or golf teams alike are more successful than low cohesive teams. Less is known about the causal paths of the relationship. There is convincing evidence that success fosters cohesion more than vice versa (Mullen and Copper 1994). Looking at the relationship of cohesion and adherence to sport and exercise reliable differences can be found between dropouts perceiving a lower cohesion and adherers perceiving a higher coherence in exercise groups and in sport teams. Perceived high cohesion may lead to more satisfaction of the group members and their overall attraction to the group, whereas perceived low cohesion reduces the motivation to stay in the group. This result is of high importance for any setting, be it exercise, recreational, or competitive sport.

The predominant approaches to leadership behavior of coaches in sport are the mediational model of Smoll and Smith (1989) and the multidimensional model of Chelladurai (see Chelladurai and Riemer 1998). The mediational model was developed in youth sport and postulates that the effects of the coaches' behaviors are mediated by the meaning that players attribute to them. Smoll and Smith (1989) could demonstrate that coaches who give general technical instruction, who prefer positive feedback, and who give mistake-contingent instruction and encouragement are evaluated most highly by their athletes. Training in these skills led to more positive evaluation of youth sport coaches, to fewer dropouts from their groups, and to an increase in the athletes' self-esteem and in team cohesion compared to nontrained youth sport coaches. However, the coaches' behaviors had no direct impact on the athletes' performance.

The multidimensional model of leadership (MDL) by Packianathan Chelladurai postulates that individual and group outcomes (satisfaction and performance) are dependent on the congruence among required, actual, and preferred leader behavior. Preferred and perceived leader behavior is measured with a five-dimensional questionnaire called the Leadership Scale for Sports (LSS). This instrument has been tested and validated in quite a few studies with athletes and coaches in various sport contexts and countries, in North America, Asia, and Europe. Research was primarily focused on the perception of coach behavior by adult and high-level athletes. The relationship to outcome measures is inconclusive. Future research has to focus on this relationship between coaches' behavior and outcome measures such as performance and satisfaction in the group.

1.3 Motivation

Considering motivation as a term for explaining intensity and direction of an individual's effort, motivation research in the field of sport and exercise is on the one hand concerned with explaining why and how certain people are attracted to which kind of sport or exercise and why others are not. On the other hand strategies to enhance motivation, like mastery training, attributional retraining, or goal setting have been developed and tested (Roberts 1992). With regard to the first issue, achievement and competition have been a traditional focus of motivation research in sport. Three theoretical perspectives were most influential: need achievement theory, attribution theory and social-cognitive approaches, mainly goal orientation theory. Starting with need achievement theory in the 1950s and 1960s, high and low achievers in sport were found to differ in their dispositional orientations (motive to achieve success or to avoid failure), their task choice, and their emotional reactions to success and failure, as was predicted by the theory.

The attributional model of achievement motivation of Bernard Weiner led to a considerable number of studies since the 1970s (Singer et al. 1993, ch. 19). They showed that the initial attributional framework of ability, task, effort, and luck attributions needs an extension to more sport specific attributions like opponents' quality or audience support. Self-serving biases in attributions were also found in the sports context, whereas gender differences were rarely found. Reattribution training for low achievers was successfully applied in sport settings like physical education, elite sport, and exercise. Another important topic was the relationship of attributions and emotions in sport. Though an attributional model would predict that emotions after success and failure depend on attributions, emotions of athletes seem to depend more on outcome than on attributions (Willimczik and Rethorst 1995).

Since the 1980s social cognitive approaches have gained attention in sport psychology. For instance, the goal perspective approach of John Nicholls was adapted to sport settings by Joan Duda and tested in numerous studies (cf. Duda 1992). Goal perspective theory assumes that in achievement contexts like sport and exercise individuals are motivated because they want to demonstrate ability or competence. This can be done with two types of goal, which are conceptualized as dispositions. The ego or outcome orientation is easily aroused in competitive situations like

sport. Success or failure is dependent on the performance of others and perceptions of ability are referenced to the ability of others. In contrast, the task goal or mastery goal focuses on individual comparison. Perceptions of ability are self-referenced. Task orientation is typically aroused in situations where the focus is on learning or mastery. Results show that task orientation is correlated with intrinsic motivation, with more enjoyment in sport, with persistence in the face of failure, and with the selection of moderately difficult tasks. Task-oriented individuals are more like high achievers. In contrast, ego-oriented individuals, especially when low in perceived competence, are more at risk to drop out of sports, they are more prone to develop fear of failure, and they emphasize fairness in sport less than task-oriented individuals. Fostering task orientation more than ego orientation is therefore highly recommended. Goal perspective theory has also focused on socialization contexts and their impact on the development of one or the other kind of goal. It is assumed that the socialization context induces a motivational climate where either competition or mastery is emphasized. A competitive climate may enhance ego orientation, whereas a mastery climate enhances task orientation.

Though achievement motivation is clearly important it is not the sole reason for sport and exercise participation. For many youngsters and adults affiliation motivation, pleasure seeking, physical challenge, adventure, and risk motivation, as well as the wish to shape an attractive body and to keep one's 'fitness' by means of exercise play an equally or even more important role. Sport and exercise become integrated into a person's lifestyle, and the wish to express a certain lifestyle is an important motivation to practice exercise and sport. A lifestyle theoretical perspective in sport and exercise psychology (Dishman 1994, Abele et al. 1997) posits that sport is an important aspect of a person's general way of living. It is a means both to pursue different motives (affiliation, achievement, risk, fun, challenge, health), and to express certain attitudes (toward youth, health, physical attractiveness) at the same time.

With increasing knowledge about the physical and mental health benefits of exercise (see Sect. 2) psychology becomes increasingly concerned with exercise adherence (Dishman 1994, Abele et al. 1997). Knowing that more than half of the adults in Western countries do not exercise enough from a health-oriented point of view and knowing that more than half of the participants who have started an exercise program for health reasons quit it again after a short time points to the importance of research on the determinants of exercise adherence and on interventions aimed at enhancing adherence and preventing dropout. Whereas early models have stated that perceived vulnerability or health protection motivation are most important, research has shown that perceived vulnerability does not lead to long-term adherence. Rather positive factors like exercise-specific self-efficacy beliefs, social support in the person's immediate environment, perceived group cohesion (see Sect. 1.2), and a suitable program and program climate are important. Participation motivation has to be understood not as a state but rather as a process undergoing at least three phases (inactivity, intention to participate and begin participation, adherence) that need specific motivational support.

2. *Short- and Long-term Effects of Sport and Exercise*

2.1 *Exercise and Physical Health*

Because physical health and psychological well-being are interrelated, it is appropriate to briefly consider the effects of sport and exercise on physical health (cf. Abele et al. 1997). These may be differentiated into cardiovascular (reduction of heart rate, decrease of diastolic blood pressure, improvement of blood circulation); hemodynamic (improvement of the blood flow characteristics); metabolic (stronger and more efficient musculature, improvement of the bone substance); and endocrinological effects (increase of catecholamines and cortisol, etc.). Immunological effects also exist; they are, however, only understood with respect to elite sports, but not yet with respect to exercise. Another distinction relates to exercise-induced changes in endurance, vigor, and coordination skills. All these changes also have an impact on psychological well-being.

However, besides studying the beneficial effects of sport and exercise on physical and psychological health, sport and exercise psychology is also concerned with high risk sports, the determinants and their possibly dangerous effects.

2.2 *Exercise and Psychological Well-being*

Studies on exercise and psychological well-being have been conducted both with nonclinical and with clinical groups. Questions addressed were the role of exercise in the reduction of anxiety and depression, exercise and mood changes, positive and negative addiction to exercise, and the relation among exercise, personality changes, and cognitive functioning. Usually the impact of aerobic exercise like walking or running or fitness training, but sometimes also the impact of more competitive games like tennis, volleyball, or soccer, was analyzed. Several studies show that participants experience both short-term anxiety reduction and long-term depression reduction if they exercise regularly at least twice a week and for a time period of not less than six weeks. The longer they continue the more these negative psychological states are reduced. Run-

ning, for instance, can be an inexpensive, time-efficient adjunct to traditional psychotherapies (Weinberg and Gould 1999).

Nonclinical participants usually show the 'iceberg profile,' which means that compared to their preexercise mood their postexercise mood is characterized by elevated vigor, activity, and elation and reduced levels of anxiety, depression, confusion, fatigue, and anger. It has been argued that fitness activities versus sport games may serve different functions in the regulation of mood. Fitness activities may primarily lead to equilibration effects. A negatively experienced tension state in advance of the exercise is transformed into a positively experienced relaxation state after it. More competitive games, on the other hand, may lead to disequilibration effects. A positively experienced 'prestart' tension state is transformed into a positively experienced postgame relaxation state. Both short-term equilibration and disequilibration effects serve the participants' long-term well-being (Abele and Brehm 1993).

The causes of these mood changes are multifaceted and relate both to biophysiological processes (hormonal changes, increased blood circulation, muscle strengthening, and relaxation; see above) and to psychological processes. Important psychological processes may be distraction and time-out. During sport and exercise the participant is distracted from stress and urgent problems, and the time-out may lead to free-floating attention and to remote associations which, in turn, may help to find new and creative problem-solving strategies. Exercise can also become an addiction. As a positive addiction it is a regular activity integrated as one important and valuable aspect into the person's life. As a negative addiction it gradually becomes overwhelming and the person cannot stop doing it at the cost of neglecting other important life tasks. Negative exercise addiction needs psychological help and intervention.

Personality changes and changes in cognitive functioning have also been studied. Physical self-concept and self-esteem are positively influenced by regular exercise (Alfermann and Stoll 2000, Sonstroem 1997). It has also been posited that cognitive functioning may be enhanced by physical exercise. Though the idea that motor development is an important determinant of intellectual development in childhood is appealing, the research findings in adulthood show a correlational but not necessarily a causal relationship between exercise and cognitive functioning (Etnier et al. 1997).

3. Conclusions

Since the early 1960s sport and exercise psychology has undergone a rapid development both with respect to its theories and methods and with respect to its aims and topics. Regarding theoretical models, instead of directly taking over models from general psychology sport and exercise psychology now adapts and modifies these models contingent to the sport context and also builds new and more specific models. Such a context-specificity of theory construction leads to more specific hypotheses and may also help to refine more general theoretical models in psychology. Regarding methodological advances, similar developments can be observed. The measures used become more refined and more specific to the respective context. The general methodological approaches both in experimental and in field research become more refined.

Most important, sport and exercise psychology has broadened its topics and perspective from a predominant concern with performance of elite athletes to a concern with sport and exercise in everyday life, too. The psychological analysis of sport and exercise in schools, in recreational settings, in health settings, and in further sports related institutions has become as important as the analysis of psychological processes in elite sports. Exercise adherence as a topic, for instance, becomes more relevant the more people acquire health problems because of lack of exercise. Research on sports and lifestyle, as another example, must receive increased attention, not only because 'trend sports' are an important economic factor in Western societies, but also because people on average have more leisure time, and sport is one of the most important leisure activities. Research on psychological processes in physical education as a school subject, as a final example, may be directed at the impact of sport and exercise in schools on an individual's lifetime exercise behavior, as well as on its impact on tension reduction and aggressive behaviors in schools.

Sport, Anthropology of

Theory production in anthropology has been characterized by the absence of sport as a field of analysis for understanding rituals, complex processes of identity construction, *rites de passage*, and bodily performances. For instance, Mauss' (1935) early piece on body techniques does not mention sport arenas and performances as privileged loci for the development of an anthropology of the body. Several reasons can be advanced as an explanation for this inattention to sport. The main explanation lies perhaps in the accepted idea that sports and games, because they produce asymmetry between winners and losers, flourish only in competitive industrial societies. In rituals, asymmetry is postulated in advance—initiated and uninitiated or sacred and profane—and the 'game' consists in making all the participants pass to the winning side by means of ritual participation (Lévi-Strauss 1966, p. 32). Therefore, almost by definition, anthropology, as the science of the nonmodern and 'primitive,' has in the past excluded the study of sports and competitive games because they were correctly perceived as central features of modernity.

The attention to the importance of sport in social theory is to a large extent related to the influence of the late Norbert Elias. In his historical sociological approach, sport was defined as a key area in the civilizing process of European societies. This process was characterized by continuous state control of the legitimate use of force, the development of social organizations to reduce open conflict among groups, and the elaboration of codes for social behavior oriented towards the exercise of individual self-control. Sport became a typical activity of leisure that, historically, fulfilled some of the required functions for the consolidation of the civilizing process. Clearly the exercise of self-control is central to sport. For Elias, one of the essential problems of many sports is how to reconcile two contradictory functions: 'the pleasurable de-controlling of human feelings and the full evocation of enjoyable excitement on the one hand, and on the other the maintenance of a set of checks to keep the pleasantly de-controlled emotions under control' (Elias 1986, p. 49). Modern sport is regulated by rules that assure equality among the contenders, make possible the maximization of inner pleasures and the relaxation of individual tensions, and contain the exercise of physical violence. Through Elias, sport becomes a privileged field for the analysis of individual and social tensions in modern societies.

In the critical tradition of social theory, best represented by Bourdieu (1984), the practice of sports has been seen as an efficient state, and bourgeois, mechanism to indoctrinate youth with values of sexism, nationalism, fanaticism, irrational violence, the cult of performance and competition, the cult of idols, and the uncritical acceptance of the values of capitalism. Bourdieu maintains that one of the perverse effects of sport is that it transforms the spectators—the consumers of the performances of the athletes—into a caricature of militancy. This is because their participation is imaginary, and their knowledge has been appropriated by the sports coaches, journalists, and bureaucrats (Bourdieu 1984, p. 185).

It is clear that the anthropological perspective of Lévi-Strauss, the critical tradition of social theory of Bourdieu, and the historical sociology of Elias have something in common: sport is perceived as an important field of analysis for achieving a better understanding of the appropriate or contradictory functioning of modern societies. In the arena of sport, individual self-fulfillment is related to games producing winners and losers, to exalted nationalism in an age of international competition, to passivity and ideological domination, and sometimes to an abnormal quest for excitement and violence. No one will deny that sport is associated with these practices and values, but recent anthropological research has shown that it is much more.

In the new type of research, the key assumption is that sport is a ritual and a game at the same time, and

as such a cultural construction that makes symbolic communication among its participants possible. The content of the communication may vary according to the degree of formality, rigidity, concentration of meaning, and redundancy. However, the ritual is also a performance in the sense that saying something is also doing something; hence ritual action makes possible a connection between the meanings and values mobilized by the participants. In every ritual, various types of participants can be distinguished: the experts in knowledge, the central participants or players, and the peripheral participants or audience.

This approximation permits the consideration of a range of discourses, practices, and identities produced by various kinds of participants. A historical analysis of the impact of sports situates these narratives and practices in specific periods and places, and enables us to follow their transformations. The empirical analysis of sport can contribute to general theories of the meaning of sport in identity construction or of the significance of bodily exploits for expanding the scope of theories of ritual and cultural performances. MacAloon's (1984) analysis of spectacle, ritual, festival, and games in Olympic competitions exemplifies a longstanding anthropological concern with ritual. In this direction, the anthropological analysis of sport is not a reflection of society, but a means of reflecting on society. Sport, understood as a central and not marginal activity, is a fruitful entrance for capturing important cultural, historical, and social processes. Sports represent a complex space for the display of identities as well as an arena for challenging dominant social and moral codes, contrary to what Bourdieu sustained.

1. *Gender and Nationhood: Sports and Politics*

It has been argued that a nation is an 'imagined political community': its members share a sovereign boundary and have a strong feeling of communion. Hence, the ideology of nationalism should be integrated in social practices that can create an image of 'the people' having 'something' in common. DaMatta (1982) has argued that Brazil is a society articulated by the sharp division between the 'home' and the 'street,' and between the family—a system of hierarchical social relations and persons—and the market and free individuals. The role of soccer is privileged because the personalized social world of the home and the impersonal universe of the street are combined in a public ritual. Impersonal rules regulating the game make possible the expression of individual qualities: 'soccer, in the Brazilian society, is a source of individualization … much more than an instrument of collectivization at the personal level' (DaMatta 1982, p. 27). The male players escape from the fate of class or race and construct their own successful biographies in an open arena. Soccer makes it possible to experience equality and freedom, important values of nationhood, in hierarchical contexts.

In order to triumph, soccer players (like *samba* dancers) must have *jogo de cintura*, the capacity to use the body to provoke confusion and fascination in the public and in their adversaries. The European identification of a Brazilian style of playing relating football and *samba*, manifested in the expression '*samba*-football,' is therefore not an arbitrary creation: it is rooted in Brazilian self-imagery (Leite Lopes 1997). This identification establishes important cultural differences—the existence and development of European styles of playing are not linked to music and dance.

The case of Brazil is not unique. In Cuba the ritual of playing baseball, the national sport, has been associated with dancing: 'each baseball match culminated in a magnificent dinner and dancing, for which orchestras were hired for playing *danzones*' (González Echeverría 1994, p. 74). As in the case of soccer, baseball was perceived as a democratic and modern game that made it possible for young male players of modest origins to experience social mobility. In Argentina, the arrival in the 1900s of millions of European immigrants in Buenos Aires and its hinterlands made possible the rapid expansion of football and tango. Leisure was transformed; the practice of different sports was accompanied by the crystallization of the choreography of tango and the formation of new orchestras. Tango was first exported to Europe in the 1910s, then to the rest of Latin America and North America, becoming a 'universal' dance to express eroticism and modernity. Argentinian soccer players were exported to Europe as early as in the 1920s. Argentinian performing bodies—dancers, musicians, and soccer players—became highly visible in the world arena of leisure (Archetti 1999).

It is interesting that both baseball and soccer, two sports originating outside the Latin American countries, were integrated into the construction of the 'national' masculinity as cricket in the West Indies, Pakistan, or India. Rules, esthetics, and style in cricket have been transformed into something that is no longer typically English because the hegemonic systems of values its practice evokes is questioned (Appadurai 1995). The rich ethnography of Alter (1992) shows that wrestling as a genuine Indian sport provides a context within which concerns with fitness, health, and strength articulate with various forms of nationalism. In the vision of many wrestlers, the various forms of self-discipline associated with the sport provide the moral coordinates around which a new India is imagined and embodied. Thus, cricket and wrestling enter into a complex relation between modernity, masculinity, decolonization, and nationalism.

The practice of sports is 'gendered' and should be understood as expressing and articulating gender

differences. MacClancy's (1996) analysis of female bullfighting in Spain is a case in point, showing how anthropologists have unproblematically accepted bullfighting as exclusively male, despite the fact that for over two centuries women have been bullfighters, taking the same risk and bearing the same scars as the male *matadores*. Brownell (1995) has demonstrated that the international success of Chinese sportswomen has allowed them to represent the nation in a way that is unlike Western women's representations of their nations. The ability to endure pain and sacrifice as feminine values is part of the national discourse transforming Chinese women into national models. Sánchez León (1993) has analyzed the gendered meaning of the two most popular sports in Peru. Football, a male practice, is related to freedom and improvisation, whereas volleyball, a female practice, displays the sense of responsibility and discipline of Peruvian women.

2. *The Production and Adoration of the Heroes*

The world of sport heroes is a world of creative enchantments because momentarily, like flashes of intense light, athletes become mythical icons representing mastery over mortality. The heroic sports figures must be seen in their cultural context in order to understand their communal impact (Holt et al. 1996). Oriard (1993) has shown that the athlete-hero in America embodies the 'land of opportunity' and is therefore the most attractive self-made man. The hero sustains the American Dream, personifies the democratic ideal of open accessibility to prestige and allows all citizens to share his glory. In relation to American football, Oriard has demonstrated that in the historical production of a restricted heroic masculinity certain competing qualities were at stake. On the one side, simple, unambiguous physical force was emphasized—what he calls an antimodern value. On the other side, the required 'manly' qualities were temperance, patience, self-denial, and self-control—which lie behind the modern and technocratic aspects of modernity (Oriard 1993, p. 192). Oriard asserts that football's cultural power derived in large part from this collision of the modern and the antimodern, one aspect of which was this dialectical embrace of competing notions of manliness.

In many cases, sporting heroes are a source of collective pride in both national and supranational settings. The case of Maradona, an Argentinian soccer player, is a clear illustration of 'transnational' heroism. He was like a God-like hero in Naples while he was playing for the Naples Football Club and in Argentina while playing on the national team. His heroism was related to mythological figures in the respective local traditions: in Naples he was identified with the mythical figure of the *scugnizzo* and in Argentina with the *pibe*. These prototypes have something in common: they are human beings endowed with grace, elegance, creativity, and freedom (Archetti 1997). The cult of sport heroes provides a social model to perceive paradoxes and dramas in society, and to recognize and question key values. When Garrincha, the extraordinary right winger of the Brazilian soccer team which won the World Cup in 1958 and 1962, died an alcoholic and in extreme poverty in 1983, the entire nation was shocked. His funeral became a part of national history. The crowds following his casket in silence in the streets of Rio de Janeiro were participants in a social drama, showing the most profound respect to a son of the working class who had suffered from injustice, maladjustment, and prejudice. The nation wondered how it had been possible to abandon so heartlessly the player defined as 'the joy of the people' (Leite Lopes and Maresca 1992).

3. *Engaged Audiences and Supporters*

Bourdieu's image of passive supporters and alienated audiences has been contradicted by ethnographic findings. Neves Flores (1982) has demonstrated that in the arena of soccer the supporters 'narrate' social stories and even produce what he calls 'ideologies of transformation.' The popular clubs, such as Flamengo in Rio de Janeiro and Corinthias in São Paulo, are seen as courageous, with lots of stamina and will to win. The 'elite' clubs, such as Fluminense in Rio de Janeiro, are *machista* and show discipline and fair play. The clubs where sons of immigrants are most represented are usually perceived as less national than the others. Neves Flores argues that the organized activity of the supporters displays the class and ethnic divisions in society and, in this sense, act against the dominant values in Brazilian society of national equality, populist integration, and political paternalism. Bromberger (1995) has shown that the narrative of the supporters of AC Torino, a soccer club from northern Italy, emphasizes local suffering and extreme loyalty, while the narrative of the supporters of Juventus, the 'other' club in the city, is based on continuous victory, international accomplishments, discipline, and efficiency. The history of Juventus is at the same time the history of Fiat, the Italian company owning it. The fans assert, in a creative way, the 'right' to identity and difference in modern societies. With his rich ethnography, Armstrong (1998) challenges the assumption that violence is wholly central to the match-day experience of soccer supporters in England. Rather, the creation of identity is at the roots of hooliganism, with all the cultural values and rituals, codes of honor and shame, and communal patterns of behavior and consumption that accompany it.

Klein (1991) has argued that baseball is a privileged field for the analysis of cultural hegemony and resistance in the Dominican Republic. Dominican supporters use the very form and symbol of American

domination—baseball—to promote resistance. Adopting the sport of baseball has also influenced cultural movements. 'Dominicans infused the game with their own raucous, melodramatic style, marked by a highly individualistic way of playing, and easy-going attitude toward the game both on the field and on the stands, music and dancing, and crowds by turn temperamental and tranquil' (Klein 1991, p. 152). Klein has shown something unusual in an era of global influences: working-class supporters in the Dominican Republic prefer wearing the shirts of national clubs rather than American ones.

Sport, Geography of

The sports central to geography's concern are institutionalized contests, frequently professional in their highest form and attractive to spectators, involving the use of vigorous physical exertion between individuals or teams of human beings. The geography of sport is a recent development, largely cultural-historical in approach. It maps and explains the changing distribution patterns of individual sports and packages of national, major, and minor sports at levels ranging from the world to district (Bale 1982). It relates these changes to the character and form of stadiums and landscape ensembles. It also deals with the quality of theater—interactions between players and spectators—in different types of stadiums (Bowden 1995). New directions of research focus on sport in the formation of working-class culture, the effects of globalization and televised sports on the distribution of sports and the map of rapidly emerging women's sports.

1. Modern Sports: Origins and Dispersals

The distribution of modern sports in the twentieth century is explained in a model of (a) primary origins in southeast England; (b) dispersal to the British Isles, Anglo-America, and the British Empire; (c) secondary origins in northern Britain and in northeastern Anglo-America; and (d) dispersal from the latter mainly to the rest of North America and the Caribbean Basin, and from Britain to the rest of the world.

The birthplace of modern sports in Metropolitan England is attributed by some to the development of the mathematical-empirical world view after 1660. Marxists correlate sport with the birth of industrial

capitalism in the 1700s (Guttmann 1994, Holt 1989). Others point to Thomas Hughes's *Tom Brown's Schooldays* (1857) which glorified Thomas Arnold's education system at Rugby School, but maintained that moral development and character training inculcated by cricket and football outranked intellect in the curriculum.

Hughes's transformation of Arnold, abetted by the ruling classes, inspired the cult of athleticism in the elite schools and universities which built principally on the first modern game—cricket—codified by the aristocracy in the eighteenth century (see James 1963). It was joined in the public schools in the middle third of the nineteenth century by hockey and athletics and by the Rugby School and dribbling games. Neither of these football games were played after the 1870s, but seven modern forms of football developed from them and one of these forms of football has become the major team sport played by men in at least one season in practically every country in the world, and by women in most First World countries and in some Third World countries. Research in the 1990s goes far to explain the diffusion and distribution of the different types of football 1870–2001 as a classic case in the geography of sport.

2. *Football Exceptions to Soccer's World Dominance*

Modern association football originated in England. By the 1880s it was the national game in England and Scotland, and diffused thereafter to become the most popular team sport throughout the world. The exceptions are seven English-speaking countries: Wales and Ireland, and five countries settled substantially from Britain—USA, Canada, Australia, South Africa, and New Zealand. The explanation lies in (a) the preference of the majority of English public schools for the more manly rugby compared to the dribbling game played by the minority, and its consequence: rugby's greater popularity among the upper and middle classes in Britain and in a majority of regions in the British Isles 1848–78, and (b) a developing English upper and middle class prejudice against the dribbling game (association football after 1863), increasingly associated in the 1870s with working class industrial regions (Murray 1994, Russell 1997).

All of this ensured that the predominantly middle class colonists and their public-school and Oxbridge-educated leaders in New Zealand and Australia and in English-speaking Canada and South Africa in this midcentury period chose to carry with them Britain's most popular football game of the time—rugby (Holt 1989). That they did so to the exclusion of dribbling soccer is explained by Foster's law of simplification in which in the survival phase of early settlement, only one of many cultural forms in the diverse homeland is chosen by colonists, usually the form found in the region whence came most of the first settlers: rugby in southern England before 1878 (see Foster 1960).

The Rugby School game—the rugby current before the rules regularization banning the violent 'hacking' by the Rugby Union in 1871—provided the framework for the nationalist forms of football: Australian Rules played in Australia outside Queensland and New South Wales (Hibbins 1992) and Canadian and American football derived from the Harvard and McGill universities' encounters in 1874.

The peaks of British settlement occurred in eastern Australia, New Zealand, and South Africa late enough that the Rugby Union code became established there in the 1870s. This was challenged in the 1900s in eastern Australia and New Zealand by the new 13-a-side Rugby League professional code developed in northern England.

Before 1880 rugby was preferred over dribbling soccer in Ireland and Wales. The continued preference for rugby over the new passing soccer after 1880 results from cultural nationalism. In Ireland the Gaelic Athletic Association modernized Gaelic football to be the national game, and its ban on English games worked selectively against 'new' soccer relative to well-established rugby. In Wales the under-the-table payment of Welsh 'amateurs' pre-empted professional soccer's attractiveness to Welsh athletes and gave them the chance to beat the middle class English at their own game (Murray 1994, Holt 1989, Wagg 1995).

In the 1860s and 1870s in Argentina, Belgium, Sweden, and France both rugby and soccer were adopted. The attractiveness of the new soccer in the early 1880s relegated rugby thereafter to the status of a minor sport in Argentina, and replaced it in Sweden and Belgium. But in France rugby union parried the counterattack of new soccer after 1880, as did rugby league in southwest France after 1900, and both contributed to a long delay in soccer's elevation as the national team sport (Guttmann 1994, LaBlanc and Henshaw 1994).

3. *Diffusion of Soccer: The World's Sport*

The football adopted in every other country in the world after 1880 was soccer. The explanation for this lies in the revolutionary transformation of soccer from the dribbling game played by unspecialized players into a simple game of high skill emphasizing accurate long- and short-ball passing, wing-play, and the crossing of the ball to forwards specialized in shooting and heading, and positional specialization. The revolution began in northern Britain, produced two professional leagues (England 1888; Scotland 1891) and swept through Great Britain, leaving rugby union more popular only in southwest England and the

Scottish border, marginal rural regions with small towns and no large cities—and in south Wales (Russell 1997, Holt 1989, Murray 1994).

4. *Diffusion and Adoption*

During the first period of diffusion of soccer to independent countries, 1890–1940, the adoption of soccer in each country followed a standard pattern. A gradual transmission of the game to young members of the local elite from: (a) British resident businessmen and agents of trading houses in the large port(s); (b) members of the British colony in the capital; (c) expatriate British teachers in schools and colleges for British residents and the local elite; and (d) elite students returning with a soccer ball from educational sojourns in Britain. Often towards the end of this gradual phase of adoption and formation of teams by denizens, members of the middle class picked up the game from the elite and also in the large inland industrial and mining towns from British mining and railway engineers and textile mill owners and skilled workers. The initial 15–20 year phase of gradual adoption by the elite was followed by a filtering-down process and an explosive 10–15 years of rapid adoption by the middle and working classes in urban areas. The three phases of the S-curve pattern of the diffusion of innovations are completed with the 10–15 year slackening of the rate of adoption by the laggards: the market-townsmen and agricultural workers/peasants of the thinly populated countryside (Guttmann 1994, Russell 1997).

The critical signifier of the establishment of soccer as a country's major form of football (national team sport) is the date of creation by the national football association of the national club championship (data from LaBlanc and Henshaw 1994, Wagg 1995). The plotting of these dates of founding of national championships establishes three discrete models of the spread of soccer worldwide, variants of the classic patterns of spatial waves and S-curve time-series of diffusion (see Rogers 1983) in men's soccer to: (a) 35 independent nations 1890–1945, peaking in the 1920s; (b) 65 newly independent nations 1946–96, peaking in the 1960s; and, in women's soccer, to (c) 65 countries 1957–2000, peaking in the 1970s–1980s.

5. *Traditional Men's Soccer: Europe, the Middle East, and Latin America*

In the first diffusion-wave model, beachheads developed in Denmark, The Netherlands, Switzerland, Italy, and Argentina in the 1890s. In the 1900s the second wave pushed out to Norway–Sweden; Belgium–Germany; Austria–Hungary–Bohemia; Spain; Uruguay–Chile–Paraguay, and to a new beachhead in Mexico. The third wave of the 1910s, blocked in Europe by World War 1 and by continued Czarist and Ottoman imperial suppressions, broke only on the shores of Iceland, France, Portugal, Algeria–Morocco, Haiti, and Brazil. The fourth wave completed the conquest of the European outer margins (the three Baltic countries and Poland, Soviet Union, and three Balkan countries and Greece), swept into the Middle East and North Africa (Turkey, Israel/Palestine, Egypt, Tunisia), broke in northern Latin America (Bolivia–Peru–Ecuador–Colombia, Surinam, Costa Rica–Guatemala), and reached East Asia (Thailand, Japan/Korea). The last countries reached by the outer wave of the 1930s were Albania, El Salvador, and Honduras.

6. *Postcolonial Men's Soccer: Asia, Africa, and Islands*

Most of the countries that adopted modern soccer after 1945 were former colonies of European powers. Soccer was the team sport offered in missionary schools, in private schools mainly for Europeans, and to the local elite in the main cities. Mine-owners and railways used it as a means for social control of workers. Lack of investment by the colonial powers in the provision of social institutions for the vast majority ensured that the game did not spread widely beyond these two groups in the large towns. The filtering-down process often extended over 40 years before emergent nationalism and independence accelerated the process and united the masses behind national soccer teams.

Soccer was established as a national sport earliest in the former British, Dutch, and Belgian colonies because of soccer's earlier acceptance by the three colonial powers compared to France and Portugal and because Britain, Holland, and Belgium established the European national association/championship model in each colony's development. By contrast the imperial family model developed in the French and Portuguese colonies funneled the better colonial players into the French and Portuguese leagues thereby stunting the development of colonial ones.

Thus, in the post-World War II period the establishment of soccer as the national team sport took place first in the 1950s in the British colonies in the Mediterranean (Malta, Cyprus), North Africa (Ghana, Sudan), and East Asia (Burma, Malaysia), the Dutch colonies in the East and West Indies and in Congo–Kinshasa (formerly Belgian). Most of the 38 countries that formed national associations and club championships in an unprecedented decade of rapid establishment of soccer in the 1960s were the larger British Caribbean islands, former British colonies in eastern and southern Africa, and the coastal countries of Francophone Africa. In the long third phase of slackening adoption from 1970 onwards, the laggards were land-locked Francophone countries, war-torn

Angola and Mozambique, the smallest British Caribbean islands and island nations in the Atlantic, Indian, and Pacific oceans, their numbers boosted in the 1970s by the new Gulf States (Murray 1994, Wagg 1995).

7. *Postmodern Women's Soccer: The First World*

After decades of being rebuffed by national football associations and FIFA, women's soccer began its international phase of growth in the 1950s in its heartland—Germany and England—spreading slowly to seven neighboring European countries by 1969 when the English Football Association became the first to recognize women's soccer officially. The Women's Football Association founded there in 1971 was soon followed by other European national football associations, of which Germany's established the first national championship in 1974.

The European-only period of gradual adoption to 1969 gave way 1970–89 (with a prospective Women's World Cup in 1991) to an explosive adoption of women's soccer in another 40 countries, mainly in Europe and East Asia, but significantly in the new postmodern football cultures of Japan as well as USA, Canada, Australia, New Zealand, and South Africa where women are choosing soccer over the more physical and 'manly' forms of football favored by the majority of men. In the First World and in the northwest European heartland, until recently the unchallenged preserve of women's field hockey, it is the young middle class women of metropolitan suburbia with their greater freedom within the realms of lifestyle and leisure politics who dominate women's soccer. However, a small but significant minority of club and international players hail from working-class male strongholds (also a source of soccer-playing women in Brazil). Conspicuously under-represented on the world map of women's soccer are Latin American countries where working class men and macho values inhibit women's soccer. Absent are the countries of sub-Saharan Africa where female soccer is culturally proscribed, and those of Western Asia and North Africa where Muslims and Hindus demand sharp cultural divisions between male and female (Giulianotti 1999, LaBlanc and Henshaw 1994).

Sport, History of

1. *Two Definitions of 'Sport'*

The English word 'sport' is etymologically derived from the late Latin 'deportare.' Originally it meant 'to divert yourself,' 'have fun,' 'amuse yourself'—in short everything which you would do 'in sport' or 'for love.' In the narrow sense of the word it meant the hunt for 'game,' a semantic connection derived from mediaeval aristocratic practices, a term which is still used in English. Horse-racing was also described as 'sport' in early-modern times. The word was first taken into everyday English usage, however, in the mid-nineteenth century when new games and pastimes became popular amongst the middle classes. In this period 'sport' became an umbrella term for ball games (cricket, football, croquet, and hockey), martial arts (boxing, fencing, and wrestling, etc.), heterogeneous outdoor pastimes (boating, riding, cycling, skating, swimming, and mountain-climbing) as well as for so-called 'athletics' (running, jumping, javelin throwing). This list of disciplines can be found in a general article on English sporting life published in 1899 (Aflalo 1899). One hundred years later a sociological survey for the city of Hamburg came to the conclusion that there were more than 240 different sporting disciplines, from BMX-cycling, to bungee jumping, and free climbing on artificial mountain walls (Heinemann and Schubert 1994).

The increasing variety of games and pastimes can have different forms of organization (neighborhood and circles of friends, clubs, schools and universities, the armed forces, political parties, or the State) and types of income (admission charges, private sponsoring, public grants). Some disciplines are popular,

others are not. Some are followed with the support of modern mass media, others have retained a more private character. Nonetheless, these games and pastimes all have one common feature: they are competitive. Therefore, they encompass only a narrow understanding of the term 'sport.' For, in the course of the development of competitive sports into a mass phenomenon and their growing significance in education, the armed forces, the economy, and culture, there has been an increasing tendency in many languages to use the word 'sport' (or its international usage as in 'deporte' (Spanish), 'desporto' (Portuguese), 'spor' (Turkish), 'сПорт' (Russian)) also for noncompetitive activities and institutions, for which there are many other—and mostly more precise—terms. Amongst these may be counted gymnastics and physical education, dancing, forms of active tourism such as rafting, and even rehabilitation. In this broad usage 'sport' today has become a collective term for many and diverse expressions of the general physical culture of mankind, including 'dead' cultures like the physical culture of the ancient Orient or the ἀγών (agon) of the ancient Greeks. Both usages of the word 'sport' have given rise to different directions in the study of the history of sporting activity.

2. *Sport History as the History of the Physical Culture of Mankind*

The direction based on the broader usage of the word—'sport history' as the history of physical culture—is the older of the two. Amongst the founders of the discipline in this sense can be counted the chronicler of the Greek ἀγών Pausanius (c. 115–180), the Enlightenment educationalist Johann Christoph Friedrich GutsMuths (1759–1839) and the 'father of gymnastics' Friedrich Ludwig Jahn (1778–1852). Their nineteenth and twentieth century descendants were physical education teachers, club and association officials, doctors, hygiene experts, military officers, journalists, and writers who have researched themes like mediaeval bathing cultures, physical bearing in the Renaissance, or the history of their local gymnastic clubs.

The great majority of these 'amateurs' were, and still are, not professional historians, but 'amateurs' and part-time writers. Thus, they have little experience in dealing with sources, do not know how to arrange their results in a more comprehensive context, and tend to indulge in off-the-cuff philosophizing about allegedly anthropological constants in human physical activities. Methodical studies are of little interest to these scholars; indeed, a good deal of them used their research into sport history to legitimize their own political standpoint. This is particularly conspicuous in publications of the 1920s and 1930s when continental Europe aired conflicts between so-called 'bourgeois' and working-class sport associations; and in later writings between 1950 and 1970 which were influenced by cold-war ideologies. They often yielded more information about the political and moral values of the respective authors than about the subject that they have researched.

The largest fund of knowledge in the field of sport history, however, is produced by academics who have made a name for themselves in university departments for physical education (*Institute für Leibesübungen*)—most particularly in German-speaking countries from the 1920s onwards and again since the 1960s. With the exception of some experts in ancient sport who are trained classical historians, a great many of these sport academics have been educated mainly in the natural sciences. Therefore, they do not make it their ambition to write elaborate historical studies. Nevertheless, they must be credited for their assiduous work in collecting and documenting sources and literature about sporting incidents, persons, institutions, and events in history.

All the more so because very early on they cast their gaze beyond national boundaries, as documented by representative volumes of collected essays like *Geschicte der Sport aller Völker und Zeiten* (Bogeng 1926) or *Geschichte der Leibesübungen* (Ueberhorst 1972/1989). Academic exchanges have occurred since the 1970s with the aid of societies like the *International Committee for the History of Physical Education and Sport* (ICOSH, founded in Prague 1967) and the *International Association for the History of Physical Education and Sport* (HISPA, founded in Zurich 1973); these two societies, representing the East and the West, amalgamated into the *International Society for the History of Physical Education and Sport* (ISHPES) in 1989. In addition, there are more specialized societies that promote exchanges of information on North America, Australia, and Europe.

3. *Sport History as the History of Competitive Games and Pastimes*

A second direction in sport history, which primarily regards modern competitive sport as its theme—i.e., is orientated towards 'sport' in the narrow sense of the word—has been adopted by professionals who have moved into sport history after a rigorous academic training in another academic discipline. Most of these scholars are historians, whilst the majority of the rest are sociologists, anthropologists, political scientists, and economists. A few are geographers, architects, or media specialists. Sport academics are only included in this group when they can be counted—as in France and the US—as trained social scientists.

This second category of sport historians is comparatively new. It sprang up in the 1970s in Great Britain, Australia, and the US, where sporting competition traditionally has been a part of the educational system. In the second half of the 1980s it also found

adherents on the European continent, and today it is in the process of spreading to South America, Africa, and Asia. Given the lack of local experts, however, studies on these regions of the earth have up to now mostly been conducted by European and American scholars.

International exchanges take place at conferences and in publications like *Sporting Traditions* (founded in 1977 in Australia) or the *British Journal of Sports History* which in 1987 became *The International Journal of the History of Sport*; further at research centers such as the *Center for Olympic Studies* at the University of Western Ontario, the University of Neufchâtel's *Centre International d'Étude du Sport*, or—in the UK—the *International Research Centre for Sport and Socialisation in Society* at the University of Strathclyde and the *International Centre for Sports History and Culture* at DeMontfort University, Leicester (this institute employs an international staff). In contrast to the first category of sport history, the international cooperation amongst these younger scholars is marked by a clear orientation towards problem-solving, and a certain pleasure in interdisciplinary experimentation, which in different ways enables themes to be looked at from completely heterogeneous perspectives. To give but one example: the phenomenon of spectators rioting in football stadiums which has been observed since the nineteenth century and which has been the object of comprehensive studies in the 1990s by historians not to speak of sociologists, social workers, architects, and media specialists (for an overview see Williams 1991).

A great many amateur historians are also active in the area of competitive sport, not least amongst them the oft-derided collectors of 'sportifacts,' who punctiliously generate lists of trophy winners, game scores and scorers, season and career averages, chronological events of team and club performances. Since these data, when put into context, have some value as source material, professional historians have a considerable interest in cooperating with the amateurs by supervising their work and giving them the chance of being published in special journals like *Sporting Heritage*.

The cooperation with academic sport scientists, however, is not as intense as it could be. One reason is that the two factions put the main stress on different subject matters, another is to be seen by the fact that scholars mainly belong to different generations. The leading sport historians in sport science were born before the World War II, whereas the social science faction, with few exceptions, were all born in the 1950s and after. Whereas the older generation grew up at a time when educationalists and politicians were interested in promoting virtues like self-discipline and strength in sport, the younger generation of research workers, which incidentally also includes women, has been imbued with a different understanding of sport. Massive state subventions during the cold-war period, expansion of educational opportunities and an increase in leisure since the 1960s, and above all the breakthrough of television and the concomitant commercialization tendencies, have not only transformed sport into a mass phenomenon but also helped to wipe out the old virtues and produce a mentality of hedonistic sporting consumption. While many of their older counterparts are irritated by, and even disgusted at this development, it is well known to the younger generation, and tracing back the traditions of this mentality is a matter of course for them.

4. *Sport History, Social History, and the Social Sciences*

The formation of this second category in sport history around the turn of the 1980s is remarkable because both professional historians and social scientists had tended to ignore sport up to this time. Therefore, alongside the generation-specific interest of young academics in sport, there needed to be a change in the disciplines of history and social sciences themselves in order to embrace sport history as a natural object of study.

The decisive change came with the rapid development of social history and historical sociology that began in the 1960s (see *Social History*). This boom was accompanied by an intensive reception of modernization theories, which made a fundamental contribution to the interest of scholars in the *social form* of modern sports, i.e., the rules, constraints, and organization of sporting competition (see *Modernization and Modernity in History*). For the features of this social form fitted very well into the categories of Max Weber and Talcott Parsons. 'Equality of opportunity to compete and in the conditions of competition,' 'specialization of roles,' 'rationalization,' 'bureaucratic organization,' 'quantification,' and 'quest for records': these were the crucial characteristics of modern sport as established by Guttmann (1978). Whereas historians and social scientists generally felt they had no responsibility for bodily movements and behavior in human beings—something which the first category of scholars from sport studies had no hesitation in writing about—the above definition seemed to imply that there might be a connection between the social formation of modern sport and the formation of modern Western society. Which political, economic, and social conditions were favorable to organized and thoroughly regulated competition? Who were the actors? What motives connected them with sport? What were the effects of their passion for sport? These and other questions were raised.

Significantly, the one modernization theorist still living at the time, the civilization theorist Elias, dedicated his work to sport research for a time. One of his hypotheses was that the emergence of organized sport as a form of relatively nonviolent physical combat was connected with a period in English history

when Parliament became a battleground for resolving and defusing interests and conflicts (Elias and Dunning 1986; see also Elias 1971).

As exciting as were scholars' attempts to emphasize the contexture of the development of sport, their theoretical ambitions began to evaporate as soon as they began exploring sources in more detail. During their researches they all discovered that modernization and other 'great' theories about society provide in many ways an unsuitable framework in which to interpret sport history.

One reason was the focus of 'great theories' on industrial society. This focus did not allow to take into account that competitive sport, at least in its 'mother country' England, had sprung up in pre-industrial times. There the most protracted impulse for development had been the early formation of a market society and the commercialization of everyday life: which explains why seemingly modern professional sport has a longer tradition in Britain than amateur sport (see *Consumption, History of*). On the other hand it was discovered that, precisely because of the rationality of its social form, sport could be effective as a transmitter of 'premodern' attitudes. Thus, in its land of origin, the notion of 'fairness,' e.g., evolved from informal aristocratic and popular cultures that can be traced back to the Middle Ages. There were also some other elements which, with the help of sport, bound 'chivalrous' gentlemen into modern civil society. Modernization theorists had not foreseen such paradoxes and even Elias, who was well acquainted with the sources, seemed at a loss to know what to do with them.

Further communication problems with interpretations based on modernization theories resulted from the increasing confirmation of research results which showed that, everywhere apart from Great Britain, modern sport was a cultural import, and that it was disseminated by international elites whose identities and loyalties were anchored not only in, but also across states, a factor which was partly responsible for disseminating a uniform, global image. Established historians and social scientists were unable to say much about this phenomenon because their studies were traditionally fixed on the modern nation state. Hence, the method of international comparison which they recommended was of some—if insufficient—help; and those sport historians who studied themes like the establishment of sporting culture in the British Empire or its diffusion in Europe as a side-effect of tourism, business contacts, and technology exchanges (Mangan 1988, Lanfranchi 1991, Guttmann 1994, Eisenberg 1997) became of necessity pioneers of cultural transfer studies in a global framework.

The significance of cultural transfer in the development of modern sport puts a different perspective on such research methods that, like oral history (see *Oral History*) or thick descriptions, were increasingly asserting themselves in social history in order to be able to reconstruct the development in small communities more accurately. True, such methods were used by sport historians, especially for Ph.D. theses (e.g., to research the social basis and the symbolic content of certain sports), and in individual cases (e.g., research work into how competitive sport was operated in totalitarian regimes) they brought to light highly surprising results. However, when it came to *explaining* social and sporting changes, this form of research contributed very little. Furthermore, completely different questions had to be addressed, such as the influence of single persons, governments, and military officers, especially in both world wars, the impact of rule changes by world sporting authorities, or media imposition of patterns of perception.

These findings gradually have led to a loosening of the relationship of sport historians to their 'parental' disciplines, historical science and historical sociology (see *Historical Sociology*), despite their fundamental ties. That this tension has not been expressed openly, nor led to an antitheoretical offensive, as happened some years ago with representatives of modern cultural history, can be attributed to the priority given to empirical research, and also to the fact that sport historians have been lucky enough to be able to pursue their interests elsewhere. The rejection of 'great theories' occurred at a period of intensive reception of 'smaller' problem-related 'theories of the middle range' (Robert Merton), which were being developed by colleagues in sociology and economics (Neale 1964, Loy and Kenyon 1969). Some historians such as Vamplew contributed actively to this discussion (Vamplew 1988).

This direction in research grew out of the awareness that social relations in sport present in many ways a different picture to those in 'real life.' A commonly given example is the nature of sporting competition. Although most businesses would regard a monopoly as the ideal market situation, in sport this would be an economic disaster: it is of little commercial value to be a world champion if you have no challengers. Another example is the financial actions of clubs and sports firms, where ambitions for success often override profit considerations. Furthermore, the borders of class, gender, and ethnicity often run differently in sport from those in society which, in addition, are considerably less fluid.

Such observations fascinated sport historians, not the least because they raised the value of the object under review. For they demonstrated that modern sport was in no way a 'mirror of society,' as was keenly asserted. It was much rather a relatively autonomous social subsystem, which functioned according to its own rules on the basis of its 'built-in' game character, and which in certain situations produced its own dynamic of development. Where this subsystem interacted with its social and economic environment, it would not only reproduce this environment, but also impose its own mark on this

environment. It could contribute to the erosion of outdated traditions like premodern value systems or social inequality; and conversely it could help to extend the life span of such anachronisms. Sport was an active, yet selective, impulse of social change.

5. The Future of Sport History

Reconstructing this capacity of sport from individual cases will be a central task for the future of sport history as a branch of social history. For this task to be fulfilled satisfactorily, sport historians, social historians, and social scientists must cooperate. Alas, the reception of the results of sport history research amongst the scientific community has left a lot to be desired. To write a synthesis of the scattered findings of the last few years is, therefore, not only a desideratum but an urgent necessity.

In addition, sport historians should target and close gaps in research. Given the fact that recent research work has almost exclusively covered the period from the eighteenth century to World War I this means, first of all, an extension of the chronological scope. A far broader look at the premodern phase of sport would be most fitting, especially a study of the effects in Great Britain of the Renaissance, which is a key epoch for questions of continuity and discontinuity between ancient and modern ideals in sport. This question, which can only be answered in cooperation with interested classical historians (cf. the journal *Nikephoros*), has been completely neglected to date.

It is however far more important for sport history to turn its attention to the later decades of the twentieth century. What is needed here is, first, the compilation of a comprehensive data collection covering the social basis of sport, the biographies of influential actors, the development of organizations on a national and international level, financing methods, etc., as has been done in the last few years for the nineteenth century. Second, the substantial entanglement of sporting associations and totalitarian regimes (e.g., Europe between the world wars, Eastern Europe, South America, and China after 1945) must be made the subject of research studies. In this respect it would be of great help if a special branch of political science could be evolved, analogous to those of sport economy and sport sociology in recent years. For there are some signs which show that relationships of dominance and power in sport take on different shapes from those in other areas of social life.

Furthermore, it is desirable for social science oriented sport historians to broaden their thematic range, i.e., extend their research activities to cover themes of the physical culture, which to date have mostly been left to amateurs and sport scientists: the movements of the human body, sexuality, education, gender-fixing, etc. Such studies should obviously avoid making naive statements about anthropological constants in humanity. They should rather reveal how regulated and organized modern competitive sport emanates into other areas of social life, what effects it has, and what consequences result from this. In other words, scholars should research subjects like the correlation between doping and the contemporary medical consumption (the first studies on the subject have already been conducted by Hoberman 1992), between the physical appearance of athletes and modern bodily ideals in the fashion industry and on the labor market in the present-day service economy, between certain easy-going manners and expressive forms of communication in sporting arenas, and in other areas of modern social life.

Because this is only possible in close cooperation with academic disciplines like media studies, which in many countries are still in the process of coming into being, there is a danger that sport history will lose its own profile and independence. But if, by doing so, it can become an established part of a methodically reflected project of writing social history in the twenty-first century, this would only be to its own advantage.

Sport Psychology: Performance Enhancement

Enhancing sport performance is part of the discipline of psychology known as sport psychology. Sport psychology is the scientific study of people in sport and exercise contexts. There are two main objectives of sport psychology: (a) learning how psychological factors affect an individual's physical performance, and (b) understanding how participation in sport affects a person's psychological development, health, and well-being (Weinberg and Gould 1995).

Although traditionally the emphasis has been on the first objective, both objectives will be considered. The rationale for this decision is that of the millions of individuals, especially children and adolescents, who play sports, only a tiny fraction will parlay those activities directly into a career in sport. For the rest, growing up means further defining their identity, discovering other skills and interests and, potentially, applying some of the principles learned during sport participation to their adult pursuits. Sport psychology, then, involves the use of sport to enhance competence and promote human development throughout the life span, and practitioners should be as concerned about 'life' development as they are about athletic development (Danish and Nellen 1997).

1. *Why Study Sports?*

The impact of sports on US society is pervasive. US culture places a tremendously high value on sport. It is a major source of entertainment for both young and old. It has been reported that between 20 and 35 million 5–18 year old youth in the USA participate in one or more nonschool sports and another 10 million 14–18 year old youth participate in school sports yearly. Only family, school, and television involve children's time more than sport. In sum, sport is a cultural phenomenon that permeates all of US society.

Sport is not only a relevant topic for study because of its importance in society; it is a significant factor in the development of a child's self-esteem and identity. However, whether it is a positive factor has been debated widely without a clear answer. Danish et al. (1990) concluded, following a review of the literature, that for sport to be a positive developmental experience, it must be designed specifically for the purpose of enhancing competence.

2. *A Brief History of Sport Psychology*

Sport psychology dates back to the turn of the twentieth century. Although Norman Triplett, a psychologist from Indiana University, is credited with conducting the first study on athletic performance in 1898, Coleman Griffith is known as the father of sport psychology. A psychologist at the University of Illinois who also worked in athletics he developed the first sport psychology laboratory, was involved in the first US coaching school, and wrote two groundbreaking books, *The Psychology of Coaching* (Griffith 1926) and *The Psychology and Athletics* (Griffith 1928). He also conducted a series of studies with the Chicago Cubs baseball team and the University of Illinois as well as consulting with a number of well-known athletes of his time.

As sport psychology evolved over the twentieth century, two different kinds of sport psychologists emerged. *Clinical sport psychologists* are trained primarily in applied areas of psychology such as abnormal, clinical, counseling, and personality psychology and are usually licensed psychologists. They tend to be less well trained in the sport sciences. *Educational sport psychologists* are usually not licensed psychologists. Their training is in exercise and sport science, physical education, kinesiology, and the psychology of human movement, especially as it is related to the context of sport. They often have additional training in counseling. They see themselves either as researchers or as 'mental coaches.'

For some time there has been conflict between these two groups, based on who is best trained to provide services that enhance sport performance. The target of the services are primarily elite and professional athletes, many of whom see little need for such services or who sometimes seek the help of individuals not trained in either area. More recently, a rapprochement between these two groups has taken place with the formation of the Association for the Advancement of Applied Sport Psychology, an organization of approximately 1,000 members, almost equally divided

between members trained in traditional areas of psychology and members trained in the sport sciences.

3. *A Framework for the Development of Performance Excellence*

Gould and Damarjian (1998) have proposed a psychological pyramid of peak performance (see Fig. 1). They consider three sets of factors that interact to produce peak performance. At the base of the pyramid is the personality, motivational, and philosophical foundation of the individual. This foundation consists of those enduring individual differences that influence one's motivational disposition to learn the psychological skills that enhance performance. Among these factors are goal orientation, self-confidence, anxiety, and attentional style.

On one side of the pyramid are the psychological strategies used to enhance peak performance. Among

Figure 1
The Psychological Pyramid of Peak Performance (adapted from Gould and Damarjian 1998).

the skills taught are: goal setting, relaxation techniques, imagery and mental rehearsal, self-talk, the development of pre-performance and performance routines, and association/disassociation strategies. However, to achieve and maintain excellence, peak performers must learn how to deal with the adversity associated with excellence. Adversity coping strategies represent the other side of the pyramid. Stressors may come from an individual's own expectations, others' expectations, time demands, injuries, and general life concerns. As a result, learning effective coping strategies is essential. Although some of the strategies needed to cope may be the same as those used to enhance peak performance, the way they are used may be markedly different.

Athletes do not live, train, and compete in a vacuum. There are social, psychological, physical, and organizational factors in their environment that can have facilitative or debilitative effects on their performance. Gould et al. (1999) studied eight teams from the 1996 Atlanta Olympics. Four of these teams met or exceeded performance expectations and four failed to meet performance predictions. Through interviews and focus groups with the athletes and coaches, the authors found that teams that met or exceeded expectations participated in resident training programs, experienced family or friend support, employed mental preparation strategies, and were highly focused and committed. Teams that failed to meet expectations experienced planning and team cohesion problems, lacked experience, faced travel problems, encountered coaching problems, and had problems related to focus and commitment.

4. *Building the Foundation of a Peak Performer: Developing the Base*

B. S. Bloom (1985) and his colleagues followed 120 individuals who had achieved world-class success in sport (tennis and swimming), esthetics (music and the arts), and cognitive or intellectual (research mathematicians and research neurologists) endeavors. They found that the development of these individuals was divided into three phases: romance, precision, and integration. During the romance phase, development was multifaceted and characterized by play, exploration, and fun. It was the time when youth developed a love for learning and learned that hard work and fun were not incompatible. They learned the importance of having high expectations of themselves. The need to have high expectations was communicated through the expectations that parents, teachers, and the community in general had for the individual. Parents and teachers played a crucial role in the development of excellence. During this first phase motivation and effort counted more than any special gifts or qualities the child had. It was during this period that qualities such as character, emotional intelligence, and life skills were taught and acquired.

The romance phase was followed by a focus on precision. This was a period of systematic learning and skill development. The teachers/coaches of the individuals became more demanding and the children became more committed to the activity. Motivation became more internal than external. Skills were learned but not necessarily demonstrated very effectively.

It was not until the integration phase that individuals experienced the behavior as part of themselves. This phase was characterized by the perfection of their talent. The individuals became increasingly responsible for their own motivation. Much of their time was spent in their area of talent.

Bloom and his colleagues noted that by age 11 or 12 only about 10 percent of these individuals had progressed sufficiently to predict their later level of achievement. Among the special qualities that characterized these talented individuals were: a strong commitment to their particular talent field, a desire to reach a high level of attainment in their chosen field, an ability to learn quickly and well, and a willingness to invest great amounts of time and effort to reach high levels of achievement in their chosen field. For each field there were specific qualities that were important. Obviously, coordination, reflexes, endurance, and strength are needed for athletic excellence, but in contrast to what is believed by many, these conditions, while necessary, are clearly not sufficient.

5. *Teaching a Psychological Skills Training Program: Developing the Sides*

Athletes are active individuals. Their life experiences suggest they learn best by doing rather than by talking. They are accustomed to being 'coached' and expect concrete suggestions, feedback, and tasks. The process of teaching psychological skills should take advantage of their preferred learning style and expectations. As a result, although many of the specific strategies used to develop peak performance are based on traditional psychological approaches, they are best implemented using a skill-based, psychoeducational format (Danish et al. 1993). As such, these strategies may be quite similar to what Seligman and Csikszentmihalyi (2000) have referred to as 'positive psychology'.

A psychological or mental skills training program for developing all kinds of talent uses a psychoeducational approach as opposed to a traditional psychotherapeutic approach. The traditional psychotherapy model is problem- or illness-focused. The illness or problem is diagnosed, a treatment prescribed, therapy is undertaken and, if successful, a cure takes place. A psychoeducational model, on the other hand, begins with the individual's dissatisfaction or am-

bition. Goals are set and then the individual learns the skills to achieve the goal. The difference between the two approaches is both in the goals of the intervention and in the methods of delivery.

In terms of the goals, it is the difference between developmental and remedial help, between pathology and health promotion. Traditional psychotherapy focuses on identifying deficits and fixing them so the individual can return to 'psychological homeostasis'. The focus of psychoeducational approaches is on identifying assets and how to enhance them. Learning the skills serves as a catalyst for attaining personal and performance excellence.

One psychoeducational approach is life development intervention (LDI; Danish and D'Augelli 1983). The central strategy of LDI involves teaching individuals how to set a goal, develop a plan to reach the goal, and to overcome the roadblocks to goal attainment. Goals are actions undertaken to reach some desired end, not the end itself. Goals are different from results in that they are actions over which the participant has control. For example, for an athlete preparing for a competition, a goal might be to decide to learn how to develop a precompetition routine that will help focus on positive thoughts. To want to improve a time or score is not a goal, but a result. Individuals have control over their goals and only partial control over the results they want. In addition to having control over one's goals, three other elements are necessary for effective goal setting; (a) setting goals one is motivated to attain, (b) making sure that the goal is stated in positive terms, and (c) having a goal that is defined specifically and can be measured.

Being able to set a goal is one thing; being able to reach or attain the goal is another. There may be roadblocks that interfere with reaching a goal, regardless of whether it is of an athletic, career, or personal nature. These roadblocks are: a lack of knowledge, a lack of skill, being afraid to take risks in order to reach the goal, and/or a lack of adequate social support to work toward the goal. A lack of knowledge means that the individual is missing some information necessary for goal attainment. A lack of skills may refer to either physical or mental skills. A skill deficiency exists when the athlete does not know 'how to' attain a needed skill level. When individuals lack social support they need to know what support they need, who can provide them with the support (and who can not), and how to ask for the support. Support can either be of a tangible or emotional nature. The final roadblock relates to risk taking. Many individuals play and live their lives in a 'comfort zone' because they are afraid of failing, or possibly even succeeding. They may believe it is better not to try to extend themselves to reach a goal than to try and fail. Or they may feel that if they reach a goal, more will be expected of them on an ongoing basis. Risks are defined as the perceived benefits of an action minus the perceived costs. If the perceived costs outweigh the perceived benefits, efforts to reach a goal may be abandoned; if the perceived benefits outweigh the perceived costs, individuals may choose to work toward the goal. To optimize risk taking the benefits of an action must be increased and the costs decreased.

As part of the intervention, the roadblock(s) must be removed so that the individual may work toward the goal. Thus, teaching the necessary knowledge, skills, means of developing social support, and/or risk taking strategies to overcome the roadblocks to a goal is a major component of how the LDI approach is implemented.

The timing of when the intervention is implemented affects how it is delivered. For example, if goal setting were being taught, it could be taught to help an athlete prepare for the competition (enhancement), facilitate the athlete's ability to fine tune the goal during competition (support), or cope with an injury resulting from competition by helping develop a rehabilitation plan (counseling). Regardless of when the intervention is implemented, the building of rapport and the development of an alliance to work together toward the attainment of an individual's goals are essential.

6. *Developing Excellence in Sport and Life*

Not every individual can be a peak performer, but most can improve through performance enhancement strategies. Improving one's performance in sport or in other life domains begins with a decision to invest time and energy in deliberate practice. Bloom (1985) describes how a single-minded focus is an integral part of performance excellence. However, Marcia (1966) and Petitpas and Champagne (1988) point out that if individuals invest all their energies in sport, or in any single area, and achieve a level of success, they may decide to forego searching for a personal identity and commit to only that activity. By not exploring other areas, the individual may gain a sense of security at the expense of a search for identity. Baltes and Baltes (1980) refer to a single-minded focus as *selective optimization*. When individuals have a limited amount of time and energy, based on an assessment of environmental demands, their motivation, skills, and biological capacities, individuals select a pathway upon which to focus.

It should be pointed out that identity foreclosure and selective optimization are not in themselves harmful. These behaviors only become problematic when they prevent permanently the exploration of alternatives. It is through this process of exploration that individuals learn more about themselves. They receive feedback about their strengths and weaknesses by testing themselves in a variety of situations. They learn *life skills* (Danish 1995). For sport to serve as an effective model for learning life skills, the sport experience must be designed with this goal in mind.

Promoting personal and performance excellence simultaneously is not incompatible. However, it must be a planned outcome of sports participation. It occurs when athletes compete against themselves—more specifically, when that competition is focused on maximizing their own potential and achieving their own goals. It occurs when knowing oneself becomes as important as proving oneself.

De Coubertin ([1918] 1966), the founder of the Olympic movement, best described the dilemma faced by athletes who are so intent on proving themselves that they lack an awareness of what they have learned through sport:

> Sport plants in the body seeds of physio-psychological qualities such as coolness, confidence, decision, etc. These qualities may remain localized around the exercise which brought them into being; this often happens—it even happens most often. How many daredevil cyclists there are who once they leave their machines are hesitant at every crossroads of existence, how many swimmers who are brave in the water but frightened by the waves of human existence, how many fencers who cannot apply to life's battles the quick eye and nice timing which they show on the boards! The educator's task is to make the seed bear fruit throughout the organism, to transpose it from a particular circumstance to a whole array of circumstances, from a special category of activities to all the individual's actions (De Coubertin 1918).

Whether the purpose is to enhance sport performance or to improve other areas of one's life, the process is the same. What becomes essential is to ensure that what is learned can be generalized to other areas of the individual's life so that the game of life is a success.

7. *Concluding Comments*

The future of psychological interventions in sport lies in teaching mental skills to the masses, especially youth, and not just working with elite athletes. Sport participation among youth will likely continue to expand. However, it will not be taught in schools, where mandatory physical education and intramurals have all but disappeared. Instead, sport will be almost exclusively an after-school activity. As a result, the coaches will probably be youth workers and volunteers who may have little or no experience in teaching/coaching the different sports and will need special training.

Traditional programs will probably not be effective. The coaches at these youth-serving agencies tend to be underpaid and poorly trained, the volunteers are hard to recruit and retain, and the goals of these new coaches may not be the same as school-based coaches. Consequently, new programs must be developed that are modular, flexible, cost and time sensitive, multimedia in format, transportable, easily taught, and scalable.

There will be challenges and opportunities in developing the materials, training the new coaches, and expanding the sport experience to more youth. One of the biggest challenges is how to help youth develop both athletically and personally. It will require integrating the physical and mental aspects of the game. If we are successful, sport will become a vehicle for learning and applying some of life's most critical lessons.

Sport Psychology: Training and Supervision

Sport psychology is a hybrid discipline more associated with physical education than with mainstream psychology. Debate over the training of sport psychologists is exemplified in the title of Brown's (1982) paper 'Are Sport Psychologists Really Psychologists?' Models of training and supervision will vary depending on how one answers that question. Sports psychologists and sport psychology organizations in different countries around the world have come up with different answers, and thus, different models of training and supervision have developed.

People pursue advanced degrees in sport psychology for reasons as varied as wanting to improve their coaching, preparing themselves for university academic positions, acquiring skills for clinical or counseling careers, and obtaining the training necessary to work in rehabilitation and sports medicine clinics (McCullagh and Noble 1996). Sport psychology as an academic discipline is almost always found in physical education/exercise science departments (other names include human movement studies and kinesiology) around the world (cf. Fujita 1987), but in many countries, those who practice come from psychology backgrounds. For example, in Flanders, virtually all of the members of the Flemish Society of Sport Psychology who practice have psychology degrees (Wylleman et al. 1999). In Australia, academic sport psychology is in human movement departments, but the current training of practitioners is in psychology departments, making graduates eligible for registration as psychologists (Morris 1995). This dual parenting of sport psychology has led to some lively debate about training.

The United States Olympic Committee (USOC 1983) stepped into the training debate when they began their Sport Psychology Registry (only those with doctoral degrees could apply). They divided their registry into three sections for three 'different' types of sport psychology service providers. 'Research sport psychologists' could apply for that category if they wished to conduct research with Olympic athletes on a variety of psychological topics. 'Educational sport psychologists' could deliver psychoeducational training (e.g., relaxation, goal setting, imagery, positive self-talk) to individuals and groups. 'Clinical sport psychologists' could deliver psychotherapeutic services for athletes with psychological problems (e.g., eating disorders, panic attacks).

This tripartite scheme was an attempt to accommodate individuals trained either in exercise science (many of the applications to the research and educational groups) or in psychology (most of the applications to the clinical group). The USOC was trying to be 'inclusive' of exercise science trained individuals who could not really use the protected title 'psychologist,' or be eligible for licensure, but who nevertheless often had extensive training in mental skills for performance enhancement. Also, one could apply for more than one designation. This classification scheme sparked some debate (e.g., Clarke 1984, Heyman 1984), and it also had a large influence on shaping how sport psychologists talked about themselves. Even today, many practitioners specifically call themselves 'educational sport psychologists' although there appears to be a trend away from using these, in many cases, somewhat restricting labels.

The question of training in sport psychology in the early to mid-1980s had become: training for what? Simplifying the USOC categories into to two broadly defined realms of research (academic posts and research center positions) and applied practice (performance enhancement, counseling, consultation, and clinical work) will help illustrate the basic paths for training that have evolved.

1. *Training*

The majority of people in academic research positions in sport psychology are still housed in exercise science departments. Sport psychology positions in psychology departments are relatively rare, and training for academic positions in sport psychology differ markedly around the world. In North America, a Ph.D. program would involve two to three years of extensive course work, involvement in a variety of research projects, and the completion of a substantial research dissertation, with many programs offering applied practica as part of the degree. In UK and other British Commonwealth nations (e.g., Australia, New Zealand), a Ph.D. in sport psychology is essentially a three-year long program of research (with little or no required course work), the product of which is often a series of three or four conceptually linked studies of a particular topic in the field. Thus, one system of training (e.g., the UK) has the doctoral student deeply immersed in the research process, and another system (e.g., the US) has extensive course work along with a major research project. Because the majority of academic research position training occurs in North America (nearly 100 universities offer graduate level programs), the majority of professional discussions on the training of sport psychologists has come from academics in those schools.

There is general agreement among sport psychologists that training should be interdisciplinary, covering both psychology and the exercise sciences (e.g., Dishman 1983). Feltz (1987), however, noted problems related to the integration of physical education/exercise science and psychology and suggested that expertise in psychology would be most appropriate to the applied aspects of the field. In the past decade many programs in North America, Australia,

and the UK have made opportunities for exercise science and psychology students to take classes in each others' departments. As sport psychology grows, it appears that training is becoming more and more interdisciplinary. Consensus on what training should be for sport psychologists, however, has not been reached. The field of sport psychology has no equivalent of the 'Boulder Model' in clinical psychology, but many programs describe themselves in their promotional material as espousing a scientist-practitioner model of training (see *Training in Clinical Psychology in the United States: Scientist–Practitioner Model*).

The organization that comes closest to setting training guidelines for those who wish to become practitioners is the Association for the Advancement of Applied Sport Psychology (AAASP) with their criteria for certification as a sport psychology consultant (see Sachs et al. 1998). Both the exercise sciences and scientific and applied psychology are well represented in the course work and training needed to become a certified consultant. The AAASP criteria also contain recommendations for supervised experience (at least 400 hours of supervised practicum working with athletes and coaches).

AAASP requires a doctoral degree for certification, but in many places around the world, a doctoral degree is not required to practice psychology. For example, in Australia sport psychologists are registered (equivalent of 'licensure' in the US) at the master degree level. Currently, Australia probably has the most integrated training and registration model of sport psychologists in the world. The Australian Psychological Society (APS) has several 'Colleges' (equivalent of Divisions in the American Psychological Association) within its structure, and one of them is the College of Sport Psychologists. The APS and the College of Sport Psychologists are the bodies that accredit master of applied psychology programs that emphasize working with sports people. Graduates of accredited programs are eligible for registration with State Psychologists Registration Boards. This integration of applied sport psychology training, program accreditation, and registration into mainstream applied psychology represents the latest level of professionalization in the field.

2. *Supervision*

The topic of supervision of sport psychology practica and internships, along with collegial supervision, arrived relatively recently on the professional practice of sport psychology debate scene. In 1993, the International Society of Sport Psychology published a short article on supervising trainees (Van Raalte and Andersen 1993), and supervision received a brief discussion in a book chapter on ethics (Sachs 1993). In 1994, however, two articles were published in the major journals of the field. The article by Andersen (1994) was a discussion piece on ethics and the supervision of applied sport psychology graduate students that offered recommendations for future training and supervision. The databased study on assessing the skills of sport psychology supervisors (Andersen et al. 1994) revealed the state of supervision in applied sport psychology training. Well over half the supervisors surveyed had never received any supervision of their own work with athletes. The median number of supervised practicum hours for students was just over 100. The opportunities for supervised experience in sport psychology graduate programs appeared seriously restricted, and the quality of the supervision could be questioned given the limited experience of many of the supervisors. Andersen et al. recommended that practitioners and trainers of future sport psychologists needed to pay more attention to supervision issues because it appeared that the training and supervision sport psychology graduates were receiving was, in many cases, inadequate.

In 1996, two more journal articles on supervision appeared. Andersen and Williams-Rice (1996) discussed, in a sport psychology service delivery context, the potential benefits of using psychodynamic, phenomenological, behavioral, cognitive-behavioral, and developmental models of supervision. They suggested that the cognitive-behavioral supervision model of Kurpius and Morran (1988) might be the most comfortable and appropriate for sport psychologists because it contains many features that sport psychologists use in practice (e.g., cognitive restructuring, mental rehearsal, cognitive self-instruction, covert modeling). Thus, a supervisor might have a supervisee mentally image and rehearse an up-coming encounter with an athlete, or supervisors might help supervisees overcome their own irrational beliefs about service delivery by using cognitive restructuring techniques. This supervision model has the potential to be the 'parallel process' model for sport psychology in that the interactions of the supervisor and the supervisee reflect similar processes that are going on with the supervisee and the athlete. Andersen and Williams-Rice also discussed transference and countertransference, along with peer and meta-supervision (supervision of supervision), misalliances, boundaries, and dual roles in supervision.

From the evidence in Andersen et al. (1994), there appeared to be very little training in how to be a sport psychology supervisor. Even in many clinical and counseling psychology programs, the main training one receives for becoming a supervisor is having been in supervision oneself. This state of affairs is similar to the wishful thinking that if one is well coached, one will become a good coach. Admittedly, current clinical and counseling programs are offering more training in supervision than they have in the past. In sport psychology education, however, training in how to supervise is quite rare.

Barney et al. (1996) presented a model for supervision training in sport psychology, borrowing and adapting Hart's (1982) three-stage developmental model of supervision. The Barney et al. model was actually a multitiered unified program of supervision and training. The model begins with background education in the sport sciences, physiology, physical education, and psychology. The training begins with a year-long course in sport psychology theory and research. Towards the end of that year students would begin their practica counseling athletes. Those beginning practicum students would be supervised by advanced students undergoing a 'supervision practicum' where they are being trained to become good supervisors. Barney et al. described three major phases for the supervisor-in-training that are interwoven. Working on the acquisition of supervisory skills (e.g., how to do a supervision intake), especially for a beginning supervisor, may take a considerable amount of time. Supervision may swing back and forth between skill acquisition and personal growth issues. The meta-supervisor helps supervisors-in-training to explore what they bring to the supervisor–supervisee relationship, their needs, their countertransferential thoughts and behaviors, and so forth. This self-exploration and personal growth are in the service of producing a more aware sport psychologist who will competently deliver service. The integration phase for the supervisor-in-training is combining new skills and personal growth for building dynamic helping relationships with athletes. Barney et al. placed great emphasis on the study of relationships in sport psychology (e.g., meta-supervisor–supervisor-in-training, supervisor–supervisee, psychologist–athlete) and how relationships are the key to successful sport psychology service delivery. This emphasis on relationships is something new in sport psychology, and this trend is exemplified in another recent article on training. Petitpas et al. (1999) have presented arguments and recommendations for making the examination of relationships one of the central features in the training of future applied sport psychologists. The recognition of the importance of relationships is nothing new in mainstream counseling and clinical psychology, but because sport psychology's original 'home' was in physical education, such counseling and clinical considerations did not arise until recently. The new emphasis on relationships represents the continuing 'psychologization' of sport psychology.

The debate on training in sport psychology has been with the field since the early 1980s, but the discussion of supervision is a relative newcomer. Supervision and training are currently becoming widely debated topics. For example, at the 1998 AAASP annual conference, there were over 20 presentations that were concerned with training and/or supervison. The study of sport psychology, even though it roots go back to Triplett (1898) and Griffith (1928), is a young, but maturing field. As applied sport psychology matures, interest in quality training and supervision will probably grow even more.

Sport, Sociology of

Sport, once considered a marginal area of interest (a subset of the sociology of leisure or sociology of culture at best) is now a distinct area of concern for sociologists. Since the 1960s, a significant body of sociological body of research has been produced constituting the area of sport sociology. The growing interest in sport as a site of research is the result of three factors: the increasing pervasiveness of competitive sport in everyday life, the growing acceptance of critical examination of sporting practices, and sport's distinctive and relatively autonomous structure. Sport sociologists are particularly interested in modern sport, a relatively new cultural form dating from the late 1800s. Modern sport shares attributes with leisure/recreation/play and with drama, but is distinct from both. It distinguishes itself from other forms of leisure/recreation/play in that it is physical, competitive and institutionalized. It can be distinguished from other forms of entertainment (e.g., drama, music) in that it is not in and of itself expressive (Gadamer 1975). The movement of a sport contest is governed by its rules. Athletes, if they are giving an 'honest effort,' are trying to win a game, not to communicate an idea or emotion. Thus, much of the social meaning of sport comes from outside of the actual playing of the game.

The relationship between spectators and sporting practices also distinguishes sport from other forms of entertainment. Sport spectators see themselves giving support to athletes. Where other forms of entertainment attempt to evoke an emotional response in the audience, the sport audience attempts to evoke an emotional response in athletes in an effort to impact the outcome of a contest. The fan/athlete bond, then, is rooted in the norms and obligations of reciprocity (Mauss 1954) that forms the foundation of the intense, sometimes fanatical, relationship between fans and sport.

Despite the rule-bound and relatively autonomous space of sport, the structure of a sport (i.e., its rules, amount of physical contact, who is allowed to compete, who governs the sport, etc.) and the meanings associated with a sport are a product of a particular culture. The social significance of a sport, argues Bourdieu (1988), cannot be apprehended in the absence of a much broader understanding of the structure of the society as a whole. For many sociologists, sport is a site through which questions related to social and political power, domination, and ideology are considered. Since the 1960s, sport sociology can be viewed as having two approaches: an institutional approach that emphasizes the unique and semi isolated nature of sporting practices and a cultural orientation which views sport as a cultural product or practice reflective of society as a whole.

1. *Sport as a Unique Institution*

The institutional approach to the study of sport has its roots in physical education. Physical education researchers in the 1960s and 1970s applied their empirical methods to sport (Kenyon and Loy 1965). For the most part, early researchers were looking for empirical proof for popular beliefs about sport's positive and character building attributes or as Coakley put it later 'socialization-as-internalization' research (1993). The results, by and large, were inconclusive (Fine 1987). At about the same time, sport and physical education became embroiled in the social movements of the 1960s and 1970s. In the United States, scholar and political activist Jack Scott published his manifesto, *Athletic Revolution* (1971) and Harry Edwards documented the protests and threatened boycott he led in 1968 in *Black Athlete Revolt* (1969). In France, Jean-Mari Brohm (1978), influenced by the student movement, argued that sport was alienated play and encouraged an anti-Olympic movement.

Beginning in the 1970s, empirical research on sport as an institution also took a critical turn, documenting structural inequalities within sport and challenging popular ideologies. One line of research following from these studies focuses on positional racial segregation on the field of play; a phenomenon dubbed 'stacking' (Curtis and Loy 1978). A related field of inquiry is the documentation of racial and gender inequalities in the hiring practices of teams and leagues. Accosta and Carpenter (1994), for example, document gender inequalities in hiring practices, salaries, and advancement of women in intercollegiate sport in the United States. More recently, sociologists have focused on disparities in media coverage. Socialization research also took a critical turn as sociologists

attempted to demonstrate a link between athletic participation and sexual assaults and other criminal or deviant behavior.

Another line of critical inquiry in sport has roots in a social problems perspective. The social problems perspective in sport tends to focus on contradictions within sport. Researchers frame sport as paradoxical, (i.e., sport promotes health and injury, both encourages and discourages drug use) or highlight positive deviance or over-conformity (i.e., a strong emphasis on winning encourages drug use or injury). Other research frames the problems of sport in the context of social-historical shifts. Debates about performance enhancing drug use, for example, are framed in light of changes in approaches to medical treatment. Commonly accepted medical interventions, such as cold remedies, therapeutic treatments for slowing down the aging process, or preventing depression, are marketed with the express intent to enhance performance in everyday life. As the standard of acceptable medicine changes, and the idea of what is a treatable ailment shifts, so will athletes' sense of fairness and prohibitions by sports organizations.

Independent of the burgeoning field of sport sociology, qualitative researchers in the 1960s, influenced by the Chicago School, began producing ethnographies of marginalized groups within sports world (Scott 1968, Polsky 1969). Ethnographers would find the relatively autonomous world of sport fertile ground for understanding common, everyday experiences. For example, Chambliss (1989) theorizes excellence through elite swimming, Adler and Adler (1991) detail the experience and consequences of role engulfment through college basketball, and Fine (1987) explores preadolescent male culture in his study of youth baseball.

2. *Cultural Orientation to Sport*

In the 1970s, Gruneau and other scholars associated with the Massachusetts School attempted to re-center the sociological study of sport within an overriding concern for political economy (Ingham and Donnelly 1997). The works of these scholars formed the basis of the cultural orientation in the United States and Canada. They found theoretical grounding in Gramsci's notion of hegemony. As a social practice, sports are produced by athletes and organizers, but within the context of historically-specific social constraints. This theoretical formulation provides the basis for Gruneau's analysis of class relations, reproductions and transformation of Canadian sport (1983). By extension, modern sport is viewed as a celebration of modern values of competition and winning and organized around principles of the division of labor, capitalism, and professionalism. Because sport offers so little social significance in and of itself (e.g., it has a veneer of neutrality), it becomes a powerful resource for constructing meaning—particularly for the benefit of the power elite. Central to the Massachusetts School is the Gramscian idea of counter hegemony or resistance. Sport, they note, could also be used by marginalized groups to challenge dominant ideologies and structures. From this perspective, sport is a site in which meaning is constructed, challenged, and reconstructed. Put slightly differently, sport is viewed as 'contested terrain.'

At about the same time in Europe, Eric Dunning, a student of Norbert Elias cultivated a somewhat different cultural orientation. Dunning incorporated Elias' grand theory of social development into a figurational approach to sport sociology (Elias and Dunning 1986, Dunning 1999). The figurational approach which focuses above all on social processes and interdependencies frame a vast range of works from hooliganism, athlete migrations and male bonding. The figurational approach distinguishes itself from the Massachusetts School in its focus on a total social structure—taking into account a wide variety of social processes that hold groups together such as emotions, gender, race, and communication patterns.

In the 1980s, feminist sport theorists incorporated aspects of the figurational approach and the Massachusetts School emphasis on hegemony and resistance and began to theorize about the changes in sport due, in large part, to the feminist movement. The influence of Dunning and Sheard's (1973) essay on rugby as a male preserve on the Massachusetts School is evident in the works of Theberge (1985) and Birrell (Birrell and Richter 1987). Arguing that sport is a male preserve that contributes to the oppression of women physically and sexually, they assert that sport nonetheless offers women the potential for subverting male dominance by enabling women to experience their bodies as strong and powerful or to restructure sport to fit feminist principles. Messner (1988), while discounting the simplistic notion that increasing participation by women signals ideological shifts, argues that images of athletic women are forged, interpreted, and contested in sport and may partially contradict masculine hegemony.

Feminist insights of contested terrain in sport were applied to a variety of concerns, including bodybuilding and masculinity (Klein 1993) and inequalities and Texas High school football (Foley 1990). These sport sociologists (often called critical sport sociologists) see sport as a site through which questions related to social and political power, ideology, and transformative possibilities are considered. The bulk of the research that follows from this conceptualization of sport is far less optimistic than the theory that inspired it. Bryson (1987), for example, found masculine hegemony is both resilient and more complex than had been previously theorized. Bryson documents the political tactics of men in Australia in response to women's athletic prowess that reframe their accomplishments to support masculine he-

gemony. In many ways, the more recent trends in sport follow from the discovery of sport's rather limited transformative potential.

3. Recent Trends, Future Challenges

Foucault, cultural studies, and postmodern theory have, to varying degrees, influenced critical sport sociology. One of the great difficulties for the sociology of sport is how to understand the physicality of sport. Most classical sociological theory ignores or diminishes the significance of body. Yet the empowerment and transformation of the body or body skills is at the heart of sport's transformative possibility for critical sport sociologists. Foucault and feminist theory enabled sport scholars to problemitize the body—to see it as a site of domination and through which power is exercised and enjoyed. Bodies are not simply empowered through sport, but they are constrained, shaped, and consumed and thus a central ideological resource (Cole 1994). Cultural studies encourages sport sociologists to make a critical analysis of the social meanings of sporting events. A growing literature offers critical readings of the discourse surrounding a sporting event or celebrity, both to expose the multiple meanings of sport and to analyze how these narratives do ideological work which reproduces and justifies race, class, and gender inequalities (Birrell and McDonald 2000). For example, images of black athletes, even those purporting to offer positive images of African–Americans in order to subvert racism, refer to and reinforce racial stereotypes associating African–Americans with crime, drugs, and poverty.

The postmodern perspectives suggest that we see sport as part of broad and fundamental social changes. One of the distinguishing features of contemporary post-industrial societies is the use of images and spectacles to enculturate individuals into a media and consumer culture. Social values, political debates, and everyday concerns are not garnered through active participation, but through the passive consumption of spectacles. Post-industrial media culture implodes sport into media spectacle. Celebrity athletes become images that are dynamic and complex—but, because they are disconnected from social life, they can be interpreted in a variety of ways. Postmodern perspectives encourage a shift in sociological concerns away from the active producers of sport and culture to an exploration of the passive consumption of sport spectacles (Kellner 1996).

Somewhat in response to the postmodern turn, another line of inquiry is the re-examination of the institutions of sport and their structural intersections with political power. These examinations of the organizational practices within the sport industry attempt to ground the discussion of power and domination in and through sport in a structural framework. The narratives surrounding sport become ancillary to the exercise of power—particularly global political and economic power—and how this shapes the institutions of sport.

One of the future challenges of sport sociology will be to find a synthesis between institutional and the cultural critiques. While the concerns of both approaches appear similar at a very basic level they are very different. The cultural critique relies essentially on the success and celebrity of people of color, women and other marginalized groups to demonstrate the resiliency of ideological domination while the institutional critique emphasizes barriers and limitations impeding the progress of these very same groups. Nonetheless the synthesis of these two perspectives seems to hold the promise for greater sociological understanding of sport.

T. W. Crosset

Sports as Expertise, Psychology of

Elite athletes represent a small and specific subset of the human population within whom the mastery of movement (motor) skill acquisition is at its most pronounced. The emerging field of sport expertise concerns itself with the detailed study of exceptional sports performers and the mechanisms underpinning the overt power, strength, grace, beauty, speed, accuracy, and apparent ease, efficiency, and effectiveness of their movement skills. Comparisons with less skilled individuals, along with detailed examinations of the developmental life histories of exceptional athletes, are used in an attempt to develop a principled understanding of the nature and limits of human perceptual–motor learning.

1. Theoretical and Applied Significance of Sport Expertise Research

Studying expert performance in sport has the potential to contribute both important theoretical and applied knowledge to the social and behavioral sciences. In a theoretical context, studying sport expertise is important because of its potential to provide valuable and unique insights into the nature of perceptual–motor skill learning. The attainment of expert performance in a whole range of domains (sport being no exception) appears to take at least 10 years, or approximately 10,000 hours, of daily, effortful practice, during which time literally millions of trials of practice are undertaken (Ericsson et al. 1993). Studying the expert therefore provides a window into learning, and skill optimization that conventional, laboratory-based learning studies of untrained participants simply cannot replicate. Studies of sports experts in particular are uniquely valuable in permitting broad assessment of the explanatory efficacy of theories and models of human skill acquisition and expertise (typically developed in domains other than sport) and, in conjunction with information from the field of kinesiology or human movement science, in helping isolate the limiting factors to performance in a range of different sport tasks.

In an applied context, sport expertise research offers promise as a means of providing information of practical significance to coaches and athletes regarding the selection of the most appropriate forms of practice and training, the assessment of skill progression, and the optimal design of sports systems and talent identification. For example, knowing what factors do, and equally importantly do not, discriminate expert and novice performers can provide a principled basis for guiding emphasis within practice. Knowing the specific information that must be learned in order to become an expert on a given task has direct implications for the structure of instruction and the provision of feedback. Knowing the early developmental experiences that adult experts in particular sports share in common can provide direct guidance with respect to the appropriate emphases to apply to the design of junior sport systems.

2. Historical Trends in the Study of Sport Expertise

While a strong case can be made for the potential importance of sport expertise research, historically it has not been a favored topic of study in either sport psychology or 'mainstream' cognitive psychology. Although a considerable number of studies comparing skilled athletes with less skilled people on a range of isolated 'abilities,' such as vision, reaction time, balance, movement speed, and agility, were undertaken throughout the 1930s to 1970s, this research work was, almost without exception, descriptive, atheoretical, and nonprogrammatic. Consequently, little progress was made during this period toward the development of a consolidated body of knowledge, nor toward the development of conceptual models or theories of sport expertise. In large part this was due to the concerted emphasis in the motor learning field at this same time

on research examining the limitations and capacities of putative information-processing stages—such work proceeded typically by studying untrained participants as they performed simple, but novel, laboratory tasks.

The foundations for a consolidated body of research on sport expertise were laid largely in the 1980s. During this period paradigms developed to study expertise in cognitive tasks (such as playing chess or solving mathematical problems) were applied progressively to the study of sport situations. Particularly prominent were the pattern-recognition paradigm developed by de Groot (1966), and Chase and Simon (1973), and the knowledge-based approaches to skill acquisition of Chi (1981), Anderson (1982) and others.

Studies using the pattern-recognition paradigm typically demonstrate superior pattern recognition and recall by experts for material that is domain-specific; however, this advantage disappears for unstructured material and for patterns derived from beyond the expert's domain. This observation holds true for sport tasks as well as more traditional cognitive tasks, although there is some controversy as to whether the expert's advantage on such tasks is a cause or merely a by-product of their expertise. The knowledge-based approaches have revealed systematically superior knowledge content and organizational structure for experts, again regardless of whether the experts are drawn from the cognitive or the motor domain (Thomas and Thomas 1994).

Studies derived from the pattern-recognition and knowledge-based approaches were invaluable in providing the impetus for the development of the sport expertise field, although on occasions the assumptions, strengths, and limitations in the use of these imported paradigms was probably not fully appreciated (Abernethy et al. 1993, 1994). For example, the verbal self-report method of data collection used within most of the knowledge-based approaches to cognitive expertise may have reduced veracity when used with sports experts. In sport settings, direct, conscious access to the mechanisms controlling highly automated, rapidly performed motor acts may simply not be possible, and any data derived from verbal self-report may need to be treated with caution.

The scholarly study of sports expertise has gained considerable momentum since the beginning of the 1980s. A number of factors have contributed to this. These include the growing interest in expert systems within cognitive science, the development of improved technology for the *in situ* experimental study of sport tasks, and a rejuvenated interest in learning as a pivotal issue within the broader motor-control field. Two additional factors are particularly noteworthy. The first is the emergence of a theoretical perspective (ecological psychology) which challenges many of the fundamental premises of cognitive psychology. Ecological psychology is influenced heavily by the work of James Gibson on perception (e.g., Gibson 1979), and by Nicholas Bernstein on action (e.g., Bernstein 1967). Its orientation toward functional couplings between perception and action places great emphasis on the study of natural actions as a central vehicle toward understanding skill learning, and such an orientation is compatible with a focus on sport tasks, and experts within such tasks (Abernethy et al. 1994). The second noteworthy factor is the renewed interest in the developmental bases and social support mechanisms for expert performance—a topic first presented in the work of Benjamin Bloom (Bloom 1985). The effective fusion of qualitative, social approaches to expertise development of the type developed by Bloom with more traditional, quantitative, empirical studies of experts represents one of the key challenges for sport expertise in the modern era.

3. *Current Emphases in Sport Expertise Research*

Many of the distinguishing characteristics of expert athletes surmised by both early skill-acquisition theorists and lay commentators have now been confirmed empirically (Abernethy et al. 1998). In comparison to less skilled individuals, exceptional athletes are demonstrably advantaged on a range of perceptual, cognitive, and motor parameters. Perceptually, they are faster and more accurate in recognizing patterns from their sport, superior in terms of both their speed and accuracy in anticipating the actions of an opponent, and better able to pick up essential biomechanical information from observation of the movement patterns of others.

Cognitively, they have superior knowledge of both factual (declarative) and procedural matters related to their sport, their knowledge is organized in a deeper, more richly structured form, they possess superior knowledge of situational probabilities for their sport, and they are better able to plan their own actions in advance. In terms of movement *per se*, expert athletes produce movements with greater consistency and adaptability, greater efficiency and effectiveness, and greater speed and accuracy than can less skilled performers. In addition, expert athletes have also been shown to be able to produce movement more automatically, with reduced attention demand and yet with superior ongoing monitoring, than can less skilled individuals.

An outstanding feature of expert performance is therefore the capacity to satisfy simultaneously competing task demands (such as speed versus accuracy, consistency versus adaptability, or attention versus monitoring) in a manner that optimizes task performance. Across each of the elements of expert sports performance, the challenge for researchers is to move beyond the existing descriptive knowledge about expertise toward the more fundamental goals of explaining and understanding how this expert ad-

vantage develops and is achieved. This challenge is being taken up at the time of writing in at least three major areas of focus for contemporary sports expertise research.

One major current research focus is the determination of the limiting factors to sports performance. While much is now known about factors that differentiate reliably the expert athlete from everyone else, an equally important body of knowledge is that accrued on factors which do *not* appear to be important discriminators. The accumulating evidence showing the inability of generalized perceptual, cognitive, and motor tests (such as simple visual tests, and generic measures of reaction time) to differentiate experts from others suggest that the attributes being measured by these tests are not the limiting factors to sports performance (Abernethy et al. 1998). Approaches which seek to improve sports skill by training these attributes are unlikely to be effective. The evidence on other aspects, such as whether or not experts and novices differ systematically in their sport-specific eye movement patterns, is less clear-cut, leaving issues as to the efficacy of training learners to model the scan patterns of experts unresolved at this time (Williams et al. 1998).

A second major current research focus is on the determination of possible differences in information usage and dependence between experts and novices. Determining the specific information (or cues) used by experts and novices in sport tasks is a challenging undertaking. To date, the main approaches that have been used involve selective temporal and/or spatial masking of potential information sources, manipulation of kinematic display information using computer digitization, and the recording of eye movement (or visual search) patterns. Such approaches indicate some systematic differences in the specific cues used by the experts and less skilled people—experts, in time-constrained sports at least, being able to pick up information from early-occurring cues that novices cannot utilize. More precise determination of the specific information sources guiding the selection and production of movement by experts in particular sport settings may, in the future, provide a more principled basis for training, and instructional and feedback augmentation than is currently possible.

A third major contemporary research focus is on the critical question of how learning to be an expert takes place. The approaches that describe sports expertise in terms of component skills and limiting factors, and in terms of differences in information usage, provide a valuable starting point for knowing the 'end product' differences between experts and novices; but they are silent with respect to the types and amount of practice, the critical role models, developmental experiences and social support structures that are necessary (if not sufficient) for expertise to be achieved. A perspective, advanced by Anders Ericsson and others (e.g. Ericsson et al. 1993), is that the sheer quantum of intense goal-directed (*deliberate*) practice is the single best predictor of the attainment of expertise. This perspective is stimulating significant research activity as others attempt to verify the validity and generality of this proposition across sports and attempt to determine the role played by the type of practice and by other contextual factors (such as parental support levels and relative age in first entering organized sport) in the development of expertise (e.g., see Singer and Janelle 1999, Starkes et al. 1996). An emerging view, though as yet supported by only a modest evidence base, is that relatively early exposure to competition with adults, opportunities to model and learn by watching from an early age, and the existence of broad diversity in practice conditions in the formative years, especially through settings that encourage creativity and experimentation without excess emphasis on outcomes, may all be important environmental ingredients for the nurturing of expert performers.

4. *Methodological Issues and Challenges*

Studying sports experts and understanding the basis of sports expertise poses some unique, and difficult, methodological challenges (Abernethy et al. 1993). Exceptional performers in any particular sport are, by definition, relatively few in number. A consequence of this is that many/most studies of sports expertise suffer from either limited statistical power (because of the difficulty in assembling a large sample size of genuine experts), or a dilution of the degree of 'expertise' within the expert group. With considerable variability evident in the stringency with which experts are defined, it is not an uncommon observation that the expert sample in one study may well qualify as the less skilled control sample in another. This absence of agreed, universal criteria or even convention as to what minimally constitutes an expert clearly works against the development of a consolidated knowledge base on sports expertise.

A further, vexing methodological problem relates to the dissociation of expertise effects from effects due not to expertise *per se* but rather due simply to experience. In the majority of the existing studies on sport expertise, key characteristics of the expert group are compared directly with those of a control group, usually consisting of task novices. As a consequence, the groups being compared differ not only in terms of their level of task expertise but also in their level of task experience. It is frequently difficult, therefore, to ascertain whether any observed differences are related genuinely to expertise or are simply a product of different levels of exposure to the task. Using additional groups differing in performance level but matched in terms of years of playing experience can go some way toward addressing this issue, although even with such controls the quality and quantity of experience are so tightly interrelated with skill level

that the confounding effect of experience cannot be completely disentangled from the issues of expertise.

Sport expertise is clearly not unidimensional, yet many of the prevailing methodological approaches used in an attempt to understand sport expertise have been of this type. As sport tasks provide the potential for minor deficiencies in some skill components to be offset by strengths in others, a raft of dependent measures tapping different facets of performance rather than unitary measures is obviously needed to capture fully the essence and individual variability that goes toward the making of an expert. More consistent use of multiple dependent measures is to be expected in future research endeavors in this field.

Unlike many other fields of study, where the key variable(s) of interest can be mapped effectively over relatively short time periods, the cumulative and uncertain nature of the development of expertise makes prospective studies—desirable as they may be—logistically very difficult. The accumulation of data on the lifespan development of experts therefore relies heavily on retrospective self-reports by athletes, yet such methods need considerable confirmation from other sources to avoid potential biases and inaccuracies. With the growing emphasis on mapping of the individual developmental histories of athletes, a key challenge for the future is to continue to modify and improve the reliability and validity of the methods used for acquiring and comparing lifespan data.

5. *Future Directions*

The major theoretical challenge for the sport expertise field is to understand, in a much more coherent way than is the case at the time of writing, the mechanisms responsible for the observable expert–novice differences in overall performance and in specific components of performance. Closer linkage of the research thrust in sports expertise with the present parallel theory development in motor control and learning, and in expert systems in cognitive science, appears imperative.

The major challenge from an applied psychology perspective is to translate the knowledge being acquired about sport expertise into useful practical directions for the guidance of sports training and instruction. Understanding more about the respective roles of implicit and explicit learning in expert performance, and utilizing fully the opportunities created through the new technologies (see *Simulation and Training in Work Settings*; *Virtual Reality*, *Psychology of*) will undoubtedly become increasingly critical in the future.

Sports, Economics of

1. *Introduction*

Sport is organized among individuals and among teams, and is professional or amateur. Most of the interesting questions on the economics of sport relate to professional team sport, which is the focus here. Over their histories, and until very recently, in some leagues, players have been restricted from moving between clubs within a league. Club owners have claimed that reservation of players or the imposition of transfer fees was necessary to maintain financial soundness of small clubs and to preserve competitive balance within leagues. In this article, pay and per-

formance under player reservation and under free agency are evaluated, along with issues relating to competitive balance. Under player reservation, player pay is less than the players' contribution to club incremental revenue. Under free agency, the players, ultimately, receive all of the incremental revenue. It is shown that the intrateam salary structure, with its wide pay differential between starting and backup players, is rational and wealth-maximizing. Competitive balance is value-maximizing, also. The effect of free agency, revenue-sharing among clubs, team salary caps, and syndicate ownership on competitive balance are evaluated.

2. Players' Market

2.1 Player Achievement: The Hot Hand and Sequences

In part, the appeal of professional team sport is the extraordinary playing ability of the athletes. This is demonstrated repeatedly on television, and commented on widely. Such feats are value-maximizing for the leagues, since they promote interest in the sport. A case can be made that baseball has been resuscitated by the record-breaking home run duel between Mark McGuire and Sammy Sosa, in the 1998 season.

While there are many ways of measuring player achievement, none excites more discussion than 'hot hands.' Mere mortals seek a causative explanation for the player who achieves a long sequence. But, hot hands is a myth, and the observed runs are no different from what one expects from a (possibly unbalanced) coin toss (successive heads in a row, when the probability of a head is some fixed number p). Even premier players in basketball do not make much more than half of their field goals. In the course of a season, such players would be expected to have one run of seven made shots in a row, and in the course of a career a sequence of 10 in a row. Naturally, players with higher shooting averages have longer sequences. Measured over the 50-odd year history of the National Basketball Association, the coin toss model predicts that at least one 0.5 shooter will make 16 shots in a row.

Research on sequences in sports (for basketball, see Gilovich et al. 1985, Camerer 1989) reveals only one exception to the coin toss model (Gould 1991). In 1941, Joe DiMaggio hit safely in 56 consecutive games. He hit 0.357 that year, and the coin toss model predicts that by chance one would see a sequence of that length once in 10 trillion trillion games. What an achievement!

2.2 Player Pay under Player Reservation and under Free Agency

Prior to the mid-1970s, baseball and basketball players could not negotiate freely with more than one team, and this restriction applied in football and in hockey, until more recent times. In European football (soccer), until 1995, player movement was restricted by the substantial transfer fee that had to be paid to the club owning the player's contract.

The result of player reservation in professional team sport was that players were exploited economically by the owners in the sense that they were paid less than the incremental revenue that their performance brought to the club (Scully 1974). It is not the case that the athletes in professional sports were poor by any means, since they were paid on average several times a working man's wage and the best of them received perhaps 10 times the pay of the less gifted performers. But, their pay was not equal to what they could have earned if they were free to offer their talent to the highest bidding club.

Veteran free agency has led to an enormous explosion in player salaries and in the share of club revenue captured by the players. Average player salaries are 50 or more times their level in the late 1960s, and player payroll costs are three or more times their share of club revenues (Scully 1989, 1995). While a superstar player then could expect to earn 10 times or so the pay of a rookie player, now a factor of 50 or more is not extraordinary. On the whole, then, the introduction of veteran free agency has eliminated monopsonistic exploitation of players in professional team sports. Nevertheless, pockets of exploitation exist, particularly among promising rookies, journeymen players, and first-round draft choices from the amateur ranks. This is so because there is not complete freedom in the players' market, such as would occur with teams competing for all players by offering one year or multiyear contracts for their services. New entrants into the professional ranks, if they survive the intense competition for their positions, must wait several years before they are free to negotiate with other clubs.

2.3 Pay Structure in Professional Team Sports

Payment for player performance is not piece rate, that is, a player who is twice as good as another, measured by some performance metric, does not receive twice the pay. Rather, relatively small differences in player performance often are associated with large differences in player compensation. The pay structure in professional team sport is hierarchical, as in a rank-order tournament (Lazear and Rosen 1981).

In professional sports, owners of clubs or sponsors of events, such as in tennis and golf, want all athletes to develop their skills to their maximum potential and for the athletes to expend maximum effort per contest. This desire is profit motivated: contests among highly skilled players who expend the maximum effort at winning are more valuable, and it is costly to monitor effort (prevent shirking). These facts imply that there will exist an optimal hierarchy of payments (an

optimal prize structure in golf and tennis, an optimal intraclub salary structure in professional team sport) that aligns player behavior (investments in developing playing skills and expending effort) with the owner's or sponsor's objective function. Individual sports, such as tennis and golf, are rank-order tournaments where the reward structure is predetermined and a competitor achieves the next higher payment by advancing one position in the rank of competitors. In professional team sports, there is a team rank-order tournament in which players compete for starting positions that are rewarded greatly and backup positions that pay a great deal less (Porter and Scully 1996). Starting players are always threatened by the performance of the lower-ranked backup players. This threat makes the performance of the starter like a serially repeated contest in the individual sports.

2.4 Pay and Performance Profiles

There are several features about player careers. Most enter the professional ranks as untested rookies, having spent a number of years in the minor leagues or in the amateur ranks. During that training period, pay is low. When a player gets a contract with a professional team, often they play infrequently and may be traded to another club. Only if their play is judged superior, will they play frequently. Player performance tends to improve over a certain portion of the playing career, reaches a peak, and then declines as age takes its toll on reflexes and physical ability. The rise in performance may be due in part to learning by doing, but mainly it is due to player and club investments in honing playing skills. The age at which the decline in performance sets in, and perhaps its rate, is related to player investments in skill and conditioning. Thus, the life cycle of performance and that of player pay is the result of a team rank-order tournament. Players invest endogenously in developing their skills, which determines their chance of securing a starting position. Under free agency, pay for starters is considerably more than for irregular players. The high rewards for starting players implies that every effort (training, conditioning, diet) will be made to maintain peak or near-peak performance for as long as possible.

Empirical evidence on the life cycle of performance and pay is measured most readily for baseball players (Scully 1995). During the monopsony era (sample period 1964–75), it was found that the peak in baseball player performance occurred at 1,596 games (about 10.6 years of play) and that the peak in salary occurred at 2,328 games (15.5 years). During the postfree agency era (sample period 1977–92), the peak in performance occurred much earlier (1,347 games or 9 years), and the peak in pay a great deal earlier (1,523 games or 10.2 years). The sharp increase in the hierarchy of earnings brought about by veteran free agency induced greater player investment in developing playing skills more rapidly. As such, baseball players reach their maximum performance potential about 1.5 years earlier under free agency.

Moreover, if one compares the profiles of performance and pay in the monopsony and the free agency periods one finds the following. Player productivity exceeds player pay up until 1,550 games (10.3 years) in the monopsony period, which is an indication of exploitation. In the free agency period, after 547 games (3.6 years) player pay exceeds player performance.

3. Competitive Balance

3.1 Competitive Balance within Professional Team Sports Leagues

An important dimension of playing quality is the relative strengths of the teams on the playing field (competitive balance). Fans want their favorite team to win under uncertainty. If the top club always beat the next ranked club, and so on, the games would be exhibitions, not contests, and they would have little market value. Some degree of uncertainty of outcome is necessary in sports, and this uncertainty is greater the more equal the playing strengths of the competitors. Greater equality of playing strengths among the clubs is wealth maximizing. Attendance at games and viewership on television is higher the closer the standings of the clubs are over a season.

Competitive balance depends mainly on the comparative financial strengths of the clubs. Teams earn revenue primarily from ticket sales and from broadcast fees. The main cost is player payroll. Attendance is determined chiefly by market (city) size and the club's record (Noll 1974). Since teams are located in cities of markedly different size, the prospect of fielding a competitive team depends in part on where the club is located, but also on how revenues are divided up among the clubs. In basketball and hockey, the home team receives all of the ticket revenue. In baseball, the gate split is about 85:15. In football, the gate division is 60:40. All national broadcast revenues are divided evenly among the clubs in all professional team sports. The difference in the formula for dividing up the gate receipts corresponds roughly to the dispersion in team financial strengths across the various leagues. The highest revenue-producing basketball team tends to have about 2.7 times the revenue of the lowest revenue-producing club, while it is about 2.9 times in hockey. The top club in baseball has about 2.5 times the revenue of the poorest drawing team. In football, the top team tends to have about 70 percent more revenue than the lowest revenue-producing team. With clubs distributed in unequal size markets and with a ban on unilateral relocation of clubs to the more lucrative markets, the more unequal the division of revenue among clubs the less will be the competitive balance within a league.

There are several ways of measuring competitive balance. The most obvious is to compare the actual number of championships with the theoretical number (one divided by the number of clubs times the number of years the club has existed). A second is to compare the historical average win records among the clubs. A third, and more precise, way is to compute the standard deviation among the win percentages of the clubs (Scully 1989). To make comparisons of competitive balance among the leagues, differences in the number of games played in a season needs to be taken into account, since the standard deviation of the win percent is inversely related to the number of games. Competitive balance is measured as the ratio of the actual standard deviation to the theoretical standard deviation under equality of playing strengths ($0.5/\sqrt{g}$, where g is the number of games).

Using this procedure, Quirk and Fort (1992) found for the period 1980–90 that football had the greatest competitive balance with a ratio ($\sigma/(0.5/\sqrt{g})$) of 1.53, while basketball had the least competitive balance with a ratio of 2.73. Baseball, with a ratio of 1.67 and hockey with 1.91 had relative playing strengths between football and basketball. Measured over the history of these leagues, the rankings of competitive balance remain unchanged. Football has always been the most competitively balanced, and basketball the least. Moreover, over time, competitive balance has improved significantly in baseball, somewhat in football, since the 1960s, but has remained substantially unchanged in basketball and hockey. Nevertheless, since the actual standard deviation of win percents greatly exceeds the theoretical standard deviation, one cannot conclude that competitive balance exists in any professional team sports league.

With the advent of veteran free agency, owners claimed that competitive balance would be destroyed. There is no difference in competitive balance in baseball in the period of veteran free agency compared to the player reservation period. While less clear cut, because freedom of player movement proceeded in steps in basketball, competitive balance has not changed in basketball in the era of freedom of player movement.

3.2 Freedom of Player Movement and Competitive Balance

Club owners, particularly in American baseball and European football, always have claimed that restrictions on player transfers are necessary to ensure competitive playing balance within a league and to protect the investments in the smaller city franchises. Economists, since Rottenberg (1956) have been very skeptical of this claim and there is no empirical evidence to support it. While it is true that there is a tendency for the best players to migrate to the larger city franchises, freedom of player movement or restrictions on player-initiated movement has no bearing on the distribution of playing talent within a league (El-Hodiri and Quirk 1971). Under free agency, players will migrate to the best paying clubs. The franchises that pay the most are those that expect the largest incremental revenue from those players' performances. Since an increment in the win percent raises revenue more in a large city than in a small city, the best players tend to migrate to the big city franchises. At issue is whether in a market where player-initiated movement is forbidden (player reservation, transfer fees), would a small city club keep a star player that it had acquired through a draft or an assignment? On the roster of that club, the player is worth, say, $1 million in incremental revenue. On a large city franchise, that player's performance is worth, say, $3 million. Without a scrupulously enforced league ban on cash sales of player contracts, the franchise in the small city has an incentive to sell the player's contract to the big city club, and capture some portion of that $2 million difference in incremental value. Therefore, players are allocated across clubs based on their highest incremental revenue. Whether the player or the club owns the contract (property right) is irrelevant to the allocation of playing talent within a league. That the efficient allocation of a resource is independent of who owns the property right is, of course, the famous Coase (1960) invariance theorem, but the essence of that theorem was discovered independently by Rottenberg (1956) in his earlier paper on the baseball players' market. While the distribution of playing talent is independent of the degree of freedom in the market for players, the distribution of the rents between owners and players is not. The players obtain a much higher share of the rents arising from their scarce talent under free agency than would be so under league restrictions on player-initiated transfers.

Figure 1
Freedom of player movement and competitive balance

The invariance of the allocation of playing talent to the degree of freedom in the players' market is illustrated in Fig. 1 for a two-club league. On the

vertical axis is club revenue and player cost per point in the win percent. On the assumption that revenue per point in the win percent declines as the win percent increases, marginal revenue (MR) declines with the win percent. MC is the cost per point in the win percent under free agency. Since top-playing talent is rarer than mediocre talent, its cost per unit is higher. Equilibrium, in the sense that both clubs maximize profits, occurs at $E(1)$ for the large city club (designated as team 1) with its higher marginal revenue, and where marginal revenue equals the marginal cost of playing talent ($MR(1) = MC$), and at $E(2)$ for the small city club (team 2), where $MR(2) = MC$. Thus, in equilibrium, $MR(1) = MR(2) = MC$. With $MR(1) > MR(2)$, the profit-maximizing distribution of playing talent is such that team 1 has a win record of 0.600 and team 2 has 0.400.

Now, assume that a reverse order of finish amateur draft, under which the club with the worst record gets to draft first, leaves each team with equal talent levels (each club will have a 0.500 record). Under this condition, the market is in disequilibrium. For club 1(cut point G), at a 0.500 win percent, marginal revenue exceeds marginal cost (the triangle GDE(1) represents potential profit), while, for club 2 (cut point D), marginal cost exceeds marginal revenue (the triangle CDE(2) represents a loss). Under free agency, club 1 will bid away playing talent from club 2 to the point at which a profit-maximizing equilibrium is re-established at $E(1)$ and $E(2)$, with club records of 0.600 and 0.400. Thus, under free agency, an initial equalizing redistribution of playing talent through a reverse order of finish drafting mechanism will be ineffective in maintaining equality of play with a league. The better players will migrate to the better paying, large city clubs, where their marginal revenue is higher.

Under player reservation, the player comes to terms with the club that owns their contract, or does not play. This condition leads to pay less than the incremental value associated with the player's contribution. The marginal cost per point in the win percent under monopsony is labeled MC′; in Fig. 1. Under monopsony, with an equal distribution of playing talent among the clubs (each club having a 0.500 record), team 2 has a level of playing talent such that marginal revenue equals marginal cost (point C in the figure), but club 1 has marginal revenue in excess of marginal cost (point G in the figure). There is more profit to be had on club 1, if it can purchase higher quality playing talent from club 2. It is in the interest of club 2 to sell that playing talent for cash, since by lowering its win percent profits increase. Equilibrium in the distribution of playing talent occurs when both clubs earn an equal profit from the distribution of playing talent (win percents). This occurs with a record of 0.400 for club 2, with $MR(2) > MC'$; by $BE(2)$, and 0.600 for club 1, with $MR(1) > MC'$; by $AE(1)$, and with $BE(2) = AE(1)$. Observe that under monopsony the profit-maximizing win percents remain as they

Figure 2
Revenue sharing and competitive balance

were under free agency. The gaps $AE(1)$ and $BE(2)$, in the figure, represent the monopsony rent transferred from the players to the owners under a player reservation rule. Thus, under monopsony, the distribution of playing talent remains the same as under free agency, but the big city club has cross-subsidized the small city team through a cash-sale purchase of player contracts. Equalization of playing talent is not possible under free agency or under player reservation with cash sales of player contracts. The only way in which reverse-order drafting will lead to equalization of playing talent among clubs that play in different size cities is under player reservation with a ban on cash sales of player contracts. But, note that under such a ban profit maximization is not achieved. Club 2 earns more profit with a win percent of 0.400 than with a record of 0.500, and club 1 earns more with a record of 0.600. Even if a formal ban on cash sales is imposed by a league, these profit opportunities are a powerful incentive to devise mechanisms for player reallocations (lopsided player trades, a player trade for compensation and a player named later) that will restore the distribution of win percents among the clubs toward their profit-maximizing distribution.

3.3 Revenue Sharing and Competitive Balance

If the degree of competiveness in the players' market does not affect competitive balance, will it be affected by the division of revenue among the clubs? Revenue division tends to moderate the distribution of revenue among teams within a league, but has no effect on competitive balance. The conclusion is illustrated in Fig. 2. Without revenue sharing, equilibrium is at $E(1)$ for team 1 and $E(2)$ for club 2. Profit maximization leads to 0.600 and 0.400 win records. Now, let revenue sharing occur such that each club has the same marginal revenue. The effect of revenue sharing is to

lower the marginal revenue for both clubs from $MR(1)$ to $MR(1)'$ for team 1 and from $MR(2)$ to $MR(2)'$ for club 2. Algebraic proof: under revenue sharing $R_i = sR_i + (1-s)R_j$, $i = 1, 2$, $j = 1, 2$, $i \neq j$, with s as the revenue share. In a two-team league, an increase in the number of games won (or, the win percent) for one club means a corresponding decrease in wins for the other club. Then, the change in revenue is $MR_i' = sMR_i - (1-s)MR_j$. The profit-maximizing equilibrium under revenue-sharing is at $E(1)'$ for club 1 and $E(2)'$ for club 2, where $MR(1)' = MR(2)' = MC''$. Note that the marginal cost of playing talent is proportionately lower under revenue division than in its absence ($MC'' < MC$). This is so because the worth of playing talent to the clubs is inversely proportional to the amount of revenue sharing. The distribution of playing strengths among the clubs is unaffected by the revenue division rule. While revenue sharing reduces the incentive of clubs to bid for scarce playing talent, it also reduces the financial incentive to win.

3.4 Team Salary Limits and Competitive Balance

Since the advent of veteran free agency in professional team sport, owners have sought mechanisms to constrain the competition for playing talent that they perceive as financially ruinous. One mechanism, invented by basketball, in 1980, is the team salary cap, a device that in theory imposes a maximum salary as a percent of gross revenue (and, a minimum percentage that applies to small city clubs). Football, since 1993, has a team salary cap, and baseball wants one, but has been blocked in its ambition by the players' union. Can a salary cap equalize playing strengths within a league? Suppose that a binding salary cap is imposed that fixes player salaries at a certain percentage of league revenues. The marginal cost of playing talent falls under the salary cap from its level under free agency. If scrupulously enforced, all clubs have the same team salary costs, and if there are no information asymmetries about expected playing talent and no differences in coaching quality, all clubs will have 0.500 records. Like the solution of player reservation with a ban on cash sales of player contracts, the distribution of win percents brought about by a hard salary cap is stable, but it is not profit maximizing, nor does it maximize league revenue. A large city team can earn more profit by acquiring better playing talent and a small market club can earn more by lowering its level of playing talent.

In basketball, the team salary constraint is relaxed significantly by the so-called Larry Bird exemption. Under the exemption, a team may re-sign a veteran free agent at whatever cost, and not have that player's salary count in the salary cap. This has led to most clubs having player payrolls well in excess of the cap, and this transforms the team salary limit concept into a soft or nonbinding constraint. The Larry Bird exemption was the main point of dispute between the basketball players and the owners, prior to the 1998–9 season. Salary caps have led, also, to creative financial arrangements such as large player signing bonuses relative to annual salary, back-end loaded long-term player salary contracts, deferred player compensation, and the shifting of revenue from team operations to other, nonteam entities. Sufficient erosion in the constraint of the salary cap, as with a player reservation system with player transfers for cash, can lead to the same distribution of playing talent as is attained with unrestricted free agency.

3.5 Syndicate Ownership and Competitive Balance

Major league soccer in the US is organized in an entirely different way than the main professional team sports leagues. The latter are composed of clubs that are privately owned and that are subject to various agreements with their respective leagues. In soccer, players contract with the league, not a club within the league, a fixed team salary is enforced, investors operate but do not own individual clubs, and all revenues are divided equally among the clubs. Thus, in theory, marginal revenue is equalized across all clubs at a win record of 0.500. Alternatively, there is no extra money to be made by a club from winning a championship. Nor is there any financial penalty for finishing in the cellar. While syndication will bring about equality of playing strengths, it raises very serious questions about club independence and competitive integrity. Baseball's early experiment with syndication failed. Interleague wars weakened many clubs and the aid from the stronger to the weaker clubs led to cross-ownership. In 1901, the surviving National League clubs formed a syndicate. Fans were not impressed, and believed that the outcomes of the games suspect. 'Trust' or cross-ownership in the National League was ended in 1902.

G. W. Scully

Sports Performance, Age Differences in

'Sports,' wrote veteran journalist Frayne (1990) in his memoir, are just 'children's games that seem to enchant millions of grownups.' Frayne's irony is fitting. Although dictionaries define sports as pleasant pastimes, to the athletes, supporters, and wider society, sport is so much more. From classical times to the modern era, sports waxed and waned in their significance for religion, militarism, business, and occupation (McIntosh 1963). Innumerable people devoted their lives to sport, and far too many lost life because of sport. At least one war was blamed on sport, and at least one war halted because of sport (Morris 1981). Nowadays, television has made sport a truly international drama, enchanting, enraging, dismaying, or even boring audiences of tens of millions.

Social and behavioral scientists study sport for many reasons. Social scientists study societal influences on sports and of sports. Behavioral scientists study sports to gain knowledge about expertise in physical performance, including its developmental progression across the life span. This article examines the attributes of expert performance in different sports in relation to the aging of expert performers.

1. Expertise and Performance

1.1 Identification of Expertise

Who is an expert? A simple answer might be someone with acknowledged skill. This interpretation equates expertise with competence. Although most people are competent at skills practiced routinely in everyday life (e.g., driving), the appellation of expertise usually connotes a higher degree of exclusivity. Experts are not people who are simply competent, but those who exhibit exclusive competence consistently (Salthouse 1991).

There are two types of experts. First, experts who are normatively exclusive lie at the upper extreme of normal distributions for everyday skills (e.g., walking, running, cycling). However, normative expertise also depends upon the population providing the distribution. Running 1,500 meters in 6 minutes certainly denotes expertise within the overall adult population, falling within the top few percentile points. But compared to other runners, such a performance might be merely average. Unless that runner was a male aged 80 years or a female aged 65 years, in which case the performance would approximate a world record. Most sports accommodate to normative relativism by including age and gender distinctions within the competitive categories.

Second, other experts have exclusive skills not possessed by the majority of the population. Only seasoned race walkers can walk 1,500 meters in 6 minutes because none but race walkers have mastered that effective but peculiar style of walking. Most race walkers, before the 1950s, were of European ancestry. Similarly, equestrians might be considered experts because few people in relatively few countries ride horses competitively. These examples illustrate cultural and historical relativism in exclusive skill, with both pedestrian and equestrian pursuits being less popular today than in previous centuries.

Athletes at the upper levels of expertise are termed elite athletes. Elite athletes include those who break world records, win international championships, or compete at the highest levels within their country. Comparison of age differences in performances by elite athletes can clarify the limits to which life-span developmental processes impact on physical performance.

1.2 Paradigms for the Study of Expertise

Research on expertise gained impetus from studies of games like chess. Chase and Simon's (1973) research with chess players of different proficiencies elucidated cognitive processes contributing to superior performance. The same dominant paradigm of comparing people at different levels of proficiency found application in studies of occupation (e.g., surgical skill, typing, computer programming), recreation (e.g., bridge, video games), and sport (e.g., badminton, soccer). Spirduso (1980) pioneered a variant of this paradigm by comparing athletes and nonathletes at different ages to identify fast reaction time as an ability retained by athletes.

Other approaches to the study of expertise derived from ability, ecological, informational, and training models (Allard 1993). These paradigms respectively seek to identify abilities common to expert performers, environmental cues that trigger skilled performance, sequencing within performance, and the limits to which expertise can be enhanced by training. A recent development is the application of compensation theory to performances by aging athletes (Stones and Kozma 1995).

Statistical modeling of age trends in athletic performance has emerged as an influential paradigm in the study of sports expertise (Moore 1975, Stones and Kozma 1986). Age-class records in individual sports such as singles rowing, swimming, track and field, and weight lifting provide invaluable sources of data about age changes in physical performance. Not only is performance measured as meticulously as in any laboratory study, but the record holders (being the best in their country, or the world, at their respective age) can reasonably be assumed to be fit and healthy, with their performance relatively unaffected by chronic disease. Although sport for veterans became organized only during the 1970s, the numbers of competitors are now very large in some sports. The biannual championship of World Association of Veteran Athletes regularly attracts 5,000 or more track and field athletes from around the world, and the US Masters swimming organization has more than 37,000 members.

It is more difficult to evaluate performances by older athletes in team sports. Changes in team tactics, the composition of a team, the overall performance by a team, and transfer to another team are all factors that can affect the contributions of individual athletes. It is difficult to disentangle such extraneous effects from those of changing skill. However, two kinds of data enable insight into the sources of age differences in performance. First, aggregated longitudinal data show age trends within a sport. Examples include Stones and Kozma (1995), who analyzed aggregated data from ice hockey, suggesting that players compensate for late-career decreases in point scoring by aggressive play (i.e., penalty minutes). Also, Langford's (1987) research showed that home runs and batting averages in baseball peaked around the age of 27 years. Second, the ages of elite athletes can be compared across different sports. Limitations to this kind of comparison include changing historical trends, such that ages at peak performance and retirement in the 1900s may not mirror those of today.

1.3 Components of Expertise

The components of motor expertise include knowledge, skill, experience, and motivation. These components are hypothesized to change in relative importance over the course of athletes' careers (Abernethy et al. 1993). Knowledge becomes less important after an early acquisition phase; motor skills decrease in significance, particularly in later life; experience increases in importance over the life span; motivation may decrease or reflect changing priorities (see *Sports as Expertise*, *Psychology of*).

Accumulated experience contributes to performance in two ways. First, athletes become more adept in the use of strategy. Second, experience helps athletes to choose among different modes of compensation if performance falls below expectations. Examples of compensation include attempts improve skill, the substitution of an alternative skill, or modification of expectations (Stones and Kozma 1995).

Motivation can be differentiated into intrinsic and extrinsic components. Intrinsic motivations include desires to achieve, retain competence, and remain healthy. Extrinsic motivations include praise and payment. Most older athletes are long-time competitors who cite intrinsic benefits to health and competence as reasons for participation.

1.4 Categorization of Sports

Sports have been categorized on three dimensions other than individual vs. team sports. The first is between closed and open skills. Closed skills sports are performed in an unvarying environment, with the performance evaluated by the quality of movement patterns. Examples include individual sports such as figure skating, diving, and gymnastics, and team sports like synchronized swimming. Open skill sports are performed in a varying environment. The sources of variation include changes produced by an opponent (e.g., boxing, baseball, soccer), as well as in physical topography (golf). In contrast to closed skill sports, performance in open skill sports is evaluated by the outcome of movement rather than the motor pattern itself.

The second distinction refers to physical effort, the main components of which are power and endurance. Power events fall into two categories, both of which are 'fueled' by anaerobic sources that are depleted rapidly. Sprinting involves a continuous expenditure of high power over a short period. Peak power events involve an explosive use of power (e.g., jumping, throwing, pole vaulting, weight lifting). Events of longer duration require endurance rather than power (e.g., distance running, race walking). Such activity draws mainly on aerobic sources that provide for relatively low power expenditures over extended periods of time. Not all sports require much physical effort. Frayne (1990) wrote the following about baseball: 'Except for the pitcher and catcher, nobody does much of anything for long periods but stand around and wait.' Cricket is similar in this respect to baseball, and contrasts with sports like rugby and football that intermittently tax both power and endurance.

The final distinction refers to the use of strategy. Open skill sports such as motor racing, snooker, and tennis all are high strategy sports. Low strategy activities include most closed skill sports, but also open skill sports such as darts, swimming, and archery.

2. Age Differences in Different Sports

The preceding categorization suggests that sports can be grouped into four main categories. Closed skill sports are different from other sports because per-

formance is evaluated by the quality of movement rather than the outcome of movement. Although such sports vary in the physical effort required (e.g., divers expend less effort than gymnasts or skaters) practice is more important to performance than strategy. Open skill sports can be divided into three groups: sports requiring (a) effort rather than strategy, (b) strategy rather than effort, and (a) both strategy and effort. Differences in the ages of the elite performers are as follows.

2.1 Closed Skill Sports

Athletes in closed skill sports typically attain peak performance at a young age. Examples include Fu Mingxia, who had never practiced a complete set of dives before she became part of the Chinese juniors' diving team at age 11 years. Within 3 years she was both world champion and the youngest Olympic champion to that time. At the same 1992 Barcelona Olympics, another Chinese diver became a men's champion at the age of 13 years. Elite gymnasts are also youthful performers, with 14-year-olds regularly appearing in elite competition. In figure skating, Tara Lipinski of the US became the Olympic champion in 1998 at age 15 years, and the youngest ever champion in an individual event. Another figure skater, Sonja Henie, previously held that distinction.

Although approximately 15 percent of Olympic triple gold medal winners (i.e., winners of the same event in three successive games) competed in closed skill sports, few such athletes participate in elite competition beyond age 30 years. Many elite skaters become professional entertainers during retirement. Many gymnasts, including former Olympic champion Olga Korbut, become coaches. These examples illustrate compensation, wherein athletes substitute skills related to those formerly practiced.

2.2 Open Skill Sports Requiring Effort Rather than Strategy

Although swimmers may break world records in their teens, the recent history of track and field overturns traditional beliefs that athletes in power events both peak and fade at earlier ages than athletes in endurance events (Spirduso 1995). With the exception of the race walker Wan Yan, the youngest and oldest world record holders and Olympic champions all competed in power events.

Statistical modeling of age differences among veteran athletes suggests that performance decreases proportionate to the demands on power and endurance (Stones and Kozma 1986, 1996). Figure 1 illustrates these trends with swimming records.

Figure 1 is based on 1999 US Masters swimming records at different ages expressed as a ratio of 1999 world records. The ratios were combined for males and females in the 50 m and 200 m backstroke and butterfly. The butterfly requires more power than the backstroke (Astrand and Rodahl 1977), and the 200 m event taxes endurance more than the 50 m. The findings show performance times to increase exponentially with age, with greater age differences in events requiring higher power (butterfly) and more endurance (200 m). Comparable trends can be obtained from analysis of track and field records (Spirduso 1995, Stones and Kozma 1996).

Figure 1
Age group records relative to world records in 50 m and 200 m backstroke and butterfly swimming events

2.3 Open Skill Sports Requiring Strategy Rather than Effort

Archery, baseball, cricket, equestrianism, golf, fencing, motor racing, and yachting all belong to this category. Although the athletes may earn elite status in their teens, their careers include the longest in any sport. Archer Galen Spencer won an Olympic gold medal at age 64 years. The youngest and oldest major league baseball players in the twentieth century were respectively aged 15 and 59 years. Seven Pakistani cricketers represented their country at 16 years or younger, and four cricketers from various countries competed internationally when aged over 50 years. In equestrian sport, the age range for the youngest and oldest qualifiers for the National Finals Rodeo in the US is the same as for baseball, and the career of Lester Piggott (England's most famous jockey) spanned 47 years (i.e., from his first win, at age 12 years, to his retirement at age 59 years). Ivan Osiier competed in Olympic fencing competitions over a 40-year span. The youngest and oldest golfers who won a national championship (Sri Lanka) were aged 12 and 54 years, respectively. Although the youngest Grand Prix motor racing winners were in their twenties, the oldest winners and competitors were aged in their fifties. Magnus Konow competed in Olympic yachting over a 40-year period. Experience undoubtedly contributes

to length of careers in these sports, with the practiced motor skills being resistant to age-related physical decline.

2.4 Open Skill Sports Requiring Strategy and Effort

Such sports include basketball, various forms of football (e.g., soccer), ice hockey, and tennis. The youngest players to compete at elite levels are in their mid-to-late teens, and the oldest generally in their forties. Examples include elite basketball players (youngest, 18 years; oldest, 43 years), Wimbledon tennis champions (youngest, 15 years; oldest, 43 years), and international soccer players (youngest, 17 years; oldest, 42 years). Within domestic soccer, Stones and Kozma (1995) reported that more than half of the oldest professional soccer players in the top European nations were goalkeepers, a position that requires the least physical effort. This finding suggests that careers may be longer if the demands on effort are lower. Very few athletes in this category compete at elite levels in their fifties, but with notable exceptions that include Sir Stanley Matthews in soccer and Gordie Howe in ice hockey.

3. Conclusions

Aging lowers the potential to perform at elite levels in sports that require power, endurance, endurance, and closed patterns of skill. Aging has less effect on performance in high strategy sports, and particularly those that require low effort.

Sports Performance, Self-regulation of

Self-regulation refers to a regulation of the psychological state of an individual by the individual her- or himself. Self-regulation becomes necessary when internal or external barriers threaten the efficient realization of an intended action. Self-regulation consists of auxiliary processes that are based on meta-knowledge (metacognitive or metamotivational knowledge). These auxiliary processes support basic action processes like attention, motivation, etc., if those are not sufficient for optimum goal attainment.

Within the last decades it has been widely acknowledged that the so-called mental side is a decisive factor in athletic performance. As physical training has become more and more optimized for all athletes participating in major competitions, the winning edge is often furnished by an athlete's self-regulatory ability. Of two equally talented and equally well-prepared athletes, the one with better psychological skills is likely to win. Without such skills athletes may become their own worst enemy during competition, imposing psychological barriers upon themselves. Self-regulation helps to overcome these barriers.

1. A Brief History of Sport Psychology and Self-regulation

Self-regulation has a comparatively short history within the not very long history of sport psychology. Although it is sometimes claimed that sport psy-

chology has a history that dates back to ancient Greece, its scientific origins are not older than about 100 years. From the late nineteenth century on, the first decades of this discipline were mainly focused on the scientific study of athletic behavior. The first book with an applied perspective, *The Psychology of Coaching*, was published in 1926 by Griffith in the USA. During the 1960s and 1970s there was a considerable increase in the application of psychology in the field of athletics. However, self-regulation was mainly restricted to the use of relaxation techniques. At the same time self-regulation had become an evolving approach within behavior therapy. In the late 1960s, behavior therapists began to fill the black box, the organism variable, within the S-O-R model of behaviorism with cognitive processes individuals could actually use to control their own behavior (e.g., Kanfer 1970). In the late 1970s behavior therapists took the models and techniques of self-regulation developed in clinical psychology to the field of athletic behavior (e.g., Mahoney and Avener 1977). These self-regulation techniques became the core elements in 'mental training' or 'psychological skill training' for athletes which today is frequently seen as the major training content of applied sports psychology.

2. *Naive Self-regulation vs. Psychological Skill Techniques*

Individuals use self-regulation in everyday life, e.g., to resist the temptations of delicious food when they have committed themselves to a diet. Most of the self-regulation techniques used in daily situations are referred to as 'naive' because they are not derived from scientific knowledge and their effectiveness has not been systematically evaluated.

Usually, naive self-regulatory techniques are highly personalized coping strategies for situations constituting a challenge or a threat for the person. These techniques have developed through the person's experience with that situation and they are based on the person's subjective criteria. Some of these techniques are rites that have developed and some of them are simply instances of superstitious behaviors. These 'naive' self-regulation techniques can have positive effects. They may, for example, reduce athletes' fear of the uncontrollable, increase self-confidence, and induce a 'winning feeling.' However, because they do not systematically address disadvantageous mental performance conditions, they are often bound to fail.

In contrast to the 'naive' self-regulation techniques, those imparted by sport psychologists are 'a formal, structured application of psychological skill techniques to the enhancement of sport performances' (Morris and Bull 1991, p. 4). Sport psychologists train athletes in the use of these psychological skills. The objectives of such psychological skill training are manifold. A study by Mahoney et al. (1987) found sport psychologists and athletes to agree that the most basic skills to be acquired by athletes are anxiety management, concentration, motivation, self-confidence, and mental preparation.

2.1 *Self-regulation and Self-control*

In general, the approach to develop self-regulation skills in athletes is based on the premise that the right psychological climate helps mobilize physiological reactions that are essential to performing at one's best. A negative psychological climate such as feelings of frustration, fear, anger, and worry, or negative thinking in general, typically does the opposite. Loehr (1984) emphasized that neither negative nor positive psychological states just happen. Athletes can identify their own ideal performance state, and they can learn, intentionally or subconsciously, to create and maintain this state voluntarily so that their talents and physical skills thrive. This is the basic credo of self-regulation. The mental skills needed to trigger and sustain one's ideal performance state are learned through practice just as physical skills are learned. Some gifted athletes seem to be able to develop efficient 'naive self-regulation' techniques, but as mentioned above, these may have their flaws. Thus, most athletes need to be taught specific mental skill techniques. Psychology has systematically studied and developed such techniques, so that they are now available in sport psychology.

Self-regulation and self-control are key terms in motivation and action. They refer especially to volitional abilities that are needed to deal with adverse conditions during the execution of an intention. Kuhl and Beckmann (1994) subsume self-regulation and self-control processes under the more general conception of action control. Action control refers to the correspondence of the actual behavior with the intended action or, more specifically, the correspondence of the actual performance with the intended performance. Under adverse performance conditions, action control processes, i.e., self-regulation and self-control, are required to achieve a high degree of such correspondence.

In general, there are three objectives to be achieved through self-regulation:

(a) positive self-related control beliefs (e.g., self-efficacy)

(b) positive self-related emotions (high self-esteem)

(c) clear-cut distinctions between self and nonself (self-discrimination).

Most self-regulation techniques that are employed in sports address the first two objectives. The third objective is a more general developmental goal. It is based on the assumption that only individuals with access to their own needs and values (i.e., their integrated self) can perform up to their potential.

There are two different routes to master adverse conditions, i.e., to cope with threats to action control. One route is the intention-driven inhibition of the counterintentional processes. The other route is the promotion of conflict-reducing processes through supporting the facilitation of intention-relevant processes. Kuhl and Beckmann (1994) refer to the former as self-control and to the latter as self-regulation. Self-control is the less sophisticated action control strategy. It is based on metacognitive and metamotivational knowledge to a much lesser degree than self-regulation. Nevertheless, in some sport disciplines self-control can actually mediate top performance. Beckmann and Kazen (1994) found that athletes who primarily use self-control excel in sport disciplines requiring a short-lived, high-energy input like shot-putting, sprint and jump disciplines in track and field. But self-control failed in sport events demanding energy regulation, for example, long distance running. In these disciplines athletes with good self-regulatory skills showed the best performance.

Different tasks or sport disciplines require various kinds of self-regulatory abilities. In endurance sport, for example, it is important to stick to one's competition plan. In disciplines like sprint, shot-putting, or weight-lifting, maximum energy mobilization combined with high concentration is required, but only for a few seconds. In decathlon it is crucial to mobilize energy for a specific discipline but relax and regenerate between the heats.

3. *Self-regulation Techniques*

Several self-regulation techniques have been developed which an athlete can acquire through mental training. There is no unified terminology for psychological skills training. Seiler (1992, p. 31) speaks of 'a certain randomness of the classification, depending on the author's initial conception of what is important in sport and competition and the construction method itself.' As a result, different mental training programs stress different elements. Most programs share a focus on the following elements: activation regulation (relaxation and energization), attention regulation (concentration), self-talk (positive thinking, thought control), imagery (visualization, mental rehearsal). In the numerous mental training programs the different techniques usually blend in with one another. For example, a lot of techniques make use of images to support self-regulation. Only the major techniques of self-regulation will briefly be described in this article.

3.1 *Activation Regulation*

Self-regulation in sports was often equated with relaxation, especially in the early days of sport psychological interventions. The goal was to generate a state of psychovegetative functioning, which was considered optimal for the performance of a certain task. The guiding idea behind this intervention was the, so-called, Yerkes–Dodson law of the relationship between arousal and performance. In 1908, Yerkes and Dodson found an inverted U-shaped relationship between arousal and performance in a learning experiment. In this experiment, rats learned slowest when they were highly aroused, or when their arousal was low. Their learning was fastest when arousal was at a medium level. As a consequence of this finding generations of coaches and athletes were taught that medium arousal was optimal for performance. Because the majority of athletes show a high level of arousal before a competition, relaxation was promoted as a major technique of mental preparation for a competition.

But contradictory empirical findings show that the relationship between activation and performance is more complicated than postulated in the Yerkes–Dodson law. Neiss (1988) assumed that performance impairment found in highly aroused individuals is mediated through task-irrelevant cognitions (worry) rather than through the arousal component itself. Supporting this assumption, Dienstbier (1989) reported numerous studies that show a general positive relationship between physiological arousal and performance. Beckmann and Rolstad (1997) conclude that thorough relaxation may not be the optimal preparation immediately before starting a competition. Rather, athletes should aim at increasing their precompetition activation through so-called 'psyching up.' But this should be combined with the self-regulation technique of thought control (avoiding negative thoughts and worries).

Although relaxation techniques may not be adequate immediately prior to or during a competition, they still play an important role in psychological skills training. They are necessary as a first step in training other self-regulation techniques. On their own, they are also an important measure for personality development (developing an even temper, the ability to 'let go,' supporting recovery, higher tolerance for unexpected and uncontrollable events).

Relaxation methods taught in mental training are progressive muscle relaxation (PMR) and autogenous training (AT). These rather extensive relaxation programs intend to reduce bodily activation through focusing on relaxing muscles (PRM) or autosuggestive formulas like 'Heart beats calmly and steadily' (AT).

A very basic technique is 'controlled breathing.' The breathing is conducted using the diaphragm rather than the chest. Athletes concentrate on 'feeling the air enter the lungs and then slowly leave' (Smith 1998, p. 42). 'Controlled breathing' has proven to be a good means to 'let go,' which means to get rid of disturbing, negative thoughts. An advantage of 'controlled breathing' compared to other relaxation techniques is that it does not necessarily reduce athletes' readiness

for competition. Consequently, it is a relaxation technique that has its place in the preparation for competition.

3.2 Attention Control

For the majority of sport disciplines, attention is crucial for performance. Attention is threatened by various sources, especially during a competition. Through distractions athletes can lose the focus which allows them to execute their tasks effectively. Therefore, the ability to refocus in the face of distractions, to manage to concentrate on the task, is a critical self-regulatory skill.

Distractions come from a variety of sources, outside and inside athletes. The crowd, the competition conditions, a starting aircraft while an athlete tries to concentrate on her high jump, thoughts about the finishing place, or a specifically difficult and dangerous section of a downhill ski run while still gliding through an earlier section.

Nideffer (1980) made techniques of attention control popular among coaches and athletes. These techniques are used to focus or refocus attention more effectively during sport performance. One of these techniques is called 'centering': this is a technique used in a stressful situation to regain concentration. It involves taking a deep abdominal breath, with the individual focusing attention on the breath and then back out to a positive external cue.

Inducing positive affect (emotion control) is a frequently suggested aid in attention control. The advice is to focus on doing what will help keep the person positive and in control. The idea is that a strong positive focus protects against distractions. Usually a cognitive component is added: the athlete should develop specific, task-related goals that can capture attention; a focus that connects or reconnects to the task. This can be supported by images. Athletes can, for example, imagine being in an invisible force field. The slalom skier imagines that the slalom course is inside a tunnel of glass that keeps all possible distractions outside. Also, athletes can imagine a guiding line that carries them through their competition e.g., the downhill skier imagines a railroad track laid out along the ideal line of the downhill run.

Another, more general strategy involves relaxation training, in this case, as a form of personality development. Through relaxation training (PMR or AT), which is combined with other training routines on a regular basis, athletes can learn to 'let go.' They can learn not to carry mistakes with them and practice getting back on track quickly.

3.3 Self-talk and Thought Control

Another major route of self-regulatory skills for athletes became popular during the 1970s. These mental strategies are based on approaches in cognitive behavior modification which address the altering of 'private' cognitive processes. These techniques aim at stopping negative and destructive thoughts and promoting positive thoughts that support performance.

Gallwey (1976) has pointed out that tennis players lose their games in their heads first. When the 'inner dialogue' changes from a positive, confident focus to a negative one, the game is lost. Gallwey developed the so-called 'inner game' technique which became popular especially in tennis and golf. The inner game addresses the inner dialogue between what Gallwey (1976) calls Self 1, the analytical problem solver, and Self 2, the intuitive and emotional self. The inner dialogue can become critical, when Self 1 primarily articulates self-doubts or anxieties and thus threatens the maintenance of positive self-related control beliefs and positive self-related emotions. Strategies either have the task-related Self 2 completely occupy attentional capacity or alter the focus of Self 1 toward more positive, supportive thoughts.

The importance of having a positive inner dialogue is underlined by a study by Mahoney and Avener (1977). They found that the self-talk of US gymnasts who did not qualify for the Olympics was dominated by self-doubts and thoughts about failures. In contrast, the self-talk of those who qualified was characterized by self-confidence.

A simple technique that is often employed to stop negative thoughts is directly taken from behavior therapy: stop rules. Athletes are trained to shout 'stop' along with, for example, imagining a large stop sign to interrupt a negative thought sequence. But stopping the negative thoughts alone is not sufficient to get back into competition. After stopping the negative thoughts, it is important to refocus on an appropriate performance-related cue or positive thought. However, this technique involves an interruption of task performance or at least a momentary loss of concentration.

It is more efficient to prevent intrusive thoughts or negative thoughts from occurring beforehand. Beckmann (1993) used a thought-stopping technique to prevent negative thoughts, which has proven to effectively stop thoughts in numerous experiments in cognitive psychology. He had downhill skiers count numbers backwards beginning with 999 during a gliding section of a downhill run. It is impossible to think of anything else while counting the numbers. Thus, this technique prevented intrusive thoughts during that section. Because it is also quite easy to quit this task, it allows athletes to switch to task-relevant thoughts when approaching the next difficult section of the run.

3.4 Visualization

There are two applications of the visualization or mental imagery technique. One of these is used in

combination with relaxation techniques to induce a positive, relaxed state of mind. The athletes visualize themselves in a favorite relaxing scene. This can be a past successful performance, that will reinstall the positive affect, the feelings of competence, or in other words, the 'winning feeling' that was experienced then.

The second application of visualization is to mentally rehearse performance. In this regard, visualization can be used to assist the learning of a new technique, continue practice during a period of injury, or to prepare for a competition. Neurophysiological data shows that the visualization of a physical activity is not restricted to brain processes, but actually involves small movements of 'neuromuscular activity' of the muscles that would be used if the activity was actually performed (MacKay 1981). The mental rehearsal of performance yields the best results, however, when visualization is used in combination with actual performance.

Eberspächer (1995) points out that ultimately athletes should be able to imagine themselves perfectly performing a task from an inner perspective, the perspective of the actor him- or herself (this is referred to as ideomotor training in a specific sense). However, it seems necessary to step by step develop and practice this inner perspective. Otherwise, an athlete may not have sufficient control over the images that come up. In visualization that is not systematically developed, unconscious fears may intrude, for example, in their 'naive' visualizations slalom skiers may see themselves missing a gate that they considered critical during the inspection of the run. This would, of course, not constitute a good preparation for the competition. To avoid this, Eberspächer (1995) suggests three steps during the acquisition of visualization skills:

(a) subvocal training: write down the course of performance and then recite this course in an inner dialogue;

(b) covered perception training: see oneself perfectly perform the activity from an outside perspective, like seeing oneself on a video (observer perspective);

(c) ideomotor training: visualize the course of performance from an inner perspective (actor perspective).

To obtain the best results, and prevent negative thoughts and fears from intruding, it is important to execute a relaxation technique before beginning with the visualization.

3.5 Goal-setting

Numerous studies have shown that goal-setting is a self-regulation technique that works (Locke and Latham 1984). Specifically, if individuals commit themselves to specific, hard, but still realistic goals, they show better performance than when they only have a 'do your best' orientation. This technique supports task motivation, but also helps to focus attention on the task.

It is often important to help athletes to make their goals realistic. This means that they learn to define their goals in terms of what they can actually achieve given the state of their condition and their skills. This involves differentiating goals into short-term goals (upcoming competition), mid-term goals (standing at half-time of the season), and long-term goals (standing at the end of the season, or what one ultimately wants to achieve). In this perspective, it is helpful to introduce the image of a ladder that one intends to climb up. Take one step after another (short-term goals). You cannot expect to get to the top (long-term goal) directly from the bottom. Stay positive and confident while climbing up. You may slip down from a step from time to time (which means: don't expect to win every time), but stay oriented toward your goal, and keep climbing up steadily.

4. Conditions for the Application of Psychological Skills Training

The mental side plays an important role in athletic performance. Athletes can learn to control the mental side through the acquisition of self-regulation techniques. It should be noted that there are other psychological factors that influence performance and can be addressed through psychological interventions. Among these are, for example, the communication skills (between coach and athletes, and among team members) and team spirit.

The focus of the present chapter was on how athletes can regulate themselves in their preparation for a competition (including technique acquisition) as well as during a competition. Numerous self-regulation techniques have been developed by sport psychologists. Only a small sample of them could be described here.

These self-regulation techniques are acquired through psychological skills training. It should be pointed out that the techniques cannot be learned overnight, as some athletes, coaches, and officials seem to assume. Continued training for some period of time is necessary before these techniques will actually start to work. The acquisition of the basic techniques requires at least six months of regular practice.

Self-regulation techniques in sport are most effective when they do not have to be activated consciously. They work most effectively when they have become an automatically activated element in an athlete's behavioral repertoire. Ultimately, these techniques work tacitly and smoothly without interrupting performance. They help to achieve the optimum state of flow (Csikszentmihalyi 1975). For best effectiveness, psychological skills training should be integrated into the normal training routines.

5. Future Perspectives

During the last two decades quite a number of mental skills training programs have been developed. They provide sets of self-regulation techniques that athletes can learn in order to improve their performance. Although these techniques seem to work, it has also become obvious for practitioners that training the skills is not enough. The athletes the sport psychology consultant deals with show large individual differences. They have different intellectual capacities, different attitudes and needs, as well as different knowledge. Based on the existing set of self-regulation techniques, mental skills training has to be tailor-made for the individual athletes with their highly specific problem situation. Furthermore, short-term programs are not sufficient. Psychological training should accompany or better become integrated into physical training routines from adolescence on. Personality development is essential and should become a major focus of sport psychological training programs. The self is the core of self-regulation. Without a conflict-free self it becomes difficult to self-regulate. An integrated self may lead to the aspired maximizing of performance and achievement and at the same time to responsibility, improved decision-making, and happiness.

Standpoint Theory, in Science

According to standpoint theorists, there are social positions from which people can obtain privileged perspectives on social relations, because those who are oppressed are in a good position to understand the social relations that constrain them. Recent work in Science and Technology Studies has shown that scientific knowledge is irreducibly social (e.g., see *Science, Sociology of*). Social relations are embedded in scientific knowledge and in different ways form topics and resources across the sciences, from physics and mathematics to primatology and psychology. Therefore standpoint theory could be relevant even in the natural sciences.

1. Standpoint Theory's Central Argument

With respect to science, standpoint theory has been most comprehensively worked out by feminist researchers. For this reason this article focuses primarily

on feminist contexts. But the arguments and conclusions can be extended to other types of standpoints: there are contexts in which the standpoints of non-Europeans or, returning to the roots of the theory, proletarians, might provide privileged epistemic positions within the sciences.

The central arguments for privileged perspectives stem from Hegel's 'master–slave' dialectic, Marx's discussions of ideology, and particularly from Georg Lukács' discussion of the privileged standpoint of the proletariat. In his 1922 essay 'Reification and the Consciousness of the Proletariat' (in Lukács 1971), Lukács argues that the proletariat potentially has a privileged standpoint from which to understand the rationalized structure of commodities and capital. Under capitalism, different classes perceive rationalization in different ways. The bourgeois, says Lukács, tend to accept their position as natural, just and even necessary, because it was created by them; they can retain an illusion of subjectivity, of themselves as actors. Through attempts to break out of the rationalized structure, the proletariat, on the other hand, can understand the constraining nature of social relations, and can also question the naturalness or necessity of those relations. As a result they can see that the system that removes much of their subjectivity is a specific historical product. Therefore particular social locations have the potential to provide insights when people in those locations run up against arbitrary structures. In essence, then, standpoint theory is an account of the blinding power of ideology, and how it can be overcome (see *Ideology, Sociology of*). If its arguments are right, it is relevant to science to the extent that scientific knowledge participates in such ideologies.

Within feminist discussions, standpoint theory has been developed in divergent directions, for example by Nancy Hartsock (1983), Patricia Hill Collins (1986), Dorothy Smith (1987), Sandra Harding (1991), and Rosemary Hennessy (1993). As do the rationalizations of capitalism, gender reifies social relations. Women have a distinctive experience, in the experience of discrimination, from which to see gender relations. And by working against discrimination they come to understand the unfairness and lack of necessity of many things normally taken for granted.

2. *Criticisms and Elaborations*

Because it has been taken up by many scholars and activists, the meaning of standpoint theory can be confusing. Its central and most controversial claim is that a particular social position potentially provides a *privileged* perspective, not merely *another* perspective. Claims that styles of thought are correlated with gender (e.g., Keller 1985) are sometimes grouped with feminist standpoint theories, but they do not contain the same sort of general argument for privilege. Even setting aside positions that do not recognize privilege, we can still differentiate between two versions of standpoint theory as it relates to scientific knowledge. A strong reading of the arguments of standpoint theorists entails that the social location of oppressed groups is a definite and positive resource for increasing the objectivity of science. A weaker reading entails only that objectivity tends to increase as more and more diverse groups are represented in science. The difference can be seen in Sandra Harding's notion of 'strong objectivity' (Harding 1991) and Helen Longino's more procedural notion of objectivity (Longino 1990). (See also *Objectivity: Philosophical Aspects*.)

The theory is often taken to imply that there is one correct feminist perspective, which will eventually reveal the true nature of gender relations. Setting aside good questions about whether the idea of a single complete theory is coherent, the claim can be challenged as overly essentialist. Essentialist assumptions of commonality in women's experiences or situations have been discredited by feminist researchers steadily finding diversity where once was seen uniformity. However, there is nothing necessarily essentialist about standpoint theory. Harding's formulation, based on 'thinking from women's lives' (Harding 1991), suggests that diversity can be built into the theory. It is not women's experiences alone that standpoint theory privileges, but experiences of working against discrimination, including in the production of knowledge. And there is no implied essentialism about women or their experiences when standpoint theory is framed, as it often is, in negative terms: interests and positions tend to blind people to features of their worlds. The call to think from women's lives does not exclude the possibility that men can acquire and develop feminist standpoints. By acting to oppose sexism, and by understanding obstacles faced by women, men can gain experience and knowledge of the social structures that maintain gender as oppressive.

Claims of privilege are limited by the fact that the oppressed typically have reduced resources with which to study their environments. Thus, even if the central arguments for standpoints are correct, they do not provide any cut-and-dried formula for correlating standpoints with more objective knowledge. Theorists representing oppressed groups may have better knowledge of the relevant social structures, but then again they may not. Thus standpoint theory's arguments are best given the weaker reading mentioned above.

The standpoint theory that emerges from these criticisms is modest and pragmatic. Without the determinism sometimes associated with standpoints—without the claim that, say, women necessarily understand some phenomena better than do men—standpoint theory is primarily an argument for the representation of diverse groups in the sciences. Those groups will be apt to take their research in

different directions, to discover different phenomena and see different strengths and weaknesses in arguments. Multiple standpoints can contribute to both the breadth and solidity of scientific thinking. But the theory does not claim that some people are simply to be believed because they command cognitively superior standpoints. The metaphor of 'privilege' is cashed out in terms of possibilities for understanding: genuinely inclusive scientific communities are likely to produce more balanced knowledge, being attuned to a broader array of social facts.

3. *The Domains of Standpoints in Science*

There are a number of contexts in the sciences for which even a cautious standpoint theory can be relevant. Three examples may be offered of broad contexts in which feminist and other standpoints can be applicable. The feminist examples easily could be modified for other standpoints.

3.1 *Gender and its Construction*

Social relations in themselves are topics of inquiry in the humanities, social, medical, and biological sciences. Research has shown ways in which law, literature, divisions of labor, and many other cultural products participate in the construction of important social categories. Many of these findings are due to the influx of feminist, Afro-American, post-colonial, and other critical theorists into academic social sciences and humanities departments, which has disrupted established patterns of thinking and added to various disciplines' understanding of their traditional as well as new subject matters.

Studies of sex differences, classifications of diseases, behavior patterns, and explanations of all of these in terms of evolutionary history also participate in the construction of the social world, for example in the construction of gender. Feminist biologists have found areas in which sexist ideology affects research, and have seen how scientists can reproduce, explain, and amplify social relations that they see in society (for a survey, see Schiebinger 1999). Standpoint theorists would claim that people who understand everyday social biases as the product of cultural formations are in a good position to see attempts to reify those formations and naturalize them, to see, for example, attempts to justify sexism by characterizing it as part of human biological heritage.

3.2 *Problem Choices*

Ideology affects the topics that are studied. For example, social scientists have looked to the structure of the household—usually taken for granted as a relatively fixed and uncontroversial unit—and have found conflicts, differences in interest, and social structures that had remained hidden when inquiry focused on the male world alone. Problem choices like these are common in the humanities, social sciences, and biological sciences, all of which self-consciously study social relations, though presumably such choices are not directly relevant in the physical sciences.

However, some areas of research may directly affect women, because the knowledge they produce can be used to reduce or exacerbate inequities (see *Gender and Technology*). Every area of inquiry has at least some instrumental uses, and many forms of applied knowledge have some relevance to the gendered structure of society. Topics within so-called 'pure' physics are connected to military uses, and are funded precisely because of those uses (see *Science, Technology, and the Military*). Women tend not to participate in benefits coming from the high status of military prowess, yet suffer many of the consequences of war. A feminist standpoint, then, is more likely to recognize and see as important the connections of certain areas of research to their consequences.

3.3 *Social Structures within Disciplines*

To varying degrees, sexism is a normal part of the working environment in all of the sciences. The allocation of funds, the structure of the tenure system, and old-boys networks can work against women. To recognize and study sexism within the sciences, however, is not just a specialized project of feminist sociology of science. To be a scientist means having knowledge (often tacit) of the norms and structures of one's discipline (see *Norms in Science*). For example, to convince colleagues to read an article, it is as important to know about form and rhetoric as it is to know something about 'subject matter.' Therefore, if feminist standpoint theory is right, feminist scientists will be in a better position than men to notice sexist aspects of their own discipline, aspects of their relations with other members of the field that perpetuate oppression.

4. *Conclusions*

Science and technology studies have pointed to the local and contextual origins of scientific knowledge (e.g., Knorr-Cetina 1981). A consequence of those origins is that scientific knowledge, even when it is deemed universal, may carry with it parochial assumptions about what is natural. As a result, science taken up outside its contexts of production needs to be corrected to take account of its own social assumptions and the knowledge of nonscientists (e.g., Wynne 1996). In this type of insight we might see the value of standpoint theory, showing how social location can be a resource for decontextualizing scientific knowledge.

Standpoint theory's arguments establish some grounds for privileged perspectives: people for whom social constraints are oppressive can more easily understand those constraints than can others. Recent studies of science and technology show that those grounds can be relevant in all branches of science: science is a thoroughly social process, and perspectives that tend to expose some of the effects of social structure are thus valuable throughout the sciences. In particular, feminist scholars have argued that because scientific communities have lacked diversity, they have typically lacked some of the resources to better enable them to see aspects of sexism and androcentrism in scientific work. Definite social locations, then, are relevant across the disciplines, though the range of particular situations in which they are relevant varies greatly in different contexts, sometimes affecting problem choices or norms of behavior, and sometimes directly affecting substantive claims. Therefore standpoint theory, together with the recognition of the social character of knowledge, shows that to increase objectivity, communities of research and inquiry should be diverse, representative, and democratic.

State and Local Taxation

State and local taxation comprises those taxes that are collected at the subfederal government levels in order to finance state and local public services, assigning discretion in the determination of rates and bases of these taxes to subfederal governments. Consider a nation with different layers of government that are only serving administrative purposes. Each government level only distributes the public services to and collects the taxes from that nation's citizens upon which they agreed at the national level. In such a country, no state or local taxation is necessary since the level of public goods and services is decided upon uniformly for the whole country. This leaves citizens in some local jurisdictions, which prefer more public services than the national average, as much dissatisfied as citizens in local jurisdictions, which prefer less. It is possible to provide public services, the benefits of which are limited geographically and which are not national in scope, at different levels in different subfederal jurisdictions. Enabling citizens to consume publicly provided goods and services at different levels according to their preferences makes everyone better off without making someone worse off. In order to let people, who want to consume more, pay a higher tax price for those state and local services, taxes must be differentiated accordingly between states and local jurisdictions. In such a world with a differentiated supply of publicly provided goods, each individual can reside in a jurisdiction where a certain level of public services is provided to adequate tax prices. The art of state and local taxation is the assignment of different kinds of taxes to government levels such that an invisible hand properly guides a nation in an ideal world to an optimal multiunit fiscal system. This is not necessarily the case in the real world and some answers exist why fiscal systems are not optimal.

1. The Rationale of Tax Assignment to the State and Local Levels

The basic idea of a power to tax for states and local jurisdictions is that their public goods and services should be financed by those citizens benefiting from them and deciding on their quantity and quality. In this case, individuals choose their place of residence according to their preferences and their dislike for congestion. A set of fiscal jurisdictions consisting of equal taste communities then results from a process of 'voting by feet' (Tiebout 1956). Olson (1969) calls the basic condition for such an outcome the 'principle of fiscal equivalence.' It requires assignment to which public goods and services should be provided at which level of government. The guideline for this decision is the geographical incidence of those benefits and the costs borne by citizens in order to finance them. As some public goods and services reasonably cannot be

provided at the local level, some kinds of taxes may not be assigned to the local level for good reasons, too.

There are numerous reasons why the proper assignment of tasks and the power to tax to the subfederal levels are crucial to avoid suboptimal outcomes. For example, take the Scala in Milan, the famous Italian opera house. As it is partly financed by user charges and partly by subsidies paid from general taxes of the city, it will be congested because residents living in the suburban towns are able to visit it paying only the user charges and thus a lower price than the city's citizens. Nonresidents receive some of the benefits from the public service without paying an adequate tax price. This spillover is one of the externalities that Gordon (1983) summarized in his treatment of an optimal tax system for subfederal jurisdictions. Another externality exists if nonresidents pay some of the taxes of state or local jurisdictions. Taxes are exported to nonresidents and state and local governments thus have an incentive to provide public services at a higher level than their residents prefer. An example of tax exporting can be found in the taxation of tourist trade or of natural resources in some US states. For the year 1962, McLure (1967) estimated for the US states that overall tax export rates were between 19 and 28 percent in the short run. In the long run, only 10 states exported more than 24 percent of their taxes or less than 16 percent. The estimates are corroborated in a more recent study by Metcalf (1993). Mieszkowski (1983) estimated the 'total waste' in Alaska in the beginning of the 1980s that accrued from excessive public revenues and expenditures that were possible because of high natural resource taxes to about $500 million or 13 percent of estimated petroleum revenues. Tax exporting is not limited to commodity taxes or natural resource taxes. It may also occur if individuals, firms, or capital are mobile.

If factor mobility is allowed for, the problems of subfederal taxation are even enhanced. If a state or community levies a higher personal or corporate income tax than its neighboring jurisdictions, its mobile citizens or firms emigrate (or move their capital there) in order to enjoy a lower tax burden. Such a situation is characterized as tax competition. In doing so, mobile factors reduce the tax burden of residents and firms in the state or community they move to and increase the tax burden in those jurisdictions they leave. These changes in tax burdens usually are not considered by public authorities in these jurisdictions when deciding on the level of public goods and services such that these are provided at a lower than 'optimal' level. Since there is a local loss from taxation that does not correspond to a social loss, the cost of public services is overstated and jurisdictions will tend to underspend on state and local public services. Buchanan and Goetz (1972) call this effect a fiscal externality.

The effects of tax competition among states and local jurisdictions are similar to those of international tax competition and they vary according to different degrees of mobility of individuals and firms, to the number of mobile factors, to the number of jurisdictions involved in that competition, on the size of the jurisdictions involved, and to the number of tax instruments available to tax authorities. The assessment of the usefulness of these effects becomes rather complicated if competition using tax instruments is complemented by competition using public expenditures, like subsidies or specific infrastructural services, but also tax expenditures like tax holidays to attract mobile production factors.

The impact of tax competition on the possibilities of state and local governments to redistribute income by tax-transfer schemes is relatively clear-cut. Stigler (1957) already stated that 'redistribution is intrinsically a national policy.' Suppose that a region adopts a progressive income tax program designed to achieve a significantly more egalitarian distribution of income than exists in neighboring jurisdictions. If rich and poor households are mobile, such a program would create strong incentives for the wealthy to move out to neighboring jurisdictions. In this case, local redistribution induces sorting of the population, with the richest households residing in the communities that redistribute the least by income taxes. A more equal distribution of income would result, but it would be caused largely by an outflow of the rich and a consequent fall in the level of per capita income in the jurisdiction under consideration (Oates 1972). At the central level, this problem does not occur, because mobility is reduced, the larger a jurisdiction.

There are not many theoretical arguments against this line of reasoning. Most of them rely on imperfect mobility of individuals. But the more mobile people become, the better this mechanism should work, the less possible should state and local redistribution by a progressive income tax be. However, according to Buchanan (1975), all individuals have an incentive at the constitutional stage to agree to income redistribution because they are fundamentally uncertain about their future positions in income, health, and employment. At the postconstitutional level the rich might agree to income redistribution by the government because they, first, are interested in a public insurance scheme against fundamental privately uninsurable risks for themselves and their children, and, second, against exploitation by the majority of the poor residents and increasing crime rates. Particularly the second reason is important for the rich: they pay a premium for obtaining social peace. Janeba and Raff (1997) argue that individuals will agree to decentralized income redistribution because it is a credible commitment of the poor majority to the rich minority that the latter is not exploited at the postconstitutional stage. The rich allow for the agreed extent of redistribution because a constitutional competence for income redistribution at the federal level leads to a larger public sector with more income redistribution.

From this perspective, decentralized redistribution might be possible and even more efficient since redistribution is closer to citizens' preferences.

2. Guidelines for a Reasonable Tax Assignment

This reasoning leads to some guidelines for tax assignment of different taxes to the state and local levels. The bottom line is that state and local jurisdictions should finance the services they provide by charges or quasicharges to the beneficiaries (Musgrave 1983) or they should use those tax bases which have low interregional mobility (Wildasin 1980). Land and natural resource taxes and to a lesser degree also real estate taxes are thus especially suited for purpose of state or local taxation. A property tax, for example, is a good candidate for being assigned to the local level at least as far as residential property instead of business property is taxed. A property tax is basically a tax on land and construction built on it and it can thus be considered to be a tax on a relatively immobile tax base.

Consumption taxes are inappropriate at the local level because the interjurisdictional mobility leads to cross-border shopping or tax exporting, but they become suitable for the state level if the region is large enough. However, the technological development, in particular Internet shopping, reduces the possibility for state governments to levy a tax upon consumption. If individuals, firms, and financial capital are fully mobile a comprehensive income or profits tax should not be assigned to the state and local levels because it is necessary for such a taxation to be optimal so that a jurisdiction should be able to tax all income of its residents in the other jurisdictions. This is certainly not a realistic case. Beyond this, taxation of wage income tends to reduce this tax base less than the taxation of capital income and it could thus be more easily taxed at the state or even local level unless tax authorities cooperate and exchange information about taxpayers' incomes. And even profits taxes can be levied at the state or local levels if investment is specific to the locality such that a firm cannot easily relocate. The latter is particularly the case for not-in-my-back-yard (NIMBY) firms like waste incinerators or nuclear power plants. These firms have difficulties finding a location and assigning local jurisdictions the power to tax their profits gives these communities an incentive to provide such firms with a location.

Following from this reasoning is another rule for tax assignment: Progressive taxation, designed to secure redistributional objectives, should be assigned to the central level. A progressive income tax should thus be a federal tax. Moreover, as the case of Alaska illustrates, a large natural resource tax base permits local jurisdictions to provide public services at a low tax price leading to an attraction of individuals and firms at an inefficient scale. On these grounds, a case for central taxation of natural resources may be made whereby the central natural resource tax may apply to an excess base only, while leaving the average base for subfederal use.

All in all, these basic considerations led Musgrave (1983) to present the following tax assignment to government levels: The local level should rely on property taxes and payroll taxes, the state level on a resident income tax, a consumption tax, and a natural resource tax, and the federal level on an integrated progressive income tax and a natural resource tax for large natural resource bases. All government levels should additionally rely on fees and user charges as far as public services are attributable to particular users or certain groups of users. This possibility is probably reduced from the local to the federal level. According to Musgrave, corporate source income ideally would be included in the integrated base of the federal income tax. These propositions become substantially more complicated, if interjurisdictional tax agreements providing for tax credits or deductibility are considered. Federal tax deductibility of state and local taxes, for example, may mainly serve taxpayers with higher income and is thus regressive.

3. Tax Assignment in Some OECD Countries

A first look at real tax systems in OECD countries quickly reveals that tax assignment is not necessarily Musgravian (Pola et al. 1996; Pommerehne and Ress 1996). The US seem to come closest to those rules of tax assignment. The US states are prohibited by the US constitution from levying taxes on imports or exports but otherwise they may adopt any type of tax that does not egregiously discriminate against citizens of other states. US states have a lot of freedom in defining their tax bases, in setting tax rates, and in offering tax abatements to induce businesses to locate within their state. Finally, the states grant tax authority to differing degrees to local jurisdictions, too. While there are only minimal restrictions on state power to tax in the US, the federal level nevertheless relies mainly on the individual income and corporate income taxes, the states on sales taxes and natural resource taxes, and the most important source of revenue at the US local level is the property tax. Although state tax revenue from individual income and corporate income taxes is nonnegligible, it is only about one fifth of the respective federal revenue. Such a favorable judgment about the US tax system is, however, only justified at a first glance. According to Feldstein and Metcalf (1987), for example, the federal tax deductibility of personal income tax liabilities led many states to rely more heavily on deductible personal income taxes than on other type of revenue.

Apart from the US, for example, in Canada and Australia and particularly in Europe, the assignment

of taxes to the state and local levels differs considerably from the Musgravian model and varies widely across countries. In Canada, personal and corporate income taxes are the most important revenue sources of the federal level. The most visible of taxes in Canada, the personal income tax, is, however, also the most important revenue source of the provinces. On the one hand, there are fairly significant income tax rate differences between provinces. On the other hand, arrangements between the Canadian federal and provincial governments on sharing the bases for the personal and corporate income taxes have a long history going back at least to the Second World War. There is also a large variation in sales tax rates from Newfoundland to Alberta as the second important revenue source of the provinces. Canadian local jurisdictions, like those in the US, mainly rely on property taxes.

In Australia, the federal government exclusively levies taxes on personal and company income, sales taxes, and (nearly exclusively) excise taxes. The bulk of a state's tax revenues are derived from payroll taxes, stamp duties, and associated taxes on financial transactions, and so called franchise (i.e., business license) fees on alcohol, tobacco, and petroleum products that are not so much differing from excise taxes as well as lots of smaller revenue sources. Local governments, on the other hand, derive their revenues almost entirely from property taxes. Australian states also obtain revenue from the central government on the basis of a revenue sharing arrangement.

The Australian tax system is not as different from the German and Austrian system of state and local taxation. In particular Germany has established an extensive revenue sharing arrangement of personal and corporate income and value added taxes as the most important taxes accounting for about three quarters of total tax revenue. These are really shared taxes in the sense that German state governments decide on them together with the federal government. The federal government has at its own discretion only the gasoline tax and a surcharge on income taxes while the states have no power to tax. Local government relies on property taxes and local business taxes.

The less federalist European countries usually have taxing authority at the local level. In the UK, however, there is not only no regional or state level of government, but local authorities basically have not much power to tax, only some power in determining tax rates of the local property tax on real property. The formerly existing local business tax in the UK was abolished by the 'Thatcher' administration which cut the contributions of local taxes to local revenue sharply after the unsuccessful attempt to introduce the poll tax in the 1980s. There have been some changes in the UK at the end of the 1990's to establish regional authorities in Scotland, Wales, and Northern Ireland providing at least the Scottish government with some power to tax. The UK thus appears to be following the trend in Europe to a more decentralized government structure with a power to tax for subfederal governments as well.

Since the 1970s, systems of regional government have been given an enhanced role in taxation in France, Italy, and Spain. In France, there are three levels of subnational government: the local level with about 36000 cities and communities, about 100 *départements* and 22 regions. Since 1986, the importance of these subnational governments has increased. All three levels have the possibility to levy a property tax on real property (land and construction built on it), a local business tax ('*taxe professionelle*') and something similar to a residents' income tax ('*taxe d'habitation*'). All three taxes are subject to central regulation, but nevertheless there is a nonnegligible variation in tax rates.

In Belgium, there is a movement towards fiscal federalism since it is agreed that the sales and property taxes will become exclusive taxes for the regional and local levels. Apart from smaller taxes, the three Belgian regions additionally can levy a supplementary rate on the personal income tax which may be positive, a surcharge, or negative, a tax reduction. Although there is some regulation of the local and regional power to tax income, the variation of rates is considerable. In contrast to that, local governments in the Netherlands can only levy property taxes.

An interesting pattern of local taxation can be observed in the Nordic countries. Basically, Denmark, Finland, Norway, and Sweden are unitary countries with only two government levels. According to the studies in Rattsø (1998), local governments have considerable power to tax in Denmark and Finland, less so in Sweden, and only to a limited extent in Norway. In Denmark and Finland, local governments can rely on taxes on property and personal income (nearly) without restrictions for setting tax rates accompanied by a considerable variation. In Sweden, local taxation consists mainly of personal income taxes with less variation in rates due to the central regulation of local governments. In Norway, most tax revenue originates from income and wealth taxes shared with the central government giving local authorities taxing power only within a narrow band. Since 1979, all local governments apply the maximum rate. The property tax is not available to all local governments, but is restricted to urban areas and certain facilities (notably power plants). In addition, local property tax rates are also limited to a narrow band.

In Switzerland, states (cantons) have the basic power to tax personal and corporate income as well as capital. The local jurisdictions can levy a surcharge on cantonal direct taxes and raise their own property taxes. The central government relies mainly on indirect (proportional) taxes, the value added tax, and specific consumption taxes like the mineral oil tax. It can also rely on a source tax on income from interest. There is,

Table 1
State and local tax assignment in selected OECD countries

Country	States	Local authorities
USA	Income tax Sales tax Natural resource tax	Property tax Sales tax
Canada	Personal and corporate income tax Sales tax	Property tax
Australia	Payroll taxes Stamp duties Franchise fees	Property taxes
Germany	No taxing power	Property tax Business tax
UK	No state level	Property tax
France	Property tax Business tax Residents' income tax	Property tax Business tax Residents' income tax
Belgium	Personal income tax surcharge Property tax	Personal income tax surcharge Property tax
Switzerland	Personal and corporate income tax Inheritance tax Wealth tax	Personal and corporate income tax surcharge Property tax
Norway	No state level	Personal income tax Property tax
Denmark	No state level	Personal income tax Property tax
Musgravian 'optimal' assignment	Residents' income tax Consumption tax Natural resource tax	Property taxes Payroll taxes

finally, a small but highly progressive federal income tax, which, together with revenue from the source tax on interest income, amounted to 34 percent of total federal tax revenue in 1995, while the cantons and municipalities rely on income and property taxes to about 50 percent of their total revenue and 95 percent of their tax revenue. In addition, personal and corporate income taxes in Switzerland vary considerably between the cantons. Taking the value of the (weighted) average for Switzerland as 100, the index of the tax burden of personal income and property taxes varies from 55.6 in the canton of Zug to 135.8 in Fribourg in 1995, while the index of corporate income and capital taxes varied from 57.6 again in Zug to 145.6 in Nidwalden.

As the overview of these selected OECD countries in Table 1 indicates, there is no clear picture of which kinds of taxes are assigned to the state and local levels. Local jurisdictions regularly levy property taxes as well as fees and user charges. Some power to tax personal income, at least labor income, is attributed to state and local governments in the US, Canada, France, Belgium, the Nordic countries, and Switzerland. In some cases, for example, Germany, France and Switzerland, there exist even local business taxes in the discretion of subfederal jurisdictions. But on the whole, the assignment of taxes does not follow along Musgravian lines and there is a considerable variation in federal regulation of subfederal taxing power.

4. *The Political Economy of State and Local Taxation*

Given these differences in tax assignment to state and local authorities, the question arises which institutional and political factors explain the tax structure in different countries. An early contribution as to the choice of taxation in a political economy framework originates from Schneider and Pommerehne (1980). They develop a model of Australian tax and expenditure structure along with a model of selfish government behavior assuming that the re-election constraint is not always binding. In choosing among

tax instruments, a government in power is only urged to follow the preferences of a majority of voters if an election approaches and the re-election constraint is binding due to low government popularity. Between elections, the government can follow its ideological preferences. This modeling of government behavior proved to be clearly superior compared to the traditional models of government behavior in ex-post predictions of important variables (government spending, GDP, etc.). In contrast, Hettich and Winer (1999) assume that the governing party or coalition always maximizes the expected votes which by themselves depend on the consequences of policies for the economic welfare of voters. In making fiscal choices, political parties thus take into account economic, political, and administrative factors that determine the nature of electoral support and opposition associated with alternative ways of taxing. The authors present empirical evidence on the reliance on income taxation and income tax structure of the US states in 1985 and 1986 supporting their hypotheses.

Inman (1989) finds that redistributive concerns strongly influenced the decision of the 41 largest US cities between 1961 and 1986 to rely on property taxes, sales taxes, or user charges. The higher the demand of local voters for redistributive services, the less city governments rely on fees and user charges as well as sales taxes and the more on property taxes. Hunter and Nelson (1989) present evidence for the impact of interest groups on the local revenue structure. The higher the share of wealthy homeowners in local jurisdictions in Louisiana, the lower the share of property tax revenue and the higher the share of charges.

Besides vote-maximizing behavior of politicians and interest-group influence for redistribution in their favor, tax competition is a third factor determining the structure of taxation. However, the expected impact is ambiguous. On the one hand, tax competition for mobile capital and workers may lead to a convergence of tax rates to a low level. On the other hand, tax competition may lead to increases in tax rates if a state's geographic neighbors follow suit when it raises its tax rates. Such behavior might occur due to yardstick competition between states and local jurisdictions (Besley and Case 1995). Due to their incomplete political information, voters evaluate the fiscal performance of representatives in their jurisdiction by comparing it to the fiscal performance of neighboring jurisdictions. If a state's neighbor increases tax rates, this state has an increased possibility to raise its taxes as well. Arkansas State Senator Doug Brandon once said: 'We do everything everyone else does.'

Finally, the structure of state and local taxation, like federal taxation, is influenced by the degree of fiscal illusion among taxpayers. The more complex a tax system, the more incorrect voters' perceptions about their true tax burden and thus their tax resistance, the more easily representatives can increase taxes in order to finance new spending. Pommerehne and Schneider (1978) present evidence for Swiss local jurisdictions that the extent of fiscal illusion attributed to the complexity of the tax system is less pronounced, the more voters can determine taxes and spending directly in fiscal referenda. Moreover, Matsusaka (1995) finds that US states which allow for the use of initiatives in their constitutions rely more on fees and user charges than on broad based taxes increasing the visibility of contributions to the public sector and the equivalence between public services and tax prices.

5. *Concluding Remarks*

Although a comprehensive assessment is still too early, state and local taxation, appears to be the outcome of political decisions shaped by constitutional provisions and influenced by economic and administrative restrictions. Voters, representatives, bureaucrats, and interest groups deciding upon taxation under the decision making provisions of their constitutions and taking into account the mobility of tax bases and the accompanied tax competition and tax exporting determine to what extent state and local jurisdictions rely on property, income and sales taxes, or on user charges. The differences in these political, institutional, and economic factors explain why there are so many differences among countries in their reliance on tax sources at the state and local levels.

State and Society

The conceptual couple 'state/(civil) society' is a product of the protracted effort through which, starting with the Enlightment, a few generations of European intellectuals sought to characterize the advance of modernization. The juxtaposition of 'state' to '(civil) society' emphasizes the growing differentiation between, on the one hand, the structures and events directly connected with public authority, with the constitution and management of the polity, and on the other the structures and events which individuals generate as they pursue their private interests, express their emotions, acquire and exercise their capacity for judgment. Some institutional outcomes of this process can be still be recognized, according to many authors, in the shape and dynamics of contemporary societies.

1. *An Unsettled Distinction*

Speaking of a 'juxtaposition' between two concepts suggests that they lie on the same plane and are unproblematically complementary to one another. But this is not the only relation in which those concepts have stood to one another. In an earlier relation, the two concepts, instead, were closely overlapped. In a philosophical and juridical vocabulary that lasts between Aristotle and Kant, the expression 'civil society' designates a condition in which humans have left the state of nature by bringing about, and subjecting themselves to, political authority; one wrote of *societas civilis SIVE res publica*. Here, what made a society civil was the very fact of its being policed and governed.

Hegel (1953) breaks with this fusion of the two concepts in the *Philosophy of Right* of 1821. The civil society is understood as the set of individuals engaged in the competitive pursuit of their private interests (chiefly economic). The state is understood as an institutional site where identified collective interests—such as the increase in the state's security, or the maintenance of the public order—are pursued through expressly political activities.

But this juxtaposition is loaded with tensions, and Hegel presents conceptual entities—the family, the corporation, or the 'police' (which here means: the administration)—intended to mediate those tensions. Further, the juxtaposition may be perceived as a contrast between state and society, leading thinkers to take sides with the one or the other. Hegel himself opts for the state, but already Lorenz von Stein, who places the paired concepts state/society at the center of his main work, resolutely opts for society.

In a sense, so does Karl Marx, who like Hegel views civil society as the locus of the formation and confrontation of private interests of an economic nature. However, he endows it with a powerful, self-sustaining dynamic, grounded on means and relations of production, with respect to which the state itself loses the creative, autonomous power to drive historical development Hegel attributed to it.

Even in the course of the twentieth century, some authors prioritize one of two concepts and subsume under it the other. Oliver Williamson's (1975) theory of markets and hierarchies, for instance, posits economic exchange as the primordial social relation, and derives from 'market failures' the emergence of hierarchical, command-based relations, and thus of organizations. Implicitly, also in this view society, conceived in the first instance as the locus of market relations, precedes and in a sense justifies the state (if one sees in it a particularly significant organization). This priority of society, naturally, imposes tight

limitations on what the state can and should do (see Karlson 1993).

Such arguments imply that state/society is not a proper dichotomy, for one concept can be made to encompass and posit the other instead of accepting it as its peer. But there are also arguments to the effect not that one concept is sufficient, rather that more than two are needed.

Thus, one may object to the Hegelian/Marxian reduction of the civil society to the political economy or the market, and suggest for it an alternative referent. A model of a social realm focused on intellectual pursuits, and constituted and regulated without political mediation and power relations, can be found in the eighteenth century *Imperium Litterarum*, the international cosmopolis of *savants* and literati. Or one may seek to comprise within civil society the phenomena of culture and religion, or the institutions concerned with play, emotions, aesthetic expression, and other inter-individual relations not reducible to exchange. The market itself may either be made to adjust itself to the presence, under the conceptual umbrella of 'civil society,' of these new and rather different referents, or may be relocated to a third realm all of its own, as if to acknowledge its peculiarly powerful and demanding dynamic.

For instance, according to Cohen and Arato (1992), in advanced societies there are three fundamental institutional complexes—the state, the market, and civil society. The latter is conceived primarily as the site not of competition between private interests, rather of the formation of collective identities, of solidarity, of the formation and transformation of institutions by means of social movements. In this perspective, *tertium datur*. *Politics and Markets* (Lindblom 1977) do not exhaust the social space.

2. *Historical Roots of the Distinction*

One reason why, at the purely conceptual level, the relations between the two terms are so unsettled, may be that 'state' and '(civil) society' should not be conceived as universal categories. Whether we conceive them as juxtaposed or counterposed to one another, both expressions refer to historically unique ways of establishing and regulating both political and economic processes (and sociocultural ones, if a tripartition is accepted as more plausible).

The state/society distinction presupposes, and profoundly modifies, arrangements which had emerged in various European countries in the late Middle Ages, and which are often characterized by the German expression *Ständestaat* (literally, 'state of the estates'). But the expression is potentially misleading, for it may lead one to think of its referent as a 'state' in the modern sense of the term.

To avoid this misunderstanding the Austrian historian Otto Brunner (1968) has proposed replacing that expression with that of *ständische Gesellschaft*. By this is meant a context where constituted estates, through arrangements partly traditional partly agreed, take an active part in the government of a territory. However they do so chiefly in the exercise of their own privileges, not on a mandate from the central government; and in those privileges political aspects are tightly fused with both economic ones and with status ones, relating to honor and rank. Their activities of government are differentiated, but not as articulations of an overriding political function, rather on the basis of each estate's claims and responsibilities.

Furthermore, typically the component units of each estate are not individuals, but collective entities with a pronounced hierarchical structure. The dominant unit is the 'house,' understood as the seat and patrimony of an aristocratic dynasty. 'The lord of the house (*Hausherr*), at the same time that he performed the function, which today we consider private in nature, of head of the family, also exercised an authentic political power (jurisdictional, administrative, representative) over the members of the house subjected to him,' which tended to include the bulk of the local rural population (Schiera 1983). Furthermore, each 'house' tended to be also a fortified place, an assemblage of autonomous military resources, which the members of the family (again, including the rural dependants) would employ at the behest and under the command of the lord. In that capacity the house normally took part in the ruler's military undertakings; but equally could also protect the house's rights, arms in hand, from encroachments by other houses, including the ruler's own.

Finally, the typical house constituted an *oikos*, which is/was the seat of a complex plurality of activities intended to make it economically self-sufficient, as much as possible without recourse to exchange. The monitoring and organization of those activities (including, critically, the periodic delivery to the lord's household of unpaid produce and labor by the rural dependants) engaged the lord's faculties of jurisdiction and coercion.

3. *The Crisis of the* staendische Gesellschaft

The 'decline and fall' of these arrangements was caused by a critical aspect of state formation, the gathering at the center of a country of the faculties and facilities of organized violence, culminating, according to Max Weber's well known formula, in a monopoly of legitimate violence. Exactly because the aristocratic houses originally possessed an autonomous military capacity, that process, when it does not dissolve them outright, turns them into subordinate components of an unchallengeable public order, centered on the sovereign, their councils, standing army, and fiscal, administrative and judicial apparatus. The political autonomy of the houses, and thus of the estates they

collectively constitute, is lost. The sovereign's superiority, while it does not suppress the houses' internal hierarchical arrangements (including, of course, 'patriarchy') relativizes them, flattens them. Seen from the summit of sovereign power even the most exalted members of the realm begin to appear relatively similar to one another, relatively powerless.

At the same time that centralized political activities become the prerogative of a sovereign power that performs them in a more unitary and rational manner, economic activities become decentralized. An increasing number of subjects decide what goods and services to produce, in what ways, by interacting according to their own interests and capacities. The provision for the needs of the individuals depends increasingly on their capacity to enter into traffics with one another on the market.

In the countryside, commercialization reduces the part played in the totality of the economic process both by the aristocratic patrimonies and by the traditional rural units constituted by villages, which had shared the aristocrats' preference for self-sufficiency and their hostility to the market. It also diminishes the significance of city-based productive units regulated by guilds, which typically contrasted the market's tendency toward innovation and the free combination and recombination of resources.

To sum up: while state-building dissolves the *staendische Gesellschaft* by taking from it tasks, resources, and legitimacy pertaining to the political sphere, the advance of an economy based on traffics pushes into the market the units let loose by that dissolution. Against an expressly political organization with a strong vertical gradient, concerned with all relations grounded on *imperium*, there stands an open-ended set of increasingly numerous social units which, in the pursuit each of its own interest, establish with one another horizontal, or apparently horizontal relations.

4. *The Political Prerequisites of the Civil Society*

This can only take place, however, insofar as the process of state building reflects two peculiar principles: first, the political center takes on all expressly political concerns and resources but only those; second, it acknowledges the existence of private subjects who, while excluded from the political sphere, act autonomously in others. In both ways, political power expressly limits itself, through complex and delicate institutional arrangements: for instance, the progressive denial of political and juridical significance to the religious interests of individuals, or the acknowledgment and guarantee of private property and of contract.

Heinrich Popitz (1986) highlights the historical rarity of such arrangements: 'Only rarely has it been possible even just to pose the question of how to constrain institutionalized violence, in a systematic and effective manner. This has only taken place with the Greek *polis*, republican Rome, a few city-states, and the constitutional state of the modern era. The answers have been surprisingly similar: the principle of the primacy of the law and of the equality of all before the law (*isonomia*); the idea of setting boundaries to all legislation (basic rights), norms of competence (separation of powers, federalism), procedural norms (decisions to be taken by organs, their publicity, appeal to higher organs), norms concerning the distribution of political responsibilities (turn-taking, elections), public norms (freedom of opinion and of assembly).'

Within this small set of experiences of limited political power not all counterpose two realms we might call 'state' and '(civil) society.' For instance, in the Greek polis individuals exist chiefly as soldiers and citizens, and the private dimension of their life is little valued and expressed. Only vis-à-vis the modern constitutional state does (civil) society emerge, through the processes indicated above.

In many other civilizations the tendency of political power to aggrandize itself, to possess itself of all resources (beginning with land and labor power) suppresses all autonomy of the society, and may even reduce all individuals to subjects or slaves. In the modern West, by acknowledging and protecting private property in productive resources, the political center allows at least some subjects to stand against it as autonomous units. This, according to North and Thomas (1973), greatly favors the advance of the division of labor and the enlargement of the traffic economy. But it has also distinctive political effects, best perceived *a contrario* in the 'decline and fall' of empires which fail to acknowledge and protect property rights (Eisenstadt 1969).

The significance of private property has two implications. First, it justifies to an extent the Hegelian/Marxian understanding of civil society primarily as the site of traffics. Second, it entails that the civil society should not be envisaged as a 'flat' space, harboring no power relations; for private property, especially in the means of production, engenders a power difference between those who do and those who do not possess it. The state/society difference does not mean that power is institutionalized only in the former, but that the latter is structured (among other things) by power relations of its own, foremost among which are those established by property.

5. *State and Society in the Twentieth Century*

The complex interactions between the power forms that lie on each side of the divide shape, to a large extent, the dynamics of modern societies. In the twentieth century the prevailing trend could be called

'statism,' for it saw a considerable enlargement of the scope of state action. In totalitarian systems, this trend suppressed all institutional limitations upon that action, and threatened the existence itself of society as a separate realm. In other systems, it pushed back considerably the boundaries of that realm, but this in response also to demands originating from it. For instance, economically underprivileged strata sought to maximize the import of citizenship and to reduce that of their market position; many economically powerful groups sought the state's assistance in securing their profits and stabilizing or correcting the market itself, which for various reasons had lost its self-equilibrating capacity. A further component of the trend consisted in the strategies of groups (sections of the 'political class,' public employees, members of the so-called 'new professions') whose livelihood and whose opportunities for a greater sway on policy depended on an expansive definition of the state's role.

Whatever its protagonists, in non totalitarian countries that definition was much assisted by the existence of a 'public sphere' and by the institutionalization of adversary politics, which gave voice to broader social strata, and found its most recurrent theme in the respective scope of the state and the market. Political parties played the central role in this dynamic, sometimes opposing but more often supporting the 'statist' trend. This expressed itself, among other things, in the formation of bodies and agencies that sat astride the traditional divide between the public and the private realm—as with the Italian *parastato* or the British *quango*.

In the last decades of the twentieth century the trend was challenged by social forces expressing themselves politically through conservative and/or right-wing parties. These sought to at least slow down 'statism,' and proclaimed the superior rationality of the market, which in their discourse, but to an extent also in practice, reasserted itself as the chief, if not the only institutional site of the civil society. This late revisitation of the economy-centered, Hegelian/Marxian conception of the civil society acknowledges that in contemporary society also human potentialities and social processes—of a cultural, communicative, symbolic, apparent noneconomic nature—which other formulations treat as a *tertium* with respect to both state and market, are in fact targeted and controlled to a large extent by great concentrations of economic power. This is achieved through new material and social technologies, and subjected to the logic of accumulation, which is increasingly focused on informational and financial resources. Mostly those technologies are developed and operate transnationally, and thus increasingly escape the reach of the political competences and facilities vested in the states. This lends a new edge to the attempt to reduce, after decades of 'statism,' the significance of public and political action, and to enhance that of the market.

Also the end of the Cold War operated in that sense, for it reduced the necessity for strong political/military tutelage of the capitalist order. It also loosened the constraints of the Keynesian compact which the dominant strata had previously made with the lower orders and implemented largely through state action.

Both dominant trends—the explicit or implicit reduction of civil society to the market, and the slogan prevalent in the advanced countries at the end of the twentieth century: market, *si*, state, *no*—are potentially worrisome. The market itself remains the site of the formation and interaction between large economic forces, endowed with great power; and these are increasingly operating in a transnational space. In contrast the state—still wedded to the territory—can no longer perform even its most traditional functions, jurisdiction and police, let alone those functions of guidance and intervention in the economic realm it had increasingly claimed during most of the twentieth century.

These recent phenomena compromise the institutional tenability of the couple state/society nearly as much as it had been threatened, earlier, by the totalitarian state or by central economic planning. A seriously dis-empowered state cannot establish and monitor an authentic civil society complementary to itself. In this sense, the Aristotelian and medieval vision according to which only a politically organized society can truly call itself 'civil,' deserves to be revisited.

State: Anthropological Aspects

The 'state' refers to a form of polity that links people and territory in 'societies' and thereby demarcates itself from other states. Although archeologists date states back to ancient Egypt and Mesopotamia (about 2500 BC), this article deals only with anthropological aspects of the modern state. It examines the implications of linking people to territory on subject formation, the administration of populations and their cultures, and on the practices of religiosity, kinship, and commerce as well as of anthropology itself.

1. *The Concept of Modern Statehood*

Modern statehood is a mode of political organization of 'society' in which the state is the primary agent charged with building the representation of society aware of itself and in harmony with itself. Modern law is the principal means by which the state attempts to create this harmony, an ideal state in which there is a coincidence between behavior and rules, and where the state can anticipate the conduct of its subjects (citizens) and develop normative frameworks (policies) to direct change (Nader 1990). States are only one of many rule-making institutions with administrative capacities. International and supranational bodies also increasingly make law, but states largely retain for themselves the power of legitimate enforcement. They remain the only institution in most parts of the contemporary world with an effective ideological and institutional apparatus that claims to represent the entire people within a particular territorial jurisdiction.

Statehood became the central principle asserted in international law in 1648, with the signing of the Treaty of Westphalia ending the Thirty-Year's War in North-Central Europe. Driven by industrial capitalism as a superior mode of production and accumulation, the state expanded its functions beyond the conduct of war, the administration of justice, and the regulation of commerce, to massive projects in the colonization of populations in the Americas, Asia, Africa, and the mid-East (Dirks 1993, Stoler 1995). Western European states, in particular, formulated projects of internal colonization and they began to usurp religious authority's control over the definitions of transcendence, the bodies of their subjects, and the institutionalization of their life courses.

Initially employed as a political program in the French Revolution and subsequently written into the United Nations Charter, the nation form grew out of transformed empires and tribes during the process of European state formation (Tilly 1990). At the same time, in a process of reciprocal copying, states in the Americas also emulated the nation form. This transformation of diverse peoples into unified nations appropriated local discourses of consanguinity and affinity and, in turn, reconstructed kinship. Unification was rarely accomplished without intermittent purges or other kinds of homogenizing processes. From the late fifteenth to the early seventeenth centuries, all Western European states engaged, with often-disastrous economic consequences, in variant forms of ethnoreligious 'cleansing' leading to population resettlement and the formation of victim groups.

In the twentieth century, national consolidations and the creation of new types of victim groups reached new heights, especially with the advent of fascist and racist ideologies originating in Europe but also employed elsewhere (Lefort 1986). The peace treaties concluding World War I introduced into Eastern and Southern Europe the two conditions of West European nation-states—homogeneity of population and rootedness in the soil. In Eastern Europe the implementation of these principles was largely elided (though tacitly encouraged) during the Cold War with the establishment of socialist states based on universal brotherhood and allied with the Soviet Union—a bloc that dissolved following the so-called 'velvet revolutions' of 1989. Western European states emerged weakened from World War II and unable to resist independence movements in their colonized states, primarily in Africa and Asia. These postcolonial states in turn nearly universally adopted the nation form to integrate diverse groups within territorial boundaries already drawn, arbitrarily, by European states. Nation-states have since become the mode by which all of the earth's polities are organized into formally comparable and sovereign governing units. Appropriation of the nation form effectively broadened the scope of the state to include the planned change of culture, variously defined, and the generation of forms of subjectivity in populations (Borneman 1992).

2. *Subject Formation through Linking Territory to People*

The 1933 Montevideo Convention defined the criteria for statehood as having: (a) a permanent population; (b) a defined territory; (c) government; and (d) the capacity to enter into relations with other states (Article 1, League of Nations Treaty Series No. 881)—with only the first two criteria consistently upheld. Between 1945 and 1999, the number of states recognized by international law as sovereign members of the United Nations increased from 51 to 189, with two nonmember states (the Holy See and Switzerland) also recognized. Defining statehood this way has numerous effects on subject formation. First, it produces pressures to unify ethnically mixed and territorially dispersed populations by centralizing legal and education systems and standardizing the life course. States uniformize by means of both bureau-

cratic technologies (the use of, e.g., interviews, surveys, and maps) and psychological appeals to the 'shared' symbolic universes they create (through the standardization of grammars and linguistic use, and the shaping of experience in ritual events and everyday routines). Second, it creates populations with mixed loyalties, settlers or migrants who live in a place among peoples separate from the place and peoples with whom they primarily identify. Third, it generates categories of automatic exclusion (e.g., resident stateless peoples, resident internal 'minorities,' nonresident external others), which are then used frequently to justify war against external or internal enemies. Fourth, the dependence of modern political representation on territorial attachment reinforces identifications with territory and the desire for statehood. These identifications exacerbate territorial conflicts and often lead to wars between potential antagonists who tend to receive international recognition only when their disagreements are articulated in terms of border violations.

Despite the ubiquity of the nation-state, different historical experiences of populations have produced a variety of ways of classifying states, some corresponding to intent of the ruler, others to the relation of ruler to ruled, and still others to their cultural form. In the twentieth century alone, classification of state forms include, for example, monarchy, oligarchy, theocracy, democracy, totalitarian, liberal, democratic, communist, fascist, socialist, authoritarian, welfare, theater, tributary, cephalic, bicephalic, romantic, satiric, colonial, postcolonial. In accounting for this variety of state forms and the historical conditions of their production, anthropologists have focused on the organization of public authority and forms of domestic control. The historian Foucault (1977, 1978) and the political scientist Anderson (1983) have inspired much recent scholarship.

The powers unleashed by science since the Enlightenment have generated what Foucault calls 'rituals of truth,' including disciplinary technologies that refigure space and the arts of governance charged with producing 'society' and 'culture' as objects of knowledge and identification. Moreover, the deployment of new procedures of power in the nineteenth century transformed state authority, from a sovereign's ability to 'take life or let live' (to order or require someone's death), to an investment in administering life by means of disciplining the body and regulating populations. States institutionalize particular cultural forms through projects of reform, education, development, incarceration, war, welfare, and family planning, along with the use of scientific techniques such as surveys, census, questionnaires, actuarial tables, economic forecasting, spatial mapping, case studies, and bureaucratic interviews. Anderson focuses on the historical conditions in which the 'imagined community' of the nation comes into being and achieves global currency, particularly in its relation to states following the collapse of empires. One of these conditions, print capitalism, enables advances in techniques of memory and collective narration through the proliferation of historicist myths and standardized accounts of experiences of national belonging across space and irrespective of local temporalities.

Because modern governing necessitates delineating a population and a territory, rulers deploy ethnographic assumptions about how to define a people. As well, through laws and policies states produce and circulate information about belonging (through families, schools, and the media), positively and negatively sanction prescriptive and proscriptive behaviors (about sexuality, gender, age, race, ethnicity, and work), and build libraries, monuments, and museums to display particular interpretations of the nation. Hence, modern states are distinctive in that they produce both laws and people; they not only administer and regulate already-existing cultural patterns but also produce new domains of objects and forms of subjectivity.

3. *The Discipline of Anthropology and the State*

Early anthropological work on the state, especially among archaeologists, was inspired above all by Friedrich Engels's study of the origin of the state and its relation to private property, Lewis Henry Morgan's evolutionary scheme, and Sir Henry Maine's theory of the progressive movement from status to contract in the development of state law (Service 1975). Without being fully conscious of it, fieldwork-based anthropologists, inspired by Bronislaw Malinowski and Franz Boas, initially participated in this expansion of the state by studying the generation, elimination, transformation, or preservation of indigenous peoples, tribes, peasants, and clans through the creation of encompassing, and simultaneously exclusionary, national forms of belonging. One of the major anthropological aspects of states has been, therefore, the deployment of anthropology: ways of defining and categorizing human populations and of systematizing knowledge about them (Ferguson 1990, Pemberton 1994). The discipline of anthropology has closely followed and defined its objects in dialogue with state projects, alternately supportive and oppositional: itemizing culture traits and social organizations of 'discrete' peoples, devising evolutionary schemes, tracing efforts at internal and external colonization, mapping the settling and resettling of territory and the transformation of property, and tracking diasporic populations, cultural diffusion, and global trade routes (Moore 1986).

By and large, however, anthropologists traditionally have focused on the production of the cultural or the social, or with forms of exchange among people

without states (Sahlins 1981). A preference for fieldwork in villages or small-scale communities also made it difficult for anthropologists to connect their subjects with states or the large-scale. Further, long-term observational fieldwork requires an intimate access that is difficult to obtain from rulers or those in the inner circles of power. Anthropologists have, therefore, often assumed an essential sociocultural opposition of the people to the state. This seemed credible, if not ethically imperative, when, as in the early twentieth century, the objects of study were so-called 'primitives' and 'indigenous peoples,' victimized and threatened with extinction, frequently through state-supported genocide. Or, alternatively, when the state was primarily a puppet of a colonial power. Nonetheless, the opposition is misleading, as society (*Gesellschaft*) vs. community (*Gemeinschaft*) originates as a project of the modern state.

Anthropology has in the meantime become a global discipline of alterity, no longer restricted to questions of origin or to particular peoples or places. Also, the relation of indigenous people to states has changed considerably, with many states now guaranteeing the 'preservation of indigenous cultures' and prioritizing their rights over those of more recent settlers. Moreover, the United Nations along with some nongovernmental organizations and a global tourist industry positively sanction states that protect and support what are called 'first peoples'—a movement that has reversed the trend toward extinction and strengthened claims of cultural authenticity or temporal priority of settlement. In any case, the notion of 'kin-based' or 'acephalic' polities as a pre-evolutionary stage to a 'state-based' polity, or of the replacement of status by contract, has become moot for ethnographic research as the entire planet is organized territorially by states unevenly integrated in global market exchanges, mutually regulated through legal contracts. The interaction of people with states is an unavoidable condition of modern life.

This interaction took three meta-narrative forms in the second half of the twentieth century: people living within the bipolar Cold War structure of socialist or communist states (planned economies, single Party rule, so-called 'Second World' of totalitarian states) vs. liberal states (free market economies, multiparty democracies, so-called 'First World') and a contested zone of people living in postcolonial states (mixed economies with diverse political forms liberated from empires, so-called 'Third World'). Until the late 1970s, anthropologists had little access to people within totalitarian states, and in other parts of the world they devoted much research to reconstructing the precolonial state. In the mid-1970s, a global trend toward democratization of authoritarian states began in southern Europe, was picked up in Latin America and parts of Asia in the 1980s, and spread to sub-Saharan Africa, Eastern Europe, and the Soviet Union in the late 1980s and 1990s, making the relation of these people to transforming states a subject of anthropological research. In effect, the space of the Second World has disappeared and the spaces of the Third and First Worlds are mixed, existing within each other, though in radically different proportions. The vast majority of states now call themselves democracies and are engaged in market reforms that open internal economic and cultural relations to global markets.

Of note at the beginning of the twenty-first century is the distinctive disjuncture between the global integration of financial markets and shifts in state strategies with respect to sovereignty over national economies, the proliferation of ethnic affirmation within states, and the denationalization of much military conflict (a process also driven by fear of the use of nuclear weapons). Whether states drive, resist, or submit to globalization, and hence thereby curtail or strengthen their sovereignty, varies greatly depending on size, wealth, location in the international system, and domestic legitimacy. Local cultural forms unable to resist pressures of cultural or economic globalization are nonetheless not homogenized, a fact apparent both in the local variations in 'society's' relation to the state, specifically to democratic form, and the continued diversity of everyday routines and rituals.

By the beginning of the twenty-first century, democracy has become the dominant form of internally organizing states, functioning as a mode of ruling, a device of power, and a strategy of self-representation. Furthermore, democracy requires systems of personal and public accountability, usually embodied in principles of 'the rule of law,' or it begins to degenerate into forms of despotism (Borneman 1997). As a mode of ruling, democracy means the introduction of regularized elections, the creation of ruling majorities and minorities, the institutionalization of an opposition, and the strengthening of principles of accountability that circumscribe the exercise of power. As a device of power, democracy is as dependent on the externalization or creation of negative others as on the internal dynamics of citizen formation. Practices of such externalization range from state-tolerated social discrimination to legal exclusion of refugees to war. As a strategy of self-representation, each democracy receives international recognition to the extent it is able to claim governance by 'rule of the people' and conformity to international norms and conventions.

Anthropologists charged with listening to others and often asked to give 'voice' to the people studied are involved in all three aspects of democracy. Hence, the discipline of anthropology unavoidably intervenes in local political struggles about defining 'the people.' Given the increasingly global nature of 'news' and accelerated information flows across state borders, local struggles about representation quickly enter inter- or supranational arenas, subjecting the state to pressure from authorities external to it and explicitly

drawing attention to the ways in which it exercises sovereignty. Such global flows also challenge state sovereignty by bringing to the world's attention local and subregional actors and events that might be in opposition to dominant groups within their own states.

The study of conflicts in democratizing states includes research on social and legal citizenship and on the relation of state policy to demands for representation and accountability. Along these lines, four basic contemporary conflicts about representation and states are observable: involving excluded people who want more social, economic, cultural, or legal inclusion into states in which they reside; diasporic people who want representation in both the place in which they reside and the place from which they are displaced; numerical minorities (usually represented as a 'culture' or a 'nation') who do not have their own state but want one; and citizens or social movements that demand more accountability from their rulers.

4. *Legitimacy and the Modern State*

Although the conception and functions of the modern state keep changing, its legitimacy is always based both on some notion of the 'consent' of its own citizens to rule and on the recognition of other states. This was not the case when rule was justified without recourse to 'the people,' in other words, rule based on coercion alone, principles of heredity or wealth, the ability to wage war and collect taxes, or the administration of justice. To obtain this consent and recognition, the state must usually go beyond Max Weber's famous dictum that its power rests on a monopoly on the legitimate use of violence.

The state does not, in fact, hold this monopoly in many parts of the world. And where the state has dissolved or weakened, the most vulnerable citizens tend to suffer the most from the lack of any protections. Indeed, today weak states are just as likely to lead to violent conflict as were strong imperial states in the last several centuries. In many places, the state's own abuse of this supposed monopoly—through genocide, strategic terrorism, the suppression of dissent, cynical uses of war—has traumatic effects on its citizens, leading to repeated and delayed suffering of past events. Irrespective of whether they initiated or were victims of the violence, states instrumentalize this trauma, not only by building monuments to the fallen soldiers but also though the construction of nationalist historiographies and support for a heritage industry that especially honors the idea of national sacrifice and organizes the process of mourning for losses after wars. So long as states continue to draw legitimacy from principles of territorial sovereignty and peoplehood, they will be motivated to generate, exacerbate, and institutionalize differences with neighbors or neighboring states. Anthropology is concerned less with the conduct of these conflicts and wars than with their effects on the organization of populations and communities (Tambiah 1992).

Also, the collapse of the Cold War's bipolar state system has resulted in the relatively unrestricted proliferation of arms, much of it driven by state-supported arms industries, and in a market for new and affordable technologies of death outside the control of states. Where the sources and agents of violence outside state control are increasing—a wide-ranging phenomena found, for example, in Colombia due to drug trafficking, in Sri Lanka and much of Africa due to civil war, and in the United States or Mexico due to poverty and class conflict—people employ private police forces.

Alternately, many states now lend their militaries for 'peace-keeping' efforts organized by the United Nations, and still others, such as states within the European Union, are relinquishing military sovereignty to continental or transcontinental military alliances. There is also a growing body of legal doctrine—and an international court established in 1999—holding states accountable to their own norms and to international covenants and agreements on issues such as human rights, environmental and maritime law, and commercial law. The state's sovereignty and legitimacy, then, is not granted as natural but conferred by its citizens and the recognition of other states and new international regimes.

The long history of linking the state to realization of the Idea of the people (Hegel), representation of the social (Durkheim), technical and bureaucratic rationality (Weber), or exploitation and class dominance (Marx), must now be supplemented by acknowledging that most states still resort to magical practices and cultivate religiosity in order to legitimate rule (Taussig 1997). State policies and edicts administered through 'law' often work through processes similar to magic: belief in the power of the utterance of the speaker, the performativity of speech, the linguistic re-articulation of group suffering and instrumentalization of memory, nationalistic narrativization of macro-political events, *ad hoc* rationalization of failures and successes. Even in the domain of criminal law in the most rational of states—Germany or Sweden, for example—most crimes are never solved and most criminals go free. Yet criminal law there still 'works'—that is, contributes to the legitimation of the state—largely through belief in the principles of justice that judicial inquiries, prosecutions, and trials efficaciously represent.

Likewise with respect to religion, states most successful in 'neutralizing' religion are those which recognize the significance of religiosity and incorporate religious traditions and symbolic forms into the secular rituals of political parties, elections, bureaucratic routines, and lifecourse *rites-de-passage* (Gauchet 1997, Herzfeld 1992). Such practices are

forms of group worship and they crystallize in patterns of national belonging when citizen and state narratives are brought into harmony. The struggle between the great world religions and the state to occupy and shape the symbolic forms of everyday life has not quieted, partly due to the development and ubiquity of new technologies of communication that make it possible for both instances to react independently and quickly to everyday events. Nonetheless, there has been a dispersion of the power over the control of religious expression, and the state is one of many benefactors from this process. In the last quarter of the twentieth century in most places of what is known as the First World, entertainment—especially involving sport and music—emerged as the field dominating both the management of experiences of transcendence and of people's affective attachments and identifications. State rituals—especially electoral campaigns, legislative debates, memorialization and mourning ceremonies, and political speeches—have, therefore, increasingly incorporated models and techniques of authority drawn from entertainment. This leads to a fusion of actors ('personalities') in the two fields and an incorporation of magic and infusion of 'charisma' in the rationalized arena of state activity.

With the end of the Cold War, First World states increasingly structure their relations to new and Third World states by promoting NGOs ('nongovernmental organizations'). Acting in a negative symbiosis with the state, such NGOs also incorporate magic into their missionary projects of rational reform and economic and political development. In much of the world they have replaced organized religion as competitors to the state in providing care (welfare) and promoting both local and global accountability in the exercise of power. Often, however, they serve primarily as instruments for the transfer of wealth or power between supranational elites. Notwithstanding liberal mistrust of the modern state, reaffirmed by the horrors of totalitarian experiments, the nation-state form still provides the possibility for local control of people's own destinies in a manner impossible for prenational communities. Stateless people are indeed the most defenseless actors in the contemporary world.

Hence, despite the wars, violent revolutions, and massive repressions of the nation-state, as the sociologist Lepsius (1988) argues, this form of polity has offered particular advantages to West European societies, including the institutionalization of peaceful conflict-solving through the rule of law, guarantees of individual freedom, the organization of interests through parliamentary democracies, and the integration of national economic development in the world economy. In each of these measures, autocratic and totalitarian states elsewhere have been at a permanent disadvantage, incapable of recognizing the subjects they seek to control for whom they are, and unable to organize power except through coercion. Such states destroy sociality and build false representations of the people, thereby creating a basis for the illusion of society against state.

State Formation

A state consists of a set of institutions whose functions are social control and authoritative decision-making and implementation processes. In addition, modern states seek autonomy in their relations with other states. Beyond these very general criteria, the concept of the state quickly becomes multidimensional with respect to its historical development, its relevant legal considerations, and its theoretical debates. The institutions of a state are subject to conflict and disagreement over their structure and the role they play. Institutions change over time, and the changes both shape and reflect differing degrees of autonomy and strengths. In the twenty-first century there is considerable interest not only in the historical trajectory of state formation and the more proximate formation of new states—dozens of new states have been created in the second half of the twentieth century—but also in the concept of state capacity. Political scientists and political economists who measure and assess the strength and relative autonomy (sovereignty) of states in national and international arenas concern themselves with the proper role of states in the domestic and international political economy. States are in constant competition with other institutions such as intergovernmental institutions and for-profit and nonprofit institutions. Political scientists study and observe the role and function of each of these various national and international institutions. Not surprisingly, the proper role, the function, as well as the capacity of today's states has become a lively and contentious issue.

1. *The Problematic of the State*

Many prominent classical theorists studied state formation and the multifaceted issues surrounding the role and function of states. Theorists such as Machiavelli (*The Prince* 1988), Rousseau (*The Social Contract* 1987), Marx and Engels (*The Communist Manifesto* 1998), and Lenin (*State and Revolution* 1993) considered the formation and role of the state to be a theoretically interesting issue. More recent students of the formation of the modern state have focused their attention on such other topics as the absolutist states of Western Europe (Anderson 1979) and states and revolution (Skocpol 1979). Contemporary writers address issues such as the state and industrialization, nationalism, colonialism, and the formation of the state, in addition to many other topics concerned with communism and the postcommunist state. Other ongoing themes among students of state formation are the state and the economy, power and legitimacy, and the relationship of states to other states. Twenty-first century analysis of the forces of globalization and their impact on the state are also frequently discussed in the context of the historical evolution of state formation.

2. *History of the State*

The modern state is a Western European creation which emerged in the fifteenth and sixteenth centuries and became more firmly grounded in the seventeenth century. The modern state came into existence in the same time frame and in geographical locations that were the wellsprings of modern capitalism, modern science, and philosophy. Many scholars link the evolution of the modern state and Christianity in its Protestant form. It is generally agreed that the emergence of a new political form—the modern state—was intimately linked to the economic, intellectual, and religious developments of the time.

The first modern states to arise were Italy, the UK, France, and Spain. The principal technical tools of modern state building were the development of permanent bureaucracies and a standing army, but it was the availability of money that enabled rulers to acquire them. Once a ruler was able to control the professional bureaucracy and the army, the nobility of medieval times lost its political role and power. The principal producers of cash were the commercial and industrial middle class and the peasantry. By the late eighteenth and early nineteenth centuries the bourgeoisie was able to curtail and even abolish the privileged status of the aristocracy and the authority of the monarch. The bourgeoisie acquired increasing control over the state. Their victory, signaled by the French Revolution, transformed the dynastic, state into the modern state. However, to define the modern state as 'bourgeois,' meaning 'civic' signifies the civil and legal equality of all subjects regardless of status by birth or occupation. The abolition of the old feudal privileges did not mean that the propertied and educated classes ceased to have privileges in the modern state. Modern theorists of state formation like Charles Tilly (Tilly 1975) and many Marxist theorists like Miliband (1969), Poulantzes, (1969), and Offe (1975) view the state as 'organized coercion' orchestrated by an elite. Other social scientists view the state as the arena of legitimate authority embodied in the rules of politics and in governmental leadership and policies.

Some thinkers, especially Marxists, tend to treat the state as an analytic construct by which to explain the modes of production, class relations, and societal struggles in general. Others, including Theda Skocpol

(1979), argue that states are 'actual organizations' that control territories and peoples. Skocpol echoes the legal definition of a state much more closely than does Tilly for example, by pointing out that while the state is anchored in class-divided socio-economic structures it also needs to be seen as part of the international system.

As a practical matter, in order for a state to engage in international relations, other states need to recognize it as a fellow state. Modern sociologists call attention to the fact that a state is a human community that successfully claims the monopoly of legitimate use of physical force within a given territory. Whether a state is considered legitimate and on what basis its legitimacy is acquired and honored in the human community within the territorial boundaries of the state and in the large international community of fellow states, is to say the least, very historically and theoretically complex.

3. *The Modern State*

The modern state and the modern state system developed simultaneously. It required coercive capacity for the state to sustain itself both domestically and internationally. The state system of the nineteenth and twentieth centuries led to two world wars and the Cold War. These wars were significant in shaping contemporary states and the international system of states. However, contemporary concern and interest in the state is not confined to questions of the legitimacy of states or even their coercive capacity. At issue in the twenty-first century is the role of states as actors, competing with other actors, to determine what the ongoing proper role and function of a state ought to be with respect to its political, social, cultural, and economic obligations to its citizens.

State formation has never been simply a 'founding.' Quite the contrary, state formation is a process of formation and reformation based on the changing nature of societies within the state and the larger international system of states. The institutions and processes of a state and of states collectively are not static. To say that a state requires the capacity to carry out the proper functions of a state is a truism, but the capacities required at the turn of the twentieth century vary greatly from state capacities required at the turn of the twenty-first century. Furthermore, states compete with other national and international institutions. For example, states vie with interstate organizations, such as the European Union, the United Nations (UN), the World Trade Organization (WTO), and with nonprofit organizations such as Greenpeace and Oxfam, and for-profit corporations such as Microsoft and CNN. Financial capacity, knowledge capacity, monetary capacity, and even legal capacities of nonstate actors all challenge state capacity. This is not to suggest that states have become defunct but merely that what it means to be a state today and what capacities a state is expected to possess by its citizens and in the larger community of states continues to go through a process of formation and reformation.

4. *The Future of the State*

As the twenty-first century begins there are almost 200 so-called sovereign states in the world. It is useful to think of contemporary states in their subgroups of differing state types: first, the 'old states,' such as the UK, France, Spain, the US, China, and Japan, which have developed reasonably stable nation states over the centuries. Some of these states, like the US for example, are multinational and multiethnic. Others, such as Japan, are more homogeneous. What these states have in common is a citizenry that views the national government as legitimate, and these states on the whole, share stable political economies. Second, there are the 'new' states. Many of these states, for example, most of the sub-Saharan African states and many states in Asia and the Middle East, emerged out of colonialism during the twentieth century. These new states tend to meet the legal criteria for statehood, yet many lack legitimacy as states in the eyes of their citizens. Most often such states are also multiethnic and have yet to achieve a sense of nationhood—a shared belief on the part of citizens that they belong to the nation-state. Some of these states, for example, Somalia or the Congo, are, at the beginning of the twenty-first century, in a state of civil conflict. States which are not able to carry out the basic function of a state, are frequently referred to as 'failed' states. Such states have the legal trappings of a state but the nation-state formation has broken down and the state's capacity to govern its territory has failed. In the category of failed or failing states are all those for which the historical process of state formation has not yet succeeded.

One may observe that the historical timeframe during which state formation takes place will determine both the internal and external factors which have a bearing on the process, as well as the outcome, of state formation. In the post-Cold War era for example, state formation and reformation—in the case of former communist states—is taking place at a time when the dominant paradigm is a democratic form of governance within the context of free market capitalism. Accordingly, state formation in the new states and postcommunist states, takes place in an international setting which exerts a distinctive global leverage on the type of state formation for which political and economic support and acknowledgement is rendered.

However, today state formation and the reformation of all states, not just new or failing states, takes place in the context of globalization. Globalization brings with it active participation in the national and international life of states by nonstate actors and a new degree of interstate and inter-actor interdepen-

dence. Today global and regional institutions, along with states, participate in rule making, rule enforcing, knowledge creation, and in fields such as commerce, banking technologies, medicine, genetic engineering, and in defining the standards for human rights. The globalized world of the twenty-first century is reshaping the idea and the reality of the sovereign state. Yet states still are extremely important in the lives of most people and hence, state formation continues to be an important ongoing process, a process which is not merely a multifaceted historical process but a multidimensional work in progress.

State, History of

1. Introduction: Problems of Definition

At present there are about 200 communities in the world that are considered sovereign nation states, according to standards developed during European history. Officially, alternative political models no longer exist. Therefore, it seems reasonable to adopt the narrow definition of modern statehood created by German professors of law (Jellinek 1959). According to them, a state is constituted by a homogenous population inhabiting a contiguous territory under one single government which is characterized by complete independence from any outside authority (sovereignty) and holding the monopoly of jurisdiction and the legitimate use of violence internally. History has shown that this kind of state need not be a nation and even less a constitutional democracy based on human rights. But today most states claim to be nations under the rule of law and a formal constitution. Nevertheless, these are recent achievements and rather exceptional in world history.

History abounds with different kinds of political organization that may also be called 'states.' This is not quite correct from the historian's point of view, because in most European languages the term 'state' was originally used to designate social status or real estate. But between the seventeenth and nineteenth centuries it became the name of a particular type of European political organization, achieving perfection during that same period. Before then, pre-state communities can be roughly classified into: (a) tribes without rulers, (b) chiefdoms, (c) city-states, and (d) empires (van Creveld 1999). Historically as well as typologically, humankind was first organized in face-to-face communities, either acephalous societies without rulers based upon kin groups, or chiefdoms based upon force, wealth, and consequent social stratification. In addition, many chiefs were distinguished by religious qualities or supported by a privileged group of priests.

All this is even truer of empires, which through religious ideology, a standing army, a kind of bureaucracy, and a tax system solved the problem of permanent control of large territories. This was a necessary precondition of future state-building, but not the sufficient one, which was to be the achievement of some city-states of Antiquity. Whereas everywhere else the distinction between ruler and owner of a polity did not exist or was at least blurred, in Greece and Rome for the first time citizens appointed certain persons to govern on behalf of the community and not for their own purposes, not as rulers, but as magistrates. These were the roots of the state as a transpersonal, abstract institution with an abstract legal personality (van Creveld 1999). Therefore, the history of the state is first of all the history of the transformation of the loosely structured 'chiefdoms' of European aristocrats and 'empires' of European kings into modern states between the high Middle Ages until the nineteenth century.

2. Theory

European state-formation was a multidimensional process, but most theories of state-building are still one-dimensional. Therefore, a multifactorial three-level theory of state-building which combines (a) the micro-level of individuals and groups, (b) the meso-level of the political system, and (c) the macro-level of

society is a more promising suggestion (Reinhard 1992).

State-building starts on the micro-level with the self-seeking lust for power of individuals, often with the competitive advantage of holding a kingship. Before the existence of the state as an abstract institution, the necessary transpersonal continuity was provided by the dynasty. Dynastic state-building consisted of the elimination or at least control of the rival holders of autonomous power dating from the prestate phase of history—the nobility, the church, urban, and rural communities—in order to establish a monopoly of power. To succeed dynasties needed the assistance of power elites, which in their own interest made the growth of state power their own cause. In the long run, lawyers of bourgeois origin proved better qualified for that role than members of the church or the nobility because, in contrast to the latter, lawyers owed all their status and power to the service of monarchs.

Far-reaching change on the meso-level of the political system resulted from successful exploitation of war, religion, and patriotism for the purpose of expanding dynastic power. The pre-existing rivalry of European monarchs inevitably grew with their power, because it became essential to outstrip their neighbors, to grow at their expense, and to protect themselves against the same objectives in turn. Therefore, they needed continuously growing armies and money in ever-increasing quantity to pay them. In its decisive phase of growth the modern state was a war state, which expanded its taxation, administration, and coercive apparatus mainly to wage war.

This resulted in a circular process, the coercion-extraction-cycle (Finer 1997) and finally in the internal and external monopoly of violence. Ultimately, only states wage war. Private wars, such as vendettas or feuds, noble or popular revolts were no longer legitimate under the powerful war and police state. 'Necessity' in the service of the common good served as key argument to legitimate this growth of state power. But when the competing 'confessional' churches lost most of their autonomy to the state after the Protestant Reformation—the price to be paid for political protection—religion became an instrument of emotional identification of the subjects with their country. 'Catholic' and 'Bavarian,' 'Polish,' or 'Spanish' became almost synonyms on the one hand, as well as 'Protestant' and 'English,' 'Prussian,' or 'Swedish' on the other hand.

Essential contributions originated from the societal and cultural environment on the macro-level. First, the geo-historical plurality of Europe was the incentive to the growth of state power through the coercion–extraction cycle. The result was a stable pluralism of internally strictly unitary states, an exceptional case worldwide. Universal empires never had a chance in Europe; the Holy Roman Empire of the Germans was at most a first among equals. But internal unity was not realized before the late eighteenth, the nineteenth, and in some cases even the twentieth century. For a long time most monarchies were composed of several parts of unequal status such as Castile and Aragon or Polonia and Lithuania.

Everywhere monarchs had to cope with a powerful system of autonomous local noble rule on the one hand, with a countrywide network of partly autonomous urban and rural communities on the other, once again European particularities. In addition, before the Reformation the Church considered itself an independent community, in some respect even a state before the state. This singular European dualism of spiritual and temporal, combined with the equally singular political pluralism turned out to be a precondition of political freedom, although neither Church nor state, neither noble landlords nor urban oligarchies were in favor of any liberty except their own. Finally, the strong position of the Church derived from its role as keeper of Latin culture. Roman law, to some extent transformed into the canon law of the Church, directly and indirectly proved fundamental not only to monarchic state-building, but also to individual liberty and property.

3. *The Age of Monarchy (Middle Ages to Eighteenth Century)*

European kings of the Middle Ages and the early modern period claimed to be emperors of their kingdoms, which is to say that like the pope in the church they held unrestricted power (*plenitudo potestatis*). For the first time in history the competence of a king was defined by the French constitution of 1791. Before that date royal power was limited only in the sense that there were some things a king could not do. The English king could not create statute law or raise taxes without consent of the realm, the French king could not change the succession to the throne or give away parts of the crown domain.

For the rest, every monarchy was 'absolute,' that is to say the king's prerogative included everything necessary to fulfill his fundamental duties as fountain of justice and keeper of peace. In that sense even Poland's 'republic of nobles' and England's parliamentary system were called 'absolute' by contemporaries. In Britain, where no written constitution defines powers, in theory the monarch today is still entitled to declare war and to conclude peace without consulting Parliament. In reality, however, since the later Middle Ages this was possible only if the necessary funds were raised with the help of representatives of the subjects. The monarchies of the European Ancien Régime were limited not so much by legal restraint as by small resources, traditional rules, and social conventions. Under these circumstances it was decisive for the process of dynastic state formation that the crowns of Castile, England, and France

became hereditary whereas the Empire and to some extent Denmark, Sweden, Poland, and Hungary remained elective monarchies. Compared with the universal competence of the modern state, including the right to extend this competence at discretion, the prerogatives of early modern monarchs were extremely modest. State activity expanded, when during the early modern period the so-called 'police' ordinances ('Policeyordnungen') started to cover new fields such as health and public welfare, moral order and communication, economic behavior, and labor relations.

This was no longer mere jurisdiction, reactive government by rescript as in the Middle Ages, but an expanding administration actively interfering with larger parts of the subjects' lives. But it was still not 'absolutism,' an anachronistic term of the nineteenth century which should be dropped (Henshall 1992), because the kind of monarchy without any legal restriction it designates never existed except in Denmark 1665–1834 and in Sweden for a few decades after 1693.

Similar to most monarchies of the world, European ones had a sacred character, practiced elaborate symbolic rituals, and were legitimized 'by the grace of God.' The coronation ceremony together with the coronation oath of the king and the corresponding oath of allegiance of the people were central in this respect. But there were varieties. In France political rituals and ideology constituted a true 'royal religion' ('religion royale'), and court life with its palaces, ceremonies, and festivities became an all-embracing total work of art. Some of its elements recur in England and elsewhere, especially the ritual of the royal touch, when French and English monarchs touched hundreds of people suffering from scrofula, the tubercular 'royal disease' ('morbus regius'), to cure them. Monarchs practiced this ritual with particular intensity when their monarchy needed additional emotional support: Henry IV and Louis XIII of France after the religious civil wars, Elizabeth I of England because of her succession problems, and Charles II after the restoration.

Other monarchies were more prosaic, including the Holy Roman Empire. And in spite of his politico-religious sanctuary, the Escorial, Philip II of Spain never wore a crown; there was not even a coronation ceremony in Castile. This was a way of demonstrating independence from the Church, but even in France political sacrality implied royal control of the Church and not the opposite.

Because of the Church's monopoly of culture, Europe's early political discourse was theological. The state was considered a consequence of the fall of man. With the reception of Aristotle natural man became a political being, a concept which was used to create an autonomous discourse of legitimation for the monarchy, erroneously, because 'political being' referred to the face-to-face community of the city and not to the state. But from Dante Alighieri down to John Locke, political theory remained essentially a theory of monarchical state-building, at most harmonizing limited monarchy with aristocracy and democracy into a mixed constitution, supposedly like the ancient Roman republic. Thomas Hobbes was the first to speak of the state instead of the monarchy, but this was not common practice before the eighteenth century, with Montesquieu and Jean-Jacques Rousseau.

This change coincided with the development of central institutions, which under the impact of enlightened rationality became more effective. Administrators were no longer the king's personal servants but transformed into professional officials of an abstract state, into modern civil servants ('Beamte') as described by Max Weber. The early medieval prince was assisted in his governmental functions by members of his court and council ('curia regis'), for written legal work by a chancellor, often an ecclesiastic. Most central institutions of European monarchies were created by segmentation of that curia. The court was reduced to a mere household, the chancery became a separate body.

Professional supreme courts and treasuries were established. To produce political consensus and financial aid an enlarged council of important subjects was created to become an assembly of estates or a parliament. What was left over of the ancient council was transformed from a multifunctional decision-making instrument such as the German aulic council ('Hofrat') into a differentiated system of governing bodies with a small group of confidants of the ruler at the core ('Privy Council,' 'Geheimer Rat,' 'Staatsrat,' etc.). From the sixteenth to the eighteenth century the conciliar principle of collegiality was common practice, to accumulate competence, to balance interests, to prevent disloyalty by mutual control, and to provide positions for as many members of the power elite as possible. Only a few very dedicated rulers such as Philip II of Spain, Louis XIV of France, and Frederic II of Prussia were still able to handle this complicated system of central government in person. Instead, many princes relied on a personal confidant as prime minister, such as Wolsey, Richelieu, Olivares, or used the new office of a secretary of state for coordination. In England, parliamentary management was a central task of royal confidants. The development of modern cabinet government was the consequence.

In France, Castile, Rome, and elsewhere many public offices were officially for sale, just another way to tap private accumulation in favor of public finance. The growth of state power was first of all a credit problem, because tax income had to be anticipated by credit to make the large sums of money which were necessary to wage war available on short term. Tax farming was another widespread technique used for that purpose. Direct taxes were based on the land, because movables and income were still not under administrative control. As usual, indirect taxes on

mass consumption proved more comfortable, whereas the rich were involved as creditors. But credit was still the personal credit of a prince, not of the state as institution. Therefore, repayment of loans was expected and interest rates were as high as risks. Under these circumstances, bankruptcy was the regular consequence of power policy until the Dutch and English invention of low interest long-term bonds with parliamentary guarantee, a decisive contribution to the further growth of the modern state.

4. *Premodern Alternatives and Their Political Heritage*

Traditionally, Europe respected man (and to some extent woman) as proprietor of his (her) person and goods. Therefore, in principle taxation was only possible with the consent of the taxed or at least their lords and guardians. For this purpose, most princes created structurally similar assemblies of important subjects or representatives of corporations, such as cities, called assemblies of estates, beginning 1188 in León. By the seventeenth century, however, most princes were strong enough to raise taxes without consent and to ignore their estates. This decline of estates has been considered the very essence of 'absolutism' by former research. In contrast, we know today that to some extent estates remained alive in most countries (with the exception of Denmark) and princes still had to bargain with them. But only in England seventeenth-century conflicts with the crown ended with victories of parliament and the definite establishment of financial control by that body. This system, imitated in most European countries after the French Revolution, finally led to parliamentary government and democracy.

In contrast to other parts of the world, in European political culture the relationship between ruler and subjects was considered a contractual one, based on legal mutuality. In case of a supposed breach of contract by the ruler, subjects felt entitled to armed resistance, because their legitimate lord had degenerated into an illegitimate tyrant. Therefore, early modern discourse and practice of the right of resistance through a series of European revolutions laid the foundations of modern liberty and democracy.

In most countries, the nobility dominated assemblies of estates, as holders of local power the true lords of the land. Not before the eighteenth century did the administrative institutions of the state start to penetrate this autonomous local power structure and not before the nineteenth century was noble rule to a large extent replaced by public administration. But beside or below noble rule existed innumerable more or less self-governing urban and rural communities, from independent republics like Venice, quasi-republics like German imperial towns, privileged English boroughs, down to villages of Polish serfs who were still entitled to regulate certain common affairs on their own. This is the 'Europe of thousand republics,' the Europe of 'communalism' (Blickle 2000), a world where members of face-to-face communities decided on their immediate concerns. These are the roots of European republicanism and of the tradition of European self-administration.

When assemblies of estates flourished, ecclesiastical power competing with princes was already declining. But the Roman church had been Europe's first state with the pope as the first absolute monarch and the priest as the first nonhereditary professional public servant. The Church practiced territoriality ('*Flächenstaat*') at a time when empires were still mainly based upon personal dependency ('*Personenverbandsstaat*'). And the church established the rules of political religion with the consequence that to the present day states remain transcendent entities in need of believers. In this sense the state is the last church because European political culture is a culture of believers.

In contrast, professional law courts such as the French 'parlements' or the English 'common law and equity courts' were not originally autonomous alternatives to state-building monarchies like aristocratic rule, communal self-government, or the Church but creations of the expanding state power. Nevertheless, because of the loose structure of early modern polities giving room for the development of specific group identity and interests, these judges under certain conditions could transform themselves into opponents of their king's policy and initiate resistance or revolution, as happened in England and France in the seventeenth and eighteenth centuries. But in this way the principles of rule of law, of an independent judiciary, and even of a judicial review of legislation were introduced into political culture.

In the end, however, the fully developed modern state replaced noble rule by his officials, reduced local self-administration to a commission of the central government, and established complete control of the churches and the legal apparatus. The principle of justice existing beyond, above, before the state was largely replaced by the arbitrary use of the state's monopoly of legislation. But nevertheless the heritage of political alternatives remained alive: liberty and democracy, rule of law and independent judges, the claim to self-government, and to have a state one could believe in.

5. *The Age of Equality (Nineteenth and Twentieth Centuries)*

The modern European state, so far developed by state-building monarchies, reached maturity with the French Revolution and the political modernization of Europe which followed. Modernity means unity, unity of territory, people, government, sovereignty, and violence. The revolutionary process took the last step

to modernity and replaced the hierarchy of orders and the plurality of privilege which had characterized the political society of the Ancien Régime with a society where stratification became a private distinction because politically all subjects were now equal before the state and its law. From now on, not families or corporations were the basic components of the state, but individuals. But mobilizing individuals emotionally in favor of the state into some kind of participation—not necessarily a democratic one—resulted in an ultimate increase of state power with incredible dimensions: the total state.

With the quasi-natural order of estates and corporations gone, the modern state of equal individuals needed a new organization. With the exception of Britain and Sweden (until 1975) this was provided from now on by a constitution. But in spite of the American and French models of 1787 and 1791 nineteenth-century European constitutions established rule of law, but neither democracy or fundamental rights. Their first purpose was equal integration and not equal participation. Most countries remained monarchies, but deprived of sacrality since the period of enlightenment, monarchy lost unquestionable legitimacy. Step by step monarchies were transformed into democratic republics or quasi-republics. But in most countries during the nineteenth century democracy was still far away. Not only informally as usual, but even legally, in their right to vote, all subjects were equal, but some were more equal than others (Orwell 1945), mostly because of their wealth. In 1830 the following percentage of the total population was entitled to vote: in Austria, Denmark, Prussia, and Spain 0 percent, France 0.5 percent, Belgium 1.1 percent, Britain 2.1 percent. In 1910 the numbers were: in Denmark 17 percent, Britain 18 percent, Austria, Belgium, Germany and Spain 21–23 percent, and France 29 percent (Reinhard 1999).

Percentages in the twenties indicate universal suffrage of adult males. Until the twentieth century, state-building and politics remained almost exclusively a business for men. There were some outstanding queens and empresses in European history—Isabella of Castile, Elizabeth I of England, Christina of Sweden, Maria Theresa of Austria, Catherine II of Russia, and others. But some of these great women had their difficulties with male political culture. And there were no female ministers and officials. Even the enlightened philosopher Immanuel Kant considered women political non entities because they lacked economic independence. After Wyoming 1869 and New Zealand 1893 female suffrage was introduced in Finland in 1906, Austria, Germany and Poland in 1918, the USA in 1920, Britain in 1928, Spain in 1931, France in 1944, and Switzerland in 1971. But in the late twentieth century female heads of state or government, ministers, parliamentarians, and even female civil servants were still a minority.

Originally, humans identify themselves mainly with their face-to-face community. 'Patria,' the land of the fathers, and 'Natio,' the community of birth, even during the early modern period quite often designated rather small territorial entities. However, through state-building people learned to apply them to their country in the large. Finally, after the French Revolution self-defined linguistic or cultural communities, peoples in search of a state considered themselves nationalities, that is, nations to be. In contrast to ideology, nations are not natural, but invented entities. This does not imply complete artificiality and arbitrariness. There is always some kind of basis in reality, such as common descent, language, religion, or territory. Most important is a common history and the consequent option for its continuity. Nationalism as a system of symbols constitutes a community as a nation, integrates its members, and defines the difference from other communities.

For radical nationalists the nation is the highest value and the ultimate source of meaning; nationalism becomes a religion and as such a way to tap the material and emotional resources of subjects, especially in war. Therefore, nation-building became the final phase of European state-building, whereas new states in Europe and worldwide tried to constitute themselves as nation-states right from their foundation.

Expanding political participation and emotional mobilization of subjects correspond to a further extension of government, of state power. A common denominator is a high degree of social discipline in the subject. Church and State had been working on this since the late Middle Ages, but achieved this goal only in the nineteenth and twentieth centuries with the assistance of armies, schools, and factories (Weber 1964). The citizens of a fully developed modern state enjoy the legal protection of their person and property and some political participation. In return, a citizen is subject to three fundamental duties, compulsory school attendance, compulsory military service, and general liability to taxation. Based upon the fiction of the sovereignty of the people the state apparatus is able to extend its competence at its own discretion and to transform itself into a totalitarian system as happened under the impact of nationalist, racist, and communist ideologies in the twentieth century. Some of them proclaimed the end of the state, but that proved impossible. In contrast, the totalitarian state turned out to be the final stage of development of the modern state. And at a closer look, even the modern welfare state proves to be a soft variety of totalitarianism. Beginning with limited social security programs before World War I (1883–89 creation of an insurance system for workers in Germany) the welfare state exploded after World War II. Between 1950 and 1983 the West-European average of social security expenses rose from 9 percent of the GNP to 25 percent. But the total care for the citizens means also total

regulation of their lives. Even the neo-liberal reaction is based upon large-scale government action in the service of a general economic and social policy; goals, not methods differ from former socialist welfare policy.

Six hundred years of European expansion made the modern European state the world's standard model of political organization. The colonial regimes of Spanish and British America established in the sixteenth and seventeenth centuries adopted premodern forms of European statehood and political culture. Therefore, most Latin American states remain authoritarian but weak states even today, whereas traditional self-government in a comparatively egalitarian society made the USA a successful nation, although it lacked certain traits of the modern state such as belief in the state as a value in itself, in bureaucratic centralism, in a strong professional army, and in an established church. From 1839 to 1935 Britain's white settler colonies became sovereign states, mostly combining the British and US models, whereas in the nineteenth and early twentieth centuries East Asian and Muslim empires tried to transform themselves into modern states to cope with the weakness of their traditional regimes when confronted with the West, in the case of Japan with tremendous success. Finally, during several waves of decolonization after World War II, the lot of quite artificially created colonies became equally artificial nation states. For the first time a global community of international law and moderately effective international organizations such as the United Nations (UN) became reality. Quantitatively and qualitatively the modern state reached its culminating point during the twentieth century.

6. *The Disintegration of States and Possible New Forms of Political Life*

In the last third of the twentieth century, culmination of the modern state turned into decline. To begin with, most 'new' states worldwide suffer from serious shortcomings, such as lack of democracy and efficiency, general corruption, and political disintegration. The export of European state models was a success only in three specific constellations: (a) where it was accompanied with the export of European civil society and political culture as in the cases of the USA and the British dominions; (b) where it met a polity and society compatible with its own structure as in the case of Japan; and (c) where colonial rule lasted long enough to create a Western-style civil society as in the case of India. For the rest, the new states of the former colonial and the former communist worlds tend to loose their sovereignty internally to the para-statehood of old or new chiefdoms or ethnic communities, externally to international organizations like the UN or the International Monetary Fund (IMF). They become mere 'quasi-states' (Jackson 1990).

At the same time European states were also, to some extent, disintegrating into 'tribes,' were loosing sovereignty to 'chiefs,' pressure groups, and international organizations, and were no longer able to provide complete social security. As a consequence of totalitarianism and mass participation, the modern state turned self-destructive. The excesses of nationalism, racism, and communism destroyed the necessary faith in the state. Social discipline was questioned by the common desire of self-realization. New ethnic, regional, social movements started to compete with the state for the loyalty of the subjects, some on the basis of democratic self-determination, some with the use of violence. Withdrawal of loyalty led to an underground economy expanding at the expense of the tax and welfare systems. The necessity to win elections by bargaining with interest groups and by providing additional welfare benefits for the electorate ended in a debt-trap with almost the whole budget allocated in advance. In addition, economic globalization allows important tax-payers to move to less restrictive countries with lower wages and taxes.

However, for economic and security reasons most states loose more of their sovereignty to international organization. The European Union has not yet become a federal state and suffers from deficient democracy and social policy, but nevertheless common economic interest has released remarkable binding forces. The right to declare and to wage war, once the very essence of sovereignty, has become obsolete. Instead of interstate wars and peace treaties we have hundreds of 'low intensity conflicts' (van Creveld 1991) which tend to respect neither non-combatant status or national borders.

Nevertheless, the national state is still there. But it has definitely lost the monopoly of power and policy. In power processes, it tends to become one competitor among others. Unity, the constituent principle of modernity, the monocratic polity, is being replaced by a postmodern plurality of multiple political units coordinated by the necessity to cooperate and not by state power. Certainly, this pluralism might end in chaos. But it might also prove a new way for humankind to seek the political pursuit of happiness.

State, Sociology of the

Few terms are as ubiquitous in the social sciences as that of the 'strong state,' yet there is no agreement on how to define its scope. The strong state crops up in

the writings of economists, political scientists, and sociologists. It has been labeled both a destroyer and creator of wealth. It has been connected both to chronic underdevelopment and, just as frequently, to high levels of economic performance. If everyone knows what a strong state is, why do they disagree over its role?

1. Strong and Weak States

In the conventional, 'neoclassical' view of the state and economic development, two types of government exist—strong and weak—with the latter usually given better grades for promoting economic performance (Klitgaard 1991). In this view, strong states typically choose interventionist strategies for development. This notion is largely based on the strong states of Latin America, where state interventions in economic affairs include populism, import substitution, and regulatory manipulation of markets, often designed to obtain substantial and, typically, unsustainable redistributive goals (see Dornbusch and Edwards 1991).

The usual justification for developing countries to adapt strong activist states has been that the private sector would not provide the massive public investments needed for economic growth. In reality, however, strong states often ended up pursuing power for the sake of their own leaders; elitism, corruption, and misallocation of resources resulted. Disillusionment with the performance of state-led growth strategies caused critics to champion weak states, which foster growth by leaving markets alone (Friedman and Friedman 1980). The minimalist state is touted for doing no more than providing a stable, credible currency and a strong legal system designed to enforce private property rights and contract law. On the other hand, such weak states have historically been unable to prevent the capture and distortion of economic policy by oligopolies and rent-seeking elites.

The conventional language of *strong* vs. *weak* thus fails to explain a government's ability to foster or hinder economic performance. East Asia's high-performing economies—South Korea, Malaysia, Taiwan, Hong Kong, and Singapore—dramatically demonstrated the inadequacy of the traditional 'neoclassical' categories. In this region strong, not weak, states enabled the private sector to make a major contribution to growth. Contrary to expectation, the weakest states in East Asia—Indonesia and the Philippines—did not nurture strong private sectors; in fact, they were much less successful than the others in terms of generating home demand and accumulating capital and skills. In response to the economic successes of these activist East Asian governments, a new generation of statist scholars has emerged to advocate the role of a strong state in promoting economic development (see Campos et al. 1994, Johnson 1982, Wade 1990a, 1990b, Evans 1992). The result is a strong polarity in the literature. In one camp, a strong state is viewed as an obstacle to economic development; in the other, state activism is touted as an essential component in the most celebrated cases of economic growth since the end of World War II. Both of these views contain important elements of truth, but both are too limited to account for the varied performance of developing nations.

2. Weak States

A weak government is handicapped by the inability to enforce property rights, or even many of its own laws. Because of the legal inadequacy of a weak state, its interventions are based not on rules, but on administrative or executive discretion; this results in corruption and opportunism rather than supervision. In fact, insufficient legal clarity is often intentional, thus facilitating random interventions by political authorities. For example, to compensate for rampant tax evasion, governments in developing countries devise tax regimes that allow considerable official discretion in assigning rates. But the capricious application of expansive tax powers drives private firms into the informal sector. Deprived of these tax revenues, the government cannot provide basic services such as law enforcement, and few benefits remain for those firms that do disclose profits. When transparency becomes a risk, firms will have difficulty attracting capital, and the government will become weaker still.

When states are too weak to control their own officials, agents of the state may act independently of one another. Thus, a policy of reform may be announced by one part of the government, while another part blocks its implementation. The inability to enforce rules reduces private business activity unless some important actor of the state, such as the president's family or inner circle, intervenes (for example, Indonesia under Suharto, the Philippines under Marcos, or Russia under Yeltsin). Political power is needed to defend property rights when the impartiality of the legal system is compromised or when the rules are themselves inadequate. When countervailing institutions such as an independent legislature or judiciary are weak, the leader can provide market access to chosen favorites in return for their loyalty, disabling the discipline of market forces.

Bureaucrats in a weak state learn to use their power and access to information to extract value from proposed economic activity rather than to promote that activity. With corruption flourishing at all levels of government (Shleifer and Vishny 1993), the deal-making authority of leadership becomes essential. In this regard, a weak state acquires the same market-destroying tendencies of strong discretionary states, in which property rights enforcement is at the discretion of a handful of individuals.

Although weak states respond to interest groups, they often cannot enforce bargains made with important constituents. Interventionist rules typically cannot be consistently enforced. As a result, reform measures, property rights, and contracts are not durable because the state lacks the means to implement and maintain them. Unable to enforce these minimal conditions, weak states can rarely sustain competitive markets. Instead, networks of individuals with special connections to the political regime are needed to sustain trade. Inevitably, officials of weak states are likely to collude with select, but powerful, private groups to extract the nation's resources. A weak state easily becomes a predatory state.

Many of the postcolonial African states fall into this category. Publicly disinterested bureaucracies in which pay and promotion were linked to performance did not emerge, compromised by governments that disbursed employment in exchange for loyalty. Dependency on foreign capital, including aid, discouraged accountability to citizens while eroding national sovereignty. Ethnic, religious, and regional fragmentation gave rise to political parties that enjoyed only narrow social support. Excessive centralization was often pursued to overcome these forces of national disintegration. However, highly centralized governments allowed bureaucracy to be replaced by a single-party or no-party system with national planning bodies controlling public goods and services. Local governments that were allowed neither independent judicial authority nor the resources to develop managerial and technical capacity failed to deliver basic services. The legislature and judiciary were dominated by the executive branch, eliminating independent oversight of budgetary allocations. The result of this excessive centralization was often a weak state dominated by the unbridled discretion of the executive, degenerating into personal rule and kleptocracy. Support for government collapsed, and many African states became incapable of providing basic public order.

3. *Strong and Unlimited States*

Strong and unlimited states, too, can act in a discretionary fashion. Lacking constitutionally defined limits, they are likely to be both interventionist and confiscatory. Able to alter rights and markets at will, they are incapable of making a credible commitment to private sector development. (Contemporary examples include Vietnam, Syria, Ethiopia, Iraq, and the USSR.) To induce participation in markets, strong and unlimited states must offer protection in the form of monopoly rights, preferential tariffs, or guild or trade union privileges. The exercise of unlimited political discretion allows them to promise excessive benefits to win the support of particular groups. This, in turn, creates political risk, reducing economic investments and undermining the possible outcomes of reform. The irony is that due to their unlimited power, no contract with the government or of interest to the government is secure. A strong and unlimited state has much in common with a weak state; both are likely to become predators of private sector wealth.

4. *Strong but Limited States*

A third type of state, which arose in Western Europe, is not only strong enough to establish and maintain property rights, but is constitutionally prevented from violating these rights. This state requires an administrative structure that keeps the economic and political activities of regime officials separate. Such a state must be strong enough not only to adopt rules that can sustain a competitive private sector, but also to prevent itself from responding to the political forces that inevitably arise to monopolize access to the marketplace. Only this type of state will ensure competitive access to open markets.

Strong but limited states are often mistaken for minimal states, since in comparison with interventionist states, they directly provide a relatively small number of goods and services. But the term *minimal* gives the impression of weakness, which is misleading. These states must instead be strong enough to withstand the political pressure on government to intervene in markets. Hong Kong under British rule was perhaps a perfect example of such a state in which 'positive noninterventionism' protected the market from pressure groups, rent seekers, and unscrupulous officials. Like the governments of Western Europe and North America, East Asia's other high-performing economies—Japan, Malaysia, South Korea, Singapore, and Taiwan—all accepted limits on their discretion over private sector profits. All adopted mechanisms to separate the political and economic functions of government and to protect property and contract rights.

5. *Implications*

In distinguishing strong but limited government from the conventional perspective that identifies only weak and strong government, the advantages of each and the contradictions between them can be understood. In the conventional view, the two types of strong states are not distinguished. A state that carries out and maintains highly interventionist policies, such as import substitution or subsidizing a highly unionized urban workforce, is confused with a strong but limited state that plays a neutral role in the allocation of rents and subsidies. Federalism in the USA, for example, offers an institutional foundation for a strong but limited state which is able to foster equitable growth (see Weingast 1995, 1997).

In many emerging states, technical and practical knowledge is unevenly distributed. Often a small group of capitalists dominates local industry, agriculture, and access to the external market. The superior technical knowledge of these small groups forces the government to depend on them to build the market, which allows representatives from that group to gain control over the government's regulatory apparatus and ultimately over the state. When economic power is concentrated in a few governmental ministries, it is more vulnerable to capture than when decision-making powers are dispersed among institutions that have veto power over each other.

Strong but unlimited states often promote corruption and rent-seeking, exacerbating social and regional inequality. As noted earlier, both strong unlimited and weak states are prone to plunder the markets. What 'neoclassical' wisdom calls a weak state can often more aptly be described as a strong but limited state that can maintain the market, providing the necessary public goods while resisting capture by interest groups.

While the champions of state activism raise reasonable doubts about the earlier neoclassical view, they do not explain why some strong states promote economic development while others pursue policies that hinder it. After all, the majority of countries that pursued activist policies experienced negative growth along with exacerbated social inequality. Even if the arguments advocated by statists—that these states have made a direct and significant contribution to economic growth—are taken at face value, they have done no more than show that this role for the state is feasible, something long known.

But why have some strong states promoted growth rather than other political goals? The conventional view offers little help. By contrast, the example of East Asia's successful regimes suggests that states are strong when critical and durable limits channel government behavior into activities compatible with economic development.

6. *Achieving Strong but Limited Government*

The development of strong but limited government depends on the existence of institutions that make it in the interests of political officials to abide by limits on their power. In many reform environments, the desire to create strong but limited government often drives leadership to increase the executive's discretionary power. Both Mikhail Gorbachev in the former USSR and Boris Yeltsin in Russia succumbed to this approach. Many Latin American leaders have also been attracted to it. Reform by mechanisms such as presidential decree is a two-edged sword, however. On the benefit side, the reform-minded leader gains the power to design and implement a reform package by eliminating many of the veto points blocking reform. On the cost side, all such reform programs can also be undone by decree and hence are only as good as the paper on which they are written.

For economic reform to be durable, it must be costly for political authorities to renege on promises once made. As the US federalists realized, durability cannot depend upon altruism. No government should expect public service to attract only godlike figures who always place the needs of the public before those of their family or friends. Institutions must be designed so that political actors have incentives to maintain and preserve the system, while carefully delineating where their power to intervene in private economic activity begins and ends.

A government's commitment to market-led growth requires the design of appropriate government institutions that ensure clear boundaries between private and public, and that protect both property rights and agreements with the business sector. The creation of such boundaries will shift the investment horizons of investors toward the long-term so that growth can be sustained.

Are boundaries that protect private wealth from government plunder more likely to be erected in weak or strong states? In their effort to establish competitive market economies, weak states often falter because narrow interest groups obtain control over the market, over the judiciary, and ultimately over the polity. Oligopolies often arise to overcome systemic market risk caused by the weak enforcement of laws and contracts. In countries as diverse as Indonesia, the Philippines, and Russia, elites have enough resources to block necessary reforms and to prevent transparent governmental practices from being implemented. Strong and unlimited states will falter because their leaders may refuse to implement reforms that dilute centralized power and allow a decentralized private sector to grow.

7. *The Asian Miracle and the Sociology of the State*

The successful economies of East Asia offer examples of strong states that encouraged economic growth by institutionalizing the following set of limits on executive discretion: (a) channels of representation for businesses to induce them to make long-term investments, (b) wealth-sharing schemes to elicit the support of the wider population for development; (c) a competent bureaucracy encouraging credible government commitment to long-term, growth-enhancing policies.

The significant improvements in income distribution that accompanied sustained economic growth in the high-performing East Asian economies resulted from effective use of public and private sector institutions and organizations. Common throughout East Asia were deliberation councils, which, although limited to particular sectors, offered input into the

policy process and had veto power over the outcome. The councils provided greater predictability, improved transparency, and procedural guidelines and precedents for the exchange of views between leadership and the private sector. The leadership of East Asia generally avoided undertaking major policy directives without first consulting with the major players targeted by the regulation. The councils made information about who gets what from government a matter of record, thereby limiting the opportunities for preferred firms to engage in behind-the-scenes favor seeking or private appropriation of gains from insider information. Ultimately, deliberation councils served as commitment devices, helping to reduce the tendency of government to renege on contracts with private holders of wealth.

A range of institutional innovations promoting broad-based health, education, and housing were designed to make credible the regime's promise of shared wealth and growth. These efforts enabled leadership to gain the cooperation of the citizenry. Businesses invested in fixed capital because the potential risks of social unrest were mitigated. Encouraged by anti-inflationary macroeconomic policies, the wider population saved a considerable portion of their income and invested in education, confident of being able to enjoy the future gains. The introduction of institutions that encouraged equitable growth was an explicit policy choice by government that contributed directly to an improved investment environment.

Sharp contrasts between the successful and less successful bureaucracies in Asia are instructive. The bureaucracies of Japan, Korea, Singapore, and Taiwan, and some bureaus in Malaysia and Thailand, enjoyed merit-based recruitment and promotion, well-defined career paths, competitive salaries relative to the private sector, pension systems, and the possibility of retirement to a board seat in a large private or public enterprise. All but Thailand and Indonesia upheld harsh penalties for corruption that generated (relative) competence and integrity among bureaucrats. Even in the less competent bureaucracies in Indonesia and Thailand, explicit spending limits and a binding commitment to monetary stability limited discretion.

Improving the productivity of the civil service so that it could enforce rules and ensure standards was a first step in the encouragement of private sector confidence among all of East Asia's high performers. The civil service was rewarded for its conformity with agreed-upon rules that circumscribed arbitrary and capricious interventions in its oversight of the economy. Merit supplanted personal patronage so that government would be more responsive to general interests.

Although direct political participation was weak, nonelites in all of the high performers shared the fruits of growth, as evidenced by declining poverty and a reduction in income disparity. In fact, the countries that grew fastest had the most income equality. Wealth-sharing mechanisms created opportunities for the nonelites to pursue productive rather than politically destabilizing activities. Moreover, growth-promoting policies contributed to regime legitimacy, helping to encourage broad social support for the government. While each country determined its own specific pattern of institutional mechanisms and the purposes to which they were devoted, their experience shows that progress toward sustained, self-reliant, and more equitable development depends, in part, on the strength and quality of a country's institutional and organizational capacity. The creation and utilization of predictable procedures distinguishes effective development leadership. The difference between development based on political will and that based on institution building is essentially that the latter is sustainable, while the former is not.

As indicated by the success of East Asia, Western Europe, and North America, strong but limited states have historically had the best record for economic performance. Having defined the character of institutions that promote growth, there remains the conundrum of why only a small minority of world leaders have based their political survival on the competent selection of economic policies.

East Asia's success firmly supports the generalization that governments will realize the goals of economic efficiency only when leadership depends on broad social foundations. The erection of such foundations continues to be the most elusive component of economic growth around the world.

States and Civilizations, Archaeology of

1. Civilizations

'Civilization' has had two meanings in reference to ancient societies both of which require critical review. First, civilization has designated complex prehistoric cultures with productive economies, class stratification, and striking intellectual and artistic achievements. Civilization in this sense has contrasted with 'primitive' or 'tribal' societies i.e., societies with modest subsistence economies, egalitarian social relations, and less extravagant art and science. Civilizations have been equated with progress and cultural superiority, a view promoted by European elites of the early modern era. Using ideas of civilization and progress, these elites assumed the role of civilizing agents to legitimate their domination of the working class at home and colonial peoples abroad. Modern anthropologists reject narratives of civilization and progress, preferring less ethnocentric accounts of non-Western cultures. Anthropologists now use more neutral terms to refer to the complex cultures of the ancient world, calling them complex societies or archaic states.

Civilization has also referred to the enduring cultural traditions of the specific regions of the world. Distinctive cultural principles characterized large geographical areas of the world for long periods of time, outliving the expansion and collapse of individual polities. For example, the idea of cyclical time was a fundamental principle among the Olmec, Maya, and Aztec people of ancient Mesoamerica, and it is an idea that persists today among indigenous peoples in Mexico and Guatemala. While contemporary anthropologists recognize the persistence of such orienting concepts, they reject the possible inference that these long-lived ideas imply cultural stasis. In the past as in the present, old concepts were reinterpreted in the face of new situations. Nor do these enduring principles imply uncontested social harmony. People of different social standing might share a set of cultural principles, but still arrive at different conclusions regarding appropriate behavior.

2. States

State has been a more useful term for analyzing complex societies. States are powerful, specialized institutions for public decision-making and control. State government was the most important element of complex ancient societies. The state created a surplus economy that supported many of the other institutions characteristic of complex societies: infra-structural investments, administrative bureaucracies, full-time craft specialization, long distance trade, market exchange, law courts, armies, and priesthoods. Every archaic state had among its key institutions: (a) some form of surplus extraction e.g., corvée, tribute, or taxation; (b) a bureaucracy that supervised the upward flow of tribute payments and the downward flow of tribute demands, and (c) coercive institutions, including armies, law courts, and police, to ensure tribute payment.

Archaeologists once characterized archaic states as having relatively simple systems of class stratification: nobles and commoners, or tribute-receivers and tribute-payers. But more recently, archaeologists have emphasized the diversity of groups within the state, their complex interactions, and the state's chronic instability. Archaic states were constantly threatened by both internal and external forces. High-ranking nobles led factions that competed for positions of rule. Provincial leaders stood ready to declare their independence from state control. Lineages and ethnic groups resisted the state's appropriation of their collective assets. Households tried to evade the state's demands on their goods and labor. The history of states and civilizations is the history of strategy and counter-strategy deployed by oppositional groups, leading to the development of complex societies and their dissolution.

3. Key Characteristics of Archaic States—Economics

Economic activity in archaic states was guided by the principles of efficiency, security, and control. All economic actors took into account the efficiency (e.g., the cost:return ratio) of economic alternatives. But peasants and household-based craft specialists often

sacrificed efficiency for security; that is, they avoided economic alternatives that placed their annual subsistence at risk. States, on the other hand, often sacrificed efficiency for control; that is, they organized some forms of production so as to monopolize output rather than to maximize returns. Peasants, too, were sometimes guided by their desire for control; they were inclined to produce goods whose attributes (e.g., perishability) made state appropriation less likely.

3.1 Agricultural and Pastoral Systems

Archaic states were characterized by highly productive agricultural systems. The vast majority of these states were dependent upon agriculture augmented by some form of water-control, terracing, and/or fertilizer. Mexico is famous for its chinampas (raised fields), Peru for its terrace systems, Mesopotamia for its irrigation canals, and China for its rice paddies. Such systems enhanced both agricultural productivity and reliability.

At one time, archaeologists believed that states came into existence in order to construct and manage intensified agricultural systems as a response to the problem of population pressure (this is the 'hydraulic hypothesis' of state formation). But periods of state formation do not coincide with periods of population pressure, and the study of contemporary irrigation systems in tribal societies suggests that such systems can be built and managed without centralized forms of government.

States did have good reason to construct agricultural facilities. First, such systems provided income to the state. Agricultural facilities constructed with corvée labor represented prime agricultural land that the state could claim as its own without alienating existing property owners. Second, agricultural facilities attracted tax-paying settlers. Peasants were drawn to newly available, high quality land, and they were willing to pay for access to it. Third, agricultural facilities expanded food production within the immediate hinterlands of political capitals, making it possible to feed the urban populace. The desire for more land, greater crop security, and larger quantities of marketable food also led peasant households to invest in agricultural facilities on their own. State-sponsored agricultural investment can be distinguished from peasant investment through careful study: uniformity in the timing and techniques used in facility construction are the best indicators of state sponsorship.

The long-term environmental consequences of agricultural development was a potentially destabilizing factor in all ancient states. In Mesopotamia, irrigation led to the salinization of the soil, first causing agriculturalists to switch from wheat to more salt-tolerant barley and then to abandon salinized areas all together.

3.2 Tribute, Taxes, and Private Estates

All archaic states needed wealth to fund their centralized power. Taxes could be paid in labor, goods, or currency. A tribute in labor was least likely to provoke peasant resistance, since labor could be 'reciprocated' with food and drink, presented to workers by the state in a party-like atmosphere. This form of taxation may characterize the earliest states (i.e., states that still had to contend with kinship groups and kinship norms) or states that legitimated their rule with ideologies of collective wellbeing. A tribute in goods may have its origins in the spoils of war, tribute representing spoils paid on a sustained-yield basis. Agricultural staples and woven cloth were the most common forms of tribute goods, but metals, precious stones, and other exotic valuables were also collected. Tribute foodstuffs were used to feed state personnel. Tribute luxury goods enabled rulers to reward loyal servants and to control the formation of social identities.

Because of their bulk, tribute goods were often stored in provincial warehouses, potentially funding revolts by provincial leaders. Substituting a monetary tax for tribute goods reduced transport costs and provided more centralized control over wealth. But monetary taxation occurred only in conjunction with market systems, where money could be converted into needed goods and services.

Tribute demands often transformed rural landscapes and households. Greek farm families under Roman rule abandoned their rural farmsteads and moved to towns where economic diversification could supplement their incomes and provide the necessary cash for taxes. In the Valley of Oaxaca, the state's demand for maize led to the cultivation of more distant fields which, in turn, altered routines of food preparation. More dry foods (i.e., tortillas) were made so that meals could be carried and eaten away from home.

Peasant households sometimes tried to escape tribute payments. In Mexico under the Aztecs, maguey cultivation expanded, perhaps because its perishable sap was not easily appropriated by the state. In Mesopotamia, peasant families wishing to avoid taxation sometimes fled to the mountains, becoming nomadic pastoralists.

3.3 Urbanism

Archaic states provided the setting for the earliest cities i.e., large, socially-heterogeneous, permanent settlements. These cities were religious and political centers; their economic functions were much less important than is the case for modern cities. Cities housed the administrative machinery of the state, usually in a multi-roomed palace complex. High-ranking nobles, bureaucrats, and military personnel resided in the capital so that their activities could be

directed and monitored by the ruler. Most state capitals also contained shrines, temples, and the residences of high-ranking priests. The concentration of political elites in the capital provided a clientele for enterprising craftspeople, merchants, and other service providers, who swelled the urban populace. Early cities did not supply many of the tools or meager furnishings used by rural peasants; these were usually produced in hinterland towns and villages, by part-time craft specialists.

In several cases, the growth of ancient cities was accompanied by the emptying out of the countryside. Both Uruk (Mesopotamia) and Teotihuacan (Mexico) grew explosively at the expense of rural settlements. In these cities, peasant farmers and farm laborers made up as much as 75 percent of the urban population. Both push and pull factors may have moved farmers from the country to the city. The security, sanctity, and commercial opportunities of the city provided powerful draws; at the same time, rural people may have been forcibly removed to the cities in order to facilitate supervision by the state and to loosen their claims on the land.

Cities developed only minimally in early Egypt. In Egypt, the concentration of population along the banks of the Nile, and the ease of water-bourne communication up and down the river, may have made it unnecessary to concentrate elites and rituals in urban centers.

3.4 Markets

Markets often appear in conjunction with cities. Anthropologists are divided on the issue of whether markets developed from the 'top down' or from the 'bottom up.' 'Top down' theorists postulate that markets developed from the demands of urban elites for food and status goods. 'Bottom up' theorists view markets as developing from the efforts of peasants to enhance the efficiency and/or economic security of their households by participating in specialized production and exchange.

Regardless of their origins, markets attracted the attention of political leaders. Market taxes were an important source of revenue to rulers, and markets provided an efficient means of provisioning cities. States provided both direct and indirect stimuli to market growth. Rulers promoted markets by offering merchants protection against thieves and bandits and maintaining market order. Indirectly, states stimulated market participation by peasant households. Tribute demands forced peasants to become more efficient producers, engaging in specialized production and market exchange. In addition, the social hierarchies that accompanied state formation sometimes prompted peasants to consume specialist-produced goods to enhance their social standing.

In the long run, markets weakened the state's control over the economy. Merchant guilds, formed during periods of state collapse, resisted state control of the economy. The wide array of goods offered for market sale made it difficult to enforce the state's sumptuary rules limiting certain forms of food and dress to state-designated groups. Buying and selling conferred economic power upon individuals who were not state functionaries.

3.5 Full-time Craft Specialists

Many forms of craft specialization antedate the origins of states. In tribal societies, it is not unusual for households or entire villages to specialize in ceramic production, stone tool production, or even metallurgy. This craft activity is carried out on a part-time basis in conjunction with basic subsistence activities. Craft products are distributed in reciprocal exchanges to strengthen social ties and/or to acquire goods from other specialists. Rural, part-time specialization of this sort was also present in archaic states, often enhanced by the opportunities for exchange provided by urban markets.

In situations of incipient social inequality, some craft specialists produced very elaborate goods that required heavy expenditures of labor. These 'hypertrophic' goods (such as embroidered textiles, jade earspools, stone sculptures, heavy bronze vessels, and gold jewelry) were commissioned by aspiring leaders to legitimate their claims to social worth. The craftsmen filling these commissions were part-time specialists either living in their own households or as members of the leader's high-ranking family.

The earliest full-time craft specialists in archaic states were the dependents of state rulers. Rulers supported craft specialists to maintain exclusive control over their output. Controlling sumptuary goods enabled rulers to consolidate their power by rewarding loyal servants and controlling social identities. Thus, for example, the Inka ruler supported a certain number of yanakuna and aqllakuna, full-time specialists in metallurgy and elaborate textile production. Gold and silver jewelry and embroidered textiles were used by the ruler to denote statuses within the state hierarchy. Maya rulers sponsored elite kinsmen who specialized in the production of elaborate painted ceramic vessels. Used in royal funerary rituals, these vessels confirmed the noble status of families. Egypt's pharaohs supported entire towns of craftsmen dedicated to the preparation of royal tombs. Royal patronage accounts for the high levels of skill and artistry that characterize the finest works of archaic states.

Full-time craft specialization also emerged in more commercial contexts when a high demand for craft goods (usually for export trade) combined with developed transportation networks and a steady supply of marketed food. These conditions were met most

fully in the Mediterranean world where the waterbourne transport of food staples from one broad region to another underwrote really large-scale production and exchange. In late precolonial India and China, reliable agricultural systems combined with riverine and oxcart transport yielded similarly high levels of commercial production and exchange.

4. Key Characteristics of Archaic States—Social Organization

Social heterogeneity is the defining characteristic of complex societies. In addition to the occupational diversity described above, the intersection of class, gender, and ethnicity created an array of social statuses and life histories in the ancient world.

4.1 Class Stratification

In the earliest states, the division between classes was based on political rather than economic status. A key division within society was between those who paid tribute and those who received it. Tribute was paid to the ruler who distributed it to servants of the state (usually close relatives). Key personnel were endowed with their own streams of tribute flow. Thus, the tribute-collecting class in archaic states comprised the ruler and his close relatives, high-ranking military personnel, government administrators, priests, and surviving elements of the pre-state nobility. For the governing class, wealth, power, and prestige coincided and were mutually reinforcing. Conversely, tribute-payers suffered a lower standard of living, a lack of formal power, and low social status.

Archaeological and historical research reveals significant variability within the commoner class. For example, Aztec households varied by size, composition, wealth, and ethnic affiliation. Rural households chose different combinations of agricultural production and craft activity. This variability complicates the traditional view that commoners were a homogeneous class. It suggests that commoners were divided by demographic, economic, and social factors.

Slaves constituted a class below commoners. Slaves were captured in warfare, purchased through the slave trade, or sentenced to servitude as punishment for crimes or failed debts. Among Aztecs and Mayas, slaves were used as household servants, but they were never very numerous. In Mesopotamia, large numbers of female war captives worked at textile production, and this may have set a precedent for the use of slave labor in commodity production. The use of slave labor in commercial enterprises was extremely important in highly commercialized economies of ancient Greece and Rome.

Private property sometimes developed out of warfare-based economic systems. In China and Aztec Mexico, lands that were seized in warfare and redistributed to loyal soldiers constituted an early form of private property. In Mesopotamia, private property developed long after states arose, through the gradual sale of lands belonging to kinship units to secular or religious elites.

4.2 Gender

In *The Origin of the Family, Private Property, and the State* (1972 [1884]), Frederick Engels argued that the development of private property brought about the state (to maintain wealth differences) and the patriarchal family (to insure the legitimacy of inheriting offspring). In the process, women's status declined from a position of approximate equality with men to an inferior position. This was the 'world historic defeat of the female sex.' Modern historic and archaeological scholarship suggests that institutions such as private property and the patriarchal family are not universal characteristics of ancient states, nor is the subordination of women. Nevertheless, gender relations and ideologies were frequently renegotiated during the process of state formation, with results that were detrimental to women.

The status of women in states was undermined by several factors. First, states were commonly created and maintained through warfare, and war was usually men's work. Through warfare, men gained access to spoils, a form of wealth that was not household-dependent. In addition, rulers often glorified male warriors and rewarded them with administrative positions in order to maintain their loyalty. Thus, warfare provided avenues of wealth, prestige and power for men that were not available to women. Furthermore, rulers dismantled kinship groups, which were nodes of resistance to state rule. These kinship groups often provided the primary rationale and defense of women's rights in ancient societies, and when they were destroyed, women were left without social recourse. It is not surprising, therefore, that many archaic states favored men. Ancient Rome and ancient China both awarded great authority to male household heads. The Classic Maya and the Aztecs conferred public prestige upon male warriors, and men dominated these state governments.

However, the subordination of women to men was not universal. States that legitimated their rule with ideologies of collective wellbeing did not emphasize warfare and did not stress gender difference. These states might have included Teotihuacan (Mexico), the Harappan states of the Indus Valley, and Egypt under the pharaohs. In the Andes, a long tradition of parallel descent favored gender equality. Even in states where patriarchy was the norm, high-ranking women were wealthier and more powerful than lower class men (i.e., class trumped gender). In peasant families, women's contribution to the household economy often translated into approximate gender equality. In ad-

dition, women found forums for resistance outside of the state. Female oracles provided social critique in Oaxaca Mexico, ancient Greece, and the Andes.

4.3 Ethnicity

Ethnicity is an identity based upon a presumption of shared history and common cultural inheritance. Ethnic identity is shaped by both ethnic affiliation and ethnic attribution. Ethnic affiliation refers to individuals' own sense of group membership and the characteristics of the group as defined by its members. Ethnic attribution concerns the characteristics of the group as defined by outsiders.

States acted opportunistically and inconsistently in dealing with ethnicity. Sometimes they suppressed ethnic affiliation to weaken the resistance of subject groups to the state. At other times they encouraged ethnic affiliation to accentuate division within the commoner class. States also used derogatory ethnic stereotypes to legitimize their exploitation of subject peoples. For example, Aztecs depicted their Otomí subjects as lazy, improvident, untrained blockheads and gaudy dressers. Stereotyping and ethnic prejudice generally heightened ethnic consciousness and perpetuated ethnic heterogeneity within ancient states.

5. Key Characteristics of Archaic States—Religion and World Views

5.1 State Religion

All archaic states had an official religion with standardized temples and full-time priests. Rulers' patronage of religion may have sprung from either piety or cynical efforts to manipulate the subordinate class. Either way, religion provided a powerful political resource that was actively exploited by ancient rulers.

Many archaeologists argue that state religion was used to forge a unified polity out of distinctive subject peoples and to legitimize the ruler's authority. For example, Chinese rulers tried to force cultural uniformity upon all the groups that they conquered, and Confucian philosophers declared that just rulers held the 'Mandate of Heaven.' The Incas' effort to impose cultural uniformity on their subjects is archaeologically visible in provincial capitals where large plazas were constructed using Inca architectural forms. Local people gathered in these plazas to attend state-sponsored rituals.

In contrast, Aztec state religion was not geared to produce a uniform world view within the empire, nor to sanctify Aztec rulers in the eyes of their subjects. Rather, Aztec religion was intended to win the loyalty of a relatively small target group, the young men who formed the core of the Aztec army, by imbuing their military exploits with cosmological significance. In the Aztec hinterlands, distinctive forms of ceramic figurines suggest that commoners did not accept the state's ideology; on the contrary, commoners successfully maintained their own world view. Distinctive commoner ideologies may have been present in all archaic states, challenging the official point of view.

5.2 Monumental Architecture

The earliest monuments were megalithic tombs and earthworks built by groups that were still organized using kinship principles. These monuments were probably constructed during communal rituals, when aspiring leaders sought social prominence by sponsoring group festivities. Under state rule, monumental construction increased in scale, creating some of the most striking icons of the ancient world: Egypt's pyramids, Mesopotamia's ziggurats, the colossus of Zeus at Rhodes. It is estimated that the great Pyramid of Khafu (Cheops) required 13,440,000 person-days of labor.

Some monuments may have been constructed by a willing populace, motivated by civic pride and religious devotion. This would have been most likely in states that legitimated their rule with ideologies of collective wellbeing. At Teotihuacan, for example, the Temple of the Sun and the Temple of the Moon may have been constructed in a surge of popular enthusiasm. In states relying upon coercive rule, monument construction expressed submission to the state. Aztec rulers invited subject communities to participate in the construction of the Great Temple in Tenochtitlan, and refusals to participate were considered acts of rebellion.

Through their size, monumental structures symbolized the ruler's exclusive link to supernatural forces. Monumental structures also expressed overwhelming power of the state and the fact of commoners' subordination. Large buildings and massive sculptures imposed themselves on social space and human psyches. In the words of Antonio Gilman (1996), they showed 'who was boss.'

5.3 Writing

Writing developed in archaic states for many different reasons. The earliest texts, from Mesopotamia at 3300 BCE, recorded the economic transactions of large temple estates. In ancient Egypt and Mesoamerica, writing was first used to record the exploits of rulers. The earliest Chinese inscriptions were questions carved on turtle carapaces and the shoulder blades of cattle for the purposes of divination. In all cases, writing was an elite activity. Writing can be regarded the product of elite efforts to establish and to preserve a single, authoritative record of events and to make its voice stronger than the spoken words of its subjects.

6. The Rise and Fall of Archaic States

In the 1970s, archaeologists believed that states arose to manage environmental problems. Since states are powerful administrative institutions, state officials can function as highly effective problem solvers. They can construct large-scale irrigation networks, insure populations against crop failure, administer markets, organize warfare, and sponsor long-distance trade. Archaeological evidence confirms that archaic states did oversee some of these activities. However, the evidence for these activities usually dates to a few centuries after state formation; thus, the problem-solving capacity of states does not appear to account for their origins.

More recently, archaeologists have begun to account for state origins by examining how individuals acquire social power. In one model, dynamic, ambitious leaders assemble coalitions of followers by sponsoring feasts and distributing gifts. Each leader with his followers then competes against other leaders and followers to establish dominance, first on the local, then on the regional, level. In these systems, personal prestige is emphasized, and dominance may be maintained through naked force. In a second model, leaders attract a broader following, by appealing to ideologies of collective wellbeing. State formation is more 'volunteeristic,' resembling a religious movement, and there is broad-based participation in collective rituals and public monument-building. Leaders are more anonymous, and when force is used, it is used on behalf of society as a whole. It has been suggested that the flamboyant Maya and the Shang rulers might exemplify the outcome of the first (individualizing) strategy, whereas the Teotihuacan (Mexico) and Harappan states might be products of the second (corporate) strategy.

Archaic states were complex, often fragile, social structures. Social dominance required balancing the needs and power of diverse social segments. Sudden shocks and long-term problems threatened the delicate balance. Over-population, excessive tax burdens, climatic deterioration or invading barbarians, all threatened to topple archaic states at one time or another. Egypt's Old Kingdom collapsed when provincial officials became increasingly independent of the pharaoh's rule; the Middle Kingdom fell because bureaucrats at the center absorbed too much of the state's wealth. Competition among the independent Classic Maya kingdoms led the Maya to over-exploit their resources and, finally, to abandon their homes. The surprise is not that archaic states eventually collapsed, but that ruling elites could devise institutional structures that enabled states to endure, sometimes for centuries at a time.

Statistical Analysis: Multilevel Methods

Multilevel, or hierarchical, data are blocked or clustered. Children within families; individuals within organizational units; longitudinal data on individuals; repeated measures on individuals; organizational units within larger organizations; multistage sample surveys; and time series of cross-sections exemplify multilevel or hierarchical data structures. When data are clustered, each observation counts for less than it would if the data points were independent. If clustering is ignored, statistical inference can be faulty. With

clustering, regression methods that assume independent observations provide inefficient and possibly biased coefficient estimates, and associated confidence intervals that are too narrow. In the context of regression modeling, any method that attempts to take account of clustering is multilevel.

Several generalized regression methods are commonly used in the analysis of hierarchical data. Hierarchical or random coefficient models are multilevel. So too are fixed effects models, marginal models, classical single-level estimation followed by regression coefficient covariance matrix adjustment, and hybrid approaches. The choice of an approach for a particular research problem must depend on the goals of the research and assessment of the design and measurement deficiencies presented by a particular body of data, and is often consequential. Multilevel modeling approaches emphasize different aspects of the data, vary in the nature and stringency of their assumptions, and support different kinds of descriptions and interpretations. Poor choice of method can lead to the application of an incorrectly specified model, and thereby to good estimates of the wrong quantities.

1. *Random Coefficient Models*

The random coefficient model offers a compelling formulation that is consistent with the social scientific goal of understanding how units at one level affect, and are affected by, units at other levels. Consider a design with two levels, and suppose that there is a single level-1 regressor (X), a single level-2 regressor (G) that is by definition *constant* over all level-1 observations within a context, and that the dependent variable (Y) is Gaussian distributed conditional on X and G. The random coefficient model can be expressed as

$$Y_{ij} = \beta_{0j} + \beta_{1j} X_{ij} + \varepsilon_{ij} \tag{1}$$

with

$$\begin{aligned} \beta_{0j} &= \eta_{00} + \eta_{01} G_j + \alpha_{0j} \\ \beta_{1j} &= \eta_{10} + \eta_{11} G_j + \alpha_{1j} \end{aligned} \tag{2}$$

where $j = 1, 2, \ldots, J$ denotes contexts (level-2 units), and $i = 1, 2, \ldots, n_j$ denotes individuals within contexts (level-1 units). The level-2 equations (Eqn. (2)) assert that the level-1 intercepts and slopes vary over contexts as linear functions of G. There is often justification for supposing that the within-context coefficients depend on contextual characteristics. It is appealing that the dependence includes random error components (α_{0j} and α_{1j}).

Assumptions about the error structure of this two-level model are that, for each context, the level-1 errors follow the Gaussian distribution, are centered on zero, have constant variance, and are independent. The error variances may vary over contexts. The level-2 errors are also Gaussian distributed, centered on zero, independent within equations, and have constant variances. The level-2 errors may be correlated across equations. It is further assumed that the level-1 errors are orthogonal to the level-2 errors, and that all error terms are orthogonal to X and G. The orthogonality assumptions are needed to secure consistent estimates of the η's.

Many generalizations of this model are possible—coefficients can be constrained to be nonrandom; the dependent variable may be discrete, counted, truncated, ordinal, or time to event; there may be more regressors at any level as well as more than two levels; the nesting of levels may be cross-classified; different assumptions about the functional forms of the distributions of the errors can be made; and the assumption of independence of errors within level-2 (or higher) units can be relaxed. Nevertheless, the assumptions of orthogonality between regressors and errors, and of cross-level orthogonality between error components, continue to remain important. Until that is no longer so, the credibility of an application of a random coefficient model rests on the plausibility of these assumptions, which should be thought of as inextricably linked to the systematic components of the model, and not as the fine print of a contract that is never read, much less enforced.

However compelling it may be on substantive grounds to specify the random coefficient multilevel model as Eqns. (1) and (2), substitution of Eqn. (2) into Eqn. (1) results in the equivalent mixed-model representation

$$\begin{aligned} Y_{ij} = \eta_{00} + \eta_{01} G_j + \eta_{10} X_{ij} + \eta_{11} X_{ij} G_j \\ + (\alpha_{0j} + \alpha_{1j} X_{ij} + \varepsilon_{ij}) \end{aligned} \tag{3}$$

which demonstrates that treating intercepts and slopes as dependent on G is the same as supposing that Y depends on X, G, and their cross-level (product) interaction.

Random coefficient models with Gaussian errors are commonly estimated by maximum likelihood or restricted maximum likelihood. For binary response the prevalent methods are marginal and penalized quasi-likelihood, although Bayesian methods based on Markov Chain Monte Carlo (MCMC) estimation are also beginning to be used. A consensus on preferred methods of estimation of multilevel binary response and other nonlinear (non-Gaussian) models has yet to emerge. Estimation of multilevel models is iterative and computationally intensive, more so for non-Gaussian cases. Especially for these cases, researchers are well advised to check numerical estimates across algorithms, methods, and software. Other problems, such as substantial design imbalance in combination with context size, also need to be eval-

uated for their potential impact on numerical estimates (see *Estimation: Point and Interval*; *Hierarchical Models: Random and Fixed Effects*; *Meta-analysis: Overview*; *Markov Chain Monte Carlo Methods*).

2. Fixed Effects Models

The fixed effects model does not require the assumption of orthogonality between X and α_0 inherent to the random coefficient model. It can be written as

$$Y_{ij} = \beta_0 + \beta_1 X_{ij} + \beta_2 X_{ij} G_j + \delta_j + u_{ij} \quad (4)$$

where the δ_j are between-context contrasts, and the u_{ij} are assumed to be classical Gaussian errors. Relative to the random coefficient model, the additive term in G has been dropped, and the intercept and slope are no longer allowed to vary randomly over contexts, although each context is allowed its own intercept and the cross-level interaction is retained. The δ_j absorb the additive component of *all possible* G-variables, not just the finite number that can be included in Eqn. (3). Additive components for any level-1 regressors that do not vary within contexts are also absorbed by the δ_j.

In the fixed effects approach, 'fixing' the between-context contrasts means that the contexts are themselves assumed to be fixed, in the sense that statistical inference is conditional on the particular selection of contexts present in the data. Because the contrasts can be defined as the coefficients of a set of indicator variables that assign individuals to contexts, there is no need to assume that context membership is orthogonal to X. This is a critical difference between the fixed effect and random coefficient models. If the assumption of orthogonality between X and α_0 is implausible in the random coefficient model, and it can be when the list of G-variables is incomplete, then the fixed effects model provides an alternative that solves the problem. In the Gaussian case, the fixed effects model is a conventional regression model. When J is large—and often when it is not—there may be little interest in describing estimated values of the δ_j, in which case estimation of the other covariate coefficients can be performed after within-context centering of the variables. For a binary response variable, conditional logistic regression can be used to estimate fixed effect models (Chamberlain 1980). In this case, the context contrasts are not estimated, although additive context differences are controlled. Software for fixed effects estimation is widely available.

If it is desired to obtain estimates of the additive component of the contextual variables, then the fixed effects approach is not the method of choice. Also, in the binary response case, conditional logistic regression does not necessarily use all of the data, and in this sense may be inefficient (see *Economic Panel Data*; *Linear Hypothesis: Regression (Basics)*; *Multivariate Analysis: Discrete Variables (Logistic Regression)*).

3. Coefficient Variance Estimates Adjusted for Clustering

The adjusted coefficient variance estimator in common use for multilevel analysis is a robust estimator. In actual applications, care must be taken to ensure that the robust estimator selected includes an extension of the algorithm for the general robust estimator that accommodates clustering. With the robust estimator, it is possible to specify a model whose systematic component is identical to that of Eqn. (3), and whose error component need not be independently and identically distributed, Gaussian distributed, or orthogonal to the regressors. The robust equivalent of Eqn. (3) can be expressed as:

$$Y_{ij} = b_0 + b_1 G_j + b_2 X_{ij} + b_3 X_{ij} G_j + e_{ij} \quad (5)$$

Least-squares computation can be used to produce coefficients whose estimated variances and covariances are subsequently adjusted for context membership. The coefficients will be unbiased estimates of the corresponding terms in Eqn. (3) if the orthogonality assumption is satisfied. The standard errors will be adjusted for clustering and other sources of heteroscedasticity regardless of whether this is so. When Eqn. (3) is true, confidence intervals for its coefficients obtained by prevailing methods will tend to be smaller than confidence intervals based on the robust clustering adjustment associated with Eqn. (5).

The robust approach is also an alternative to the fixed effects approach. The latter achieves orthogonality between the regressors and the error component by including context membership in the systematic component of the model, but is unable to include main effects of contextual variables even though it controls for all possible contextual variables. In the robust approach coefficients of contextual regressors are estimated, but all possible contextual variables are not controlled. Coefficient standard errors are adjusted for clustering, but the coefficient estimates are not efficient.

The robust, variance adjustment approach to multilevel analysis has been extended to models of discrete and counted outcomes, and to survival problems, and can be used where a fixed effects approach is not available. Nevertheless, where it can be justified, explicit incorporation of clustering into model specification is preferable to *post hoc* adjustments of estimators that ignore clustering (see *Sample Surveys: The Field*; *Sample Surveys: Survey Design Issues and Strategies*; *Sample Surveys: Model-based Approaches*).

4. Marginal Models

When Y is a discrete or count response variable, it is possible to specify a multilevel model in which the within-context correlatedness of observations is in-

corporated as a side condition on the model, rather than as a consequence of a random intercept. For Y binary and ω_{ij}, the logit of 'success' for the ijth observation, the multilevel dependence of Y on regressors, can be written as

$$\omega_{ij} = \beta_0 + \beta_1 G_j + \beta_2 X_{ij} + \beta_3 X_{ij} G_j \quad (6)$$

with an additional specification indicating the pattern of correlation between observations within a context (corr(Y_{ij}, $Y_{i'j}$), $i \neq i'$). Specifying that all pairs of observations within a context are equally correlated corresponds to the assumption of correlatedness induced by a random coefficient model, but virtually any pattern can be specified.

Models that characterize the marginal distribution of Y as a function of regressors are said to be marginal models. The model of Eqn. (6) and its side condition on correlated observations is a member of this class. The generalized linear model (McCullagh and Nelder 1989), a unifying theoretical framework for the linear model and discrete and count response variables, has been extended to allow for the analysis of multilevel data (Liang and Zeger 1986, Zeger and Liang 1986). This extension, known as the generalized estimating equations approach (GEE), provides a marginal model (population-average) alternative to random coefficient models when Y is discrete or a count. Equation (6) can be estimated using the GEE method.

Gaussian random effects models sustain a marginal model interpretation of regression coefficients. Random effects models for discrete and count response variables do not. Marginal models are appropriate when the analytic goal is to infer how Y depends on covariates for a population of level-1 units averaged over contexts. Random effects models are appropriate when within-context estimates are desired. For the logistic response case, the estimated coefficients of marginal models tend to be smaller in absolute value than the corresponding coefficients in random effects models (Diggle et al. 1994, p. 141).

Marginal models for Y discrete or a count can be estimated for a broad range of structures of potential within-context correlation; random coefficient models for discrete and count response variables currently cannot. Computation is fast (iterative generalized least squares), and estimation is relatively straightforward compared to binary response random coefficient models, although issues surrounding optimal characterization of within-context correlation and estimation of coefficient standard errors continue to attract attention.

5. *Omitted Variables*

Omitted variables in random coefficient models are of particular concern when they are endogenous, that is, correlated with Y and the included regressors, because they induce coefficient bias. The fixed effect approach provides one solution to this problem when the omitted variables are contextual. There are others: measurement of omitted variables, random assignment to contexts, and instrumental variables estimation.

Measuring the omitted variables is not an option in secondary analysis or in the midst of primary analysis—by then the data have been collected and returning to the field is generally infeasible. This should not, however, preclude future attempts to extend the range of measurement.

Random assignment to contexts presumes that an experimental design is feasible in the study of a particular phenomenon. Often it is not. Even when randomization is possible, it is not necessarily well suited to answering certain kinds of questions (see *Experimental Design: Randomization and Social Experiments*; *Quasi-Experimental Designs*; *Experimental Design: Large-scale Social Experimentation*).

Instrumental variables estimation is often used in an effort to solve an endogeneity problem. When an instrumental variables approach is used, aspects of the clustering problem may be sacrificed to solve what is perceived as a much more important one—selection into contexts. In Eqn. (3) replace X by T, suppose that the underlying data structure is quasi-experimental, and let $T_{ij} = 1$ if an individual is treated (0 otherwise). If Y is a health outcome and contexts are hospitals, and if assignment to treatment is not random, then ε potentially contains unmeasured variables correlated with T and also with Y. In quasi- and nonexperimental data, whether a patient receives a particular kind of treatment can be nonrandom with some causes known, others not. An instrumental variables approach to this problem attempts to find one or more covariates W correlated with T and Y, where Y and W controlling T are uncorrelated, and W and ε are uncorrelated. It is often difficult to find plausible instruments (W), although contextual variables are sometimes used. Thus, instrumental variables estimation cannot be employed with the automaticity of any of the other approaches to clustered data.

6. *Examples*

An example of a Gaussian application, and another of a binary response application, illustrate the kinds of differences in findings that can occur using alternative multilevel approaches. The data are from a one percent clustered sample of the 1990 Census of China, and are specific to Hainan province. Clustering is at the enumeration district level, and within clusters enumeration is 100 percent.

6.1 *Gaussian Example*

In the Gaussian example, there are 17,662 men in the data, distributed over 332 clusters, the smallest having 114 men and the largest having 3,735. The occupational socioeconomic status (SEI) of men ages 20–65

Table 1

	(25.51)/(21.78)/(3.06)	(20.81)	(4.72)
Intercept	15.50	11.48	12.89
	(33.08)/(32.15)/(4.63)	(29.42)	(6.71)
R^2	0.45	0.57	

Source: One percent sample, males ages 20–65, Hainan Province, 1990 Census of China.
$N = 17{,}662$. Quantities in parentheses are ratios of coefficients to standard errors. The coefficients of Regressions (1)–(3), estimated by ordinary least squares, are identical. The standard errors of (1) are unadjusted; those of (2) are adjusted, but without taking explicit account of clustering; those of (3) are adjusted for cluster membership. The context contrasts in the fixed effects regression (4) are not shown. The level-2 error variances in the random coefficient regression (5), not shown, are significant.

is a function of age and years of schooling at the individual level, type of place of residence (rural vs. urban), and the square of a contextualized measure of education. Type of place of residence is a characterization of place, and constant within contexts. Substantive theory and exploratory data analysis lead to this random effects model:

$$\begin{aligned} SEI &= \beta_{0j} + \beta_{1j} Age + \beta_{2j} Ed + \varepsilon \\ \beta_{0j} &= \eta_{00} + \eta_{01} Rural + \alpha_{0j} \\ \beta_{1j} &= \eta_{10} + \eta_{11} CED^2 + \alpha_{1j} \\ \beta_{2j} &= \eta_{20} + \eta_{21} CED^2 + \alpha_{2j} \end{aligned} \tag{7}$$

Table 1 reports coefficient estimates and ratios of coefficents to standard errors ('t-ratios') for several approaches. Regressions 1–3 are the same ordinary least squares (OLS) regression, differentiated to keep track of the type of standard error. When clustering is ignored, the t-ratios are far larger (regressions 1 and 2). Unstructured adjustment of standard errors makes little difference. Adjusting OLS standard errors for clustering radically reduces the t-ratios (regression 3). The fixed effects coefficients (regression 4) are roughly the same as the OLS coefficients, with larger t-ratios than obtained with the clustering adjustment. Only one term is 'significant' when the clustering adjustment is used, whereas three of the four estimable coefficients are highly 'significant' in the fixed effects model. The coefficients of the random effects model (regression 5) are comparable with those for the fixed effects model (where present), but the t-ratios are smaller. For those terms present in both the fixed effects and random coefficient models, coefficients are either significant in both models, or not significant in both. In computations not displayed here, the random coefficient specification was computed twice within two different programs, once using maximum likelihood and once using restricted maximum likelihood. There was agreement across programs and methods. Although the basic conclusion is the same for the fixed effects and random coefficient models and differs somewhat from that provided by the clustering adjustment, the variation in coefficient magnitudes and t-ratios across the models is cautionary. Even in the Gaussian case, it can be misleading to estimate a model using only one approach.

6.2 *Binary Response Example*

In the binary response example, data from the 1990 Hainan sample are again used. Infants and toddlers born in the 18 months prior to the starting date of the Census enumeration are the level-1 units of observation, and enumeration districts are level-2 observations. The available data do not record child mortality, which has been inferred from maternal information elicited in the Census questionnaire. The response variable is whether an imputed death to a child born after 1988 occurred prior to July 1, 1990. There are 43 imputed deaths out of 2,572 mother–child pairs. A majority of enumeration districts have no imputed deaths. For this reason, only the within-context intercept is treated as random. For ω, the logit of a death within the first 18 months of life, the specifi-

$N = 2{,}572$. Quantities in parentheses are ratios of coefficients to standard errors.

cation treats the probability of death as a function of maternal years of schooling, the sex of the child, and the interaction between maternal education and sex of child. The intercept is treated as a function of type of place of residence (the same for all residents of an enumeration district) and a random error:

$$\omega_{ij} = \beta_{0j} + \beta_1 Ed + \beta_2 Male + \beta_3 Ed \cdot Male$$
$$\beta_{0j} = \eta_{00} + \eta_{01} Rural + \alpha_{0j} \qquad (8)$$

Table 2 presents a selection of regressions based on alternative multilevel approaches and algorithms. Regression 1 is the result of classical maximum likelihood estimation followed by an adjustment for clustering. Using this approach, neither the sex of the child nor the sex–education interaction is 'significant.' Using the GEE approach, the coefficient for sex is at the cusp of conventional significance and the sex–education interaction is significant (regression 2). The fixed effects results, using conditional logistic regression, indicate significance for all included terms (regression 3). Penalized quasi-likelihood estimates are provided by regression 4. These are consistent with the fixed effects results for those terms present across the fixed and random effects specifications. Regression 5 presents Bayesian results based on MCMC. The type of place of residence coefficient is smallest and not significant in the Bayesian regression. Application of a clustering adjustment to the GEE results (not shown) also substantially affects conclusions about statistical significance.

It is not unusual to encounter sparse data. This binary response example is perhaps even more cautionary than the Gaussian example. Researchers are not yet routinely able to determine whether convergence is to a local or a global maximum, whether sufficient iterations have been calculated using MCMC, whether all of the assumptions required for a particular method are valid in a given instance, or whether software is performing as intended.

7. *Conclusions*

Analysis of multilevel data structures using methods that ignore the clustering of observations in the data is unsatisfactory because it can lead to confidence intervals that are too narrow, and to coefficient bias. Random coefficient models—and their specializations and generalizations—are attractive tools for the analysis of multilevel data. When there is selection into contexts, the random coefficient approach is subject to coefficient bias, as it is more generally when there are omitted regressors at any level. The fixed effects approach provides one kind of solution to the omitted variables problem. Instrumental variable estimation offers another. A posterior adjustment to accommodate clustering, applied to the estimated variances of coefficients, is robust but inefficient when the random effects model is correct. Although this adjustment does not require orthogonality between errors and covariates, robust standard errors for biased coefficients are far from universally desirable. For discrete and count responses, marginal models estimated using GEE provide an alternative to random effects models. Marginal models are attractive when there is little interest in within-context estimates, or when the pattern of within-context correlation is not simple. The choice of a multilevel modeling approach is ideally governed by research goals, the study design, and the nature of the data. There is also value in cross-checking results across methods and software.

8. *Further Reading*

For an introduction to random coefficient models (terminology often used interchangeably with random effects models and hierarchical models), see Snijders and Bosker (1999). The level of exposition in Bryk and Raudenbush (1992) ranges from introductory to advanced, as is also true for Goldstein (1995). The

exposition in Longford (1993) is technically demanding. Littell et al. (1996) survey mixed models in general, and include material on hierarchical models. Gilks et al. (1998) and Gelman et al. (1995) are useful for Bayesian random coefficient models. Draper (2002) provides a detailed introduction to random coefficient models from the Bayesian perspective.

Fixed effects modeling is treated in econometrics texts (e.g., Greene 2000), and is often discussed as one approach to the analysis of panel data (Baltagi 1995). For the binary response case, see Pendergast et al. (1996), who provide a review with broad scope. Robust adjustments of standard errors for clustering (e.g., Rogers 1993) are an extension of the methodology of Huber (1967) and White (1980, 1982). The GEE approach is well exposited in Diggle et al. (1994), who provide detailed comparisons with random coefficient and other models. In this same vein, Allison's (1999) introduction should not be missed. Instrumental variables estimation is a standard subject in econometrics texts (e.g., Greene 2000).

For an illuminating use of random coefficient models in the study of neighborhoods see Sampson et al. (1997). Geronimus and Korenman (1992) use a fixed effects approach in the study of teen pregnancy. Hamilton and Hamilton (1997) use a fixed effects approach in the analysis of surgery outcomes. For the same kind of problem, but using a different data structure, McClellan et al. (1994) employ an instrumental variables approach. Applications of marginal models are found largely in the epidemiological and biomedical literature. Multilevel analysis has long been mainstream in economics, and will soon become so in the rest of the social sciences.

9. *Software*

Dedicated random coefficient packages include HLM5 (Raudenbush et al. 2000) and MLwiN (Goldstein et al. 1998). HLM5 additionally offers GEE estimation; MLwiN includes Bayesian MCMC estimation. Most major statistical packages include facilities for all of the approaches discussed here, as integral components or contributed macros. Software for multilevel analysis is in continuous development. The multilevel models mail list is an essential portal for current information (multilevel@jiscmail.ac.uk), as is the website hosted by the Multilevel Models Project (http://www.ioe.ac.uk/multilevel/).

Statistical Analysis, Special Problems of: Grouped Observations

Often data are available to social and behavioral scientists only in grouped form, i.e., data presented in tables or using display techniques such as frequency polygons or histograms. Reasons for having the data only in grouped form might be because of the confidentiality of data or because access to the individual observations might be too costly (e.g., data suitable for an international comparison might be found in tabular form in the United Nations Demographic Yearbook, but to collect the original data even if it is available will be costly and time consuming) or because the data sets are vast and it is desirable to group it in order to economize on data handling and computation. In the last two cases the researchers must judge the cost of obtaining the original data against the loss of precision in estimating from grouped, relative to ungrouped, data.

The literature on grouped observations can be divided into three broad categories. The first is inference made from a sample of grouped observations about the ungrouped population. The second involves the relationship between moments calculated from grouped observations, before and after grouping, and the third is that of optimal grouping. Since the latter two were quite intensively discussed in Haitovsky (1983), most of the present entry is devoted to a discussion of the cases which are of major interest to the social and behavioral scientist. They are:

(a) Estimation of linear models (or regression models) from observations cross-classified by all the explanatory variables in the model in which only the cell means and frequencies are reported; or when the observations are differently grouped by subsets of the explanatory variables and only the corresponding marginal means and their frequencies are available to the researcher.

(b) The estimation of distribution curves when only mean values and frequencies are available. A case in point is the estimation of income or wealth distributions, when the individual data points are not available either because of confidentiality or its abundance. This has been historically the typical case of estimation of income or wealth distributions. A related curve is the so called Lorenz Curve or Relative Concentration Curve, used for the representation of the size distribution of income or wealth and inequality measures based on the latter, such as the Gini coefficient.

It is interesting to note that in spite of a history of over hundred years of analyzing the relationships between various statistics estimated from grouped observations and their ungrouped counterparts and of making statistical inference from ungrouped observations about the parent, ungrouped, distribution, a rigorous theory about the legitimacy of the use of grouped observations for statistical inference has not been developed until very recently. A unified theory about data coarsening, of which grouping is a special case, with the emphasis on coarsening at random (CAR) has just started to evolve in the last five years.

1. *Definition and Notation*

Data grouping is the process by which any variable W with a given distribution function $F(w)$, continuous or discrete, is condensed into a discrete distribution function, i.e.,

$$p_i = \int_{c_{i-1}}^{c_i} dF(w), \quad i = 1,\ldots, m \tag{1}$$

where $W \in [c_0, c_m]$ is partitioned by $c_0 < c_1 < \cdots < c_m$ into m disjoint and exhaustive groups, where the c_i's are set in advance. The c_i's are called interval limits or boundaries and (c_{i-1}, c_i) is the ith interval or class. Thus, p_i is the probability of an observation falling in the ith class. Hence, grouping is a transformation of one distribution function into a multinomial distribution function. The number of cases within the ith class is denoted by n_i, $\sum_i^m n_i = n$, and is called the ith group frequency. The condensations are usually into the interval mid-point $k_i = (c_{i-1} + c_i)/2$ or into the interval mean or centroid $\bar{w}_i$. The latter is the conditional mean of W, given $c_{i-1} \leqslant W < c_i$, i.e., $\bar{w}_i = \int_{c_{i-1}}^{c_i} w dF(w)/p_i$. If all the intervals are equally spaced, i.e., are of the same width $h = c_i - c_{i-1}$ $\forall i$, we will refer to them as equidistant.

It is useful to represent the grouping by an $m \times n$ grouping matrix $G = N^{-1}A$ where A is an $m \times n$ aggregation matrix with elements 0 or 1, the 1's in the ith row indicate the unit to be aggregated into the ith class and N is an $m \times m$ diagonal matrix with the class frequencies along its main diagonal. Hence, N^{-1} is an averaging matrix. Thus, the ith row of A sums to $n_i (\sum n_i = n)$ due to the exhaustiveness of the classification and each column sums to 1, due to the disjointedness of the classification.

Note that irrespective of how the observations are arranged.

$$GG' = \begin{bmatrix} \frac{1}{n_1} & 0 & \ldots & 0 \\ 0 & \frac{1}{n_2} & \ldots & 0 \\ \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & \ldots & \frac{1}{n_m} \end{bmatrix} \tag{2}$$

The transformation of ungrouped to grouped data is obtained by $\bar{W} = GW$. Cross-classifications can be presented in a similar manner: the two (or more) different groupings can be performed by different grouping matrices, say, G_i $(i = 1.2)$ and the two matrices, which have necessarily the same number of columns, but not necessarily of the same number of rows, are stacked one upon the other to produce the piled matrix G_p to yield

$$G_p G_p' = \begin{bmatrix} N_1^{-1} & N_1^{-1} Q^T N_2^{-1} \\ N_2^{-1} Q N_1^{-1} & N_2^{-1} \end{bmatrix} \tag{3}$$

where N_i $i = 1, 2$ are diagonal matrices with group frequencies of the ith classification along their main diagonal and Q is the matrix with the joint frequencies as entries. For a simple numerical example the reader is referred to Haitovsky (1973, pp. 3–5). A k-way classification will be represented by stacking k matrices of type G.

2. *The Linear (Regression) Model*

Consider the linear (regression) model

$$Y = X\beta + \varepsilon \tag{4}$$

where Y is an $n \times 1$ vector of the original (ungrouped) observations on the dependent variable, X is an $n \times p$ matrix of n original observations on p explanatory variables, ε is an $n \times 1$ vector of disturbances, and β is the $p \times 1$ vector of unknown parameters to be estimated. If instead observations grouped into only m classes are available, the model can be transformed into:

$$\bar{Y} = \bar{X}\beta + \bar{\varepsilon}, \tag{4a}$$

where

$$\bar{Y} = GY$$
$$\bar{X} = GX \quad \text{and}$$
$$\bar{\varepsilon} = G\varepsilon,$$

where G is a grouping matrix of either type G or G_p from above.

Furthermore, if it is assumed that

$$E\{\varepsilon_i\} = 0 \quad \text{and} \quad E\{\varepsilon_j \varepsilon_j'\} = \sigma^2 I_n \tag{5}$$

by grouping the observations, we group the corresponding disturbances, resulting in:

$$\left.\begin{aligned} E\{\bar{\varepsilon}\} &= GE\{\varepsilon\} = 0 \quad \text{and} \\ E\{\bar{\varepsilon}\bar{\varepsilon}'\} &= GE\{\varepsilon\varepsilon'\}G' = \sigma^2 GG'; \end{aligned}\right\} \tag{5a}$$

that is, unless the grouping scheme is such that the same number of observations appear in each class of each classification, the transformation matrix destroys the homoscedastic (equal-variance) properties of the regression disturbances. In order to restore homoscedasticity, we use generalized least-squares estimation, resulting in

$$\bar{\beta} = \{\bar{X}'(GG')^{-1}\bar{X}\}^{-1}\bar{X}'(GG')^{-1}\bar{Y} \tag{6}$$

$$V(\bar{\beta}) = \sigma^2\{\bar{X}'(GG')^{-1}\bar{X}\}^{-1} \tag{7}$$

$$(\bar{Y} - \overline{X\beta})'(GG')^{-1}(\bar{Y} - \overline{X\beta})/(m-p)$$
$$\text{is an unbiased estimate of } \sigma^2, \tag{8}$$

and the coefficient of determination R^2, which serves as a measure of the goodness with which the model fits the data, is computed as

$$R^2 = \frac{\bar{\beta}'\bar{X}'(GG')^{-1}\bar{Y}}{\bar{Y}'(GG')^{-1}\bar{Y}} \tag{9}$$

Finally, under the assumption of the normality of the disturbances ε the analysis-of-variance table can be constructed as shown in Table 1.

For testing the null hypothesis $\beta = 0$ one uses the central F-statistics, where

$$F_{(p,\,m-p)} = \frac{\bar{\beta}'\bar{X}'(GG')^{-1}\bar{Y}}{\bar{Y}'(GG')^{-1}\bar{Y} - \bar{\beta}'\bar{X}'(GG')^{-1}\bar{Y}} \frac{m-p}{p}, \tag{10}$$

where the subscripts of F denote the numbers of degrees of freedom of the F-distribution.

The intuitive explanation of the proposed procedure is that, in the absence of direct information on all individuals in the sample, the best one can do is to assign the class centroids to all individuals falling within that class. The weighting has the effect of repeating the values recorded in the tables as many times as the number of individuals comprising the category, without of course attributing more degrees of freedom in the calculation of the variance. That is, each sum, sum of squares and sum of cross-products, is weighted by the corresponding frequencies of the

Table 1

Source of variation	Degrees of freedom	Sums of squares	E {sum of squares}
Total ungrouped	n	$Y'Y$	
Due to grouping	$n-m$	$Y'(I - G'(GG')^{-1}G)Y$	
Total after grouping	m	$\bar{Y}'(GG')^{-1}\bar{Y}$	
Due to grouped regression	p	$\bar{\beta}'\bar{X}'(GG')^{-1}\bar{Y}$	$\beta'\bar{X}'(GG')^{-1}\bar{Y} + p\sigma^2$
Residual after grouped regression	$m-p$	$\bar{Y}'(GG')^{-1}\bar{Y} - \bar{\beta}'\bar{X}'(GG')^{-1}\bar{Y}$	$(m-p)\sigma^2$

ungrouped data in each category. The typical elements in the cross-product matrices obtained by so doing will be $\sum_j n_j x_{ij} x_{sj}$ and $\sum_j n_j x_{ij} y_j (j = 1, ,\ldots, m_i; i, s = 1, \ldots, p)$.

2.1 How to Group

There still remains the question: how should the original observations be grouped to assure estimates as close as possible to those obtained from the original ungrouped observations? The question was addressed by Cramer (1964) for the case of one explanatory variable model and generalized by Haitovsky (1973, pp. 10–11) to the multivariate case, who showed that the observations should be cross-classified by all explanatory variables which are included in the model and each cell in the cross-classified table should include the sums (or centroids) of all the variables in the model—explanatory and dependent—falling within each cell and the number of observations making each cell, namely, the joint frequencies. We refer to such grouping as 'full cross-classification.' Fully crossed-classified data maximize the correlation between grouped and the corresponding ungrouped estimates, or alternatively it maximizes their respective relative efficiencies. In this sense it assures the closeness of the respective estimates. The reader is referred to Haitovsky (1973) for numerical examples that show how bad estimates not based on fully cross classified data can get, even though they are unbiased.

2.1.1 Estimation with differently grouped observations. The problem is that tables with data cross-classified by more than two variables are rarely available, while models with more than two explanatory variables are very prevalent in the social and behavioral sciences. What is often available are one-way-classification tables classified by each one of the model explanatory variables, where all the variables in the model and their frequencies are reported in each column of the table. In other words, the observations are differently grouped by all explanatory variables in the model, constituting the marginal means and frequencies of the fully cross classified tables. For this data set up Houthakker (reported by Haitovsky 1966) devised a Generalized-Least-Squares-type estimators of the form (6)–(10) except that here $\bar{X}$ and $\bar{Y}$ are the stacked $\bar{X}$ matrix and $\bar{Y}$ vector from the different one-way-classification tables, the number of degrees of freedom for the estimators of the model variance is the number of independent rows of the stacked $\bar{X}$ minus the number of estimated parameters required for the estimation of the model variance, and GG' is replaced by $G_p G_p'$. (Note that care must be taken before inverting $G_p G_p'$ since it is a singular matrix: either the appropriate rows and the corresponding columns must be deleted (Haitovsky 1973, p. 15) or generalized inverses must be applied (see Farebrother 1979 and the correction by Baksalary 1982). An apparent shortcoming of Houthakker's method is that there is no reason to believe that, if the full cross-classification of the necessary variables is not available, the corresponding joint frequencies will be available. However, there are quite a few good and relatively easy ways to construct the joint frequencies from the marginal frequencies.

The way to estimate the joint frequencies from the marginal frequencies varies according to the researcher's assumption about the nature of the cross classification. Farebrother (1979) considers the case where the grouping by the explanatory variables is independent and therefore the joint frequencies can be approximated by $n_{ij} = n_{i\cdot} n_{\cdot j} / \sum_i^{m_1} \sum_j^{m_2} n_{ij}$ where $n_{i\cdot}$ $(i = 1,\ldots, m_1)$ are the row sums and $n_{\cdot j}$ $(j = 1_j, \ldots, m_2)$ are the column sums of the joint frequency matrix N. Bewley (1989) showed however that, under the independence of grouping assumption, Farebrother's method can be very closely mimicked by stacking the marginal $\bar{X}$ matrices and $\bar{Y}$ vectors from the different tables and then applying to them the method of weighted least squares, where the weights are the corresponding marginal frequencies (see also Haitovsky 1973, footnote p. 59). Thus there is no need to construct the joint frequencies. Fukushige and Hatanaka (1991) suggested an improvement upon Farebrother's method by using Goodman's (1985) RC correlation method for estimating the joint frequencies from the marginals, which entails the calculation of correction factors based on the standardized scores of the rows and columns of the marginal frequencies and the correlation between them, applied to $n_{ij} = n_{i\cdot} n_{\cdot j} / \sum\sum n_{ij}$. Fukushige and Hatanaka (1991) also suggested a Bayesian estimation of the joint frequencies considering them as being jointly generated by a multinomial density, subject to $\sum_i \sum_j n_{ij} = n$, with a Dirichlet density as a natural conjugate prior. Fukushige and Hatanaka (1991) then went further to estimate the model parameters by the ordinary Bayes method as applied to the linear model, given the joint frequencies estimated either by the Bayesian or by Goodman's methods.

2.1.2 Haitovsky's methods. Estimations not based on Houthakker's method are Haitovsky's (1966, 1973, Chap. 4) unbiased estimators and extentions (1973, pp. 35–36), shown by Farebrother (1979) to be instrumental variables estimators (he also corrected an error in Haitovsky's calculation of the variance of the estimator), and Haitovsky's 'Efficient Estimator' (1968, 1973, Chap. 5), which also requires iterations.

Haitovsky's (1973) unbiased estimators utilize the property that only estimates from observations group-

Table 2
Effect of different grouping and estimation methods on the estimates of a model with two explanatory variables using Houthakker's data

Model	Intercept	Coefficient of X_1	Coefficient of X_2	$\hat{\sigma}^2$
Ungrouped data ($n = 1218$)	17.10 (7.30)[a]	0.7578 (0.1398)	−0.1778 (0.0367)	5250
Fully cross classified data ($n = 56$)	16.47 (10.32)	0.7473 (0.1203)	−0.1624 (0.0323)	3914
Classified by X_1 ($n = 7$)	10.86 (5.78)	0.5505 (1.6139)	0.0382 (1.8752)	9027
Classified by X_2 ($n = 8$)	73.74 (11.26)	−0.6532 (2.5391)	−0.0931 (0.1572)	1345
Haitovsky's 'unbiased method' ($n = 15$)	18.0335 (6.6065)[b]	0.7271 (0.1033)	−0.1718 (0.0282)	4337
Haitovsky's 'unbiased method' explanatory variables are differently grouped[c] ($n = 15$)	17.8659	0.7319	−0.1723	
Haitovsky's '2 stage efficient method' ($n = 15$)	16.7025 (8.9025)	0.7560 (0.2006)	−0.1725 (0.0187)	
Weighted regression applied to stacked data[d] ($n = 14$)	18.5065 (5.2765)	0.7133 (0.1320)	−0.1698 (0.0355)	4331
Estimation based on Houtakker's method				
Joint frequencies are available ($n = 14$)	18.08 (5.87)	0.7263 (0.1259)	−0.1719 (0.0338)	4285
Joint frequencies are available, using generalized inverse ($n = 15$)	18.0745 (5.8691)	0.7263 (0.1259)	−0.1719 (0.0338)	4286
Joint frequencies are estimated by RC correlation method ($n = 15$)	18.491	0.7147	−0.1704	4322
Bayes estimates, joint frequencies are available[e]	18.542	0.7174	−0.1728	5419
Bayes estimates joint frequencies are estimated by RC correlation method[e]	18.581	0.7120	−0.1700	5238

Source: Haitovsky (1973), lines 1–5, 7–9, Farebrother (1979), line 10, Fukushige & Hatanaka (1991), lines 11–13.
[a] Figures in parentheses are the estimated standard errors of the coefficients above them. [b] The standard error is a correction suggested by Farebrother (1979). [c] Here the tables of Y and X_1 classified by X_1 and Y and X_2 classified by X_2 have 7 and 8 classes as in the previous entry in Table 1, but the X's are cross classified in four classes in each X_1 and X_2. [d] The estimates are identical to those obtained by Houthakker's method where the joint frequencies are constructed from the marginal frequencies under the independence of the cross classification assumption. See Bewley (1989). [e] The estimates reported here are based on 10000 replicates and on the highest level of precision imposed on the hyper parameter in the Bayesian estimates. The differences between the extreme values for the different level of precision are 4%, 1%, and 4% for the estimates for the intercept, coefficient of X_1, and coefficient of X_2.

ed by all explanatory variables featuring in the model, either cross-classified or differently classified, assures the credibility of the estimates in the following way. Suppose that the researcher estimates only $\hat{\beta}_j$ ($j = 1, \ldots, p$) from the table grouped by the jth variable, using the least squares formula for the estimation of a simple, one explanatory variable, model, namely, $\sum_i^{(j)} y_i x_{ji} / \sum_i^{(j)} x_{ji}^2$, where x_{ji} and y_i are measured as deviation from their respective weighted means, the superscripts designate the table used for the estimation, and the weighting by the marginal frequencies is subsumed under the summation sign. But since the appropriate model is given by eqn. (4a), upon substituting it in the last formula and replacing the β_j by $\hat{\beta}_j$ one obtains

$$\frac{\sum_i^{(j)} y_i x_{ji}}{\sum_i^{(j)} x_{ij}^2} = \hat{\beta}_j + \sum_{l \neq j}^{p} \hat{\beta}_l \frac{\sum_i^{(j)} x_{ji} x_{li}}{\sum_i^{(j)} x_{ji}^2} \quad (j = 1, \ldots, p) \qquad (11)$$

which is a system of p equations linear in the p unknown $\hat{\beta}_j$'s. Multiplying both sides by $\sum_i^{(j)} x_{ji}^2$ (assuming they are all strictly positive), one obtains a normal-equation-like system, in which the jth equation is calculated from the table classified by the jth variable. If there are as many one-way-classification tables as there are explanatory variables, where each one of the tables is classified by each of the explanatory variables, and in each of these tables all the explanatory variables appear as data (centroids), the $\hat{\beta}_j$'s can be derived yielding unbiased, or conditionally unbiased, estimates depending on whether the x variables are random or fixed. This method is the 'unbiased method.'

However, if the dependent variable and only one explanatory variable are classified by the latter in a one-way-classification table and in addition each one of the explanatory variables is classified by each of the others, and both the classified and classifying variables appear in all the tables, eqn (11) can be solved to yield unbiased (or conditionally unbiased) estimates. The advantage of the latter option is that the different tables need not be grouped by the same number of classes, nor with the same interval limits.

As for Haitovsky's 'efficient method' the reader is referred to Haitovsky (1968).

2.1.3 A numerical example. To complete this section, it will be instructive to present some numerical results. The data set originally used by Houthakker (see Haitovsky 1973, Appendix 1) has been extensively used to examine the performance of various methods by comparing to the estimates obtained from the ungrouped or fully cross classified data. As can be seen from Table 2, all the regression coefficients based on cross-classified data or on properly weighted data, classified in a one way classification table, are remarkably close to the ungrouped estimates, providing that there are tables classified by all explanatory variables. It is true even in cases where the information about the ungrouped observations is substantially reduced by grouping.

3. Estimation of Distribution Functions

Another important application of grouped observations is in the estimation of distribution functions. A case in point is the estimation of income or wealth distributions. Typically, confidentiality disallows the reporting of the original observations by, say, the US Internal Revenue Service. Instead only the grouped observations including the class boundaries, the class frequencies and often the centroids are available. Another case is data measured on a discrete, rather than continuous scale, and grouped into classes. The latter often happens in the estimation of survival curves where a subject is inspected for failure only at prespecified time intervals. Note that in this case the midpoints rather than the centroids are available, except for open-ended intervals; the latter are to be treated differently.

3.1 Estimation of Income or Wealth Distributions

Income and wealth distributions are often assumed to follow a parametric distribution, such as Pareto or Log-Normal distributions, and the grouped data are applied in the estimation of the parameters that characterize these distributions. Alternatively, a nonparametric approach is taken, namely, the underlying data generation process is ignored and a distribution free curve is fitted to the available income points. For the latter, we quote Mazzarino (1986) for an interesting experiment investigating the effect of the number of groups on the estimated curve. A natural starting point for the two approaches is to consider the group frequencies as a random sample from a multinomial distribution and write the likelihood function $L(\theta)$ of the vector of parameters θ as proportional to $L \propto \prod_{i=1}^{m} p_i^{n_i}$, p_i being the probability of an observation falling in the ith group, as defined in Sect. 2 (see Kulldorff 1961).

In addition to the maximum likelihood estimate of Pareto's scale parameter, Aigner and Goldberger (1970) apply a regression framework to the estimation of the scale parameter, making use of the mean, variance and covariance of the multinomial distribution and applying the least squares principle to the differences between the observed relative group frequencies n_i/n and their corresponding probabilities p_i. Alternatively, least squares can be applied to the differences between the observed cumulative 'greater than' relative frequencies and the corresponding probabilities or to the log cumulative frequencies relative to the corresponding log probabilities. Aigner and Goldberger (1970) found that, although the latter is easiest to compute, its relative asymptotic efficiency deteriorates fast when compared to the maximum likelihood and generalized least squares estimates, the two most (asymptotically) efficient estimators considered by them, as the scale parameter grows beyond 1.5.

3.2 Estimation of Lorenz Curve

The Lorenz curve (also called relative concentration curve) is widely used for the representation and analysis of the size distribution of income (or wealth). It relates the cumulative income (wealth) fraction earned by various proportions of the population to the proportion receiving this income, when the units are arranged in increasing order of their income (wealth). Thus, if income is given by the probability density function $f(u)$, the proportion of units having income less than w is

$$F(w) = \int_0^w f(u)\,du$$

while their mean income is

$$\bar{w} = \int_0^w u\,f(u)\,du,$$

the latter is often called the incomplete first moment. Given that μ, the average of all the units receiving income, exists, then $L(w) = \bar{w}/\mu$ is the cumulative relative income earned by those whose income is less than w. The Lorenz curve is obtained by relating $L(w)$ to $F(w)$ and plotting its values in a unit square with $L(w)$ as the ordinate and $F(w)$ as the abscissa, or as was defined by Lorenz:

> plot along one axis the cumulated percent of the population from the poorest to the richest, and along the other axis the percent of the total wealth held by these percents of the populations. (1905)

For grouped data we define here

$$p_i = \sum_{j=1}^{i} n_j \Big/ \sum_{j=1}^{m} n_j,$$

the relative population frequencies of the first i groups, and $\bar{w}_j$ the average income within group i, $L(w)$ is estimated by

$$\hat{L}(p_i) = \sum_{j=1}^{i} n_j \bar{w}_j \Big/ \sum_{j=1}^{m} n_j \bar{w}_j$$

and the fraction of the population earning less than c_i is given by $\hat{F}^{-1}(p_i)$. For estimating the Lorenz curve, Kakwani and Podder (1973, 1976) assume income to follow Pareto's law, from which the Lorenz curve is easily derived, and then follow Aigner and Goldberger's (1970) framework to estimate the Lorenz curve. The formula derived from Pareto's law suggests two extensions (Kakwani and Podder 1973) which seems to fit the data better. Another extension was proposed by Ortega et al. (1991), who also list a few more functional forms previously suggested for the estimation of Lorenz curves. Another interesting formulation that takes account of some mathematical restrictions on the Lorenz curve and hence improves its estimation was proposed by Kakwani and Podder (1976). A non-parametric approach is suggested by Gastwirth and Glauberman (1976), who use Hermite interpolation for smoothing the curve. An alternative approach to distribution-free methods was suggested by Brown and Mazzanino (1984). Still another approach was taken by Gastwirth (1975), Gastwirth and Krieger (1975), and Krieger (1979). They put lower and upper bounds on the Lorenz curve and on its moments.

A bivariate version of the Lorenz curve has been applied to measure the progressivity of taxation (Suits 1977) and to the design of welfare dominating tax policies (Yitzhaki and Slemrod 1991). Another application is in the field of finance where the second degree of stochastic dominance criterion (Levy 1992) is applied to ordering risky prospects in accordance with maximization of expected utility, when the shape of the utility function is not known (Yitzhaki 1982) and for the evaluation of rising prospects (Shalit and Yitzhaki 1994).

3.3 Estimation of Inequality Measures Based on Lorenz Curves

Perfect equality is represented by the 45° line in the Lorenz curve unit box, connecting the origin with the opposite corner, hence called the egalitarian line. The larger the area between that line and the Lorenz curve the less egalitarian is the society represented by the latter. There are numerous ways to calculate the Gini coefficient, but most of them are not suitable for its calculation from grouped data because they ignore the intra-class inequality and thus bias the measure downward (see Lerman and Yitzhaki 1989). A simple way to estimate the Gini coefficient non-parametrically is by

Figure 1
Lorenz curve and the estimation of Gini coefficient

$$G = 1 - 2\sum_{i=1}^{m} \Delta p_i Q_i \tag{12}$$

where

$$Q_1 = \hat{L}(p_1)/2,\ Q_i = \hat{L}(p_{i-1}) + n_i \bar{w}_i / 2 \sum_{j=1}^{m} n_j \bar{w}_j,$$

$$i = 2\ldots, m,$$

$$\Delta p_1 = p_1, \quad \Delta p_i = p_i - p_{i-1} \qquad i = 2,\ldots m,$$

and $\sum_{i=1}^{m} \Delta p_i Q_i$ is the area of the rectangles and triangles in Fig. 1.

Note that $\sum_{i=1}^{m} \Delta p_i Q_i$ overestimates the area to the right of the Lorenz curve in the typical strictly convex Lorenz curve and hence G underestimates the Gini coefficient, but this bias decreases rapidly as the number of groups increases. The Gini coefficient, as estimated by G, lends itself to various types of decompositions, such as decomposition by income source or by population class, e.g., urban/rural division, where both can be further decomposed by, say, regions, resulting in a two-tier decomposition. Another possible decomposition is by intra-class, inter-class, and overlapped components. The latter arises from the fact that poor people in a high-income class may be worse off than rich people in a low income-class (Yao 1999). Bounds on the Gini coefficient were proposed by Gastwirth (1975) and by Gastwirth and Krieger (1975). Parametric estimation can be derived from the parametric estimation of

Lorenz curves by the method of moments or maximum likelihood (Slottje 1990). Other parametric estimation were proposed by Kakwani and Podder (1976) and by Kakwani (1976) to overcome the downward bias inherent in most derivations of the Gini coefficients from grouped observations.

4. Coarsening at Random

A question that only recently has been investigated concerns the effect of coarsening mechanism (grouping in the context of our article) on statistical inference using grouped observations about the ungrouped distribution. Alternatively, the question is: when can the grouping mechanism be ignored if the above inference is desired? Gill et al. (1997) and Gill and Robins (1997) investigated this question in terms of the conditional distribution of the grouped observations given the corresponding ungrouped observations. This question is of particular interest in cases of statistical inference when the above-mentioned conditional distribution is being used, e.g., in the calculation of score functions, in using the EM algorithm (the E-step), or in going through the Gibbs' sampler. The intuition in the grouped observations case is straightforward: if we know, or can safely assume, that the grouping mechanism is independent of the ungrouped observations, the grouped observations can be legitimately used for statistical inference without the explicit introduction of the grouping mechanism into the analysis.

To put it more formally, does the marginal distribution of the grouped observations, indexed by the parameters that characterize the ungrouped distribution and the particular mechanism applied in the grouping process respectively (i.e., the joint likelihood for these two parameters) factor into the conditional distribution of the grouped observations, given the ungrouped observations, and the distribution of the ungrouped observations, indexed by its parameter? If such factorization is possible, the grouping mechanism can be ignored in making the inference from the grouped to the ungrouped distribution. In the grouped observations case, if the grouping is done by intervals set in advance and independent of the ungrouped observations and the statistics used in the inference are calculated from the observations grouped this way, the above factorization is possible and the statistics calculated from the grouped observations can be legitimately used for the desired inference. The good news is that indeed most grouping mechanisms obey this rule.

5. Conclusion

Although it is evident from the discussion above that methods are available for drawing inference from grouped observations with little loss of precision, the cost of storing, handling and analyzing large data sets has gone down with the fast growing speed and capacity of computers and the parallel development of the necessary software for its utilization. It seems that inference from grouped observations will be mainly needed for cases in which access to the individual data is too costly or impossible, e.g., because of data confidentiality, and therefore the use of grouped observations will be cost efficient.

Y. Haitovsky

Statistical Analysis, Special Problems of: Outliers

Anyone analyzing data may expect sometimes to encounter one or more observed values which appear to be inconsistent or out of line with the rest of the data. Such a value is called an outlying observation or outlier. Judged subjectively, it looks discrepant or surprising. There are two main ways of dealing with outliers, discordancy testing (Sects. 2, 3) and accommodation (Sect. 4). In simpler types of data set, the presence of an outlier is evident by inspection. In more complex data situations such as designed experiments, an outlying observation may disrupt the expected pattern of results, though its presence is not obvious by inspection and a statistical procedure is needed to detect it (Sect. 5).

1. Two Simple Examples

1.1 A Disputed Paternity Case

In 1921 Mrs Kathleen Gaskill was sued for divorce in the British courts by her husband, a serving soldier, because she had given birth to a child 331 days after he had left the country to serve abroad. He claimed that the child could not be his, since 331 days was not credible as a duration of pregnancy. She denied adultery and claimed, with medical support, that the length of pregnancy, though unusual, was genuine. Viewed as a duration of pregnancy, 331 days is an outlier. In the legal case (which the court decided in favor of the wife), the only evidence of the alleged adultery was the abnormal length of this duration. This exemplifies the situation where the judgment of an outlier depends purely on its position in relation to a main data set. Table 1 gives the durations of pregnancy for 1669 women who gave birth in a maternity hospital in the north of England in 1954 (summarized from Newell 1964). Clearly 331 days, exceeded certainly by 1 case and possibly by 2 out of 1669 in this data set, cannot be regarded as an incredible duration.

1.2 Predicting College Grades

Figure 1 shows a scatter plot of points (x, y) for a small sample of 22 college students; x is the student's score in an aptitude test, used as a predictor of college performance, and y is the student's freshman year grade-point average. There are two outlying points $A(x_A, y_A)$ and $B(x_B, y_B)$; the desired predictive relationship of y from x could be modeled satisfactorily by a linear regression omitting these two points. Should they be included in the relationship or not? This is discussed in Sect. 5. See *Linear Hypothesis: Regression (Basics)*.

2. Outliers in Univariate Samples

The nature of outliers and the range of issues in dealing with them are first discussed in the simple situation of a univariate sample of n observations $x_1, x_2, \ldots, x_n$ of a variable X. Denote the observations arranged in ascending order by $x_{(1)}, x_{(2)}, \ldots, x_{(n)}$,

Table 1
Durations of pregnancy for 1669 women

Duration (weeks)	11–20	21–25	26–30	31–35	36–38	39–41	
Numbers	4	10	23	113	333	962	
Duration (weeks)	42	43	44	45	46	47	56
Numbers	144	53	12	10	3	1	1

Figure 1
Scatter plot of grade-point average y vs. predictive test score x for 22 college students

$x_{(1)} < x_{(2)} < \cdots < x_{(n)}$. If, say, the upper extreme observation $x_{(n)}$ appears (to an analyst or investigator examining the data) to be, not only higher than the rest of the sample but surprisingly high, it is declared an outlier. This is a subjective judgment. Is the outlier credible as a value of X? This depends on the form the investigator is assuming for the distribution of X, e.g., whether it is, say, normal or on the other hand a skew distribution such as exponential in which a high value $x_{(n)}$ is less surprising. Call this assumed model for the distribution of X the basic model and denote it by F; $x_{(n)}$ is an outlier relative to model F (e.g., normal), but may not be an outlier relative to a different model (e.g., exponential).

Table 2, with dotplot Fig. 2, gives the scores by 30 children in a reading accuracy test. There is an upper outlier $x_{(30)} = 62$ and possibly a second one $x_{(29)} = 53$. The variable X is here the reading accuracy test score obtained by a child in a population of children of the relevant age group and educational characteristics. A reasonable working assumption is that its distribution is normal; this is supported by a plot of ordered values against normal order scores, which is roughly linear.

2.1 Causes of Outliers

No statistical issue arises if there is a tangible explanation for the presence of an outlier, e.g., if in the above example the score was misrecorded, or component subscores were wrongly totaled, or if the child tested was known to be unrepresentative of the population under study. The outlying value would simply be removed from the data set, or corrected where appropriate, e.g., in the case of wrong totaling.

Otherwise, a statistical judgment is required for interpreting the outlier and deciding how to deal with it, based on the apparent discrepancy between it and the pattern the investigator has in mind for the data—the basic model F. This judgment requires a test of the null hypothesis or working hypothesis H that all n observations belong to F. On this hypothesis, the upper outlier $x_{(n)}$ is a value from the distribution of a variable $X_{(n)}$, the highest observation in a random sample of size n from F. If H is rejected by a statistical test at some level (e.g., 5 percent), $x_{(n)}$ is judged to be not credible (at the level of the test) as the highest value in a sample of size n from F. It is then said to be a discordant outlier (relative to the basic model F); the test of H is a discordancy test. (See *Hypothesis Testing in Statistics*; *Significance, Tests of*. See also Sect. 2.3.)

In a Bayesian approach, there is no direct analogue of a test of discordancy. Its place is taken by procedures designed to obtain a posterior probability assessment of the 'degree of contamination' of the data. This means the degree to which the data contain observations ('contaminants') generated not by F but by some other model G; a basic model is used which contains additional parameters relating to a possible G (see *Bayesian Statistics*).

2.2 Treatment of Outliers: Retention, Identification, Rejection, Incorporation

If the result of the test is to accept H and find $x_{(n)}$ nondiscordant, all the data can be taken to come from F, including the outlier. Although it has been thought to

Table 2
Reading accuracy test scores (in ascending order) for 30 children

2	4	5	8	9	12	12	12	12	14	16	16	18	19	20	21	23	23
23	26	27	27	28	30	34	38	40	42	53	62						

Figure 2
Dotplot of the 30 test scores in Table 2

look somewhat unusual, it is consistent with having arisen purely by chance under the basic model and can be retained in the data set.

When on the other hand the outlier is adjudged discordant, there are three possibilities.

If the focus of interest is the outlier itself (as in the disputed paternity case), it is identified as a positive item of information, inviting interpretation or further examination; it might reveal, for instance, a novel teaching method causing an exceptional test score.

The other two possibilities, rejection and incorporation, arise when the investigator's concern is with the main data set, and the aim of the research is to study characteristics of the underlying population, e.g., to estimate the mean of a distribution of examination scores. The outlier is only of concern insofar as it affects these inferences about the underlying population. It is not of interest in itself; for example, the students giving rise to points A and B in Fig. 1 are effectively unknown!

Either the model F is firmly adopted without challenge, and estimates or tests of the population parameters are to be based on F; or there is the option of changing the model.

If the model is not under question and inferences are to be based on it, the outlier, being adjudged inconsistent with F, is a nuisance item and should be rejected. Historically, outlying values have been studied since the mid eighteenth century, often in the context of astronomical observations. Until the 1870s rejection was often the only procedure envisaged for dealing with outliers, as typified by such publications as Peirce (1852) 'Criterion for the rejection of doubtful observations' and Stone (1868) 'On the rejection of discordant observations.'

The fact that an outlier is omitted for purposes of analyzing a data set does not necessarily mean that it is erroneous or undesirable. Consider, for example, Fig. 3. The ordinates are annual figures for the population of the UK, in millions, published in each year's *Annual Abstract of Statistics*. Those for 1985 through 1990 are estimates based on the 1981 census, while the outlier at 1991, the true value from the 1991 census, is the only genuine data point!

The alternative possibility, when the outlier is adjudged discordant relative to F, is that all the observations, including the outlier, belong to the same distribution, but this distribution is not satisfactorily represented by the initial basic model F. The analysis then needs to start afresh with a more appropriate choice of model F* (e.g., a skew distribution instead of a symmetrical F), in relation to which $x_{(n)}$ is not

Figure 3
Some annual figures for the UK population

discordant. It was an outlier relative to F, but is not an outlier relative to F*, which satisfactorily models the entire data set. It has been incorporated in the data set in a non-discordant fashion, and the outlier problem disappears.

2.3 Other Meanings of the Word 'Outlier'

In the entry, an observation which appears inconsistent with the main data set is called an outlier; this is a subjective judgment. If a statistical test provides evidence that it cannot reasonably be regarded as consistent with the main data set, it is a discordant outlier. It is important to bear in mind, however, that some writers use the word 'outlier' for a discordant outlier, and refer to an observation which looks anomalous but may or may not be discordant as a 'suspicious' or 'suspect' value.

Note also the different meaning given to the word 'outlier' in graphical displays in exploratory data analysis (EDA), such as boxplots. With Q_1 and Q_3 denoting (essentially) the lower and upper quartiles in the sample, observations greater than $Q_3+k(Q_3-Q_1)$ or less than $Q_1-k(Q_3-Q_1)$ are flagged as outliers. These values are sometimes outliers and sometimes not. With the typical value of 1.5 for k, a normal sample of size 100 has more than 50 percent chance of containing one or more of these 'outliers'! (See *Exploratory Data Analysis: Univariate Methods*.)

3. Multiple Outliers: Block and Consecutive Tests

Any particular discordancy test (taking univariate samples as context) is specified by three items: the particular outlier configuration (e.g., a lower outlier; an upper and lower outlier pair), the distribution of the data on the working hypothesis (e.g., normal with unknown mean and variance), and the test statistic. Taking Table 2 for illustration, there is a discordancy

test for $x_{(30)} = 62$, in a normal sample, based on its difference from the sample mean $\bar{x} = 22.53$ in relation to the sample standard deviation $s = 14.13$, with test statistic $T = (x_{(n)} - \bar{x})/s = (62 - 22.53)/14.13 = 2.79$.

For $n = 30$ the tabulated 5 percent point of T on hypothesis H is 2.74; 62 is declared discordant (just) at the 5 percent level. The observation $x_{(29)} = 53$, which is also high, can now be tested for discordancy in relation to the other 28 values; this is a consecutive test procedure for 2 outliers. The value of T is $(53 - 21.17)/12.22 = 2.61$, $P \simeq 8$ percent, the evidence of discordancy is weak.

Alternatively, 62 and 53 could be considered together as an outlying pair in relation to the other 28 observations. This can be tested, in a block test procedure for 2 outliers, by the statistic $(x_{(n-1)} + x_{(n)} - 2\bar{x})/s$, which here $= (53 + 62 - 2 \times 22.53)/14.13 = 4.95$, to be compared with the tabulated 1 percent point 4.92. So, on this block test, there is quite strong evidence that (62, 53) are a discordant pair.

3.1 Masking and Swamping

If $x_{(29)}$ were nearer to $x_{(28)} = 42$, the T-value for $x_{(30)}$ would be higher than 2.79, and the evidence for the discordancy of $x_{(30)}$ would be stronger. This is called the masking effect. A discordancy test of the most extreme observation is rendered insensitive by the nearness of the next most extreme observation; the second observation has masked the first.

Conversely, a block test could be insensitive if the second observation $x_{(n-1)}$ is close to $x_{(n-2)}$ and not outlying. The pair $x_{(n)}$, $x_{(n-1)}$ might not reach discordancy level when tested jointly, even though $x_{(n)}$ on its own is discordant in relation to the other $n-1$ observations. This is called the swamping effect of $x_{(n-1)}$. If $x_{(n-1)}$ is unduly high, there is the risk of masking; if it is unduly low, there is the risk of swamping.

4. Accommodation of Outliers

When the aim is to make inferences about a population of values of a variable X by analyzing a sample of observations of X, there is an alternative to detecting outliers and testing them for discordancy. This is to use procedures (testing or estimation) which are relatively unaffected by possible outliers, by giving extreme values less weight than the rest of the observations, whether they are discordant or not. Such a procedure is called robust against the presence of outliers (see *Robustness in Statistics*).

There is a great range of procedures available in the literature. The approach is well illustrated by the following simple methods for robust estimation of the mean and variance of a univariate sample $x_{(1)} < x_{(2)} < \cdots < x_{(n)}$.

4.1 Trimming

The mean is calculated after one or more extreme values have been omitted from the sample. Omission of the r (lowest) and the s (highest) values gives the (r, s)-fold trimmed mean

$$(x_{(r+1)} + x_{(r+2)} + \cdots + x_{(n-s)})/(n - r - s).$$

4.2 Winsorizing

Instead of omitting the r (lowest) values $x_{(1)}, \ldots, x_{(r)}$, they are each replaced by the nearest value which is retained unchanged, i.e., $x_{(r+1)}$; similarly for the s (highest) values. The mean of the resulting modified sample, still of size n, is the (r, s)-fold Winsorized mean

$$((r+1)x_{(r+1)} + x_{(r+2)} + \cdots + x_{(n-s-1)} + (s+1)x_{(n-s)})/n.$$

The choice of r and s depends on various factors such as the form of the distribution of X (e.g., symmetrical or asymmetrical) and the level of robustness required. The greatest possible amount of trimming or Winsorizing, with $r = s$, gives the sample median.

Robust estimates of variance can be based in various ways on the deviations $x - m$, where m is a trimmed or Winsorized mean, instead of the usual $x - \bar{x}$.

For an extensive account of accommodation issues and procedures, see Barnett and Lewis (1994).

5. Outliers in More Complex Data Situations

In a regression of a variable y on a single regressor variable x, an outlying point is apparent by inspection, as instanced by Fig. 1. For a regression on 2 or more regressor variables $x_1, x_2, \ldots$, this is no longer the case. The data may nonetheless contain an outlying point (or more than one), i.e., a point (x, y) which departs to a surprising degree from the overall pattern of the data. Its observed response value y deviates 'surprisingly' from the fitted value from the regression equation; in other words, it has an outlying residual. Detection of an outlying point requires essentially a statistical examination of residuals.

To illustrate this, consider the regression data in Fig. 1, with two outlying points A and B. Denote the fitted regression line CD by $y = a + bx$ ($a = -1.528$, $b = 0.003528$), with residual mean square $s^2 = 0.148$. The residual for the outlying point A is $y_A - (a + bx_A) = 1.4 - 2.447 = -1.047$, and its estimated standard deviation is

$$s\sqrt{\left\{1 - \frac{1}{n} - \frac{(x_A - \bar{x})^2}{\sum(x - \bar{x})^2}\right\}} = 0.371.$$

A discordancy test statistic for the point A is its studentized residual (the residual divided by its esti-

mated standard deviation), viz. $-1.047/0.371 = -2.82$; this is just significant at the 5 percent level. On a similar test the outlying point B is not discordant at all. The most outlying point in the regression (in this case, A) is the one with the largest studentized residual, ignoring sign. See *Linear Hypothesis: Regression (Basics)*.

An equivalent criterion to the studentized residual for testing discordancy is the proportional reduction in the residual sum of squares when the outlier is omitted, or, equivalently again, the increase in the maximized log-likelihood. The test then reflects directly how much the fit of the regression model to the data is improved on omission of the outlier. This approach—the deletion method—obviously extends to the detection and testing of multiple outliers, with the choice between block and consecutive deletion (see *Likelihood in Statistics*). It is also the appropriate approach to outliers in multivariate data; see *Multivariate Analysis: Overview*.

Similar considerations apply to the detection and testing of outliers in designed experiments and outliers in contingency tables, with use of residual-based or deletion procedures. See *Experimental Design: Overview*. Accommodation procedures are also available in the literature. Outliers also occur in time series (see *Time Series: General*). For details of methods for dealing with outliers in the various data situations mentioned above, see Barnett and Lewis 1994.

Some work has been done on outliers in sample surveys, but the methodology for outliers in this vital field urgently needs developing. See *Sample Surveys: Methods*; *Sample Surveys: Model-based Approaches*; *Sample Surveys: The Field*.

In multilevel, or hierarchical, data the concept of an outlier becomes more complex, and much work needs to be done. See *Hierarchical Models: Random and Fixed Effects*; *Statistical Analysis: Multilevel Methods*; Lewis and Langford (2001). See also Langford and Lewis (1998), from which the following passage is quoted:

In a simple educational example, we may have data on examination results in a two-level structure with students nested within schools, and either students or schools may be considered as being outliers at their respective levels in the model. Suppose … that … a particular school is found under test to be a discordant outlier; we … need to ascertain whether it is discordant owing to a systematic difference affecting all the students measured within that school or because one or two students are responsible for the discrepancy. At student level, an individual may be outlying with respect to the overall relationships found across all schools or be unusual only in the context of his or her particular school. … [Again,] masking [see Sect. 3.1] can apply across the levels of a model. The outlying nature of a school may be masked because of another similarly outlying school or by the presence of a small number of students within the school whose influence brings the overall relationships within that school closer to the average for all schools.

6. Conclusion

'The concern over outliers is old and undoubtedly dates back to the first attempt to base conclusions on a set of statistical data. … The literature on outliers is vast … ' (Beckman and Cook 1983). As this article has shown, outliers occur commonly in data and the problem of how to deal with them in any particular case is an unavoidable one. A massive armory of principle, model, and method has built up over the years. For a review of the relevant literature, see the extensive coverage of outlier methodology by Barnett and Lewis (1994), whose book, which includes some 970 references, still remains the only comprehensive treatment of the subject. A valuable survey of many outlier problems is also given in Beckman and Cook (1983).

Statistical Analysis, Special Problems of: Transformations of Data

Data transformations such as replacing a variable by its logarithm or by its square-root are often used to simplify the structure of the data so that they follow a convenient statistical model or are more suitable for graphing. Transformations have one or more objectives, including:

(a) inducing a simple systematic relationship between a response and predictor variables in regression;

(b) stabilizing a variance, that is, inducing a constant variance in a group of populations or in the residuals after a regression analysis; and

(c) inducing a particular type of distribution, e.g., a normal or symmetric distribution, or removing extreme skewness so that the data are more appropriate for plotting.

The second and third goals are concerned with simplifying the 'error structure' or random component of the data.

The need for transformation can be seen in Fig. 1, showing assets and sales for a sample of 79 'Forbes 500' companies. The data were taken from the Data and Story Library at Carnegie Mellon University's StatLib (http://lib.stat.emu.edu/DASL/). Panel (a) shows that both assets and sales are highly right skewed and that the scatter of sales, conditional on the value of assets, is greater for larger values of assets. Because of this extreme right skewness, most of the data are crowded into the lower left-hand corner of the plot and it is difficult to ascertain what type of regression model is appropriate for these data.

The normal probability plot in panel (b) also shows the right skewness of sales. Panel (c) is a normal plot of the residuals from a linear regression of sales on assets. Notice that the extreme residuals are much larger in absolute value than the corresponding normal quantiles. These outliers are due to the nonconstant conditional variance of sales, given assets; the outliers are from the observations with large values of assets. The skewness and heteroscedasticity in this example is quite typical of economic data.

Figure 2 uses the same raw data as Fig. 1, but in Fig. 2 both assets and sales are log transformed. Notice in panel (a) that log(sales) appear linearly related to

Figure 1
Assets and sales of a sample of Forbes 500 companies: (a) plot of sales and assets; (b) normal probability plot of sales; (c) normal probability plot of residuals from a linear fit of assets to sales; (d) plot of absolute residuals vs. assets with a scatterplot smooth

Figure 2
Log(assets) and log(sales) of a sample of Forbes 500 companies. (a) plot of log(sales) and log(assets); (b) normal probability plot of log(sales); (c) normal probability plot of residuals from a linear fit of log(assets) to log(sales); (d) plot of absolute residuals versus log(assets) with a scatterplot smooth

log(assets). The normal probability plots in panels (b) and (c) suggest that both log(sales) and the residuals from the regression of log(sales) against log(assets) are approximately normally distributed. Panel (d) shows that these residuals are far less heteroscedastic than those from the untransformed data.

Data transformations were developed at a time when there were far fewer tools available to the applied statistician than now. Many problems that in the past would have been tackled by data transformation plus a linear model are now solved using more sophisticated techniques; for example, generalized linear models, nonlinear models, smoothing, and variance function models. Nonetheless, model simplification is still important, and data transformation is still an effective and widely used tool.

1. *Transformations to Simplify the Systematic Model*

In regression, if the expected value of the response y is related to predictors $x_1, \ldots, x_J$ in a complex way, often a transformation of y will simplify this relationship by inducing linearities or removing interactions. For example, suppose that

$$y = \beta_0 x_1^{\beta_1} \ldots x_J^{\beta_J} + \varepsilon \tag{1}$$

where ε is a small random error and y and $x_1, \ldots, x_J$ are all positive. The Taylor series approximation $\log(\mu+\varepsilon) \approx \log(\mu) + \varepsilon/\mu$ is appropriate for small values of ε. Using this approximation with $\mu = \beta_0 x_1^{\beta_1} \ldots x_J^{\beta_J}$, one finds that $\log y$ follows approximately the linear model

$$\log y = \beta_0^* + \beta_1 x_1^* + \ldots + \beta_J x_J^* + (\beta_0 x_1^{\beta_1} \ldots x_J^{\beta_J})^{-1}\varepsilon \tag{2}$$

where $\beta_0^* = \log(\beta_0)$ and $x_j^* = \log(x_j)$. Model (1) is nonlinear in each x_j and has large and complex interactions.

In contrast, model (2) is linear and additive in the transformed predictors. However, transformations should not be used blindly to linearize a systematic relationship. If the errors in Eqn. (1) are *homo-*

scedastic, then the errors in Eqn. (2) will be *heteroscedastic*. Also, the log transformation can induce skewness and transform the data nearest 0 to outliers. On the other hand, if the original data exhibit heteroscedasticity and skewness, then these problems might be reduced by transformation. Any intelligent use of transformations requires that the effects of the transformations on the error structure be understood; see Ruppert et al. (1989), where the use of transformations to linearize the Michaelis–Menten equation is discussed.

In our example of Forbes 500 companies, log(sales) seems linearly related to log(assets), which suggest that the untransformed data satisfy

$$\text{sales} \approx \beta_0 \text{assets}^{\beta_1}. \tag{3}$$

Moreover, the log transformed data is less skewed and heteroscedastic than the original data, so transformation brings the data more closely in line with usual assumptions of linear regression.

2. *Transformations to Simplify Error Structure*

The effects of a transformation upon the distribution of data can be understood by examining the transformation's derivative. A nonlinear transformation tends to stretch out data where the transformation's derivative is large in absolute value, and to squeeze together data where the absolute value of that derivative is small. These effects are illustrated in Fig. 3(a) where the logarithm transformation is applied to normalize right-skewed lognormally distributed data. Along the x-axis one sees the probability density function of the lognormal data. The log transformation is shown as a solid curve. On the y-axis is the normal density of the transformed data. The mapping of the 5th percentile of the original data to the same percentile of the transformed data is shown with dashed lines, and similar mappings for the median and 95th percentiles are shown with *solid and dashed lines*.

The log is a concave transformation; that is, its derivative is decreasing. Therefore the long right tail

Figure 3
(a) A transformation to remove right skewness. Here the concave log transformation converts right-skewed lognormal data to normally distributed data. The densities of the original and transformed data are shown on the x and y axes, respectively. The lines show the mappings of the 5th, 50th, and 95th percentiles; (b) A variance-stabilizing transformation. Here the square-root transformation converts heteroscedastic data consisting of two populations to data with a constant variance; '*' and 'o' denote the two populations. The lines show the mappings of the first and third quartiles of the two populations

and short left tail of the lognormal distribution are shrunk and stretched, respectively, by the mapping to produce a symmetric distribution of the transformed data. The density on the y-axis is evaluated at equally spaced points. Their inverse images on the x-axis are spread out increasingly as one moves from left to right. The same effect can be seen in the percentiles.

In general, concave transformations are needed to symmetrize right-skewed distributions. Analogously, convex transformations which have increasing first derivatives are used to symmetrize left-skewed distributions.

Data often exhibit the property that populations with larger means also have larger variances. In regression if $E(Y|\mathbf{X}) = \mu(\mathbf{X})$ is the mean of the conditional distribution of the response Y given a vector $\mathbf{X}$ of covariates, then we might find that the conditional variance $\mathrm{var}(Y|\mathbf{X})$ is a function of $\mu(\mathbf{X})$, i.e., $\mathrm{var}(Y|\mathbf{X}) = g\{\mu(\mathbf{X})\}$ for some function g. If Y is transformed to $h(Y)$, then a delta-method linear approximation (Bartlett 1947) shows that

$$\mathrm{var}(h(Y)|\mathbf{X}) \approx \{h'(\mu(\mathbf{X})\}^2\, g\{\mu(\mathbf{X})\}. \qquad (4)$$

The transformation h stabilizes the variance if $\{h'(y)\}^2\, g(y)$ is constant. For example, if $g(y) \propto y^{\alpha}$, then $h(y) \propto y^{1-\alpha/2}$ is variance-stabilizing for $\alpha \neq 2$. For Poisson data, $\alpha = 1$ and the square-root transformation is variance-stabilizing. For data with a constant coefficient of variation, $\alpha = 2$ and the log transformation is variance-stabilizing. Exponentially distributed data, or, more generally, gamma-distributed data with a constant shape parameter, are examples with a constant coefficient of variation. For binomial data with a constant sample size, n, $g(y) = ny(1-y)$ and the 'angular' transformation, $\sin^{-1}(\sqrt{y})$, is variance-stabilizing.

When g is an increasing function, then the variance-stabilizing transformation will be concave, as illustrated in Fig. 3(b). The original data on the x-axis are such that their square roots are normally distributed data, except that they are truncated in the extreme tails to be strictly positive. There are two original populations with different means and variances. After a square-root transformation, the two populations have different means but equal variances. The dashed lines show the mapping of the first and third quartiles of the first population of the original data to their transformed values. The solid lines show the same mapping of the second population.

When $\mathrm{var}(Y|\mathbf{X})$ is not a function of $\mu(\mathbf{X})$, then there is no variance-stabilizing transformation, and variance function modeling (Carroll and Ruppert 1988) should be used as an alternative, or at least an adjunct, to transformation of Y.

3. *Power Transformations*

There are several parametric families of data transformation in general use. The most important are the power or Box and Cox (1964) family and the power-plus-shift family. The Box–Cox power transformations, that are used for positive y, are:

$$\begin{aligned} h(y;\lambda) &= (y^{\lambda}-1)/\lambda \quad \lambda \neq 0 \\ &= \log(y) \qquad \lambda = 0. \end{aligned}$$

For $\lambda \neq 0$ the ordinary power transformation, y^{λ}, is shifted and rescaled so that $h(y;\lambda)$ converges to $\log(y)$ as λ converges to 0. This embeds the log transformation into the power transformation family in a continuous fashion. The shift and rescaling are linear transformations and have no effect on whether the transformation achieves the three objectives enumerated in Sect. 1. Power transformations with $\lambda = -1/2, 0, 1/2, 1, 1.5, 2$, and 2.5 are shown in Fig. 4. Notice that the transformations are upward bending (convex) when $\lambda > 1$ and downward bending (concave) when $\lambda < 1$. Transformations which are either convex or concave are called 'one-bend' by Kruskal (1968).

As mentioned before, power transformations are variance-stabilizing when the variance is a power of the mean, a model that often fits well in practice. The cube-root transformation, called the Wilson–Hilferty (1931) transformation, approximately normalizes, and therefore symmetrizes, gamma-distributed data.

The effect of $h(y;\lambda)$ on data depends on its derivative $h'(y;\lambda) = (\partial/\partial y)h(y;\lambda) = y^{\lambda-1}$. Consider two points $0 < y_1 < y_2$. The 'strength' of the transformation can be measured by the ratio.

$$\frac{h'(y_2;\lambda)}{h'(y_1;\lambda)} = \left(\frac{y_2}{y_1}\right)^{\lambda-1}$$

which shows how far data are spread out at y_2 relative to y_1. This ratio is one for $\lambda = 1$ (linear transformation), is less than one for $\lambda < 1$ (concave transformations), and is greater than one for $\lambda > 1$ (convex transformation). For fixed y_1 and y_2, the ratio is increasing in λ, so that its concavity or convexity becomes stronger as λ moves away from 1. If a certain value of λ transforms a right-skewed distribution to symmetry, then a larger value of λ will not remove right-skewness completely, while a smaller value of λ will induce some left-skewness. Analogously, if the variance is an increasing function of the mean, and a certain value of λ is variance-stabilizing, then for a larger value of λ the variance of the transformed data is still increasing in the mean, while for a smaller value of λ, the variance is decreasing in the mean. Understanding this behavior is important when a symmetrizing or variance-stabilizing power transformation is sought by trial and error.

The shifted-power transformation is

$$h(y;\lambda,\theta) = h(y+\theta;\lambda)$$

Figure 4
Box–Cox power transformations. The linear transformation with $\lambda = 1$ is shown as a heavy solid line. The convex transformations with $\lambda > 1$ are above this line and the concave transformations with $\lambda < 1$ are below

Figure 5
Angular, logit, and probit transformations. To facilitate comparisons of shapes, each of the transformations was shifted and scaled so that the mean and variance of the transformed values were 0 and 1, respectively

which is a location shift of y to $y+\theta$ followed by a Box–Cox power transformation. The ordinary power transformation can be applied only to nonnegative data, but the shifted power transformation can be used for any data set provided that $\theta > -\min(Y)$, where $\min(Y)$ is the smallest value of the data. Thus, shifted power transformations are particularly well suited to variables that have a lower bound, but no upper bound.

Kruskal (1968) and Atkinson (1985) discuss families of transformations that are appropriate for percentages, proportions, and other variables that are constrained to a bounded interval. The most common transformations for variables constrained to lie between 0 and 1 are the angular transformation, $\sin^{-1}(\sqrt{y})$, the logit transformation, $\log\{y/(1-y)\}$, and the probit transformation, $\Phi^{-1}(y)$, where Φ is the normal (0, 1) cumulative distribution function. These transformations, shown in Fig. 5, are concave for $y < 1/2$ and convex for $y > 1/2$; Kruskal (1968) calls them 'two-bend' transformations.

For data that are bounded neither above nor below, Manly (1976) proposes the exponential data transformations.

$$\begin{aligned} h(y;\lambda) &= \{\exp(\lambda y)-1\}/\lambda, \quad \lambda \neq 0 \\ &= y, \qquad\qquad\qquad\quad \lambda = 0 \end{aligned}$$

which is the transformation from y to $\exp(y)$, a positive variate, followed by the Box–Cox power transformation.

4. *Estimation of Transformation Parameters*

There are situations where a transformation may be selected based on *a priori* information. For example, if we know that model (1) holds, then we know that the log transformation will linearize and remove inter-

actions. In other situations, transformations are often based on the data, though perhaps selected from a predetermined parametric family, e.g., shifted power transformations. Trial and error can be an effective method of parameter selection. For example, one might try power transformations with λ equal to $-1, -1/2, 0, 1/2$, and 1, and see which value of λ produces the best residual plots.

When all aspects of the data are modeled parametrically, then the transformation parameter, as well as other parameters, can be estimated simultaneously by maximum likelihood. Semiparametric transformations are used when the model is not fully parametric, e.g., it is assumed that there is a parametric transformation to symmetry but not to a specific symmetric parametric family.

4.1 Maximum Likelihood Estimation

Maximum likelihood estimation is possible once a parametric model is specified. However, there are at least three possible parametric transformation models in common use: the Box and Cox (1964) model; the transform-both-sides (TBS) model of Carroll and Ruppert (1981); and the Box and Tidwell (1964) model. In practice it is essential to consider which, if any, of these models is most appropriate.

Box and Cox (1964) assumed that after a parametric transformation of the response, the data follow a simple linear model with homoscedastic, normally distributed errors. Therefore, the Box–Cox model is that

$$h(Y;\lambda) = \beta_0 + \beta_1 x_p + \ldots \beta_p x_p + \varepsilon \tag{5}$$

where ε is normal $(0, \sigma^2)$ for some unknown value of λ. They find the likelihood for this model as a function of $(\lambda, \sigma^2, \beta_0, \ldots, \beta_p)$ and show how to maximize likelihood to estimate the transformation parameter, the regression parameters, and the variance of the errors. The Box–Cox model attempts to achieve each of the three objectives in Sect. 1 with a single transformation. Although it may be rare for all three goals to be achieved exactly, often in practice both the systematic model and the error structure can be simplified by the same transformation, and because of this the Box–Cox technique has seen widespread usage. Simultaneous estimation of a power and shift by maximum likelihood is not recommended, for technical reasons (Atkinson 1985), but λ can be estimated by maximum likelihood for a fixed value of the shift, which can be chosen by trial and error.

Model (5) with only an intercept, i.e., $h(Y;\lambda) = \beta_0 + \varepsilon$, is commonly used to choose a normalizing transformation for a univariate sample. When maximum likelihood estimation was applied to this model using the Forbes 500 data, the maximum likelihood estimations of λ were -0.07 and -0.04 for sales and assets, respectively. These values are quite close to the log transformation, $\lambda = 0$, which partially justifies the use of the log transformation for this example.

Carroll and Ruppert (1981, 1988) apply maximum likelihood estimation to a somewhat different parametric model than that of Box and Cox, called TBS. They assume that there is a known theoretical model relating the response to the predictors, i.e., that

$$Y \approx f(x_1, \ldots, x_p; \beta_1, \ldots, \beta_q)$$

where $f(x_1, \ldots, x_p; \beta_1, \ldots, \beta_q)$ is some nonlinear regression model. Transforming only the response will destroy this relationship, so they transform both the response and the theoretical model in the same way. It is assumed that after transforming by the correct λ, the errors are homoscedastic and normally distributed. Therefore, the Carroll–Ruppert model is

$$h(Y;\lambda) = h\{f(x_1, \ldots, x_p; \beta_1, \ldots, \beta_q); \lambda\} + \varepsilon.$$

TBS simplifies only the error structure while leaving the systematic model unchanged.

In the Forbes 500 example, if one starts with the power model (3), then the model used in Fig. 2, i.e.,

$$\log(\text{assets}) = \beta_0^* + \beta_1 \log(\text{assets}) + \varepsilon, \quad \beta_0^* = \log(\beta_0) \tag{6}$$

is the TBS model with $\lambda = 0$.

The model of Box and Tidwell (1962) assumes that the untransformed Y is linear in the transformed predictors, for example, that

$$Y = \beta_0 + \beta_1 h(x_1;\lambda_1) + \ldots + \beta_p h(x_p;\lambda_p) + \varepsilon.$$

This model is a special case of nonlinear regression and can be fit by ordinary nonlinear least-squares. Atkinson (1975) discusses a combination of the Box–Tidwell model and the Box–Cox model, where

$$h(Y;\lambda) = \beta_0 + \beta_1 h(x_1;\lambda_1) + \ldots + \beta_p h(x_p;\lambda_p) + \varepsilon.$$

A special case of Atkinson's model restricts the transformation parameters so that $\lambda = \lambda_1 = \ldots = \lambda_p$. Atkinson's model with $\lambda = \lambda_1 = 0$ is equivalent to the TBS model (6).

4.2 Semiparametric Estimation

Hinkley (1975) estimates a transformation to symmetry by setting a skewness measure of the transformed data to zero and solving for the transformation parameter.

Ruppert and Aldershof (1989) estimate a variance-stabilizing transformation by minimizing the correlation between the squared residuals and the fitted values.

4.3 Effects of Outliers and Robustness

An outlier is an observation that is poorly fit by the model and parameter values that fit the bulk of the data. When the model includes a transformation, outliers can be difficult to identify. For example, if the original data are lognormally distributed, apparent outliers in the long right tail may be seen to be conforming after the normalizing transformation. Conversely, the smallest observations may be quite close to the bulk of the original data but outlying after a log transformation. It is essential that the transformation parameter not be chosen to fit a few outliers but rather to fit the main data set. Diagnostics and robust transformations can be useful for this purpose. The semiparametric estimators discussed above are often chosen to be insensitive to outliers, e.g., in Hinkley (1975), by choosing λ to minimize a robust measure of skewness. Because of the potentially serious effects of not accounting for the effects of outliers properly, users of transformations are advised to consult the monographs by Atkinson (1985) and Carroll and Ruppert (1988) for practical advice.

4.4 Inference after a Transformation

There has been some debate on whether a data-based transformation can be treated as fixed when one makes inferences about the regression parameters (Box and Cox 1982). This is a serious practical question. In the Box–Cox model, the values of the regression parameters are highly dependent on the choice of transformation, and there is a general consensus that inference for regression parameters should treat the transformation parameters as fixed; see Box and Cox 1982 for discussion. If one is estimating the expected response or predicting responses at new values of the predictors, then the predictions are more variable with an estimated transformation than when the correct transformation is known (Carroll and Ruppert 1981). Prediction intervals can be adjusted for this effect to obtain coverage probabilities closer to nominal values (Carroll and Ruppert 1991).

5. Multivariate Transformations

Most of the classical techniques of multivariate analysis assume that the population has a multivariate normal distribution, an assumption that is stronger than that the individual components are univariate normal. Andrews et al. (1971) generalize the Box–Cox model to multivariate samples. They transform each coordinate of the observations using the same transformation family, e.g., power transformations for all coordinates, but with coordinate-specific transformation parameters. It is assumed that within this family of multivariate transformations, there exists a transformation to multivariate normality. All parameters in this model are estimated by maximum likelihood. See Gnanadesikan (1997) and Ruppert (2001) for further discussion.

6. Nonparametric Transformations

For interpretability, a data transformation should be continuous and monotonic, but parametric assumptions are made only for simplicity. A nonparametric estimate of a transformation allows one to select a suitable parametric family of transformation, to check if an assumed family is appropriate, or to forgo parametric assumptions when necessary. Tibshirani's (1988) transformation to additivity and variance stabilization (AVAS) method uses nonparametric variance function estimation and Eqn. (2) to estimate the variance-stabilizing transformation. Nychka and Ruppert (1995) use nonparametric spline-based transformations within the TBS model. Nonparametric transformations should not be confused with semiparametric transformation, as discussed above; in the latter a transformation is selected from within a *parametric* family but the data are not assumed to have a density within a parametric family.

7. Further Information

Atkinson (1985), Carroll and Ruppert (1988), and Draper and Smith (1998) are good places to learn more about the practical aspects of data transformation.

Statistical Clustering

Every formal inquiry begins with a definition of the objects of the inquiry and of the terms to be used in the inquiry, a *classification* of objects and operations. Since about 1950, a variety of simple explicit classification methods, called clustering methods, have been proposed for different standard types of data. Most of these methods have no formal probabilistic underpinnings. And indeed, classification is not a subset of statistics; data collection, probability models, and data analysis all require informal subjective prior classifications. For example, in data analysis, some kind of binning or selection operation is performed prior to a formal statistical analysis.

However, statistical methods can assist in classification in four ways:

(a) in devising probability models for data and classes so that probable classifications for a given set of data can be identified;

(b) in developing tests of validity of particular classes produced by a classification scheme;

(c) in comparing different classification schemes for effectiveness; and

(d) in expanding the search for optimal classifications by probabilistic search strategies.

These statistical methods are referred to as *cluster analysis* or *statistical classification*. The second term is preferred, because a cluster, from its astronomical origin, tends to connote a crowd of points close together in space, but a class is a set of objects assembled together for any kind of reason, and so the more general term *classification* is to be preferred. Part of the reason for the narrower term *cluster analysis* is that the term *classification* was once used in Statistics to refer to *discriminant analysis* (see *Multivariate Analysis: Classification and Discrimination*). In discriminant analysis, a classification rule is developed for placing a multivariate observation into one of a number of established classes, using the joint distribution of the observations and classes. These problems are regression problems: the variable to be predicted is the class of the observations. For example, logistic regression is a method for discriminant analysis with two classes (see *Multivariate Analysis: Discrete Variables (Logistic Regression)*). More recently, classification in statistics has come to refer to the more general problem of constructing families of classes, a usage which has always been accepted outside of statistics.

1. Algorithms

The first book on modern clustering techniques is Sokal and Sneath (1963). The most comprehensive recent review of a huge diverse literature is Arabie et al. (1996) which includes in particular an excellent survey of algorithms by Arabie and Hubert and of probabilistic methods by Bock.

A classification consists of a set of classes; formal clustering techniques have been mainly devoted to either *partitions* or *hierarchical clustering* (see, however, the nonhierarchic structures in Jardine and Sibson 1968 and the block clusters in Hartigan 1975).

1.1 Partitions

A partition is a family of *classes*, sets of objects with the property that each object lies in exactly one class of the partition. *Ideal-object* partitions are constructed as follows. Begin with a set of given objects, a class of ideal objects, and a numerical dissimilarity between any given object and any ideal object. A fitted ideal object is associated with each class having minimum sum of dissimilarities to all given objects in the class.

The algorithm aims to determine k ideal objects, and a partition of the objects into k classes, so that the dissimilarity between an object and the fitted ideal object of its class, summed over all objects, is minimized. The usefulness of such a clustering is that the

original set of objects is reduced with small loss of information to the smaller set of fitted ideal objects. Except in special circumstances, it is impracticable to search over all possible partitions to minimize the sum of dissimilarities; rather some kind of local optimization is used instead.

For example, begin with some starting partition, perhaps chosen randomly. First fit the ideal objects for a given partition. Second reallocate each object to the class of the fitted ideal object with which it has smallest dissimilarity. Repeat these two steps until no further reallocation takes place. The *k-means* algorithm, MacQueen (1967), is the best known algorithm of this type; each object is represented by a point in p-dimensional space, the dissimilarity between any two points is squared euclidean distance, and the ideal object for each class is the centroid of the class. Asymptotic behaviour of the k-means algorithm is described in Pollard (1981).

1.2 Hierarchical Clustering

Hierarchical clustering constructs *trees* of clusters of objects, in which any two clusters are disjoint, or one includes the other. The cluster of all objects is the root of the tree.

Agglomerative algorithms, Lance and Williams (1967), require a definition of dissimilarity between clusters; the most common ones are *maximum or complete linkage*, in which the dissimilarity between two clusters is the maximum of all pairs of dissimilarities between pairs of points in the different clusters; *minimum or single linkage or nearest neighbor*, Florek et al. (1951), in which the dissimilarity between two clusters is the minimum over all those pairs of dissimilarities; and *average linkage* in which the dissimilarity between the two clusters is the average, or suitably weighted average, over all those pairs of dissimilarities.

Agglomerative algorithms begin with an initial set of singleton clusters consisting of all the objects; proceed by *agglomerating* the pair of clusters of minimum dissimilarity to obtain a new cluster, removing the two clusters combined from further consideration; and repeat this agglomeration step until a single cluster containing all the observations is obtained. The set of clusters obtained along the way forms a hierarchical clustering.

1.3 Object Trees

A different kind of tree structure for classification is a graph on the objects in which pairs of objects are linked in such a way that there is a unique sequence of links connecting any pair of objects. The *minimum spanning tree*, Kruskal (1956), is such a graph, constructed so that the total length of links in the tree is minimized. There may be more than one such optimal graph. The minimum spanning tree is related to single linkage clusters: begin by removing the largest link, and note the two sets of objects that are connected by the remaining links, continue removing links in order of size, noting at each stage the two new sets of objects connected by the remaining links. The family of connected sets obtained throughout the removal process constitutes the single linkage clusters.

In a Wagner tree, the given objects are end nodes of the tree, and some set of *ideal* objects are the possible internal nodes of the tree. A Wagner tree for the given objects is a tree of minimum total length in which the given objects are end nodes and the internal objects are arbitrary. A Wagner tree is a minimum spanning tree on the set of all objects and the optimally placed internal nodes. This tree has application in evolutionary biology as the *most parsimonious* tree reaching the given objects (Fitch and Margoliash 1967).

A third kind of tree structure arises from the CART algorithm of Breiman et al. (1984). This algorithm applies to regression problems in which a given target variable is predicted from a recursively constructed partition of the observation space; the prediction is constant within each member of the partition. If the predictors are numerical variables, the first choice in the recursion looks over all variables V and all cutpoints a for each variable, generating the binary variables identifying observations where $V < a$. The binary predictor most correlated with the target variable divides the data set into two sets, and the same choice of division continues within each of the two sets, generating a *regression tree*. It is a difficult problem to know when to stop dividing. These regression trees constitute a classification of the data adapted to a particular purpose: the accurate prediction of a particular variable.

Usually, only the final partition is of interest in evaluating the regressive prediction, although the regression tree obtained along the way is used to decide which variables are most important in prediction, for example, the variables appearing in the higher levels of the tree are usually the most important. However, if there are several highly correlated variables, only one might appear in the regression tree, although each would be equally useful in prediction.

2. Probabilistic Classification

The aim is to select an appropriate classification C from some family Γ based on given data D.

2.1 Mixture Models

It is assumed that there are a number of objects, denoted $x_1, \ldots, x_n$, which are to be classified. A probability model specifies the probability of an

observation x when x is known to come from a class with parameter value θ, say $p(x|\theta)$. The parameter value θ corresponds to an ideal point in the partition algorithm [Sect. 1.2]. The *mixture* model assumes that there is a fixed number of classes k, that an object x_i comes from class C_j with mixing probability p_j, so that the probability of observation x is $p(x) = \Sigma_j p_j p(x|\theta_j)$, and collectively the observations have probability $\Pi_i p(x_i)$. The parameters p_j and θ_j usually are estimated by maximum likelihood in a non-Bayesian approach. No single partition is produced by the algorithm, but rather the conditional probability of each partition at the maximum likelihood values of the parameters. How do these statistical partitionings compare with the dissimilarity based partitions of Sec. 1.2? Suppose the partition itself is a parameter to be estimated in the statistical model; estimate the optimal partition $C = \{C_1, \ldots, C_k\}$, and the parameters p_j, θ_j to maximize the probability of the data given the partition $\Pi_j \Pi_{x_i \in C_j} p_j p(x_i|\theta_j)$. Thus, the optimal partition in the statistical model is the optimal partition in a dissimilarity model with dissimilarities between the object x_i and the ideal object θ_j

$$d(x_i, \theta_j) = \log(p_j) + \log p(x_i|\theta_j) \tag{1}$$

It is, thus, possible to translate back and forth between statistical models and dissimilarity models by taking dissimilarities to be log probabilities.

However, it is wrong to estimate the optimal partition by maximizing the probability of the data given the partition and parameters over all choices of partitions and parameters; as the amount of data increases, the limiting optimal partition does not correspond to the *correct* partition obtained when the parameters p_j, θ_j are known. (The correct partition assigns x_i to the class that maximizes $p_j p(x_i|\theta_j)$. In contrast, the estimate of p_j, θ_j that maximizes the data probability averaged over all possible partitions, is consistent for the true values under mild regularity conditions, and the partition determined from these maximum likelihood estimates is consistent for the correct partition.

In a Bayesian approach, the probability model is a joint probability distribution over all possible data D and classifications C. The answer to the classification problem is the conditional probability distribution over all possible classifications C given the present data D. Add to the previous assumptions a prior distribution on the unknown parameters p_j, θ_j (Bock 1972). Again, consistent estimates of the correct classification are not obtained by finding the classification C and parameters p, θ of maximum posterior probability. Use the marginal posterior distribution of p, θ, averaging over all classifications, to give consistent maximum posterior density estimates $\hat{p}$, $\hat{\theta}$ say. Then find the classification C of optimal posterior probability C given the data and given $p = \hat{p}$, $\theta = \hat{\theta}$. This classification will converge to the optimal classification for the mixture distribution with known p and θ.

If in addition a prior distribution is specified for the number of clusters, a complete final posterior distribution is available for all possible partitions into any number of components.

2.2 Hierarchical Models

Many of the hierarchical methods assume a dissimilarity function specifying a numerical dissimilarity $d(i, j)$ for each pair of objects i, j. If d satisfies the *ultrametric inequality* for every triple i, j, k

$$d(i, j) \leqslant \max[d(i, k), d(j, k)] \tag{2}$$

then the various hierarchical algorithms discussed in Sect. 1.2 all produce the same clusters. The dissimilarity between a given object and another object in a given cluster C is less than the dissimilarity between that object and another object not in C. Thus hierarchical clustering may be viewed as approximating the given dissimilarity matrix by an ultrametric; methods have been proposed that search for a good approximation based on a measure of closeness between different dissimilarities.

With slightly more generality, *evolutionary distances* between a set of objects conform to a tree in which the objects are end nodes and the internal nodes are arbitrary. A nonnegative link distance is associated with each link of the tree, and the evolutionary distance between two objects is the sum of link distances on the path connecting them. Evolutionary distances are characterised by the following property: any four objects i, j, k, l may be partitioned into two pairs of objects in three ways; for some pairing (i, j), (k, l) say, the *evolutionary equality* is satisfied

$$d(i, k) + d(j, k) = d(i, l) + d(j, k) \tag{3}$$

The pairing (i, j), (k, l) means that the tree path from i to j has no links in common with the tree path from k to l. We can construct an evolutionary tree on a set of objects by approximating a given dissimilarity by an evolutionary distance.

One case where evolutionary distances arise probabilistically is in the factor analysis model in which the objects to be classified form a set of v variables on which a number of independent v-dimensional observations have been made (Edwards and Cavalli-Sforza 1964). The variables are taken to be end-nodes in an evolutionary tree whose links and internal objects remain to be determined. Associated with each link of the tree is an independent normal variable with mean zero and variance depending on the link; this variance is the link distance. Each observation for the v variables is generated by assigning the random link values; then the variable $V_i - V_j$ is a sum of independent normal variables along the path of directed

links connecting i and j. The random normal associated with each link is of opposite sign when the link is traversed in the opposite direction. The quantities $d(i, j) = E(V_i - V_j)^2$ form a set of evolutionary distances, which are estimated by $\hat{d}(i, j) =$ sample have $(V_i - V_j)^2$.

For each observation $\{V_1 - V_i, i = 2, \ldots p\}$ is multivariate normal with a covariance matrix determined by the link variances, and the log likelihood may be written, for a certain weight function w

$$\sum_{i,j} (\hat{d}(i, j) - d(i, j)) w_{i,j}(\sigma) \tag{4}$$

This expression is maximized to estimate the unknown σ values. In this case the sample distances form a sufficient statistic for the parameters, and no information is lost in using distances rather than the complete data set. Similar discrete Markovian models due to Felsenstein (1973) reconstruct evolutionary trees from DNA sequence data.

A nonparametric model for hierarchical clustering assumes that the objects $x_1, \ldots, x_n$ to be clustered are sampled randomly from a space with values $x \in S$ and density f with respect to some underlying measure, usually counting measure or lebesgue measure. It is necessary to have a concept of connectedness in the space S. The family of connected sets of points having density $f(x) > c$, computed for each nonnegative c, together form a hierarchical clustering called *high density* clusters (Bock 1974, Hartigan 1975). The statistical approach estimates this hierarchical clustering on the density f from the given sample $x_1, \ldots x_n$ by first estimating the density f by $\hat{f}$ say, then forming the estimated clusters as the high density clusters in $\hat{f}$. There are numerous parametric and nonparametric estimates of density available.

How do the standard hierarchical clustering methods do in estimating these high density clusters? Badly. The single linkage clusters may be re-expressed as the high density clusters obtained from the nearest-neighbor density estimator; the density estimate at point x is a decreasing function of $d(x, x_i)$, where x_i is the closest sample point to x. This estimator is inconsistent as an estimate of the density, and the high density clusters are correspondingly poorly estimated. However, it may be shown that the single linkage method is able to consistently identify distinct modes in the density. On the other hand, complete linkage corresponds to no kind of density estimate at all, and the clusters obtained from complete linkage are not consistent for anything at all, varying randomly as the amount of data increases. In evaluating and comparing clustering methods, a statistical approach determines how well the various clustering methods recover some known clustering when data is generated according to some model based on the known clustering (Milligan 1980). The most frequently used model is the multivariate normal mixture model.

3. *Validity of Clusters*

A typical agglomerative clustering produces $n-1$ clusters for n objects, and different choices of dissimilarities and cluster combination rules will produce many different clusterings. It is necessary to decide 'which dissimilarity, which agglomeration method, and how many clusters?'.

In partition problems, if a parametric mixture model is used, standard statistical procedures described in Sect. 2.1 are available to help decide how many components are necessary. These models require specific assumptions about the distribution within components that can be critical to the results. The nonparametric *high density* cluster model associates clusters with modes in the density. The question about number of clusters translates into a question about number of modes.

The *threshold or kernel width* test, (Silverman 1981), for the number of modes is based on a kernel density estimator, for example, given a measure of dissimilarity, and a threshold d, use the density estimate at each point x consisting of the sum of $1 - d(x, x_i)/d$ over observed objects x_i within dissimilarity d of x. The number of modes in the population is estimated by the number of modes in the density estimate. To decide whether or not two modes are indicated, the quantity d is increased until at $d = \hat{d}_1$, the estimated density $\hat{f}_1$ first has a single mode. If the value $\hat{d}_1$ required to render the estimate unimodal is large enough, then more than one mode is necessary. To decide when $\hat{d}_1$ is large, resample from the unimodal distribution $\hat{f}_1$, obtaining a distribution of resampled $\hat{d}_1$ values for those samples, the values of d in each of those resamples required to make the density estimate unimodal. The tail probability associated with the given $\hat{d}_1$ is the proportion of resampled $\hat{d}_1$ that exceed the given $\hat{d}_1$. A similar procedure works for deciding whether or not a larger number of modes than 2 is justified. An alternative test that applies in 1-dimension for two modes vs. one uses the DIP statistic (Hartigan and Hartigan 1985), the maximum distance between the empirical distribution function and the unimodal distribution function that is closest to the empirical distribution function. The null distribution is based on sampling from the uniform.

4. *Probabilistic Search*

Consider searching for a classification C in a class Γ that will maximize $l(C)$ the log probability of C given the data. Γ is usually too large for a complete search, and a local optimization method is used. Define a neighborhood of classifications $N(C)$ for each classification C. Beginning with some initial classification C_0, steepest ascent selects C_i to be the neighbor of C_{i-1} that maximizes $l(C)$, and the algorithm terminates at C_m when no neighbor has greater probability. Of course, the local optimum depends on the initial classification

C_0, and the local optimum will not in general be the global optimum.
