The search may be widened probabilistically by *randomized steepest ascent or simulated annealing* (Klein and Dubes 1989), as follows: rather than choosing C_i to maximize $l(C)$ in the neighborhood of C_{i-1}, choose C_i with probability proportional to $\exp(\mathrm{l}(\mathrm{C})/\lambda)$ from the neighborhood of C_{i-1}. In running the algorithm, we keep track of the highest probability classification obtained to date, and may return to that classification to restart the search. The degree of randomness λ may be varied during the course of the search. To do randomized ascent at randomness λ add to the log probability of each classification the independent random quantity $-\lambda \log E$, where E is exponential; then do deterministic steepest ascent on the randomized criterion.

To be specific, consider the probabilification of the *k-means* algorithm, that constructs say k clusters of n objects in v dimensions to minimize the total within cluster sum of squares S. Use a probability model in which within cluster deviations are independent normal with variance σ^2, the cluster means are uniformly distributed, and σ^2 has density $\sigma^{-(2vk+4)}$ (these prior assumptions match maximum likelihood), the log probability of a particular classification into two clusters given the data is

$$-[\tfrac{1}{2}(n+1)vk+1]\log S \tag{5}$$

Steepest ascent k-means switches between clusters the observation that most decreases S; randomized steepest ascent switches the observation that most increases the randomized criterion

$$-[\tfrac{1}{2}(n+1)vk+1]\log S-\lambda \log E \tag{6}$$

Finally, to choose the number of clusters, allowing k to vary by permitting an observation to 'switch' to a new singleton cluster. Penalize against many clusters by the BIC penalty; the number of parameters (cluster means and the variance) specifying k clusters in v dimensions is $vk+1$, so the final randomized criterion is

$$-\tfrac{1}{2}nvk\log S-\lambda \log E-\tfrac{1}{2}(vk+1)\log n \tag{7}$$

This formula adjusts only for the increase in log probability due to selecting optimal parameter values, and not for the increase in the log probability caused by selecting the highest probability partitions. A number of alternative choices of information criterion are proposed by Bozdogan (1988).

5. Conclusion

Although probabilistic and statistical methods have much to offer classification, in providing formal methods of constructing classes, in validating those classes, in evaluating algorithms, and in spiffing up algorithms, it is important to realise that classifications have something to contribute to statistics and probability as well. The early extensive development of taxonomies of animals and plants in Biology proceeded quite satisfactorily without any formal statistics or probability through 1950; the big methodological change occurred in the late-nineteenth century following Darwin, who demanded that biological classification should follow genealogy.

Classification is a primitive elementary basic form of representing knowledge that is prior to statistics and probability. Many of the standard algorithms were developed without allowing for uncertainty. Many of them, such as complete linkage, say, do not seem supportable by any statistical reasoning. Others will benefit by statistical evaluations and by probabilistic enhancements, as suggested in Hartigan (2000) and Gordon (2000).

Classification is both fundamental and subjective. If an observer classifies a set of objects to be in a class, for whatever reason, that class is valid in itself. Thus, there is no correct natural classification that our formal techniques can aim for, or that our statistical techniques can test for. Since classification is fundamental, it should be used to express formal knowledge, and probabilistic inferences and predictions should be based on these classificatory expressions of knowledge, Hartigan (2000). More formal and refined classifications may be assisted and facilitated by probability models reflecting and summarizing the prior fundamental classifications.

Statistical Data, Missing

1. Introduction

Missing values arise in social science data for many reasons. For example:

(a) In longitudinal studies, data are missing because of *attrition*, i.e., subjects drop out prior to the end of the study.

(b) In most surveys, some individuals provide no information because of noncontact or refusal to respond (*unit* nonresponse). Other individuals are contacted and provide some information, but fail to answer some of the questions (*item* nonresponse). See *Sample Surveys: The Field*.

(c) Information about a variable is partially recorded. A common example in social science is *right censoring*, where times to an event (death, finding a job) are recorded, and for some individuals the event has still not taken place when the study is terminated. The times for these subjects are known to be greater that corresponding to the latest time of observation, but the actual time is unknown. Another example of partial information is *interval censoring*, where it is known that the time to an event lies in an interval. For example in a longitudinal study of employment, it may be established that the event of finding a job took place some time between two interviews.

(d) Often indices are constructed by summing values of particular items. For example, in economic studies, total net worth is a combination of values of individual assets or liabilities, some of which may be missing. If any of the items that form the index are missing, some procedure is needed to deal with the missing data.

(e) Missing data can arise by design. For example, suppose one objective in a study of obesity is to estimate the distribution of a measure Y_1 of body fat in the population, and correlate it with other factors. Suppose Y_1 is expensive to measure but a proxy measure Y_2, such as body mass index, which is a function of height and weight, is inexpensive to measure. Then it may be useful to measure Y_2 and covariates, X, for a large sample but Y_1, Y_2 and X for a smaller subsample. The subsample allows predictions of the missing values of Y_1 to be generated for the larger sample, yielding more efficient estimates than are possible from the subsample alone.

Unless missing data are deliberately incorporated by design (such as in (e)), the most important step in dealing with missing data is to try to avoid it during the data-collection stage. Because data are likely to be missing in any case, however, it is important to try to collect covariates that are predictive of the missing values, so that an adequate adjustment can be made. In addition, the process that leads to missing values should be determined during the collection of data if possible, since this information helps to model the missing-data mechanism when an adjustment for the missing values is performed (Little 1995).

Three major approaches to the analysis of missing data can be distinguished:

(a) discard incomplete cases and analyze the remainder (complete-case analysis), as discussed in Sect. 3;

(b) impute or fill in the missing values and then analyze the filled-in data, as discussed in Sect. 4; and

(c) analyze the incomplete data by a method that does not require a complete (that is, a rectangular) data set.

With regard to (c), we focus in Sects. 6, 7, and 8 on powerful likelihood-based methods, specifically maximum likelihood (ML) and Bayesian simulation. See *Bayesian Statistics*. The latter is closely related to multiple imputation (Rubin 1987, 1996), an extension of single imputation that allows uncertainty in the

imputations to be reflected appropriately in the analysis, as discussed in Sect. 5.

A basic assumption in all our methods is that missingness of a particular value hides a true underlying value that is meaningful for analysis. This may seem obvious but is not always the case. For example, consider a longitudinal analysis of employment; for subjects who leave the study because they move to a different location, it makes sense to consider employment history after relocation as missing, whereas for subjects who die during the course of the study, it is clearly not reasonable to consider employment history after time of death as missing; rather it is preferable to restrict the analysis of employment to individuals who are alive. A more complex missing data problem arises when individuals leave a study for unknown reasons, which may include relocation or death.

Because the problem of missing data is so pervasive in the social and behavioral sciences, it is very important that researchers be aware of the availability of principled approaches that address the problem. Here we overview common approaches, which have quite limited success, as well as principled approaches, which generally address the problem with substantial success.

2. Pattern and Mechanism of Missing Data

The *pattern* of the missing data simply indicates which values in the data set are observed and which are missing. Specifically, let $Y = (y_{ij})$ denote an $(n \times p)$ rectangular dataset without missing values, with ith row $y_i = (y_{i1}, \ldots, y_{ip})$ where y_{ij} is the value of variable Y_j for subject i. With missing values, the pattern of missing data is defined by the *missing-data indicator matrix* $M = (m_{ij})$, such that $m_{ij} = 1$ if y_{ij} is missing and $m_{ij} = 0$ if y_{ij} is present.

Some methods for handling missing data apply to any pattern of missing data, whereas other methods assume a special pattern. An important example of a special pattern is *univariate* nonresponse, where missingness is confined to a single variable. Another is *monotone* missing data, where the variables can be arranged so that $Y_{j+1}, \ldots, Y_p$ are missing for all cases where Y_j is missing, for all $j = 1, \ldots, p-1$. The result is a 'staircase' pattern, where all variables and units to the left of the broken line forming the staircase are observed, and all to the right are missing. This pattern arises commonly in longitudinal data subject to attrition, where once a subject drops out, no more subsequent data are observed.

The missing-data mechanism addresses the reasons why values are missing, and in particular whether these reasons relate to values in the data set. For example, subjects in a longitudinal intervention may be more likely to drop out of a study because they feel the treatment was ineffective, which might be related to a poor value of an outcome measure. Rubin (1976) treated M as a random matrix, and characterized the missing-data mechanism by the conditional distribution of M given Y, say $f(M \mid Y, \phi)$, where ϕ denotes unknown parameters. When missingness does not depend on the values of the data Y, missing or observed, that is, $f(M \mid Y, \phi) = f(M \mid \phi)$ for all Y, ϕ, the data are called missing completely at random (MCAR). MCAR does not mean that the pattern itself is random, but rather that missingness does not depend on the data values. An MCAR mechanism is plausible in planned missing-data designs as in example (e) above, but is a strong assumption when missing data do not occur by design, because missingness often does depend on recorded variables.

Let Y_{obs} denote the observed values of Y and Y_{mis} the missing values. A less restrictive assumption is that missingness depends only on values Y_{obs} that are observed, and not on values Y_{mis} that are missing. That is:

$$f(M \mid Y, \phi) = f(M \mid Y_{obs}, \phi) \quad \text{for all } Y_{mis}, \phi$$

The missing data mechanism is then called missing at random (MAR). Many methods for handling missing data assume the mechanism is MCAR, and yield biased estimates when the data are not MCAR. Better methods rely only on the MAR assumption.

3. Complete-case, Available-case, and Weighting Analysis

A common and simple method is complete-case (CC) analysis, also known as *listwise* deletion, where incomplete cases are discarded and standard analysis methods applied to the complete cases. In many statistical packages this is the default analysis. Valid (but often suboptimal) inferences are obtained when the missing data are MCAR, since then the complete cases are a random subsample of the original sample with respect to all variables. However, complete-case analysis can result in the loss of a substantial amount of information available in the incomplete cases, particularly if the number of variables is large.

A serious problem with dropping incomplete cases is that the complete cases are often easily seen to be a biased sample, that is, the missing data are not MCAR. The size of the resulting bias depends on the degree of deviation from MCAR, the amount of missing data, and the specifics of the analysis. In sample surveys this motivates strenuous attempts to limit unit nonresponse though multiple follow-ups, and surveys with high rates of unit nonresponse (say 30 percent or more) are often considered unreliable for making inferences to the whole population.

A modification of CC analysis, commonly used to handle unit nonresponse in surveys, is to weight respondents by the inverse of an estimate of the probability of response. A simple approach is to form adjustment cells (or subclasses) based on background

variables measured for respondents and nonrespondents; for unit nonresponse adjustment, these are often based on geographical areas or groupings of similar areas based on aggregate socioeconomic data. All nonrespondents are given zero weight and the nonresponse weight for all respondents in an adjustment cell is then the inverse of the response rate in that cell. This method removes the component of nonresponse bias attributable to differential nonresponse rates across the adjustment cells, and eliminates bias if within each adjustment cell respondents can be regarded as a random subsample of the original sample within that cell (i.e., the data are MAR given indicators for the adjustment cells).

With more extensive background information, a useful alternative approach is *response propensity* stratification, where (a) the indicator for unit nonresponse is regressed on the background variables, using the combined data for respondents and nonrespondents and a method such as logistic regression appropriate for a binary outcome; (b) a predicted response probability is computed for each respondent based on the regression in (a); and (c) adjustment cells are formed based on a categorized version of the predicted response probability. Theory (Rosenbaum and Rubin 1983) suggests that this is an effective method for removing nonresponse bias attributable to the background variables when unit nonresponse is MAR.

Although weighting methods can be useful for reducing nonresponse bias, they do have serious limitations. First, information in the incomplete cases is still discarded, so the method is inefficient. Weighted estimates can have unacceptably high variance, as when outlying values of a variable are given large weights. Second, variance estimation for weighted estimates with estimated weights is problematic. See *Estimation: Point and Interval*. Explicit formulas are available for simple estimators such as means under simple random sampling (Oh and Scheuren 1983), but methods are not well developed for more complex problems, and often ignore the component of variability arising from estimating the weight from the data.

Available-case (AC) analysis (Little and Rubin 1987 Sect. 3.3) is a straightforward attempt to exploit the incomplete information by using all the cases available to estimate each individual parameter. For example, suppose the objective is to estimate the correlation matrix of a set of continuous variables $Y_1, \ldots, Y_p$. See *Multivariate Analysis: Overview*. Complete-case analysis uses the set of complete cases to estimate all the correlations; AC analysis uses all the cases with both Y_j and Y_k observed to estimate the correlation of Y_j and Y_k, $1 \leqslant j, k \leqslant p$. Since the sample base of available cases for measuring each correlation includes at least the set of complete cases, the AC method appears to make better use of available information. The sample base changes from correlation to correlation, however, creating potential problems when the missing data are not MCAR or variables are highly correlated. In the presence of high correlations, there is no guarantee that the AC correlation matrix is even positive definite. Haitovsky's (1968) simulations concerning regression with highly correlated continuous data found AC markedly inferior to CC. On the other hand, Kim and Curry (1977) found AC superior to CC in simulations based on weakly correlated data. Simulation studies comparing AC regression estimates with maximum likelihood (ML) under normality (Sect. 6) suggest that ML is superior even when underlying normality assumptions are moderately violated (Little 1988a). Although AC estimates are easy to compute, standard errors are more complex. The method cannot be generally recommended, even under the restrictive MCAR.

4. *Single Imputation*

Methods that impute or fill in the missing values have the advantage that, unlike CC analysis, observed values in the incomplete cases are retained. A simple version of the method imputes missing values by their unconditional sample means based on the observed data. This method can yield satisfactory point estimates of means and totals, but it yields inconsistent estimates of other parameters such as variances, covariance matrices or regression coefficients, and it overstates precision (Little and Rubin 1987, Chap. 3). Thus it cannot be recommended in any generality.

An improvement is *conditional mean* imputation, in which each missing value is replaced by an estimate of its conditional mean given the values of observed values. For example, in the case of univariate nonresponse with $Y_1, \ldots, Y_{p-1}$ fully observed and Y_p sometimes missing, one approach is to classify cases into cells based on similar values of observed variables, and then to impute missing values of Y_p by the within-cell mean from the complete cases in that cell. A more general approach is regression imputation, in which the regression of Y_p on $Y_1, \ldots, Y_{p-1}$ is estimated from the complete cases, and the resulting prediction equation is used to impute the estimated conditional mean for each missing value of Y_p. For a general pattern of missing data, the missing values for each case can be imputed from the regression of the missing variables on the observed variables, computed using the set of complete cases. Iterative versions of this method lead (with some important adjustments) to ML estimates under multivariate normality (Little and Rubin 1987, Chap. 8).

Although conditional mean imputation incorporates information from the observed variables and yields best predictions of the missing values in the sense of mean squared error, it leads to distorted estimates of quantities that are not linear in the data, such as percentiles, correlations and other measures of

association, as well as variances and other measures of variability. A solution to this problem of point estimation is to use random draws rather than best predictions to preserve the distribution of variables in the filled-in data set. An example is *stochastic regression* imputation, in which each missing value is replaced by its regression prediction plus a random error with variance equal to the estimated residual variance.

Hot-deck methods impute actual values observed in the dataset. An example is the Current Population Survey (CPS) hot deck for imputing income items in that survey. For each nonrespondent on one or more income items, the CPS hot-deck finds a matching respondent based on variables that are observed for both; the missing income items for the nonrespondent are then replaced by the respondent's values. When no match can be found for a nonrespondent based on all of the variables, the algorithm searches for a match at a lower level of detail, obtained by omitting some variables and collapsing the categories of others. A more general approach to hot-deck imputation matches nonrespondents and respondents using a distance function based on the observed variables. For example, *predictive mean matching* (Little 1988b) that have similar predictive means from a regression of the missing variable on observed variables. This method is somewhat robust to misspecification of the regression model used to create the matching metric.

The imputation methods discussed so far assume the missing data are MAR. In contrast, models that are not missing at random (NMAR) assert that even if a respondent and nonrespondent to Y_p appear identical with respect to observed variables $Y_1, \ldots, Y_{p-1}$, their Y_p-values differ systematically. Lillard et al. (1986), for example, discussed NMAR imputation models for missing CPS data. It is also possible to create a NMAR hot-deck procedure; for example, respondents' values that are to be imputed to nonrespondents could be multiplied by an inflation or deflation factor that depends on the variables that are observed. A crucial point about the use of NMAR models is that there is never direct evidence in the data to address the validity of their underlying assumptions. Thus, whenever NMAR models are being considered, it is prudent to consider several NMAR models and explore the sensitivity of analyses to the choice of model (Rubin 1977, Little and Wang 1996).

5. *Multiple Imputation*

A serious defect with imputation is that it invents data. A single imputed value cannot represent the uncertainty about which value to impute, so analyses that treat imputed values just like observed values generally underestimate uncertainty, even if nonresponse is modeled correctly and randomly drawn imputations are created. Large-sample results show that for simple situations with 30 percent of the information missing, single imputation under the correct model results in nominal 90 percent confidence intervals having actual coverages below 80 percent. The inaccuracy of nominal levels is even more extreme in multiparameter testing problems (Rubin 1987, Chap. 4).

A modification of imputation that fixes this problem is multiple imputation (MI) (Rubin 1987). Instead of imputing a single set of draws for the missing values, a set of M (say $M = 5$) datasets are created, each containing different sets of draws of the missing values from their joint predictive distribution. We then apply the standard complete-data analysis to each of the M datasets and combine the results in a simple way. In particular for scalar estimands, the MI estimate is the average of the estimates from the M datasets, and the variance of the estimate is the average of the variances from the five datasets plus $1+1/M$ times the sample variance of the estimates over the M datasets (The factor $1+1/M$ is a small-M correction). The last quantity here estimates the contribution to the variance from imputation uncertainty, missed (i.e., set to zero) by single imputation methods. Another benefit of multiple imputation is that the averaging over datasets results in more efficient point estimates than does single random imputation. Often MI is not much more difficult than doing a single imputation—the additional computing from repeating an analysis M times is not a major burden, and methods for combining inferences are straightforward. Most of the work involves generating good predictive distributions for the missing values, which is needed for consistent point estimation in any case. A more detailed discussion of multiple imputation appears elsewhere in this encyclopedia.

6. *Maximum Likelihood for Ignorable Models*

There are statistical methods that allows the analysis a nonrectangular dataset without having to impute the missing values. In particular, maximum likelihood (ML) avoids imputation by formulating a statistical model and basing inference on the likelihood function of the incomplete data. Define Y and M as above, and let X denote an $(n \times q)$ matrix of fixed covariates, assumed fully observed, with ith row $x_i = (x_{i1}, \ldots, x_{iq})$ where x_{ij} is the value of covariate X_j for subject i. Covariates that are not fully observed should be treated as random variables and modeled with the set of Y_j's (Little and Rubin 1987 Chap. 5). The data and missing-data mechanism are modeled in terms of a joint distribution for Y and M given X. *Selection models* specify this distribution as:

$$f(Y, M \mid X, \theta, \psi) = f(Y \mid X, \theta) f(M \mid Y, X, \psi) \quad (1)$$

where $f(Y \mid X, \theta)$ is the model in the absence of missing values, $f(M \mid Y, X, \psi)$ is the model for the missing-

data mechanism, and θ and ψ are unknown parameters. The likelihood of θ, ψ given the data Y_{obs}, M, X is then proportional to the density of Y_{obs}, M given X regarded as a function of the parameters θ, ψ, and this is obtained by integrating out the missing data Y_{mis} from Eqn. (1), that is:

$$L(\theta, \psi \mid Y_{obs}, M, X) = \text{const} \times \int f(Y, M \mid X, \theta, \psi)\, dY_{mis} \quad (2)$$

The likelihood of θ *ignoring the missing-data mechanism* is obtained by integrating the missing data from the marginal distribution of Y given X, that is:

$$L(\theta \mid Y_{obs}, X) = \text{const} \times \int f(Y \mid X, \theta)\, dY_{mis} \quad (3)$$

The likelihood (3) is easier to work with than (2) since it is easier to handle computationally; more important, avoids the need to specify a model for the missing-data mechanism, about which little is known in many situations. Hence it is important to determine when valid likelihood inferences are obtained from (3) instead of the full likelihood (2). Rubin (1976) showed that valid inferences about θ are obtained from (3) when the data are MAR, that is:

$$p(M \mid X, Y, \psi) = p(M \mid X, Y_{obs}, \psi) \quad \text{for all } Y_{mis}, \psi$$

If in addition θ and ψ are distinct in the sense that they have disjoint sample spaces, then likelihood inferences about θ based on (3) are equivalent to inferences based on (2); the missing-data mechanism is then called *ignorable* for likelihood inferences. Large-sample inferences about θ based on an ignorable model are based on ML theory, which states that under regularity conditions

$$\theta - \hat{\theta} \sim N_k(0, C) \quad (4)$$

where $\hat{\theta}$ is the value of θ that maximizes (3), and $N_k(0, C)$ is the k-variate normal distribution with mean zero and covariance matrix C, given by the inverse of an information matrix; for example $C = I^{-1}(\hat{\theta})$ where I is the observed information matrix $I(\theta) = -\partial^2 \log L(\theta \mid Y_{obs}, X)/\partial\theta\partial\theta^T$, or $C = J^{-1}(\hat{\theta})$ where $J(\theta)$ is the expected value of $I(\theta)$. As in (Little and Rubin 1987), Eqn. (4) is written to be open to a frequentist interpretation if $\hat{\theta}$ is regarded as random and θ fixed, or a Bayesian interpretation if θ is regarded as random and $\hat{\theta}$ fixed. Thus if the data are MAR, the likelihood approach reduces to developing a suitable model for the data and computing $\hat{\theta}$ and C.

In many problems maximization of the likelihood to compute $\hat{\theta}$ requires numerical methods. Standard optimization methods such as Newton-Raphson or Scoring can be applied. Alternatively, the *Expectation-Maximization* (EM) algorithm (Dempster et al. 1977) can be applied, a general algorithm for incomplete data problems that provides an interesting link with imputation methods. The history of EM, which dates back to the beginning of this century for particular problems, is sketched in Little and Rubin (1987) and McLachlan and Krishnan (1997).

7. *The EM Algorithm for Ignorable Models*

For ignorable models, let $L(\theta \mid Y_{obs}, Y_{mis}, X)$ denotes the likelihood of θ based on the hypothetical complete data $Y = (Y_{obs}, Y_{mis})$ and covariates X. Let $\theta^{(t)}$ denote an estimate of θ at iteration t of EM. Iteration $t+1$ consists of an E-step and M-step. The E-step computes the expectation of $\log L(\theta \mid Y_{obs}, Y_{mis}, X)$ over the conditional distribution of Y_{mis} given Y_{obs} and X, evaluated at $\theta = \theta^{(t)}$, that is, $Q(\theta \mid \theta^{(t)}) = \int \log L(\theta \mid Y_{obs}, Y_{mis}, X) f(Y_{mis} \mid Y_{obs}, X, \theta^{(t)})\, dY_{mis}$. When the complete data belong to an exponential family with complete-data sufficient statistics S, the E-step simplifies to computing expected values of these statistics given the observed data and $\theta = \theta^{(t)}$, thus in a sense 'imputing' the sufficient statistics. The M-step determines $\theta^{(t+1)}$ to maximize $Q(\theta \mid \theta^{(t)})$ with respect to θ. In exponential family cases, this step is the same as for complete data, except that the complete-data sufficient statistics S are replaced by their estimates from the E-step. Thus the M-step is often easy or available with existing software, and the programming work is mainly confined to E-step computations. Under very general conditions, each iteration of EM strictly increases the loglikelihood, and under more restrictive but still general conditions, EM converges to a maximum of the likelihood function. If a unique finite ML estimate of θ exists, EM will find it.

Little and Rubin (1987) provided many applications of EM to particular models, including: multivariate normal data with a general pattern of missing values and the related problem of multivariate linear regression with missing data; robust inference based on multivariate t models; loglinear models for multiway contingency tables with missing data; and the general location model for mixtures of continuous and categorical variables, which yields ML algorithms for logistic regression with missing covariates. An extensive bibliography of the myriad of EM applications is given in Meng and Pedlow (1992).

The EM algorithm is reliable but has a linear convergence rate determined by the fraction of missing information. Extensions of EM (McLachlan and Krishnan 1997) can have much faster convergence: ECM, ECME, AECM, and PX-EM (Liu et al. 1998). EM-type algorithms are particularly attractive in problems where the number of parameters is large. Asymptotic standard errors based on bootstrap methods (Efron 1994) are also available, at least in simpler situations. An attractive alternative is to switch to a Bayesian simulation method that simulates the posterior distribution of θ (see Sect. 9).

8. Maximum Likelihood for Nonignorable Models

Nonignorable, non-MAR models apply when missingness depends on the missing values (see Sect. 2). A correct likelihood analysis must be based on the full likelihood from a model for the joint distribution of Y and M. The standard likelihood asymptotics apply to nonignorable models providing the parameters are identified, and computational tools such as EM, also apply to this more general class of models. However, often information to estimate both the parameters of the missing-data mechanism and the parameters of the complete-data model is very limited, and estimates are sensitive to misspecification of the model. Often a sensitivity analysis is needed to see how much the answers change for various assumptions about the missing-data mechanism.

There are two broad classes of models for the joint distribution of Y and M. *Selection* models model the joint distribution as in Eqn. (1). *Pattern-mixture* models specify:

$$f(Y, M \mid X, \pi, \phi) = f(Y \mid X, M, \phi) f(M \mid X, \pi) \quad (5)$$

where ϕ and π are unknown parameters, and now the distribution of Y is conditioned on the missing-data pattern M (Little 1993). Equations (1) and (5) are simply two different ways of factoring the joint distribution of Y and M. When M is independent of Y, the two specifications are equivalent with $\theta = \phi$ and $\psi = \pi$. Otherwise (1) and (5) generally yield different models. Rubin (1977) and Little (1993) also consider *pattern-set mixture* models, a more general class of models that includes pattern-mixture and selection models as special cases.

Although most of the literature on missing data has concerned selection models of the form (1) for univariate nonresponse, pattern-mixture models seem more natural when missingness defines a distinct stratum of the population of intrinsic interest, such as individuals reporting 'don't know' in an opinion survey. However, pattern-mixture models can also provide inferences for parameters θ of the complete-data distribution, by expressing the parameters of interest as functions of the pattern-mixture model parameters ϕ and π. An advantage of the pattern-mixture modeling approach over selection models is that assumptions about the form of the missing-data mechanism are sometimes less specific in their parametric form, since they are incorporated in the model via parameter restrictions. This idea is explained in specific normal models in Little and Wang (1996), for example.

Heitjan and Rubin (1991) extended the formulation of missing-data problems via the joint distribution of Y and M to more general incomplete data problems involving coarsened data. The idea is replace the binary missing-data indicators by coarsening variables that map the y_{ij} values to coarsened versions $z_{ij}(y_{ij})$. Full and ignorable likelihoods can be defined for this more general setting. This theory provides a bridge between missing-data theory and theories of censoring in the survival analysis literature. The EM algorithm can be applied to ignorable models by including the missing data (or coarsening) indicator in the complete-data likelihood.

9. Bayesian Simulation Methods

Maximum likelihood is most useful when sample sizes are large, since then the log-likelihood is nearly quadratic and can be summarized well using the ML estimate of θ and its large sample variance-covariance matrix. When sample sizes are small, a useful alternative approach is to add a prior distribution for the parameters and compute the posterior distribution of the parameters of interest. For ignorable models this is

$$\begin{aligned} p(\theta \mid Y_{obs}, M, X) &\equiv p(\theta \mid Y_{obs}, X) \\ &= \text{const} \times p(\theta \mid X) \times f(Y_{obs} \mid X, \theta) \end{aligned}$$

where $p(\theta \mid X)$ is the prior distribution and $f(Y_{obs} \mid X, \theta)$ is the density of the observed data. Since the posterior distribution rarely has a simple analytic form for incomplete-data problems, simulation methods are often used to generate draws of θ from the posterior distribution $p(\theta \mid Y_{obs}, M, X)$. Data augmentation (Tanner and Wong 1987) is an iterative method of simulating the posterior distribution of θ that combines features of the EM algorithm and multiple imputation, with M imputations of each missing value at each iteration. It can be thought of as a small-sample refinement of the EM algorithm using simulation, with the imputation step corresponding to the E-step (random draws replacing expectation) and the posterior step corresponding to the M-step (random draws replacing MLE).

An important special case of data augmentation arises when M is set equal to one, yielding the following special case of the 'Gibbs' sampler.' Start with an initial draw $\theta^{(0)}$ from an approximation to the posterior distribution of θ. Given a value $\theta^{(t)}$ of θ drawn at iteration t:

(a) Draw $Y_{mis}^{(t+1)}$ with density $p(Y_{mis} \mid Y_{obs}, X, \theta^{(t)})$;

(b) Draw $\theta^{(t+1)}$ with density $p(\theta \mid Y_{obs}, Y_{mis}^{(t+1)}, X)$.

The procedure is motivated by the fact that the distributions in (a) and (b) are often much easier to draw from than the correct posterior distributions $p(Y_{mis} \mid Y_{obs}, X)$ and $p(\theta \mid Y_{obs}, X)$. The iterative procedure can be shown in the limit to yield a draw from the joint posterior distribution of Y_{mis}, θ given Y_{obs}, X. The algorithm was termed chained data augmentation in Tanner (1991). This algorithm can be run independently K times to generate K iid draws from the approximate joint posterior distribution of θ and Y_{mis}.

Techniques for monitoring the convergence of such algorithms are discussed in a variety of places (Gelman et al. 1995, Sect. 11.4). Schafer (1996) developed data

augmentation algorithms that use iterative Bayesian simulation to multiply-impute rectangular data sets with arbitrary patterns of missing values when the missing-data mechanism is ignorable. The methods are applicable when the rows of the complete-data matrix can be modeled as iid observations from the multivariate normal, multinomial loglinear or general location models.

10. Overview

Our survey of methods for dealing with missing data is necessarily brief. In general, the advent of modern computing has made more principled methods of dealing with missing data practical (e.g., multiple imputation, Rubin 1996). Such methods are finding their way into current commercial and free software. Schafer (1996) and the forthcoming new edition of Little and Rubin (1987) are excellent places to learn more about missing data methodology.

Statistical Identification and Estimability

A statistical identification problem arises when a sample of infinite size, assumed to be generated by an element of a class of statistical models indexed by a parameter, does not lead to certain knowledge of one or more components of that parameter. Roughly, a model is identified if enough observed data could allow one to distinguish elements of the parameter set from one another.

Statistical identification problems are ubiquitous, occurring in fields as diverse as reliability, optimal control theory, experimental design, and epidemiology. A rich array of statistical identification problems appear in the social sciences: latent structure analysis, factor analysis, and analysis of covariance structures are based on multivariate statistical models that possess, by construction, this problem. Nonresponse and data censoring in the conduct of sample surveys often lead to an identification problem and the problem is a central feature of the analysis of econometric structural equation models and of errors-in-variables regression models. Experimental designs in which treatments are confounded lead to an identification problem. A nonparametric identification problem occurs in the theory of competing risks.

Understanding if a statistical model is identified, non-identified, or unidentified is a necessary prelude to the construction of a sensible method for making inferences about model parameters from observed data.

1. Background

The problem of statistical identifiability appears in economics as early as Pigou (1910). Thurstone discusses identification in his applications of factor analysis to intelligence (1935, 1947) and, in his latent structure analysis of opinion research and attitudes, Lazarsfeld deals with identification issues (1950).

Principal contributions to a rigorous mathematical treatment of the problem began in the 1950s with the work of Haavelmo (1944), Hurwicz (1950), Koopmans et al. (1950) and Koopmans and Reiersøl (1950) and spawned a huge literature on the subject. Fisher (1966) provides a thorough rigorous treatment of identification for simultaneous equation systems. He laid to rest the issue of whether or not identifiability is a discrete or continuous property of parameter estimation by demonstrating that estimators which are consistent given a correct model specification converge in probability to true parameter values as specification error approaches zero. Thus identifiability may be regarded as a continuous property of a set of parameters and small specification errors lead to small inconsistencies in parameter estimation. Rothenberg (1971) and Bowden (1973) extend identification theory to embrace nonlinear models, distinguishing local from global identifiability. Hannan (1969, 1971) generalizes the theory of identification for linear structural equation systems with serially uncorrelated residual errors in another direction: he establishes conditions for identifiability for the important case of auto-regressive moving average error terms (see *Time Series: General*).

Probabilistic models employed in linear system optimal control theory have much in common with econometric structural (simultaneous) equation systems in which observations are measured with random error. In the psychometric literature, the later class of models goes under the acronym LISREL (Linear Structural Relationships). Jöreskog and Sörbom (1984) have developed methods for specifying LISREL model structure, algorithms for calculating various types of parameter estimators and a framework for interpretation of results. As with econometric structural equation systems, applications of LISREL span a wide domain of social science applications, marketing, psychology, sociology, and organizational behavior among them.

A Bayesian treatment of identification began with Dawid (1979) and Kadane's (1974) studies of identification in Bayesian theory and Drèze's (1972), (1974) analysis of econometric simultaneous equation systems from a Bayesian perspective. Identification through a Bayesian lens is currently a vigorous area of research yielding new insights into how to construct meaningful prior distributions for parameters.

2. Example 1

A sample survey is conducted to determine attitudes of individuals in a population toward a particular subject. The sample frame consists of N individuals, each of whose response is classified as either 'Favorable' or 'Unfavorable.' This sample yields $N_{R\cdot}$ respondents and $N_{S\cdot} = N - N_{R\cdot}$ non-respondents. Of the $N_{R\cdot}$ respondents, N_{FR} are classified as 'Favorable' and $N_{UR} = N - N_{FR}$ are classified as 'Unfavorable.' In the absence of information bearing directly on the fraction of non-respondents who would be classified as 'Favorable,' statistics available for inference are N_{FR}, N_{UR}, $N_{S\cdot}$ subject to $N_{FS} + N_{US} = N_{S\cdot}$ and to $N_{FR} + N_{UR} + N_{S\cdot} = N$. Suppose that the process generating data about both respondents and non-respondents is modeled as a double dichotomy with probabilities p_{FR}, p_{UR}, p_{FS} and $p_{US} > 0$ and $p_{FR} + p_{UR} + p_{FS} + p_{US} = 1$ as shown in Table 1. Table 2 shows the corresponding tables for the model of observed data.

The probability distribution for observations N_{FR}, N_{UR} and $N_{S\cdot}$ in Table 1 is proportional to

$$(p_{FS} + p_{US})^{N_{S\cdot}} p_{FR}^{N_{FR}} p_{UR}^{N_{UR}}$$

Observations N_{FR}, N_{UR} and $N_{S\cdot}$ are sufficient for joint inference about $p_{S\cdot} = p_{FS} + p_{US}$, p_{FS} and p_{UR} but even an infinite sample will not lead to knowledge of p_{FS} and p_{US} with certainty: p_{FS} and p_{US} are not identifiable in the presence of non-response as an infinite sample yields knowledge only that p_{FS} and p_{US} satisfy $p_{FS} + p_{US} = p_{S\cdot}$

3. Definitions

A statistical 'model' is a family $\{P_\theta, \theta \in \Theta\}$ of probability distributions indexed by a parameter $\theta \in \Theta$. A statistical 'structure' is P_θ for a particular $\theta = \theta_0 \in \Theta$. Parameters θ and $\theta' \in \Theta$ are 'observationally equivalent' if and only if $P_{\theta'}(A) = P_{\theta'}(A)$ for all A in a measurable space $\mathscr{S}$.

Definition: Θ is 'identifiable' if and only if $\theta = \theta'$ for all observationally equivalent pairs $\theta, \theta' \in \Theta$.

In practice, it is useful to couch these definitions in terms of distribution functions: let X be an observable random variable with range $\mathscr{S}_X$ and distribution function $F_\theta(x) \equiv P(X \leqslant x \mid \theta)$ belonging to a model $\{F_\theta, \theta \in \Theta\}$. If there exists at least one pair (θ, θ') for which $\theta, \theta' \in \Theta$ and $\theta \neq \theta'$ such that $F_\theta(x) = F_{\theta'}(x)$ for

Table 1

	Parameters			Observations		
Favorable (F)	p_{FR}	p_{FS}	$p_{\cdot F}$	N_{FR}	N_{FS}	$N_{\cdot F}$
Unfavorable (U)	p_{UR}	p_{US}	$p_{\cdot U}$	N_{UR}	N_{US}	$N_{\cdot U}$
	$p_{R\cdot}$	$p_{S\cdot}$	1.0	$N_{R\cdot}$	$N_{S\cdot}$	N

Table 2

	Parameters		Observations		
Favorable (F)	p_{FR}		N_{FR}		
Unfavorable (U)	p_{UR}		N_{UR}		
	$p_{R\cdot}$	$p_{S\cdot}$	$N_{R\cdot}$	$N_{S\cdot}$	N

all $x \in \mathscr{S}_x$ then we say that $\boldsymbol{\Theta}$ is 'non-identifiable' by X. If $\boldsymbol{\Theta}$ is not non-identifiable by X it is identifiable. These definitions of identifiability can be recast to embrace nonparametric models as well (Basu 1981, Berman 1963).

4. *Example 2*

In general, unobservables in an 'econometric simultaneous equation model' are restricted to residuals (errors in model equations). A 'factor analysis model,' on the other hand, possesses both unobservable latent and unobservable explanatory variables. Each is a special case of a more general 'structural equation model' in which a 'latent variable model' displaying interactions among latent variables and a 'measurement model' specifying how observable variables are related to latent variables are conjoined. Properties of the covariance matrix of observable variables are at center stage and structural equation test procedures are designed to measure the quality of fit between an observed (sample) covariance matrix $\boldsymbol{\Sigma}$ and a model based covariance matrix $\boldsymbol{\Sigma}(\boldsymbol{\theta})$ indexed by a vector $\boldsymbol{\theta}$ of model parameters.

Even when the structure of relations between observable variables and latent variables and the structure of relations among latent variables are both linear, the model covariance matrix $\boldsymbol{\Sigma}(\boldsymbol{\theta})$ may be a complicated, nonlinear function of elements of the parameter vector $\boldsymbol{\theta}$. In this setting, in order for an element of the parameter vector $\boldsymbol{\theta}$ to be identified it must be an explicit, known function of one or more elements of the sample covariance matrix $\boldsymbol{\Sigma}$ under the hypothesis that $\boldsymbol{\Sigma} = \boldsymbol{\Sigma}(\boldsymbol{\theta})$. (See Bollen (1989) for a comprehensive treatment. Also Hoyle (1995) for applications.) If PDS $\boldsymbol{\Sigma}(\boldsymbol{\theta})$ is $(k \times k)$ it has at most $\frac{1}{2}k(k+1)$ functionally independent components so for $\boldsymbol{\theta}$ to be identifiable, it can possess at most $\frac{1}{2}k(k+1)$ functionally independent components. This is a generic, easy-to-apply, necessary but not sufficient condition for identifiability of $\boldsymbol{\theta}$.

In the notation of Bollen 1989 we have a

Latent Variable Model:

$$\boldsymbol{\eta} = \mathbf{B}^*\boldsymbol{\eta} + \boldsymbol{\Gamma}\boldsymbol{\xi} + \boldsymbol{\zeta}$$

The $(m \times m)$ coefficient matrix $\mathbf{B}^*$ induces interactions among latent endogenous variables $(m \times 1)$ $\boldsymbol{\eta}$, the $(m \times r)$ coefficient matrix $\boldsymbol{\Gamma}$ establishes the effect of exogenous variables $(r \times 1)$ $\boldsymbol{\xi}$ on $\boldsymbol{\eta}$ and $(m \times 1)$ $\boldsymbol{\zeta}$ represents a random residual error term assumed to be uncorrelated with $\boldsymbol{\xi}$ and to possess mean zero and finite (PDS) variance matrix $\boldsymbol{\Psi}$. In addition $\mathbf{B} \equiv \mathbf{I} - \mathbf{B}^*$ is assumed to be nonsingular.

Measurement Model:

$$\mathbf{y} = \boldsymbol{\Lambda}_y\boldsymbol{\eta} + \boldsymbol{\varepsilon}$$
$$\mathbf{x} = \boldsymbol{\Lambda}_x\boldsymbol{\xi} + \boldsymbol{\delta}$$

The elements of the $(p \times m)$ coefficient matrix $\boldsymbol{\Lambda}_y$ determine the magnitude of the effect of levels and changes in levels of latent variables $\boldsymbol{\eta}$ on observable variables $\mathbf{y}$; $(q \times r)$ $\boldsymbol{\Lambda}_x$ relates exogenous variables $\boldsymbol{\xi}$ to observable variables in $\mathbf{x}$ in a similar fashion. Residual errors $(p \times 1)$ $\boldsymbol{\varepsilon}$ and $(q \times 1)$ $\boldsymbol{\delta}$ are random variables, generally assumed to be uncorrelated with one another, with $\boldsymbol{\eta}$ and with $\boldsymbol{\xi}$ and to possess common mean zero, but possibly different (PDS) covariance matrices Θ_ε and Θ_δ respectively.

To be specific, focus on the composition of the variance matrix Var($\mathbf{y}$) of $\mathbf{y}$ as a function of latent variable model parameters $\mathbf{B}$, $\boldsymbol{\Gamma}$, $\boldsymbol{\Phi}$, and $\boldsymbol{\Psi}$ and measurement model parameters $\boldsymbol{\Lambda}_y$ and $\boldsymbol{\Theta}_\varepsilon$:

$$\mathrm{Var}(\mathbf{y}) = \boldsymbol{\Lambda}_y\mathbf{B}^{-1}[\boldsymbol{\Gamma}\boldsymbol{\Phi}\boldsymbol{\Gamma}^t + \boldsymbol{\Psi}](\mathbf{B}^{-1})^t\boldsymbol{\Lambda}_y^t + \boldsymbol{\Theta}_\varepsilon$$

The $(p \times p)$ PDS matrix Var($\mathbf{y}$) possesses $\frac{1}{2}p(p+1)$ functionally independent components. The variance matrix $\mathrm{Var}(\boldsymbol{\varepsilon}) = \boldsymbol{\Theta}_\varepsilon$ alone also possesses $\frac{1}{2}p(p+1)$ functionally independent components and, in the absence of restrictions, other than just $\boldsymbol{\Phi}$ and $\boldsymbol{\Psi}$ are PDS, $\boldsymbol{\Lambda}_y$, $\mathbf{B}$, $\boldsymbol{\Gamma}$, $\boldsymbol{\Phi}$, and $\boldsymbol{\Psi}$ possess $\frac{1}{2}m(m+1) + \frac{1}{2}r(r+1) + m(m+p+r)$ additional functionally independent components. As the above equation suggests, it

can be a formidable task to verify by direct algebraic analysis whether or not a particular model parameter is, or is not identifiable.

Clearly, parameter matrices $\mathbf{\Lambda}_y$, $\mathbf{B}$, $\mathbf{\Gamma}$, $\mathbf{\Phi}$, and $\mathbf{\Theta}_\varepsilon$ cannot be expressed as unique functions of elements of $\mathrm{Var}(\mathbf{y})$ unless restrictions are placed upon them. When one or more components of $\mathbf{B}$ cannot be recovered uniquely as a function of elements of $\mathrm{Var}(\mathbf{y})$, such components are called 'under-identified' or 'non-identified.' A central task then, is to select constraints on latent variable model parameters and measurement model parameters that renders desired parameters 'identifiable.'

If a priori restrictions on parameters of latent variable and measurement model parameters are specified in a way that leads to two or more distinct representations of some components of $\mathbf{B}$ as a function of components of $\mathrm{Var}(\mathbf{y})$, those components of $\mathbf{B}$ are called 'over-identified.' It can happen, of course, that some elements of $\mathbf{B}$ are identified, some are under-identified and others are over-identified. Bartels (1985) provides an easily accessible treatment of these concepts.

A common form of a priori constraint is to 'specify' that some parameter values are equal to zero. For example, if the modeler assumes that $\mathbf{y}$ and $\mathbf{x}$ are measured without error and that $\mathbf{\Lambda}_y = (m \times m)\,\mathbf{I}$, $\mathbf{\Lambda}_x = (r \times r)\,\mathbf{I}$, $\mathrm{Var}(\boldsymbol{\eta}) = \mathrm{Var}(\boldsymbol{\xi}) = \mathbf{\Theta}_\varepsilon = \mathbf{\Theta}_\delta = \mathbf{0}$ and the variance of $\mathbf{y}$ becomes

$$\mathrm{Var}(\mathbf{y}) = \mathbf{B}^{-1}[\mathbf{\Gamma\Phi\Gamma}^t + \mathbf{\Psi}](\mathbf{B}^{-1})^t.$$

If, in turn, as is often the case in econometric applications, exogenous variables $\mathbf{x}$ are assumed to be predetermined and known with certainty, $\mathbf{\Phi} = \mathbf{0}$. With all of these restrictions in force $\boldsymbol{\eta} = \mathbf{y}$, $\boldsymbol{\xi} = \mathbf{x}$ and the latent variable model becomes $\mathbf{B}\,\mathbf{y} = \mathbf{\Gamma z} + \boldsymbol{\delta}$. Then observable $\mathbf{y} = \mathbf{\Pi z} + \mathbf{u}$, with $\mathbf{\Pi} \equiv -\mathbf{B}^{-1}\mathbf{\Gamma}$, $\mathbf{u} = \mathbf{B}^{-1}\boldsymbol{\delta}$ and $\mathrm{Var}(\mathbf{y}) = \mathbf{B}^{-1}\mathbf{\Psi}(\mathbf{B}^{-1})^t \equiv \mathbf{\Omega}$, is called the 'reduced form' of this model.

Provided that predetermined variables $\mathbf{z}$ are uncorrelated with variables $\mathbf{u}$ (weaker assumptions are possible) and that the asymptotic variance matrix of the $\mathbf{z}$'s exists, both $\mathbf{\Pi}$ and $\mathbf{\Omega}$ can be consistently estimated by ordinary least squares. However, the distribution of $\mathbf{y}$ given $\mathbf{z}$ now depends exclusively on parameters $\mathbf{\Pi}$ and $\mathbf{\Omega}$. Pre-multiplication of both sides of $\mathbf{B}\ \mathbf{y} = \mathbf{\Gamma z} + \boldsymbol{\delta}$ by any nonsingular $(m \times m)$ matrix leads to the same reduced form, so all such structures are observationally equivalent and without further restrictions the system is underidentified.

Fisher (1966) provides an elegant and thorough exposition of conditions for identifiability of linear simultaneous equation system model parameters. Among the most important are 'order' and 'rank' conditions established by Koopmans et al. (1950). Suppose interest focuses on a single equation and that exclusion restrictions alone on $\mathbf{y}$ and $\mathbf{z}$ are in force. A (necessary but not sufficient) 'order condition' for parameters of this equation to be identifiable is that the number of variables excluded be greater than or equal to $m-1$—one less than the number of components in (endogenous) $\mathbf{y}$. Alternatively, the total number of excluded predetermined variables must be greater than or equal to the number of variables not excluded from this equation, less one (Fisher 1966, pp. 40–1).

The following argument due to Fisher is a transparent explanation of the origin of the 'rank condition' for linear simultaneous equation systems, first proved by Koopmans et al. (1950). Exclusion of the lth element of the first row $\mathbf{a}_1$ of $m \times (m+r)\mathbf{A} \equiv [\mathbf{B}, \mathbf{\Gamma}]$ is representable as $\mathbf{a}_1\mathbf{c}^{(l)} = 0$, $\mathbf{c}^{(l)}$ an $(m+r) \times 1$ column vector with a 1 at element l and zeros elsewhere. Thus k such exclusions of distinct variables may be written in terms of $(m+r) \times k$ $\mathbf{C}$ as $\mathbf{a}_1\mathbf{C} = \mathbf{0}$. Clearly if $\mathbf{a}_1$ is some linear combination of other rows of $\mathbf{A}$, it is not identifiable. Thus, a sufficient condition for $\mathbf{a}_1$ to be identified is that $\mathbf{xAC} = \mathbf{0}$ holds only for $(1 \times m)$ $\mathbf{x}$ of the form $= (\alpha, 0, \ldots, 0)$, α a scalar. In the absence of other a priori restrictions on elements of $\mathbf{a}_1$, this condition is also necessary. When it obtains, the rank of $\mathbf{AC}$ must be $m-1$. The order condition follows from the observation that the rank of $\mathbf{AC}$ must be less than or equal to that of $\mathbf{C}$, so the number of independent restrictions imposed by $\mathbf{C}$ must be at least $m-1$.

5. *Estimation*

When a linear statistical model is just identified, both consistent and unbiased estimators of its parameters exist. A more general notion of estimability for linear statistical models, first proposed by Bose (1944, 1947), says that a parameter $\boldsymbol{\theta}$ of such a model is (linearly) estimable if there exists a linear function of observations with expectation equal to $\boldsymbol{\theta}$ for each $\boldsymbol{\theta}$ in a prespecified set $\mathbf{\Theta}$. This special case of identifiability, apparently developed independently of the more general theory of identification outlined in this review, has generated a large literature of its own (see *Factor Analysis and Latent Structure: Overview*).

Deistler and Seifert (1978) address the interplay between identification and estimability for a quite general (possibly nonlinear) version of an econometric structural equation model without measurement error. They answer the question 'When, for such systems, does identifiability imply existence of consistent estimators?'

Jöreskog (1973) and Wiley (1973) were among the first to specify practical procedures for estimation of parameters by analysis of the covariance structure of observations generated by a general structural equation model of the form described in Example 2. For a detailed description of parameter estimation via maximum likelihood, instrumental variables and least squares see, for example, Jöreskog and Sörbom (1984).

Simultaneous Equation Estimates (Exact and Approximate), Distribution of is a crisp summary of methods designed to recover consistent estimates of structural equation parameters, such as Full Information Maximum Likelihood (FIML), Limited Information Maximum Likelihood (LIML), R-class estimators, two- and three-stage least squares (2 SLS, 3 SLS). A more leisurely presentation of econometric simultaneous equation system identification issues, couched in terms of a two-equation supply and demand model, and the nature of estimation problems they pose, appears in *Simultaneous Equation Estimation: Overview*.

6. *Bayesian Identification*

Non-Bayesians typically assign exact numerical values to a subset of parameters of a statistical model in order to achieve identification of one or more other parameters. Fisher (1961) suggested broadening this special type of a priori specification by replacing exact numerical values with probabilistic constraints. Drèze (1962) took up the challenge in his treatment of Bayesian identification for simultaneous equation estimation models. As before, let $\mathbf{By}+\mathbf{\Gamma z}=\mathbf{u}$ be a 'structural equation system' indexed by matrix parameters consisting of nonsingular $\mathbf{B}$, $\mathbf{\Gamma}$, and PDS $\mathrm{Var}(\mathbf{u})=\mathbf{\Sigma}$ with reduced form $\mathbf{y}=\mathbf{\Pi z}+\mathbf{v}$, $\mathbf{\Pi}=-\mathbf{B}^{-1}\mathbf{\Gamma}$ and disturbance variance $\mathrm{Var}(\mathbf{v})=\mathbf{B}^{-1}\mathbf{\Sigma}(\mathbf{B}^{-1})^{t}\equiv\mathbf{\Omega}$. Because the likelihood function for observations $\mathbf{y}$ can be written as a function of reduced form parameters $\mathbf{\Pi}$ and $\mathbf{\Omega}$ alone, full knowledge of the exact numerical values of elements of $\mathbf{\Pi}$ and $\mathbf{\Omega}$ does not permit recovery of unique values for elements of $\mathbf{B}$, $\mathbf{\Gamma}$, and $\mathbf{\Sigma}$. The map from $\mathbf{\Pi}$ and $\mathbf{\Omega}$ to $\mathbf{B}$, $\mathbf{\Gamma}$, and $\mathbf{\Sigma}$ is one to many. In effect, all nonsingular matrices $\mathbf{B}$ are observationally equivalent and $\mathbf{B}$ is only identifiable in the special case when $f(\mathbf{B}\,|\,\mathbf{\Pi},\mathbf{\Omega})$ is concentrated on a single point in the space of nonsingular matrices $\mathbf{B}$. Nevertheless, one can assign a prior density $g(\mathbf{B},\mathbf{\Gamma},\Sigma)$ to structural parameters, observe data $(\mathbf{Y},\mathbf{Z})$ and compute a posterior density $f(\mathbf{B},\mathbf{\Gamma},\mathbf{\Sigma}\,|\,\mathbf{Y},\mathbf{Z})$ for $\mathbf{B}$, $\mathbf{\Gamma}$, and $\mathbf{\Sigma}$ whether or not the model is identified in a classical sense. Because identifiability is a property of the likelihood function alone, if a proper prior distribution is assigned to a complete set of parameters ($\boldsymbol{B}$, $\mathbf{\Pi}$, and $\mathbf{\Omega}$ here) the posterior for these parameters is proper whether or not the likelihood function is identified. Such priors must be chosen judiciously: too tight a prior will anchor the posterior on the prior until sample size becomes very large; a very loose proper prior may fail to reflect relevant prior knowledge. In order to streamline computation of posteriors, Raiffa and Schlaifer (1961) introduced the concept of 'natural conjugate' priors. The functional form of a natural conjugate prior is derived by interpreting parameter as sufficient statistic and sufficient statistic as parameter in the likelihood function. A consequence is that both prior and posterior possess the same functional form, a form dictated by the shape of the likelihood function. For simultaneous equation systems, multivariate-, matric- and poly-t posterior distributions for parameters follow and figure prominently in work by Drèze (1976), Drèze and Morales (1976), Drèze and Richard (1983), and Mouchard (1976). (See *Bayesian Statistics*.)

To minimize the impact of a priori evidence or, in some cases, to exploit invariance with respect to mapping from one representation of a parameter to another, a diffuse (vague, noninformative) prior can be the prior of choice. However, in some settings, this choice comes at a cost as a diffuse prior may lead to an improper posterior. Lindley and El Sayeed (1968) foreshadow much recent work on the character of diffuse priors. They were perhaps the first to recognize several important features of prior to posterior analysis. First, a proper prior always yields a proper posterior. Second, '…in the functional relationship problem [improper priors] can cause considerable difficulties….' Third, even when the likelihood function is not identifiable, observed data can lead to a posterior that is informative; i.e., different from the prior. Fourth, 'Uncritical use of improper distributions can lead to inconsistent estimates.'

A simple example often used to introduce the idea of nonidentifiability highlights issues raised by diffuse priors.

7. *Example 3*

Suppose observations to be independent, identically normal with mean $\theta=\mu_1+\mu_2$ and variance 1. Then μ_1 and μ_2 are non-identifiable. Nevertheless, assignment of a proper prior to μ_1 and μ_2 leads to a proper posterior. As the number of observations approaches infinity, the posterior for θ converges in distribution to a true value θ_0 of θ and the (proper) posterior for μ_1 and μ_2 concentrates on the line $\theta_0=\mu_1+\mu_2$.

If, however, a diffuse prior $d\mu_1$, $-\infty<\mu_1<\infty$, is assigned to μ_1 and proper prior $g(\theta)$ to θ, the posterior for μ_1 remains diffuse irrespective of sample size. Replace the proper prior $g(\theta)$ for θ with a proper prior $h(\mu_2)$ for μ_2. Then, provided the prior for μ_1 is diffuse, the posterior for μ_2 remains the same as the prior $h(\mu_2)$, no matter how many observations are made.

These features of Example 3 suggest that uncritical choice of a diffuse prior can lead to a posterior with unsatisfactory or even unacceptable properties, in particular when the parameter space is of large dimension. For example, Kleibergen and Van Dijk (1997) point out that for simultaneous equation systems '… the order condition reflects overall identification while the rank condition reflects local (non) identification.' They show that local non-identification coupled with a diffuse prior leads to posterior pathology when one attempts Limited Information analy-

sis of a single equation and suggest an alternative approach. (See Gelfand and Sahu (1999) for other examples.)

Dawid (1979) and Kadane (1974) use conditional independence as a device for a definition of non-identifiability which embraces both Bayesian and non-Bayesian perspectives. Suppose that an observable X possesses a distribution F_θ determined by a parameter $\boldsymbol{\theta}$ which we partition into two pieces $\boldsymbol{\theta}_1$ and $\boldsymbol{\theta}_2$. If the distribution of $\boldsymbol{X}$ is fully determined by $\boldsymbol{\theta}_1$ alone, $\boldsymbol{\theta} = (\boldsymbol{\theta}_1, \boldsymbol{\theta}_2)$ is non-identifiable.

When a Bayesian assigns a prior distribution $g(\boldsymbol{\theta})$ to $\boldsymbol{\theta}$, Bayes theorem tells her that the posterior distribution $f(\boldsymbol{\theta}|\mathbf{y})$ for a parameter $\boldsymbol{\theta}$ given data $\mathbf{y}$ is proportional to the product of the likelihood function $\mathbf{L}(\boldsymbol{\theta}|\mathbf{y})$ for $\boldsymbol{\theta}$ given $\mathbf{y}$ and the prior $g(\boldsymbol{\theta})$ assigned to $\boldsymbol{\theta}$. The (posterior) distribution for $\boldsymbol{\theta}_2$ given $\boldsymbol{\theta}_1$ and data $\mathbf{y}$ given prior $g(\boldsymbol{\theta}) = g(\boldsymbol{\theta}_2|\boldsymbol{\theta}_1)h(\boldsymbol{\theta}_1)$ is

$$f(\boldsymbol{\theta}_2|\boldsymbol{\theta}_1, \mathbf{y}) \propto \mathbf{L}(\boldsymbol{\theta}_1, \boldsymbol{\theta}_2|\mathbf{y})g(\boldsymbol{\theta}_2|\boldsymbol{\theta}_1)h(\boldsymbol{\theta}_1)$$

If $\boldsymbol{\theta}_2$ is absent from the likelihood function,

$$f(\boldsymbol{\theta}_2|\boldsymbol{\theta}_1, \mathbf{y}) \propto g(\boldsymbol{\theta}_2|\boldsymbol{\theta}_1)h(\boldsymbol{\theta}_1|\mathbf{y}) \propto g(\boldsymbol{\theta}_2|\boldsymbol{\theta}_1)$$

so that while data will modify her prior judgements about $\boldsymbol{\theta}_1$, no amount of observable data $\mathbf{y}$ will change her a priori probability assessment $g(\boldsymbol{\theta}_2|\boldsymbol{\theta}_1)$ for $\boldsymbol{\theta}_2$ given $\boldsymbol{\theta}_1$. Data $\mathbf{y}$ is, however, unconditionally informative about $\boldsymbol{\theta}_2$; as data accrues and we learn more about $\boldsymbol{\theta}_1$, prior judgements about $\boldsymbol{\theta}_2$ are modified in accord with

$$f(\boldsymbol{\theta}_2|\mathbf{y}) \propto \int g(\boldsymbol{\theta}_2|\boldsymbol{\theta}_1)h(\boldsymbol{\theta}_1|\mathbf{y})\,\mathrm{d}\boldsymbol{\theta}_1$$

provided that both $g(\boldsymbol{\theta}_2|\boldsymbol{\theta}_1)$ and $h(\boldsymbol{\theta}_1|\mathbf{y})$ are proper distributions.

Return to Example 1. As Bayesians, (noting that $\mathrm{p}_{FR}+\mathrm{p}_{UR}+\mathrm{p}_{FS}+\mathrm{p}_{US} = 1$), we assign a prior distribution $g(\mathrm{p}_{FR}, \mathrm{p}_{UR}, \mathrm{p}_{FS})$ to p_{FR}, p_{UR}, p_{FS}. If observed data $\mathrm{y} = (\mathrm{N}_{S\cdot}, \mathrm{N}_{FR}, \mathrm{N}_{UR})$ is generated in accord with Table2, the likelihood function for p_{FR}, p_{UR}, p_{FS},

$$[1-\mathrm{p}_{FR}-\mathrm{p}_{UR}]^{N_{S\cdot}}\,\mathrm{p}_{FR}^{\mathrm{N}_{FR}}\mathrm{p}_{UR}^{\mathrm{N}_{UR}}$$

does not depend on p_{FS}. Consequently,

$$f(\mathrm{p}_{FS}|\mathrm{p}_{FR}, \mathrm{p}_{UR}, \mathbf{y}) \propto g(\mathrm{p}_{FS}|\mathrm{p}_{FR}, \mathrm{p}_{UR})$$

This matches our intuition: given $\mathrm{p}_{FR}+\mathrm{p}_{UR} = \alpha$ we then know with certainty that $\mathrm{p}_{FS}+\mathrm{p}_{US} = 1-\alpha$, p_{FS}, $\mathrm{p}_{US} \geqslant 0$. Data of type $(\mathrm{N}_{S\cdot}, \mathrm{N}_{FR}, N_{\mathrm{UR}})$ refines our knowledge about the value of α, but even an infinite sample of this type will not lead to knowledge certain of p_{FS}. The conditional distribution of p_{FS} given $\mathrm{p}_{FR}+\mathrm{p}_{UR} = \alpha$ prior to observing $\mathbf{y}$ is the same as the conditional distribution of p_{FS} given $\mathrm{p}_{FR}+\mathrm{p}_{UR} = \alpha$ posterior to observing $\mathbf{y}$.

While the theory of identification in a classical statistical context is now well understood, the story of identification from a Bayesian viewpoint is still unfolding. Markov Chain Monte Carlo [MCMC] methods breathe new life into Bayesian inference, allowing efficient computation of normalizing constants and parameter estimates for complex models. An explosion of Bayesian application of MCMC methods surfaces new identification issues. In their study of Bayesian identifiability for 'Generalized Linear Models' (GLMs), Gelfand and Sahu (1999) present conditions under which assignment of an improper prior distribution to some components of a parameter set leads to a proper posterior distribution. More particularly, if a posterior distribution for parameters is improper, under what conditions does there exist a lower-dimensional parameter set that possesses a proper posterior distribution? Ghosh et al. (2000) prove that when data $\mathbf{y}$ is uninformative about $\boldsymbol{\theta}_2$ given $\boldsymbol{\theta}_1$ so that $\boldsymbol{\theta}_2$ is not identifiable, the posterior density $f(\boldsymbol{\theta}_2, \boldsymbol{\theta}_1|\mathbf{y})$ is proper if and only if both $h(\boldsymbol{\theta}_1|\mathbf{y})$ and $g(\boldsymbol{\theta}_2|\boldsymbol{\theta}_1)$ are proper, a fact that Gelfand and Sahu use to establish that for GLMs at least, even when the posterior distribution for all parameters is improper, there are embedded lower dimensional models that possess a proper posterior distribution, although in general, that distribution is not uniquely determined. (See Gelfand and Sahu (1999) for conditions that guarantee uniqueness.) They warn, however, that model fitting using MCMC methods is '…somewhat of an art form, requiring suitable trickery and turning to obtain results in which we can have confidence.'

Statistical Methods, History of: Post-1900

1. Introduction

In *Statistical Methods for Research Workers*, Fisher (1925) characterizes statistics as '(i) the study of populations, (ii) the study of variation, (iii) the study of methods of the reduction of data.' This is still the field of statistics in a nutshell. The three forms of studies are interwoven, and one thread cannot fully be understood without the other in the fabric of statistics that they weave.

During the early decades of the twentieth century, the theory of probability and of statistical methodology of the least-squares tradition from Laplace and Gauss continued to be developed and the two fields married permanently. Methods of regression, correlation, and analysis of variance found their final form. As did survey sampling, which was given a probabilistic footing. The discussion of Bayesian analysis and inverse probability continued and led to a split between the frequentist and the Bayesian schools of thought.

This period also saw the emergence of fundamentally new ideas and methodologies. Statistical inference, e.g., in the forms of hypothesis testing and confidence interval estimation, was identified as distinct from data description. Parametric models, allow-

ing exact inference, even for small samples, were found, and led to constructive concepts of inductive logic and optimality for estimation and testing.

This impressive development in the concepts and methods peaked with Fisher's 1922 paper. It was a paradigmatic revolution of statistics, along those of Laplace and Gauss around 1800 (Hald 1998). It took about 20 years and many papers for each of these authors to work out their basic ideas in detail and it took half a century for the rest of the statistical community to understand and develop the new methods and their applications.

The impact of statistics on society and the social sciences also changed and expanded fundamentally. Statistical thinking spread and was integrated in several of the social sciences as part of their basic thinking. The development of psychology, sociology and economics was influenced in essential ways by statistics and statistics itself benefited from ideas and methods developed in these fields, as well as in biology and other sciences.

2. *Impacts of Statistics on the Social Sciences*

The term 'statistics' has its origin in the social sciences. Statistics meant the assemblage of numerical data describing the state, its population, institutions etc., with focus on the particulars. With Adolphe Quetelet this changed. Statistical mass phenomena attracted more and more interest from social scientists throughout the nineteenth century. It was asked whether distributions in society followed laws of chance, such as the binomial, the Poisson, and the normal distribution. Most phenomena were found to show 'supernormal' variation, and the question arose whether the population could be stratified to obtain 'normal' variation within strata.

The emphasis in statistical work changed around 1900 from the general study of variability to more specific issues. Statistical data were requested and brought forward into discussions of social policy and social science. In 1910, Karl Pearson and Ethel M. Elderton, for example, gathered data to see whether children of heavy drinkers were more disabled than other children. Their conclusion (Elderton and Pearson 1910) was in the negative:

> the alcoholic propensities of parents seemed utterly unrelated to any measurable characteristics of the health or intelligence of offsprings, and what relations were found were as likely to be the reverse of what the temperance movement expected as not.

Stigler (1999) summarizes this paper and the ensuing discussion with the leading economist Alfred Marshall and others. Pearson (letter to the *Times*, 12 July 1910) scolded the economists for only arguing theoretically and not bringing forward empirical support:

> to refute these data the only method is to test further equally unselected material … Professor Marshall suggested that the weaklings among the sober had grandparents who were profligate. This may be so but, as a statistician, I reply: 'Statistics—and unselected statistics—on the table, please.' I am too familiar with the manner in which actual data is met with the suggestion that other data, if collected, might show another conclusion to believe it to have any value as an argument. 'Statistics on the table, please,' can be my sole reply.

The call for focused unbiased statistics spread, and the growth in statistical data was impressive both in official statistics and in social and other sciences. The toolbox of statistical methods also grew and the concepts and methods were steadily used more widely.

Even though statistics and probability originated in the social sphere with gambling, insurance and social statistics, statistical thinking in the modern sense came late to the core social sciences. It was, in a sense, easier for Gauss to think statistically about errors in his measurement of the deterministic speed of a planet and for the experimental psychologist to randomize their design and to use corresponding statistical models in the analysis, than it was for Pearson to study how children were affected by their parents' drinking and than it was for the economists to study business cycles. The difficulty is, according to Stigler (1999) that statistics has a much more direct role in defining the object of study in the social sciences. This relative unity of statistical and subject matter concepts was a taxing challenge that delayed progress. When statistical thinking took hold, however, the fields themselves changed fundamentally and received new energy.

This delayed but fundamental impact of statistics can be traced in various disciplines. Consider the study of business cycles. Good times follow bad times, but are these cycles of business regular in some way? While the nineteenth century economists mostly were looking for particular events that caused 'crises' in the economy, Karl Marx and others started to look for regular cyclic patterns. Moving averages and other linear filtering techniques were used to remove noise and trend from the series to allow cycles of medium length to be visible. Statisticians worried whether a cycle of wavelength 20 years were due to the data or to the filtering methods. George Udny Yule found in 1926 that 'nonsense correlations' between time series of finite length are prone to show up and stand conventional tests of significance simply because of internal auto-correlation. He had earlier coined the term 'spurious correlation,' but found that nonsense-correlation are flukes of the data that 'cannot be explained by some indirect catena of causation' (Yule 1926). Eugene Slutsky's Russian paper of 1927 made things even worse for descriptive business cycle analysis. By a simulation experiment using numbers drawn in the People's Commissariat of Finance lottery, he demonstrated that linear filters can produce seemingly

regular cycles out of pure noise. It has later been found that the filter used to find the popular 20-year cycles tends to produce 20-year cycles even from random data.

Slutsky's experiment and Yule's analysis highlighted the limitations of model-free descriptive statistical analysis. It gradually became clear that economic data had to be interpreted in light of economic theory, and the field of econometrics emerged. This revolution peaked with Trygve Haavelmo's *Probability Approach in Econometrics* (1944). Mary S Morgan (1990) holds further that the failure of descriptive business cycle analysis was instrumental in the development of dynamic models for whole economies, starting with the work of Ragnar Frisch and Jan Tinbergen.

Other disciplines saw similar developments of delayed but fundamental impact of statistical methodology, but perhaps not to the same extent as economics. The study of intelligence and personality was, for example, transformed and intensified by the advent of statistical factor analysis stemming from Spearman (1904) and Thurstone (1935).

3. *Statistics Transformed*

3.1 *The Study of Populations*

Populations can be real, such as the population of Norway in 1894 with respect to the number of sick and disabled. Theoretical populations, on the other hand, are the hypothetical possible outcomes of an experiment, an observational study, or a process in society or nature.

For finite realized populations, Kiær proposed in 1895 to the International Statistical Institute that his representative method should be considered as an alternative to the method of the day, which was to take a complete census. The idea of survey sampling was extensively debated and was gradually accepted internationally. Results from Kiær's 1894 survey of sickness and disability were, however, questioned in Norway by Jens Hjorth. He had no problem with sampling *per se* but he criticized the particulars of the survey and the questionnaire. From actuarial reasoning he claimed that Kiær had underestimated the number of disabled. At issue was a proposed universal insurance system for disability and Hjorth argued that a snapshot picture of the population obtained from a survey would be insufficient. Estimates of transition probabilities to disability were also needed. In the background of Hjorth's reasoning was, in effect, a theoretical population, e.g., a demographic model, with disability probabilities by age, occupation group and other determinants as primary parameters. Equipped with the statistical competence of the day, Hjorth presented error bounds based on the binomial distribution for the fraction of disabled and he discussed the sample size necessary to obtain a given precision for various values of the true fraction. Kiær apparently did not understand probability. In 1906, he had to concede that the number of disabled was grossly underestimated in his 1894 survey, and he became silent on his representative method for the rest of his life.

This debate over survey sampling continued over the ensuing decades until Jerzy Neyman (1934) described in clear and convincing form the modern frequentist probability model for survey sampling including stratification, cluster sampling, and other schemes. Neyman's model for a survey of a given finite population can be seen as a theoretical population consisting of the collection of all the possible samples that could be drawn, with a probability associated with each.

The distinction between sample quantities and theoretical parameters were not always observed. For example, instead of asking how data could be used to draw inferences about theoretical quantities, Karl Pearson and others proposed to assess the degree of association in two-by-two tables by means of various coefficients, e.g., the coefficients of mean square contingency and tetrachoric correlation, by emphasizing the importance of substantive theory, and the distinction between theoretical and empirical quantities.

R A Fisher cleared up the confusion caused by the wilderness of coefficients. By 1920, he had introduced the notion of 'parameter' for characteristics of the theoretical population and he used the word 'statistics' for estimates, test variables, or other quantities of interest calculated from the observed data. Fisher's interest was not focused on describing data by statistics, but on using them to draw inferences about the parameters of the underlying theoretical population. In the mid-1920s, Fisher pursued these notions of inference and he incorporated his evolving principles of statistical estimation into a new chapter in the second 1928 edition of his pioneering 1925 book, *Statistical Methods for Research Workers*. Here he presented his new measure of the statistical information in the data with respect to a particular parameter and he stressed the importance of using efficient estimators. Fisher's ideas were based on the concept of a parametric statistical model that embodies both the substative theory, e.g., relevant aspects of Mendel's theory of genetics, and a probabilistic description of the data generating process, i.e., the variational part of the model. This probabilistic model led Fisher to formulate the likelihood function, which in turn led to a revolutionary new methodology for statistics.

Fisher also picked up on William S. Gosset's 1908 development of the t-distribution for exact inference on the mean of a normal distribution with unknown variance. From a simulation experiment and guided

by distributional forms developed by Karl Pearson, Gosset guessed the mathematical form of the *t*-distribution. Later, Fisher was able to prove formally the correctness of Gosset's guess and then go on to show how the *t*-distribution also provided an 'exact solution of the sampling errors of the enormously wide class of statistics known as regression coefficients.' (Fisher 1925)

3.2 The Study of Variation

There are two related aspects of the term variation: uncertainty in knowledge, and sampling variability in data, estimates or test statistics. In the tradition of inverse probability stemming from Thomas Bayes, no distinction was drawn between uncertainty and variation. This inverse-sampling probability tradition dominated well into the twentieth century, although unease with some of the implicit features was expressed repeatedly by some critics as early as the mid-nineteenth century.

Inverse probability is calculated via Bayes' theorem, which turns a prior distribution of a parameter coupled with a conditional distribution of the data given the parameter into a posterior distribution of the parameter. The prior distribution represents the *ex ante* belief/uncertainty in the true state of affairs and the posterior distribution represents the *ex post* belief. The prior distribution is updated in the light of new data.

Before Fisher, statistical methods were based primarily on inverse probability with flat prior distributions to avoid subjectivity, if they were grounded at all in statistical theory. Fisher was opposed to the Bayesian approach to statistics. His competing methodology avoided prior distributions and allowed inference to be based on observed quantities only. When discussing Neyman's paper on survey sampling Fisher (1934), stated:

> All realized that problems of mathematical logic underlay all inference from observational material. They were widely conscious, too, that more than 150 years of disputation between the *pros* and the *cons* of inverse probability had left the subject only more befogged by doubt and frustration.

The likelihood function was the centerpiece of Fisher's methodology. It is the probability density evaluated at the observed data, but regarded as a function of the unknown parameter. It is proportional to the posterior density when the prior distribution is flat. The maximum-likelihood estimate is the value of the parameter maximizing the likelihood. Fisher objected, however, to the interpretation of the normed likelihood function as a probability density. Instead, he regarded the likelihood function and hence the maximum likelihood estimator as a random quantity, since it is a function of the data which are themselves considered random until observed.

To replace the posterior distribution, he introduced the fiducial distribution as a means of summing up the information contained in the data on the parameter of interest. In nice models, the fiducial distribution spans all possible confidence intervals by its stochastic quantiles. A confidence-interval estimator for a parameter is a stochastic interval obtained from the data, which under repeated sampling bounds the true value of the parameter with prescribed probability, whatever this true value is. Neyman was the great proponent of this precise concept. He even claimed to have introduced the term 'degree of confidence,' overlooking Laplace, who had introduced the large sample error bounds and who spoke of '*le degré de confiance*' in 1816 (Hald 1998). Fisher's fiducial argument helped to clarify the interpretation of error bounds as confidence intervals, but Fisher and Neyman could not agree.

Neyman thought initially that confidence intervals, which he introduced in his (1934) paper on sampling, were identical to Fisher's fiducial intervals and that the difference lay only in the terminology. He asked whether Fisher had committed a '*lapsus lingua*' since Fisher spoke of fiducial probability instead of degree of confidence (Neyman 1941). Neyman's point was that no frequentist interpretation could be given for the fiducial probability distribution since it is based on the observed data *ex post* and is a distribution over the range of the parameter. He shared with Fisher the notion of the parameter having a fixed but unknown value and to characterize it by a probability distribution made no sense to him. Fisher stressed, however, that his fiducial distribution is based on the logic of inductive reasoning and provides a precise representation of what is learned from the observed data. He could not see that the frequentist property of the confidence interval method allowed one to have 'confidence' in the actually computed interval. That intervals computed by the method in hypothetical repetitions of the experiment would cover the truth with prescribed frequency was of some interest. It was, however, the logic and not this fact that made Fisher say that the computed interval contained the parameter with given fiducial probability.

Harrold Hotelling (1931) staked out an intermediate position. He generalized Gosset's *t*-distribution to obtain confidence regions for the mean vector of multivariate normal data with unknown variance-covariance matrix. He concluded

> confidence corresponding to the adopted probability P may then be placed in the proposition that the set of true values [the mean vector] is represented by a point within this boundary [the confidence ellipsoid].

Although fierce opponents on matters of inference, Fisher and Neyman agreed that inverse probability had left the subject only more 'befogged by doubt and frustration' (Fisher 1934) and they united in their fight against Bayesianism. The tradition from Bayes survived, however. One solution to the flawed indifference

principle is to go subjective. By interpreting the prior distribution as a carrier of the subjective belief of the investigator before he sees the data, the posterior distribution is interpreted correspondingly, as representing the subjective believes *ex post* data. This was the approach of Bruno de Finetti. Harold Jeffreys proposed another solution. He argued that the prior should be based on the statistical model at hand. For location parameters, the flat prior is appropriate since it is invariant with respect to translation. Scale parameters, like the standard deviation, should have flat priors on the logarithmically transformed parameter. These and other priors were canonized from invariance considerations.

The basic idea of statistical hypotheses testing had been around for some 200 years when Karl Pearson developed his chi-square test in 1900 (Hald 1998). The chi-square test and Gosset's t-test initiated a renewed interest in the testing of statistical hypotheses. A statistical test is a probabilistic twist of the mathematical proof by contradiction: if the observed event is sufficiently improbable under the hypothesis, the hypothesis can reasonably be rejected. Fisher formulated this logic in his p-value for tests of significance.

A given statistical hypothesis can usually be tested by many different test statistics calculated from the data. Fisher argued that the likelihood ratio was a logical choice. The likelihood ratio is the ratio of the likelihood at the unrestricted maximum to the likelihood maximized under the hypothesis. Neyman and Egon S. Pearson, son of Karl Pearson, were not satisfied with this reasoning. They looked for a stronger foundation on which to chose the test. From Gosset, they took the idea to formulate the alternative to the hypothesis under test. To them, testing could result either in no conclusion (there is not sufficient support in the data to reject the null hypothesis), or in a claim that the alternative hypothesis is true rather than the null hypothesis.

The alternative hypothesis, supposed to be specified *ex ante*, reflects the actual research interest. This led Neyman and Pearson to ask which test statistic would maximize the chance of rejecting the null hypothesis if indeed this hypothesis and not the null hypothesis is true, when the probability of falsely rejecting the null hypothesis is controlled by a pre-specified level of significance. In nice problems, they found the likelihood ratio statistic to produce the optimal test in 1933. This result is the jewel of the Neyman–Pearson version of frequentist inference. As important as their optimality result is, perhaps, their emphasis on the alternative hypothesis, the power of the test, and the two types of error (false positive and false negative conclusion) that might occur when testing hypotheses.

Gauss asked in 1809 whether there exists a probability distribution describing the statistical variability in the data that makes the arithmetic mean the estimator of choice for the location parameter. He showed that the normal distribution has this property and that his method of least squares for linear parameters is indeed optimal when data are normally distributed. This line of research was continued. The distribution that makes the geometric mean the estimator of choice was found and John M. Keynes discussed estimating equations and showed that the double exponential distribution makes the median an optimal estimator. In 1934 Fisher followed up with the more general exponential class of distributions. When the statistical model is within this class, his logic of inductive inference gives unambiguous guidance.

Probability remained as the underpinning of formal statistical methods and the probability theory saw many advances in the early twentieth century, particularly in continental Europe. The Central Limit Theorem, which is at the heart of Laplace's approximate error bounds, was strengthened. Harald Cramér (1946) summed up this development and he exposed its statistical utility since many estimators and other statistics are approximately linear in the observations and thus are approximately normally distributed. Related to the Central Limit Theorem is the use of series expansions to find an approximation to the distribution of a statistic. Thorvald N. Thiele completed his theory of distributional approximation by way of half invariants, which Fisher later rediscovered under the name of cumulants. Francis Y Edgeworth proposed another series expansion in 1905 (see Hald 1998). Probability theory is purely deductive and should have an axiomatic basis. Andrei N Kolmogoroff gave probability theory a lasting axiomatic basis in 1933, see Stigler (1999) who calls 1933 a magic year for statistics.

3.3 The Study of Methods of the Reduction of Data

Raw statistical data need to be summarized. Fisher (1925) says

> no human mind is capable of grasping in its entirety the meaning of any considerable quantity of numerical data. We want to be able to express all *relevant* information contained in the mass by means of comparatively few numerical values … It is the object of the statistical process employed in the reduction of data to exclude the irrelevant information, and to isolate the whole of the relevant information contained in the data.

It is theory that dictates whether a piece of data is relevant or not. Data must be understood in the light of subject matter theory. This was gradually understood in economics, as well as in other fields. Fisher (1925) showed by examples from genetics how theory could be expressed in the statistical model through its structural or parametric part. The likelihood function is, for Fisher, the bridge between theory and data. Fisher introduced the concept of sufficiency in 1920: a statistic is sufficient if the conditional distribution of the data given the value of the statistic is the same for

all distributions within the model. Since statistics having a distribution independent of the value of the parameter of the model is void of information on that parameter, Fisher was able to separate the data into its sufficient (informative) statistics, and ancillary (non-informative) statistics.

The likelihood function is sufficient and thus carries all the information contained in the data. In nice cases, notably when the model is of the exponential class, the likelihood function is represented by a sufficient statistic of the same dimensionality as the parameter. It might then be possible to identify which individual statistic is informative for which individual parameter. If, say, the degree of dependency expressed by the theoretical odds ratio in a two by two contingency table is what is of theoretical interest, the marginal counts are ancillary for the parameter of interest. Fisher suggested therefore conditional inference given the data in the margins of the table. In the testing situation, this he argued leads to his exact test for independence. Conditional inference is also often optimal in the Neyman–Pearson sense.

4. Conclusion

Statistical theory and methods developed immensely in the first third of the twentieth century with Fisher as the driving force. In 1938, Neyman moved from London to Berkeley. The two men were continents apart and kept attacking each other. The question is, however, whether this was more grounded in personal animosity than real scientific disagreement (Lehmann 1993). In the US, where Neyman's influence was strong, there has been a late-twentieth-century resurgence in Fisherian statistics (Efron 1998) and even more so in Bayesian methods. Fisher and Neyman both emphasized the role of the statistical model. Both worked with the likelihood function, and suggested basically the same reduction of the data. Fisher gave more weight to the logic of inductive reasoning in the particular case of application, while Neyman stressed the frequentistic properties of the method. To the applied research worker, this boils down to whether the level of significance or the confidence coefficient should be chosen *ex ante* (Neyman), or whether data should be summarized in fiducial distributions or *p*-values. These latter *ex post* benchmarks are then left to the reader of the research report to judge.

Over the period, probabilistic ideas and statistical methods were slowly dispersed and were applied in new fields. Statistical methods gained foothold in a number of sciences, often through specialized societies like Econometric Society and through journals such as *Econometrica* from 1933 and *Psychometrica* from 1936.

Statistical inference was established as a new field of science in our period, but it did not penetrate empirical sciences before World War II to the extent that research workers in the various fields were required to know its elements (Hotelling 1940). Statistical ideas caught the minds of eminent people in the various sciences, however, and new standards were set for research. Fisher's *Statistical Methods for Research Workers* has appeared in 14 editions over a period of 47 years. His ideas and those of Neyman and others spread so far and so profoundly that C Radhakrishna Rao (1965) declared, perhaps prematurely, statistics to be the technology of the twentieth century.

Statistical Methods, History of: Pre-1900

Statistics first assumed its recognizably modern form, as a set of tools and rationales for analyzing quantitative data, during the decade of the 1890s. Even then, it remained a far-flung and heterogeneous endeavor. Before this time, statistical methods were developed and put to use in the context of a variety of scientific and bureaucratic activities. These were sometimes recognized as analogous, but there were no common textbooks, nor even a shared name. The history of statistical methods up to 1900 means an examination of the development of statistical knowledge in various social and intellectual settings, and of the migration of techniques and understandings among them. The fields involved include mathematical probability, observational astronomy, quantitative natural history, physics, and an array of social science projects.

1. From Political Arithmetic to Statistics, 1660–1830

The name 'statistics' was coined in eighteenth-century Germany for a descriptive science of states. Whether or not statistical descriptions should involve numbers was left open at first. After 1800, in the polarizing era of the French Revolution, this question became more ideological, and the mere purveying of numerical tables was denounced for its slavishness, and for viewing the state as lifeless and mechanical. It thus entailed a change of mentality, suggestive also of new structures of government and administration, when this 'state science' began to be defined in terms of the collection and deployment of numbers. That happened first in Britain and France, where it was largely settled by 1840. The new science of statistics was closely related to censuses and other official information agencies, which expanded enormously in this same period (Hacking 1990).

The new statistics, commonly called a science, was practiced mainly by reformers and administrators. Its methods involved organization and classification rather than mathematics. Procuring reliable numbers, then as now, was no small achievement. Among those who hoped to move this social science in the direction of finding laws and abstract relationships, the highest priority was to standardize categories. In this way, they hoped, the 'statist' could compare rates of crime, disease, or illegitimacy across boundaries, and try to discover how they varied according to nationality, language, religion, race, climate, and legal arrangements. Such figures might also enable them to predict the potential for improvement if, for example, laws were changed or educational systems were put in place. A series of statistical congresses beginning in 1853 undertook to negotiate statistical uniformity, with very little success.

The comparative neglect of mathematics among the social statisticians was not simply a consequence of a lack of appropriate tools. Social numbers had been collected since the late seventeenth century under the rubric of 'political arithmetic,' a bolder and more freewheeling enterprise than statistics. John Graunt, a tradesman by origin, was elected to the Royal Society of London for his 'Observations upon the Bills of Mortality' (1662), a compilation and analysis of mortality records. William Petty, rather more daring, used what figures he could procure to calculate such quantities as the total wealth of Britain, including the monetary value of its human lives. On this basis he even proposed modestly to increase the wealth of the nation by transporting the Irish to England. In the eighteenth century, probability theory was deployed by the most illustrious of mathematicians to investigate social numbers. Jakob Bernoulli's *Ars conjectandi* (1713) addressed the convergence of observed ratios of events to the underlying probabilities. A discussion was provoked by the discovery that male births consistently outnumber female ones, in a ratio of about 14 to 13. In 1712, John Arbuthnot offered a natural theology of these birth numbers. The ratio was nicely supportive of belief in a benevolent God, and indeed of a faith without priestly celibacy, since the excess of male births was balanced by their greater mortality to leave the sexes in balance at the age of marriage. The odds that male births should exceed female ones for 82 consecutive years by 'chance' alone could be calculated, and the vanishingly small probability value stood as compelling evidence of the existence of God. Against this claim, Nicolas Bernoulli of the famous Swiss mathematical family showed that the steadiness of these odds required no providential intercession, but was about what one would anticipate from repeated tosses of dice with—he revised slightly the ratios—18 sides favoring M and 17 F (Hacking 1975).

Pierre Simon Laplace investigated birth ratios in the 1780s, and also discussed how to estimate a population from a partial count. He was party to an alliance in France between mathematicians and administrators, which also included the mathematician and philosopher Condorcet (Brian 1994). Laplace's population estimate was based on a registry of births for all of France, and on the possibility of estimating the ratio of total population to births through more local surveys. Proceeding as if the individuals surveyed were independent, and the birth numbers accurate, Laplace

used inverse probabilities to specify how many should be counted (771,469) in order to achieve odds of 1,000 to 1 against an error greater than half a million. The estimated population, which had to be fed into the previous calculation, was 25,299,417, attained by multiplying the average of births in 1781–2 by a presumed ratio of 26 (Gillispie 1997).

Laplace and Condorcet wrote also about judicial probabilities. Supposing a jury of 12, requiring at least 8 votes to convict, and that each juror had a specified, uniform probability of voting correctly, these mathematicians could calculate the risk of unjust convictions and undeserved acquittals. They also determined how the probabilities would change if the number of jurors were increased, or the required majority adjusted. The study of judicial probabilities reached its apex in the 1830s when Siméon-Denis Poisson made ingenious use of published judicial records to inform the calculations with empirical content. By this time, however, the whole topic had become a dinosaur. The use of mathematics to model human judgment now seemed implausible, if not immoral, and inverse probabilities (later called Bayesian) came under challenge (Daston 1988). Political arithmetic had come to seem weirdly speculative, and probabilistic population estimates both unreliable and unnecessary. In the new statistical age, sound practice meant a complete census. On this basis, some of the more mathematical methods of statistical reasoning were rejected around 1840 in favor of empirical modesty and bureaucratic thoroughness. Not until the twentieth century was sampling restored to favor.

One important application of probability to data grew up and flourished in place of these old strategies and techniques. That was the method of least squares. The problem of combining observations attracted a certain amount of attention in the eighteenth century. The first formal method to gain wide acceptance was worked out between about 1805 and 1810. It was initially published in 1805 by the French mathematician Adrien-Marie Legendre, who was then at work on the problem of measuring a line of meridian in order to fix the meter. Carl Friedrich Gauss asserted soon afterwards that he had already been employing least squares for several years, though there are reasons not to take his claim at face value (Stigler 1999, Chaps. 17 and 20). From 1809 to 1811, Gauss and then Laplace published probabilistic derivations of the method, and provided interpretations that shaped much of its subsequent history (see *Gauss, Carl Friedrich (1777–1855)*). Particularly crucial was its connection to what became known as the astronomer's error law, and later as the Gaussian or normal distribution. Gauss derived least squares by assuming that errors of observations conform to this law. Laplace showed how the error curve would be produced if each observation was subject to a host of small disturbances, which could equally well be positive or negative. The mathematics of error, and of least squares, formed the topic for a line of mathematical publications throughout the century. It provided a means of analyzing quantitative data in astronomy, meteorology, surveying, and other related observational sciences. Later, through a paradoxical transformation, the same mathematics was used to describe and analyze variation in nature and society.

2. *Social Science and Statistical Thinking*

The mathematical tools of statistics worked out by Laplace and Gauss were extended but not decisively changed in the period from 1830 to 1890. They engaged the attention of some excellent mathematicians, including Auguste Bravais, I.-J. Bienaymé, and A.-L. Cauchy (Hald 1998). The work of the Russian school of probability theory, initiated by P. L. Chebyshev, had consequences for statistical methods. But the really decisive development in this period involved statistics as a form of reasoning, worked out mainly in relation to social science, and involving, for the most part, comparatively rudimentary mathematics. This *statistical thinking* arose first of all in relation to the social science that bore the name 'statistics.' Statistics as a method was conceived by analogy to this substantive science. It was, to rely here on anachronistic terms, less a mode of *inference* than a family of *models*. They involved, at the most basic level, the production of collective order from the seemingly irregular or even chaotic behavior of individuals.

Like most discoveries, this one had ostensible precedents. Since, however, the Belgian Adolphe Quetelet had in the 1820s learned probability from Laplace, Poisson, and Joseph Fourier in Paris, and published several memoirs on vital statistics, his astonishment in 1829 should count for something. In that year, inspired by newly published French statistics of criminal justice, he attached a preface on crime to a statistical memoir on the Low Countries. He declared himself shocked at the 'frightening regularity with which the same crimes are reproduced,' year after year. He introduced a language of 'statistical laws.' At first he worried that such laws of moral actions might conflict with traditional doctrines of human free will, though he eventually rejected the idea of a 'strange fatalism' in favor of interpreting these laws as properties of a collective, of 'society.' His preoccupation with statistical regularities reflected the new emphasis in moral and political discussion on society as an autonomous entity, no longer to be regarded as subordinated to the state. But there was also something more abstract and, in the broadest sense, mathematical, in Quetelet's insight. It implied the possibility of a quantitative study of mass phenomena, requiring no knowledge at the level of individuals (Porter 1986).

Quetelet was an effective publicist for his discovery, which indeed was not uniquely his. Statistical laws

were widely discussed for half a century in journalism, literature, and social theory by authors like Dickens, Dostoevsky, and Marx. Moralists and philosophers worried about their implications for human freedom and responsibility. Natural scientists invoked social-statistical analogies to justify the application of this form of reasoning to physical and biological questions. The creation of a statistical physics by James Clerk Maxwell, Ludwig Boltzmann, and Josiah Willard Gibbs, and of statistical theories of heredity and evolution by Francis Galton and Karl Pearson, attests to the increasing range of these statistical theories or models. Precisely this expansion made it increasingly credible to define statistics as a method rather than a subject matter. At the same time, a new body of analytical tools began to be formulated from within this discourse, drawing from probability and error theory, but applying and adapting them to issues in social statistics.

The most pressing of these issues was precisely the stability of statistical series. A particularly forceful and uncompromising restatement of Quetelet's arguments in Henry Thomas Buckle's 1857 *History of Civilization in England* provoked an international debate about statistics and free will. One strategy of response was to explore this stability mathematically. The presentation and analysis of time series had long been associated with economic and population statistics, and with meteorology (Klein 1997). These debates provided a new focus. Was there really anything remarkable in the much-bruited regularities of crime, marriage, and suicide? Robert Campbell, schoolboy friend of the physicist Maxwell, published a paper in 1859 comparing Buckle's examples with expectations based on games of chance. He found the social phenomena to be much less regular than were series of random events. In Germany, where statistics was by this time a university-based social science, this question of the stability of social averages formed the core of a new mathematical approach to statistics. Wilhelm Lexis set out to develop tools that could simultaneously raise the scientific standing of statistics and free it from the false dogmas of 'French' social physics.

The normal departure of measured from true ratios in the case of repeated independent random events was expressed by Poisson as $\sqrt{(2pq/n)}$, where p and q are complementary probabilities and n the number of repetitions. Lexis began his investigation of the stability of statistical series in 1876 with a paper on the classic problem of male to female birth ratios. In this case, the tables of annual numbers were reasonably consistent with Poisson's formula. He called this a 'normal dispersion,' though it appeared to be unique. Nothing else—be it rainfall or temperature, or time series of births, deaths, crimes, or suicides, whether aggregated or broken down by sex or age—showed this much stability. He understood Buckle's deterministic claims as implying 'subnormal dispersion,' that is, an even narrower range of variation than the Poisson formula predicted. This could easily be rejected. Lexis's limits of error, defined by three times the Poisson number, corresponded with a probability of about 0.999978. Virtually every real statistical series showed a 'supernormal' dispersion beyond this range.

Laplace and Poisson seemed often to use legal and moral questions as the occasion to show off their mathematics. Lexis was serious in his pursuit of a quantitative social science, one that would reveal the social and moral structure of society. Against Quetelet, who had exalted the 'average man' as the type of the nation, he undertook to show that human populations were highly differentiated—not only by age and sex, but also by religion, language, and region. His program for social science was to begin by disaggregating, seeking out the variables that differentiate a population, and using statistical mathematics to determine which ones really mattered. Society, it could be shown, was not a mere collection of individuals with identical propensities, but a more organic community of heterogeneous groups. The wider than chance dispersions revealed that society was not composed of independent atomic individuals.

3. *Origins of the Biometric School*

Institutionally, the crucial development in the rise of modern methods of statistics was the formation of the biometric school under Karl Pearson at University College, London. The biometric program began as a statistical theory or model of natural processes, not a method of inference or estimation. Francis Galton, who pioneered the statistical study of heredity and evolution, derived his most basic conceptions from the tradition initiated by Quetelet. He was impressed particularly by the error curve, which Quetelet had applied to distributions of human measurements such as height and circumference of chest. Since he regarded the applicability of the error law as demonstrating the reality of his 'average man,' he minimized the conceptual novelty of this move. The mathematics, for him, showed that human variation really was akin to error. Galton strongly rejected this interpretation. The 'normal law of variation,' as he sometimes called it, was important for statistics precisely because it provided a way to go beyond mean values and to study the characteristics of exceptional individuals. The biometricians used distribution formulas also to study evolution, and especially eugenics, to which Galton and Pearson were both deeply committed (MacKenzie 1981).

Galton attached statistics to nature by way of a particulate theory of inheritance, Darwin's 'Pangenesis.' His statistical concepts were also, at least initially, biological ones: 'reversion' meant a partial return of ancestral traits; 'regression' a tendency to return to a

biological type; and 'correlation' referred to the tendency for measures of different bodily parts of one individual to vary in the same direction. By 1890, however, he recognized that his statistical methods were of general applicability, and not limited to biology. Pearson drew his statistical inspiration from Galton's investigations, though he may well have required the mediation of Francis Edgeworth to appreciate their potential (Stigler 1986). Edgeworth, an economist and statistician, was, like Pearson, a skillful and even original mathematician of statistics, but no institution builder.

Thus it was Pearson, above all, who created and put his stamp on this new field. Interpreting it in terms of his positivistic philosophy of science, he strongly emphasized the significance of correlation as more meaningful to science than causation. While he was committed above all to biometry and eugenics, he also gave examples from astronomy, meteorology, and education. Beginning in the mid-1890s, he attracted a continuing stream of postgraduate students, many but not all intending to apply statistics to biology. Among the first was George Udny Yule, an important statistician in his own right, who worked mainly on social and economic questions such as poverty. Pearson fought with many of his students, and also with other statisticians, most notably R. A. Fisher, and his reputation among modern-day statisticians has suffered on this account. Nevertheless, the 1890s were decisive for the history of statistical methods. Their transformation was not exclusively the work of the biometricians. This is also when the Norwegian A. N. Kiaer drew the attention of statisticians once again to the possibilities of sampling, which Arthur Bowley began to address mathematically. These trends in social statistics, along with the new mathematics of correlation and the chi-square test, were part of something larger. This was the modern statistical project, institutionalized above all by Pearson: the development of general mathematical methods for managing error and drawing conclusions from data.

Statistical Pattern Recognition

Statistical pattern recognition is concerned with the problem of using statistical techniques to design machines that can classify patterns of measurement data in useful ways. For example, such techniques have been successfully exploited in areas such as object recognition, speech recognition, fingerprint recognition, data analysis, signal processing, cognitive modeling, and artificial intelligence. After identifying key 'features' of information in the measurement data, a statistical pattern recognition machine uses its expectations about the 'likelihood' of those features and the 'losses' of making situation-specific decisions to select a classification action which minimizes an appropriate expected risk function. In many cases, the statistical pattern recognition machine must 'learn' through experience the relative likelihood of occurrence of patterns of features in its environment. Although typically viewed as a branch of artificial intelligence (see *Decision Support Systems*) statistical pattern recognition methods have been extensively and successfully applied to many behavioral modeling and data analysis problems (see *Multidimensional Scaling in Psychology*; *Multivariate Analysis: Overview*). The present entry discusses some of the essential features of the generic statistical pattern recognition problem (see Andrews 1972, Duda and Hart 1973, Golden 1996, Patrick 1972).

1. Generic Statistical Pattern Recognition Problem

As shown in Fig. 1, the generic statistical pattern recognition problem may be described in terms of four major components: feature selection and feature extraction, probabilistic knowledge representation, Bayes decision rule for classification, and a mechanism for learning.

1.1 Feature Selection and Extraction

The pattern of measurement data to be classified is represented as a measurement vector (i.e., a point in 'measurement space'). The choice of the measurement space is primarily determined by problem-imposed considerations such as the types of transducers which are available and the types of patterns which must be processed. The particular pattern classification methodology embodied in the pattern recognition machine usually has little or no influence over the choice of the measurement space. Each measurement vector is then mapped into a feature vector (i.e., a 'point' in feature space) whose dimensions are primarily chosen to facilitate pattern classification by the pattern recognition machine. This process which maps a measurement vector **s** into a feature vector **x** is called the feature selection and extraction stage of the pattern recognition process.

1.2 Probabilistic Knowledge Representation

Knowledge is implicitly represented in a statistical pattern recognition machine in several ways. The particular process for mapping points in measurement space into feature space (as well as the dimensions of the feature space) is one important knowledge source. However, the expected likelihood of observing a particular feature vector and the associated losses for making different situation-specific decisions are also critical knowledge sources (see *Utility and Subjective Probability: Contemporary Theories*).

Specifically, let the symbol ω denote the pattern class. Thus, ω_1 refers to the first pattern class (e.g., a set of photographs of 'dogs') that might have generated the observed feature vector **x**, while the symbol ω_2 refers to a second competing pattern class (e.g., a set of photographs of 'cats') that might have generated **x**. The likelihood of observing a feature vector **x**, corresponding to a particular pattern class is expressed in terms of two types of probability distributions. The *a priori* class probability distribution $p(\omega_i)$ indicates the likelihood that a feature vector will be generated from the pattern class ω_i before the feature vector **x** has been observed. The class conditional probability distribution $p(\mathbf{x}|\omega_i)$ indicates the conditional likelihood of observing the feature vector **x** given that the feature vector **x** had in fact been generated from pattern class ω_i.

Figure 1
Flow chart diagram of a generic statistical pattern recognition machine. In this example, the sensor array (represented as a measurement vector) detects a pattern of light intensities produced from light reflecting off the head of a dog. A feature selection and extraction stage transforms the measurement vector into a feature vector. Using the feature vector and its probabilistic knowledge representation the pattern recognition machine selects the minimum expected risk decision (i.e., 'Decide Dog')

Knowledge regarding the expected consequences of taking a particular classification action α_j, given the feature vector came from pattern class ω_i is also exploited. Typically, the classification action takes the form of a decision indicating which of a finite number of pattern classes generated the feature vector. Formally, it is assumed that a loss $\lambda(\alpha_j|\omega_i)$ is incurred when classification action α_j is taken when the feature vector was in fact generated from pattern class ω_i.

1.3 Bayes Decision Rule for Classification

The optimal decision rule for selecting a classification action α_j if the pattern class ω_i generated the feature vector simply requires that the classification action α^* which minimizes the loss for the pattern class ω_i be chosen (i.e., $\lambda(\alpha|\omega_i) \geqslant \lambda(\alpha^*|\omega_i)$ for all α). In practice, however, the pattern class ω_i which actually generated the feature vector is unknown. The statistical pattern recognition machine only has access to the observed feature vector **x** and its probabilistic knowledge base.

One possible rational inductive decision making strategy is called the Bayes decision rule for classification; it forms the basis for classification decisions in most statistical pattern recognition algorithms. The Bayes decision rule for classification dictates that the pattern recognition machine should select the classification action α^* which minimizes the expected loss or

conditional risk given feature vector $\mathbf{x}$ is observed. Formally, the risk $R(\alpha|\mathbf{x})$ is defined by the formula:

$$R(\alpha|\mathbf{x}) = \sum_{i=1}^{M} \lambda(\alpha|\omega_i) p(\omega_i|\mathbf{x}) \tag{1}$$

The important minimum probability of error case of Eqn. (1) arises when $\lambda(\alpha_k|\omega_i) = 1$ when $i \neq k$ and $\lambda(\alpha_k|\omega_i) = 0$ for $i = k$. In this case, Eqn. (1) becomes:

$$R(\alpha_k|\mathbf{x}) = \sum_{i \neq k}^{M} p(\omega_i|\mathbf{x}) = 1 - p(\omega_k|\mathbf{x}) \tag{2}$$

The action α_k which minimizes the probability of error case of the risk function in Eqn. (1) is usually called a maximum *a posteriori* (MAP) estimate since α_k maximizes the *a posteriori* distribution $p(\omega_j|\mathbf{x})$ (i.e., the distribution obtained after observing the feature vector $\mathbf{x}$).

Now note that the risk $R(\alpha|\mathbf{x})$ in Eqn. (1) can be expressed in terms of the *a priori* class likelihoods and class conditional likelihoods using the formula:

$$p(\omega_i|\mathbf{x}) = \frac{p(\mathbf{x}|\omega_i)p(\omega_i)}{p(\mathbf{x})} \tag{3}$$

Substituting this expression into Eqn. (1), it follows that the risk, $R(\alpha|\mathbf{x})$, for selecting action α given feature vector $\mathbf{x}$ is observed can be expressed as:

$$R(\alpha|\mathbf{x}) = \left(\frac{1}{p(\mathbf{x})}\right) \sum_{i=1}^{M} \lambda(\alpha|\omega_i) p(\mathbf{x}|\omega_i) p(\omega_i) \tag{4}$$

For computational reasons, some monotonically decreasing function of $R(\alpha_i|\mathbf{x})$ is usually exploited and referred to as a discriminant function $g_i(\mathbf{x})$. For example, a useful discriminant function for Eqn. (4) is:

$$g_i(\mathbf{x}) = -\sum_{i=1}^{M} \lambda(\alpha_i|\omega_i) p(\mathbf{x}|\omega_i) p(\omega_i) \tag{5}$$

which does not require computation of $p(\mathbf{x})$.

Such discriminant functions define 'decision boundaries' in feature space. For example, suppose that there are only two pattern classes with corresponding discriminant functions g_1 and g_2. In this situation, the feature vector $\mathbf{x}$ is classified as a member of pattern class ω_1 if $g_1(\mathbf{x}) - g_2(\mathbf{x}) < 0$ and a member of pattern class ω_2 if $g_1(\mathbf{x}) - g_2(\mathbf{x}) > 0$. Thus, the 'decision boundary' between the two pattern classes in feature space is defined by the set of feature vector which satisfy the equation: $g_1(\mathbf{x}) - g_2(\mathbf{x}) = 0$.

1.4 Learning as Bayes Estimation

Just as the classification problem involves selecting that classification action which minimizes an appropriate expected classification loss function, the learning problem can also be formulated within a minimum expected loss framework as well. Typically, the measurement vector, feature vector mapping from measurement space into feature space, *a priori* class distributions, and loss functions are known. Also the family of class conditional distributions or the 'class conditional probability model' is typically indexed by the values of some model parameter β. Given this latter assumption, a model is a set such that each element is a class conditional probability distribution $p(\mathbf{x}|\omega;\beta)$. The goal of the learning problem is then reduced to the problem of selecting a particular value of the parameter β.

1.4.1 A Bayes risk function for learning. Assume the measurement vector to feature vector mapping, classification decision loss function λ, and *a priori* class probabilities $\{p(\omega_1), \ldots, p(\omega_M)\}$ have been specified. In addition, assume a class conditional probability model defined by a set of class conditional distributions of the form $p(\mathbf{x}|\omega;\beta)$. The learning problem then reduces to the problem of estimating a value of the parameter β given a set of training data.

Let $\mathbf{X}_n = [\mathbf{x}^{(1)}, \ldots, \mathbf{x}^{(n)}]$ denote a set of n feature vectors which define a set of training data. For expository reasons, simply assume $\mathbf{x}^{(1)}, \ldots, \mathbf{x}^{(n)}$ are observed values (realizations) of independent and identically distributed (i.i.d.) random vectors. Let $p(\beta)$ denote the *a priori* probability distribution of β (i.e., the distribution of the parameter vector β before the training data $\mathbf{X}_n$ has been observed). Let $l(\beta, \beta^*)$ denote a loss function associated with the action for selecting a particular value of β when the correct choice of the parameter β is in fact β^*. A popular and general risk function for selecting parameter β given the training data $\mathbf{X}_n$ involves finding a β that minimizes the Bayes risk function for learning (e.g., Patrick 1972 pp. 71–2) given by the formula:

$$E(\beta|\mathbf{X}_n) = \int l(\beta, \beta^*) p(\beta^*|\mathbf{X}_n) d\beta^* \tag{6}$$

The quantity $p(\beta|\mathbf{X}_n)$ (known as the *a posteriori* density or *a posteriori* mass function for parameter vector β) is not explicitly provided since it can be expressed in terms of $p(\mathbf{x}|\omega;\beta)$ (the class conditional likelihood function), $p(\beta)$ (the *a priori* likelihood of β which is not dependent upon the pattern recognition machine's experiences), and the 'training data' $\mathbf{X}_n$. It then follows from the i.i.d. assumption that:

$$p(\beta|\mathbf{X}_n) = \frac{p(\mathbf{X}_n|\beta)}{p(\beta)} = \frac{\prod_{j=1}^{n} p(\mathbf{x}^{(i)}|\beta)}{p(\beta)} \tag{7}$$

For expository reasons, assume β is quantized so that it can take on only a finite number of values. Then minimizing Eqn. (6) using the loss function $l(\beta, \beta^*) = 1$ if $\beta \neq \beta^*$ and $l(\beta, \beta^*) = 0$ if $\beta = \beta^*$ corresponds to

maximizing Eqn. (7) (i.e., computing the MAP estimate or most probable value of β). It can be shown that for many popular *a priori* and class conditional distribution functions, $p(\beta|\mathbf{X}_n)$ can be well approximated by the 'likelihood of the observed data,' $p(\mathbf{X}_n|\beta)$ for sufficiently large sample size n (e.g., Golden 1996 pp. 299–301). Accordingly, a popular approach to parameter estimation known as maximum likelihood estimation involves maximizing the likelihood function $p(\mathbf{X}_n|\beta)$ by selecting a parameter vector value, β_n, such that $p(\mathbf{X}_n|\beta_n) \geqslant p(\mathbf{X}_n|\beta)$ for all β.

1.4.2 Nonparametric and parametric learning algorithms. Learning algorithms that make minimal assumptions regarding how the data was generated are referred to as nonparametric learning algorithms. For such algorithms, the parametric form of the class conditional distribution is often quite flexible. Nonparametric Parzen-window-type learning algorithms (e.g., Duda and Hart 1973, Patrick 1972) essentially count the observed occurrence of different values of the feature vector $\mathbf{x}$. Learning algorithms that incorporate considerable prior knowledge about the data generating process are referred to as parametric learning algorithms. The classical Bayes classifier which assumes that the class conditional distributions have a Gaussian distribution is a good example of a parametric learning algorithm (e.g., Duda and Hart 1973, Patrick 1972).

Nonparametric learning algorithms have the advantage of being relatively 'unbiased' in their analysis of the data but may require relatively large amounts of the right type of training data for effective learning. Parametric learning algorithms are 'biased' algorithms but if the right type of prior knowledge is 'built-in' to the learning algorithm then a parametric learning algorithm can exhibit superior learning from even poor quality training data. Statistical pattern recognition algorithms which are typically viewed as 'nonparametric' can be transformed into parametric learning algorithms if a sufficient number of constraints upon the class conditional distributions are imposed. For example, polynomial discriminant function (e.g., Duda and Hart 1973, Patrick 1972) and the closely related multilayer backpropagation neural network and perceptron type learning algorithms (e.g., Golden 1996; also see *Perceptrons*) can learn to approximate almost any desired form of the class conditional distribution function (given sufficiently many free parameters). Thus, such learning algorithms are best viewed as nonparametric statistical pattern recognition algorithms. On the other hand, prior knowledge in the form of constraints on the parametric form of the class conditional distributions can usually be introduced resulting in parametric variations of such classical nonparametric learning algorithms (e.g., Golden 1996).

1.4.3 Supervised, unsupervised, and reinforcement learning algorithms. Supervised, unsupervised, and reinforcement learning algorithms have the common goal of estimating the class conditional distribution from the training data. The essential difference among these different learning algorithms is the availability of information in the feature vector indicating which pattern class generated the feature vector. In supervised learning, each feature vector in the training data set contains explicit information regarding which pattern class generated that feature vector. In unsupervised learning, information regarding which pattern class generated a particular feature vector is not available in either the training data set or the test data set. In reinforcement learning, 'hints' about which pattern class generated a particular feature vector are provided either periodically or aperiodically throughout the learning process (Sutton and Barto 1998).

2. Applications

2.1 Artificial Intelligence

Statistical pattern recognition methods have been extensively applied in the field of artificial intelligence. Successful applications of these methods in the field of computer vision include extraction of low-level visual information from visual images, edge detection, extracting shape information from shading information, object segmentation, and object labeling (e.g., Chellapa and Jain 1993, Duda and Hart 1973). Statistical pattern recognition methods such as Hidden Markov models play an important role in speech recognition algorithms and natural language understanding (Charniak 1993). Bavesian networks defined on directed acyclic graphs and the closely related Markov random field methods are being applied to problems in inductive inference (Chellapa and Jain 1993, Golden 1996, Jordan 1999). In the fields of robot control and neurocomputing, the general stochastic dynamical system control problem (see *Optimal Control Theory*) is naturally viewed within a statistical pattern recognition framework where the control signal corresponds to the pattern recognition machine's 'action' (Golden 1996).

2.2 Behavioral Modeling

In an attempt to develop and refine theories of human behavior, some psychologists have compared the behavior of a class of statistical pattern recognition machines known as 'connectionist' algorithms with human behavior (see Golden 1996, and Ellis and Humphreys 1999, for some introductory reviews also see *Connectionist Models of Concept Learning*; *Connectionist Models of Development*; *Connectionist Models of Language Processing*). Although such algorithms

are typically not presented within a statistical pattern recognition context, they can usually be naturally interpreted as statistical pattern recognition machines (Golden 1996).

2.3 Data Analysis

Increasingly sophisticated methods for discovering complex structural regularities in large data sets are required in the social and behavioral sciences. Many classical statistical pattern recognition techniques such as factor analysis, principal component analysis, clustering analysis, and multidimensional scaling techniques have been successfully used (see *Multidimensional Scaling in Psychology*; *Multivariate Analysis: Overview*). More sophisticated statistical pattern recognition methods such as artificial neural networks (see *Artificial Neural Networks: Neurocomputation*; *Connectionist Approaches*) and graphical statistical models will form the basis of increasingly more important tools for detecting structural regularities in data collected by social and behavioral scientists.

Statistical Sufficiency

In the language of statistical theory, a statistic is a function of a set of data, and a sufficient statistic contains as much information about the statistical model as the original set of data. Statistical sufficiency has served as a powerful concept in the theory of inference in helping to clarify the role of models and data, and in providing a framework for data reduction.

1. Introduction

Statistical sufficiency is a concept in the theory of statistical inference that is meant to capture an intuitive notion of summarizing a large and possibly complex set of data by relatively few summary numbers that carry the relevant information in the larger data set. For example, a public opinion poll might sample one or two thousand people, but will typically report simply the number of respondents and the percentage of respondents in each of a small number of categories. A study to investigate the effectiveness of a new treatment for weight loss may well report simply the average weight loss of a group of patients receiving the new treatment. This study would usually report as well some measure of the range of weight loss observed; variability in this setting would be a crucial piece of information for evaluating the effectiveness of the new treatment.

In order to make precise the vague notion of an informative data summary, it is necessary to have a means of defining what we mean by relevant information. This in turn is highly dependent on the use we wish to make of the data. The formal mechanism for doing this is to use a *statistical model* to represent a (usually idealized) version of the problem we are studying. Statistical sufficiency and information are defined relative to this model. A statistical model is a family of probability distributions, the central problem of statistical inference being to identify which member of the family generated the data currently of interest. The basic concepts of statistical models and sufficiency were set out in Fisher (1922, 1925) and continue to play a major role in the theory of inference.

For example, we might in an idealized version of the weight-loss problem assume that the potential weight loss for any particular patient can be described by a model in the family of *normal distributions*. This specifies a mathematical formula for the probability that the weight loss of an individual patient falls in any possible interval, and the mathematical formula depends on two unknown parameters, the mean and standard deviation. If we are willing to further assume that the same statistical model applies to all the potential recipients of the weight-loss treatment, then the data collected in a careful study will enable us to

make an inference on the two parameters that depends only on two data summaries: the average weight loss in the data and the standard deviation of the weight loss in the data.

The normal distribution is also referred to as the 'bell curve,' but there is in fact a family of bell curves, each differing from the others by a simple change of mean, which fixes the location of the bell curve, and standard deviation, which fixes the scale of the bell curve. Standardized tests for measuring IQ are designed so that the scores follow a bell-curve model with parameter values for the mean and standard deviation of 100 and 15, respectively. The parameters for the potential weight loss under our hypothetical new treatment are unknown, and the role of the data collected on the treatment is to shed some light on their likely values. Should the weight loss bell curve turn out to be centered at or near zero, one would be wise not to invest too heavily in the new company's stock just yet. As long as we are willing to accept the bell-curve model for the weight loss data, *all* the information about that model is contained in two numbers: the average and the standard deviation of the weight loss recorded in our data set.

An idealized model that lies behind most media reporting of polls is a *Bernoulli* or *binomial* model, in which we assume that potential respondents will choose one of two categories with a fixed but unknown probability, that respondents choose categories independently of each other, and with the same, constant probability. In such an idealized version of the problem, we have complete information about this unknown probability from the knowledge of the number of responses and the proportion of responses in each of the two categories.

These two examples are by construction highly idealized, and it is easy to think quickly of a number of complexities that have been overlooked. An educated reader of report on the weight-loss study would want to know how the patients were selected to receive the new treatment, whether the patients were in any way representative of a population of interest to that reader, whether any comparison has been made with alternative, possibly conventional, treatments, the length of time over which the study was conducted and so on. Public opinion polls typically offer more than two categories of response, even to a 'yes/no' question, including something equivalent to 'don't know,' or 'won't say,' and also often break down the results by gender, geographic area, or some other classification. Randomized selection of respondents by computerized telephone polls is very different to a 'reader response' survey often conducted by magazines and media outlets. These and a wide variety of other issues are studied in the fields of experimental design and sample survey design, by statisticians and researchers in a variety of subject matter areas, from economics to geophysics. See also *Observational Studies: Overview* and *Experimental Design: Overview*.

Statistical sufficiency is concerned with a much narrower issue, that of formalizing the notion that for a given family of models, a complex set of data can be summarized by a smaller collection of numbers, and lead to the same statistical inference. The following sections describe statistical sufficiency with reference to families of models and related concepts in the theory of statistics. Section 2 provides the main definitions and examples, Sect. 3 some related concepts, and Sect. 4 some more advanced topics.

2. *Statistical Models and Sufficiency*

2.1 *Basic Notation*

We describe a statistical model by a *random variable* Y and a family of *probability distributions* for Y, $\mathscr{F}$. A random variable is a variable that takes values on a *sample space*, and a probability distribution describes the probability of observing a particular value or range of values in the sample space. The sample space is in a great many applications either *discrete*, taking values on a countable set such as (some subset of) the nonnegative integers, or *continuous* taking values on (some subset of) the real line $\mathscr{R}$ or p-dimensional Euclidean space $\mathscr{R}^p$. A typical data set will be a number of realizations of Y, and the goal is to use these observations to deduce which member of $\mathscr{F}$ generated these realizations. The members of $\mathscr{F}$ are often conveniently indexed by the probability mass function or probability density function $f(y)$, where

$$f(y) = \text{Prob}(Y = y) \tag{1}$$

if the sample space is discrete, and

$$f(y) = \lim_{h \to 0} h^{-1}\{\text{Prob}(Y \leqslant y + h) - \text{Prob}(Y \leqslant y)\} \tag{2}$$

if the sample space is continuous. If Y is a vector then Prob $(Y \leqslant \text{y})$ is defined component-wise, i.e. Prob $(Y_1 \leqslant y_1, \ldots, Y_p \leqslant y_p)$.

Very often the mathematical form of the probability distributions in $\mathscr{F}$ is determined up to a finite number of unknown constants called parameters, so we write $\mathscr{F}_\theta = \{f(\cdot;\theta)\}$, or more precisely $\mathscr{F}_\theta = \{f(\cdot;\theta);\ \theta \in \Theta\}$, where Θ is a set of possible values for θ, such as the real numbers $\mathscr{R}$ or real-valued vectors of fixed length p, $\mathscr{R}^p$, or [0, 1], and so on. The problem of using data to make an inference about the probability distribution is now the problem of making inference about the parameter θ, and is referred to as *parametric inference*. Sufficiency also plays a role in *nonparametric inference* as well, and we illustrate this at the end of this section.

We assume in what follows that the random variable $Y = (Y_1, \ldots, Y_n)$ is a vector of length n with observed

valued $y = (y_1,\ldots, y_n)$. A *statistic* is a function $T = t(Y)$ whose distribution can be computed from the distribution of Y. Examples of statistics include the mean, $T_1 = n^{-1}\Sigma Y_i$, the variance $T_2 = (n-1)^{-1}\Sigma (Y_i - T_1)^2$, the standard deviation $T_3 = T_2^{1/2}$, the range $T_4 = \max Y_i - \min Y_i$, and so on. The probability distribution of any statistic is obtained from the probability distribution for Y by a mathematical calculation.

2.2 Sufficiency and Minimal Sufficiency

A statistic $T = t(Y)$ is sufficient for θ in the family of models $\mathscr{F}_\theta = \{f(y; \theta); \theta \in \Theta\}$ if and only if its conditional distribution

$$f_{Y|T}(y \mid t) \tag{3}$$

does not depend on θ.

Example 1. Suppose $Y_1,\ldots, Y_n$ are independent and identically distributed with probability mass function

$$f(y_i; \theta) = \theta^{y_i}(1-\theta)^{1-y_i}, \quad y_i = 0, 1; \quad \theta \in [0, 1] \tag{4}$$

which can be used to model the number of successes in n independent Bernoulli trials, when the probability of success if θ. The joint density for $Y = (Y_1,\ldots, Y_n)$ is

$$f(y; \theta) = \prod \theta^{y_i}(1-\theta)^{1-y_i} = \theta^{\Sigma y_i}(1-\theta)^{n-\Sigma y_i} \tag{5}$$

and the marginal density for $T = \Sigma Y_i$ is

$$f(t; \theta) = \sum_{y:\Sigma y_i = t} \theta^{\Sigma y_i}(1-\theta)^{n-\Sigma y_i} = \theta^t(1-\theta)^{n-t}c(t, n) \tag{6}$$

where $c(t,n) = n!/t!(n-t)!$ is the number of vectors y of length n with t ones and $n-t$ zeroes. The conditional density of Y, given T, is the ratio of (5) and (6) and is thus free of θ.

The intuitive notion that the definition is meant to encapsulate is that once the sufficient statistic T is observed, i.e. once we condition on T, no further information about the θ is available from the original data Y.

The definition of sufficiency in terms of the conditional distribution is not very convenient to work with, especially in the case of continuous sample spaces where some care is needed in the definition of a conditional distribution. The following result is more helpful.

Factorization theorem. A statistic $T = t(Y)$ is sufficient for θ in the family of models $\mathscr{F}_\theta = \{f(y; \theta); \theta \in \Theta\}$ if and only if there exist functions $g(t; \theta)$ and $h(y)$ such that for all $\theta \in \Theta$

$$f(y; \theta) = g(t; \theta)h(y) \tag{7}$$

Example 2. Let $Y_1,\ldots, Y_n$ be independent, identically distributed from the normal distribution with mean μ and standard deviation σ:

$$f(y_i; \mu, \sigma) = \frac{1}{\sqrt{(2\pi)}\sigma} \exp\left\{-\frac{1}{2\sigma^2}(y_i - \mu)^2\right\} \tag{8}$$

The joint density of $Y = (Y_1,\ldots, Y_n)$ is

$$\begin{aligned} f(y; \mu, \sigma) &= \left(\frac{1}{\sqrt{2\pi}\sigma}\right)^n \exp\left\{-\frac{1}{2\sigma^2}\sum(y_i - \mu)^2\right\} \\ &= \frac{1}{\sigma^n} \exp\left\{-\frac{1}{2\sigma^2}\sum(y_i - \bar{y})^2 + \frac{n}{2\sigma^2}(\bar{y} - \mu)^2\right\} \\ &\quad \times \left(\frac{1}{\sqrt{2\pi}}\right)^n \end{aligned} \tag{9}$$

where $\bar{y} = n^{-1}\Sigma y_i$ is the saple mean, $\theta = (\mu, \sigma)$, and $\Theta = \mathscr{R} \times \mathscr{R}^+$. From (9) we see that $T = \{\bar{Y}, \Sigma(Y_i - \bar{Y})^2\}$ is sufficient for θ, with $g(t; \theta)$ identified with all but the final factor in (9).

Strictly speaking, there are a number of other sufficient statistics in both the examples above. In Example 2, $(\Sigma_1^4 Y_i, \Sigma_5^n Y_i, \Sigma_1^7(Y_i - \bar{Y})^2, \Sigma_8^n(Y_i - \bar{Y}))$ is also sufficient, as is, trivially, the original vector Y itself. Clearly $(\bar{Y}, \Sigma_1^n(Y_i - \bar{Y})^2)$ is in some sense 'smaller' than these other sufficient statistics, and to be preferred for that reason. A *minimal sufficient statistic* is defined to be a function of every other sufficient statistic. One-to-one functions of the minimal sufficient statistic are also minimal sufficient and are not distinguished, so in Example 2 $(\Sigma_1^n Y_i, \Sigma_1^n Y_i^2)$ is also minimal sufficient. Any statistic defines a partition of the sample space in which all sample points leading to the same value of the statistic fall in the same partition, and the minimal sufficient statistic defines the coarsest possible partition.

Since the central problem of parametric statistical inference is to reason from the data back to the parameter θ, extensive use is made of the *likelihood function*, which is (proportional to) the joint density of the data, regarded as a function of θ:

$$L(\theta; y) = c(y)f y; \theta) \tag{10}$$

The factorization theorem suggests, and it can be proved, that the minimal sufficient statistic in the family of models $\mathscr{F}_\theta$ is the likelihood statistic $L(\cdot; Y)$. This result is easily derived from the factorization theorem if Θ is a finite set, but extending it to cases of more practical interest involves some mathematical intricacies (Barndorff-Nielsen, 1978, Chap. 4).

Example 3. To illustrate the concept of sufficiency in a nonparametric setting, suppose that $Y_1,\ldots, Y_n$ are independent, identically distributed on $\mathscr{R}$ with probability density function f; i.e. $\mathscr{F}$ consists of all

probability distributions which have densities with respect to Lebesgue measure. Denote by $Y_{(\cdot)}$ the vector of ordered values $Y_{(\cdot)} = (Y_{(1)} \leqslant Y_{(2)} \leqslant \ldots \leqslant Y_{(n)})$ (see *Order Statistics*). Then $Y_{(\cdot)}$ is sufficient for $\mathscr{F}$, as

$$f_{Y|Y_{(\cdot)}}(y|y_{(\cdot)}) = \begin{cases} \dfrac{1}{n!} & \text{if } y \text{ is a permutation of } y(\cdot) \\ 0 & \text{otherwise} \end{cases} \tag{11}$$

is the same for all members of $\mathscr{F}$

Example 4. Let $Y_1, \ldots, Y_n$ be independent, identically distributed according to the uniform distribution on $(\theta-1, \theta+1)$, where $\theta \in \mathscr{R}$. The order statistic $Y_{(\cdot)}$ is sufficient, as this is a special case of Example 3 above, but is not minimal sufficient. The minimal sufficient statistic is determined from the likelihood function:

$$L(\theta; y) = \begin{cases} \prod_{i=1}^{n} (\tfrac{1}{2}), & y_{(n)} - 1 \leqslant \theta \leqslant y_{(1)} + 1 \\ 0 & \text{otherwise} \end{cases} \tag{12}$$

from which we see that the minimal sufficient statistic is $T = (Y_{(1)}, Y_{(n)})$, as this is a one-to-one function of the likelihood statistic.

2.3 Exponential Families

A random vector $Y \in \mathscr{R}^p$ is said to be distributed according to an exponential family of dimension k if the probability mass or density function can be expressed in the form

$$f(y; \theta) = \exp\{\varphi(\theta)^T t(y) - c(\theta) - d(y)\} \tag{13}$$

for some functions $\varphi(\theta) = \{\varphi_1(\theta), \ldots, \varphi_k(\theta)\}$, $t(y) = \{t_1(y), \ldots, t_k(y)\}$, $c(\theta)$ and $d(y)$.

Many common distributions can be expressed in exponential family form, including Example 1 with $\varphi(\theta) = \log\{\theta/(1-\theta)\}$, $t(y) = \Sigma y_i$ and Example 2 with

$$\varphi(\theta) = \left(\frac{\mu}{\sigma}, -\frac{1}{2\sigma^2} \right)$$
$$t(y) = (\textstyle\sum y_i, \sum y_i^2)$$

Other examples of exponential families include the Poisson, geometric, negative binomial, multinomial, exponential, gamma, and inverse Gaussian distributions. Generalized linear models are regression models built on exponential families that have found wide practical application. See Dobson (1990) or McCullagh and Nelder (1989) and *Analysis of Variance and Generalized Linear Models*.

From (13) we can see that exponential families are closed under independent, indentically distributed sampling, and that the minimal sufficient statistic for θ is the k-dimensional vector $T = \Sigma t(Y_i)$. Exponential families are said to permit a *sufficiency reduction* under sampling; we can replace the original n observations by a vector of length k. Possibly for this reason exponential families are used widely as models in applied work.

A partial converse of this is also true, that if a finite dimensional minimal sufficient statistic exists in independent sampling from the same density, and the range of values over which the density is positive does not depend on θ, then that density must be of exponential family form.

Versions of the material in this appear in most mathematical statistics textbooks. Suggested references, roughly in order of increasing difficulty, are Azzalini (1996), Casella and Berger (1990), Lehmann and Casella (1998), Cox and Hinkley (1974), Pace and Salvan (1997), and Barndorff-Nielsen and Cox (1994).

3. Some Related Concepts

3.1 Ancillary Statistics

A companion concept for the reduction of data to a number of smaller quantities is that of *ancillarity*. A statistic $A = a(Y)$ is said to be ancillary for θ in the family of models $\mathscr{F}_\theta$ if the marginal distribution of A,

$$f_A(a) = \int_{\{y:\, a(y) = a\}} f(y; \theta)\, \mathrm{d}y \tag{14}$$

is free of θ. If every other ancillary statistic is a function of a given ancillary statistic, the given statistic is a maximal ancillary statistic.

Example 4 (continued). In independent sampling from the $U(\theta, \theta+1)$ distribution, $T = (Y_{(1)}, Y_{(n)})$ is a minimal sufficient statistic, and $A = Y_{(n)} - Y_{(1)}$ is a maximal ancillary statistic.

If an ancillary statistic exists, all the information about θ is in the conditional distribution of Y, given the ancillary statistic. If a minimal sufficient statistic exists, all the information about θ is in the marginal distribution of T. These two data reductions, to A or to T, are complementary, and can sometimes be combined.

Example 5. Let $Y_1, \ldots, Y_n$ be independent, identically distributed from the one parameter *location* family $f(y_i; \theta) = f_0(y_i - \theta)$, $\theta \in \mathscr{R}$, where $f_0(\cdot)$ is known. Then the vector of residuals $A = (Y_1 - \bar{Y}, \ldots, Y_n - \bar{Y})$ is ancillary. An extension of this to the location scale family is possible: let $f(y_i; \theta) = \sigma^{-1} f_0\{\sigma^{-1}(y_i - \mu)\}$, then

$$A = \{(Y_1 - \bar{Y})/S, \ldots, (Y_n - \bar{Y})/S\}, \tag{15}$$

where $S^2 = \Sigma(Y_i - \bar{Y})^2$, is a maximal ancillary. The normal distribution of Example 4 is a location-scale

model, with minimal sufficient statistic $T = (\bar{Y}, S^2)$, which in this case is independent of A.

The importance for the theory of statistics in concepts of dimension reduction such as ancillarity and sufficiency is that inference for a k-dimensional parameter is encapsulated by a probability distribution on a k-dimensional space. This immediately provides tests of significance, confidence intervals, and point estimates for the unknown parameter. From this point of view it now appears that ancillarity is possibly a more central notion to the theory of statistics, although sufficiency is regarded widely as more natural and intuitive.

It should be noted that inference from a Bayesian point of view automatically provides a k-dimensional distribution for inference for a k-dimensional parameter, which is the posterior distribution given the observed data y. This is achieved at the expense of constructing a probability model for the unknown parameter θ. See *Bayesian Statistics*.

3.2 Asymptotic Sufficiency

The normal distribution is used widely for modelling data from a variety of sources, but is also very important in the theory of inference in providing approximate inferences, when exact inferences may be unavailable. While the likelihood function is equivalent to the minimal sufficient statistic, a special role in approximate inference is played by some functions computed from the likelihood function.

The *maximum likelihood estimator* of θ in the model $f(y; \theta)$ is defined by

$$\sup_{\theta} L(\theta; y) = L(\hat{\theta}; y) \tag{16}$$

and the *observed information function* for θ is

$$j(\theta) = -\partial^2[\log\{L(\theta; y)\}]/\partial\theta\partial\theta' \tag{17}$$

Under regularity conditions on the family of models for $Y = (Y_1, \ldots, Y_n)$ we have the following asymptotic result for a scalar parameter θ as $n \to \infty$:

$$(\hat{\theta} - \theta_0)\,\{j(\theta_0)\}^{1/2} \xrightarrow{d} \theta_0\, N(0, 1) \tag{18}$$

which means that for sufficiently large n the distribution of the maximum likelihood estimator is arbitrarily close to a normal distribution with mean zero and variance $j^{-1}(\theta_0)$, under sampling from $f(y; \theta_0)$. A similar result is available for vector θ.

The maximum likelihood estimator has by construction the same dimension as the unknown parameter θ, so (18) provides a means of constructing an inference for θ using the normal approximation. This suggests that a notion of *asymptotic sufficiency* could be formalized, the maximum likelihood estimator having this property. This formalization relies on showing that the likelihood function is asymptotically of normal form, with minimal sufficient statistic $\hat{\theta}$; see Fraser (1976, Chap. 8). The argument is very similar to that showing that the posterior distribution for θ is asymptotically normal. More generally, in models with smooth likelihood functions, a Taylor series expansion of the likelihood function around $\hat{\theta}$ suggests a refinement of asymptotic sufficiency: the set of statistics $\hat{\theta}$ and second and higher order derivatives of the likelihood function evaluated at $\hat{\theta}$ form a set of *approximate sufficient statistics* in a certain sense (Barndorff-Nielsen and Cox 1994, Chap. 7).

In general models the maximum likelihood estimator is not the minimal sufficient statistic, although it is always a (many-to-one) function of the minimal sufficient statistic. Much of the recent development of the parametric theory of inference has been concerned with combining sufficiency or approximate sufficiency with ancillarity or an appropriate notion of approximate ancillarity, to effect a dimension reduction with minimal loss of information. In general models if the maximum likelihood estimator is used in place of the minimal sufficient statistic, information is lost. The idea of recovering this information, via conditioning on an ancillary statistic, was put forth in Fisher (1934). With some exceptions this idea was not exploited fully in the statistical literature until about 1980, when it was discovered that an asymptotic version of Fisher's argument holds in very general situations. The subsequent 20 years saw continued development and refinement of Fisher's original idea. A brief overview is given in Reid (2000), and the books Barndorff-Nielsen and Cox (1994) and Pace and Salvan (1997) give a detailed account.

3.3 Inference in the Presence of Nuisance Parameters

Many statistical models have vector valued parameters θ, but often some components or scalar valued functions of θ are of particular interest. For example, in evaluating the hypothetical new weight-loss treatment under a normal model, the mean parameter μ is in the first instance of more interest than the standard deviation σ. In studying results from a poll we may wish to introduce parameters describing various aspects of the population, such as gender, age group, income bracket, and so on, but the main purpose of the poll is to construct an inference about the proportion likely to vote for our candidate, for example.

The idealized modelling of these types of situations is to describe θ as consisting of two components $\theta = (\psi, \lambda)$, of *parameters of interest*, ψ and *nuisance parameters*, λ. An extension of this would be to define $\psi = g(\theta)$ as determined by a set of constraints on θ,

but only the component version will be considered here.

There are in the literature several different definitions of sufficiency for a parameter of interest ψ in the presence of a nuisance parameter λ. To illustrate some of the issues we consider again the normal distribution with $\theta = (\mu, \sigma)$, $T = (\bar{Y}, s^2)$. We have

$$f_T(t; \mu, \sigma) = f_{\bar{Y}}(\bar{y}; \mu, \sigma) f_{S^2|Y}(s^2; \sigma^2) = f_{\bar{Y}}(\bar{y}; \mu, \sigma) f_{S^{12}}(s^2; \sigma^2) \quad (19)$$

where $f_{\bar{Y}}(\cdot)$ is the density of a normal distribution with mean μ and standard deviation $\sigma/\sqrt{n}$, and $f_{S^2}(\cdot)$ is proportional to that of a chi-squared distribution on $n-1$ degrees of freedom. As the conditional distribution of S^2, given $\bar{Y}$ is free of μ, we could define $\bar{Y}$ as sufficient for μ, by analogy to (3). However it is not sufficient for μ in the sense of providing everything we need for inference about μ, since its distribution depends also on σ. In this latter sense S^2 is sufficient for σ.

There have been a number of attempts to formalize the notions of partial sufficiency and partial ancillarity, but none has been particularly successful. However, the notion of dimension reduction through exact or approximate sufficiency and ancillarity has played a very important role in the theory of parametric inference.

Sufficiency in the presence of nuisance parameters is considered in Barndorff-Nielsen (1978, Chap. 4), Jorgensen (1997) and Bhapkar (1991). A discussion of partitions like (19) and the role of conditional and marginal inference is given in Reid (1995).

4. Conclusion

A sufficient statistic is defined relative to a statistical model, usually a parametric model, and provides all the information in the data about that model or the parameters of that model. In many cases the sufficient statistic provides a substantial reduction of complexity or dimension from the original data, and as a result the concept of sufficiency makes the task of statistical inference simpler. The related concept of ancillarity has a similar function. Recent developments in likelihood inference have emphasized the constructions of approximately sufficient and approximately ancillary statistics in cases where further dimension reduction is needed after invoking sufficiency and ancillarity. Excellent textbook references for the definitions and examples include Casella and Berger (1990) and Azzalini (1996). More advanced accounts of recent work are given in Barndorff-Nielsen and Cox (1994) and Pace and Salvan (1997).

Statistical Systems: Censuses of Population

1. Early Sporadic Censuses

'The Census at Bethlehem,' painted by Pieter Bruegel (the Younger, around 1600) shows the Virgin Mary on a donkey, going to Nazareth to be counted at home by the Roman Census. There are countries even at the

beginning of the twenty-first century where the patriotic 'ceremony' of the census requires people to be at their usual (*de jure*) home for easier counting. A census was also conducted in AD 2 in the relatively newly unified China, where they counted 60 million persons, about a quarter of the world's population then. (At 1.3 out of 6 billions today, China is still one-fifth of the world's population and would be one-quarter without her rigorous population controls.) A millennium later in 1086, a sort of census was conducted in England for William the Conqueror, known as the Domesday Book. These are three prominent examples from several known to have been undertaken in different countries at different times, and they illustrate the importance placed on population counts. However, they were only sporadic and highly variable attempts, for which we have no complete records, especially because some of them were kept as 'state secrets.' There were also many censuses for only single cities, districts, or provinces. Furthermore, they were not usually counts of households or of all persons. Some counted only men of military age for allocating levies of troops; some counted only chimneys, used as an easy proxy for households. The chief aims of censuses were to apportion to administrative units legislative seats, the burden of taxation, army levies, or of work assignments. These aims survive today, but others have been added in modern times. All of these aims are supported by the details for small domains that complete censuses yield. (See Goyer 1992, Taeuber 1986).

2. Rise of Modern Censuses

The first modern, national census of households and persons was established in the Constitution of the new USA in 1790 and has been continued decennially since then. Its first major purpose was allocating seats in the new national Congress, but it also served other purposes and needs (Anderson 1988). Those purposes and needs increased gradually and the variables collected by the census increased likewise. The idea spread and decennial censuses began in the UK in 1801 and in Belgium in 1846. The International Statistical Institute's Congresses of 1853, 1872, and 1897 passed recommendations in favor of decennial censuses for all countries, with some basic requirements, aiming at standardization for better international comparability. It also urged open publication and dissemination of results. In 1900 some 68 different countries already conducted and made available population censuses, which included 43 percent of the world's population. The quality and content of the censuses improved gradually. For example, it is only since 1850 that the data for USA censuses covered all individuals rather than just families.

The greatest international impetus came after 1946 from the Population Division and the Statistical Division of the new United Nations. The stimulation, guidance, and coordination of the UN Statistical Division were crucial for spreading the establishment of censuses and their comparability (UN 1980). The efforts of the UN's sister agencies (FAO, WHO, and UNESCO) were also important. Beyond the growing coverage of most countries and improved coverage within countries, population censuses have advanced in five other dimensions. First, the quality of the census data has been improved. Second, that improvement has been subjected to measurement by quality checks, often with duplicate observations. Third, both the contents and the quality have been increasingly standardized across countries in order to facilitate international comparability of data. Fourth, the number, diversity, and depth of census variables have been greatly increased. Fifth, the analyses of census variables have been vastly deepened and improved, with the help of modern computing machines and methods.

In addition to censuses of population and housing, many countries also conduct censuses of agriculture, business, manufacturing and mineral industries, etc. These are usually done separately, often by different and specialized staffs and enumerators. The censuses of agriculture may still be linked to population censuses in less developed countries, where most households still also operate small farms. However, in industrialized countries most agricultural products come from large firms of 'agro-business.'

2.1 Contents of Population Censuses

Beyond mere head counts, modern population censuses obtain several classes of variables, as shown below, condensed from the UN's recommended list:

Residences—usual, on the census date, duration, previous, at birth; place of work

Sex, age, marital status, relation to head of family and household

Citizenship, religion, language, national/ethnic origin

Children: born alive, living. Births last year: live and dead

Marriage: age, duration, order

Education: attained, literacy, qualifications, attendance

Occupation: status, industry sector, time worked

Income, socioeconomic status, economic dependency

From this recommended list, most countries omit some topics or include them only in some years. On the other hand, some countries add other topics, of course, as desired. With all those variables, and with increasingly complex and detailed analyses, the published outputs of censuses grew into census monographs of many volumes, and then took years to finish (Farley

1995). Therefore statistical offices are continuing to develop cheaper and faster methods of dissemination, with the aid of computers and electronic publishing.

2.2 Timing of Censuses

Censuses of the population must assign specific locations on specific dates (the census day or reference period) to people. The collection period for enumerating may be one week or a few weeks. However, the reference period is a single census day for items like residence and age; for items like income (or crops) it may be the preceding year. However, humans are highly mobile and they are becoming even more so: with longer and more vacations, longer travel to work, more second homes, more split families, and so on. *De facto* is the census term for the actual location of persons on census day and *de jure* for their 'usual place of residence' (home). Without this distinction city workers would make the central cities larger in the daytime when their 'usual place of residence' locates them in the suburbs. But location problems are more difficult for students living away from home in university cities; for death rates in cancer hospitals far from home; large institutional populations in prisons or in the military; for second vacation homes, etc. These are all examples that census definitions and operations must cover, in the field and in the office. Nomadic populations pose a great variety of special problems in timing and locations, of too great a variety for us to attempt to cover here.

For the census work in most countries, tens or hundreds of thousands of enumerators must be hired and trained for just one or two weeks of fieldwork and a few months in the offices. In China and India they need millions of enumerators. Some experts have doubts about how well they can be trained. However, others contend that the 'ceremony,' the patriotic campaign that can be mounted every 10 years, with educational campaigns, and exhortations in the media, increases awareness, participation, and response rates. Still others fear that the campaign arouses the latent and dormant opposition to fact-finding.

Decennial censuses may be regarded as systematic samples of a continuous time dimension: samples of a single census day in the 3,652 days of 10 years, or one year every 10 years for variables like yearly income. Estimates for intercensal and postcensal periods must depend on models and methods, and these are called intercensal and postcensal estimates. Other methods are also available for national and large domain estimates; but what are lacking above all are estimates for small areas and small domains that are also more detailed in time than decennial censuses. These needs have given impetus to methods of small area estimates and small domain estimates (Platek et al. 1987, Purcell and Kish 1986). Their accuracy depends on relations to auxiliary data from registers and sample surveys; also on the stability of variables like total population. But they are not accurate for unstable and fluctuating variables, like unemployment, infectious diseases, and financial variables. Sample surveys have been developed for some of these (see Sect. 3).

2.3 Coverage by Censuses

All censuses have problems of coverage; and even the best suffer a few percentages of noncoverage (or missing units). Furthermore, typically the units (households, persons) are not missed evenly, or at random; they are typically missed more often among the lower socioeconomic classes, some ethnic groups, and areas. These uneven coverages persist despite efforts to find and to measure them. However, the size and bias of this noncoverage may often be smaller than the even greater distortions due to the uses of obsolete decennial censuses for 10 years. All national census results also consist of combinations of regions or provinces or states, also of districts or counties or communes, and so on down to small domains. The populations of the provinces may differ greatly in culture and standards and the national results represent averages of the provincial levels. For some provinces different languages and questionnaires may be needed. Further, deliberate omissions may exclude some areas because: (a) they are vast, 'uninhabited' mountains, deserts, jungles, or small islands; or (b) they may be areas under hostile populations or rebellions. Changes of boundaries that have occurred, either losses or acquisitions, after wars and treaties cause problems for publishing and reading census monographs, tables, and graphs.

2.4 Costs of Censuses

The fine spatial detail of complete censuses is bought with high total costs. Because the total costs of censuses are high, they are usually only held every 10 years; and only a few countries had five-year censuses. The growing number of topics covered by censuses have also increased their total high costs and these prevent more frequent census taking, despite demands for annual data with spatial detail. At the same time the large size of the census is also an obstacle to obtaining greater richness of data (with more variables) with spatial details. This high cost is one cause of the sporadic political controversies about censuses in many countries. But even more serious are the conflicts due to the policy implications of census results, especially those that are used for apportionment between provinces and between ethnic groups. Apportionment of seats in Congress (Parliament), of taxation, of armies, of welfare funds—the very reasons for collecting census data—can also lead to conflicts, and even (rarely) to suppression of data. The collection

and open publication of reliable and trusted statistical data is (like liberty) 'the fruit of constant vigilance.'

The costs of censuses must vary with the methods used to collect and process them. Door-to-door personal interviews have been the standard throughout history. However, now they have been modified in places with telephoned and mailed-in questionnaires, and also with mailed-out-mailed-in postal methods. Processing and editing have been speeded with mechanical and electronic methods; but the savings seem to be swallowed by increased complexities of analyses. The comparison of total costs across times, and between countries are complicated by population sizes, exchange rates, and living standards; but guesses are made that the total cost of censuses per capita population equal about 1/2 to 1 hour of the countries' median hourly wage for every 10 years.

3. Sampling and Censuses

Two other methods for collecting population data have emerged as both complementary to and competitive with complete census taking: sampling methods and administrative registers. Sampling methods have come to be used in several distinct ways in different countries.

3.1 Census Samples

The addition of great numbers of desirable topics increased the costs of censuses, and since 1950 a solution to this problem was increasingly found in the use of census samples. In addition to the complete count using the 'short form' containing a few basic questions, a sample of the population completes a 'long form' with many variables. This sampling reduces both the total cost of the census and the burden on the majority of respondents in 2000. The rates and methods of sampling differ between countries. The sampling units may be enumeration districts (areas—EDs or EAs), or households, or persons. Selection of persons has lower sampling variance, but selecting EDs may have better enumerative controls and greater flexibility. The sample population may only get the long form or they may get duplicates of both the short and the long forms. Census samples generate large samples, whether 5 or 10 or 20 percent of the complete count, and thus they can provide detailed spatial data, but with reduced costs. They are still much larger than ordinary survey samples, which have selection rates of 1/100, 1/1,000 or 1/10,000 of complete counts.

3.2 Postenumerative Surveys, Quality Checks, Coverage Checks

Samples may be taken for quality checks with measurements that may use more costly and (hopefully) improved methods. These measurements may be in addition to, or instead of, the regular census data collection and the sampled units may be persons, households, or enumeration districts. Coverage checks are attempts to find the sort of persons missed by the regular census count. The surveys are often called postenumerative because they are usually done after the census collection, but they may be done simultaneously.

3.3 Sample Censuses

These have been conducted by a few countries, and sometimes are called 'minicensuses,' perhaps based on one-percent samples and with fewer topics than the sample surveys described below. The greatest expressed need is for annual data to supplement the decennial censuses, which are increasingly judged to be inadequate because of obsolescence. Typically, census monographs containing the richer data of the long form become available five or more years after the census year, although the simple counts may be released quickly (Farley 1995).

3.4 Sample Surveys

Generally, sample surveys differ greatly from complete censuses; they are much smaller; they are much cheaper, but they also lack detail in spatial (geographic) and other domains. But periodic samples yield much needed temporal detail, and also have other advantages. They can yield much richer data, especially because the content and the methods can be focused on specific contexts. Also because that greater concentration can be achieved for the questionnaires, for the interviewers and for the respondents as well.

'Representative sampling' was first proposed by F. N. Kiaer in 1895 in Norway, for replacing censuses. The fundamental concept requires a careful, scientific method for selecting a sample from the population and then estimating the population variables from the sample statistics. Many statisticians, academic and practical, in many journals and in the International Statistical Institute for about 50 years, opposed sampling as a substitute for complete enumeration. Meanwhile probability samples came into use for social surveys, notably for unemployment rates and then for the famous quarterly surveys of the labor force, which became the Current Population Surveys of the US Bureau of the Census (1978). All countries in the European Union and many others now have quarterly or monthly surveys of the national labor force. These surveys, mostly of 5,000 to 100,000 households, are financed because governments need current monthly or quarterly data on (un)employment and its periodic fluctuations. National statistical offices generally conduct many other samples every year, some of them only once, some repeatedly, and

some periodically. Some of the censuses are also produced by sampling methods and the Food and Agriculture Agency (FAO) has been in the forefront of promoting agricultural censuses by means of sample surveys (see *Social Survey, History of*).

4. Administrative Registers

Administrative registers related to population counts, sometimes called civil or population registers, may be of different kinds, purpose, and quality in different countries and at various times. Vital registers of births and deaths may be the most common examples, but others exist for voter registration, or recently auto licenses, telephone numbers, etc. The most relevant registers date from 1749 in Sweden and the Nordic countries, where the official church started keeping records of the parish populations, which continues today. Some statisticians propose replacing decennial censuses with data from administrative registers of different kinds, or with the combined social resources available in specific countries (see *Databases, Core: Demography and Registers*). The data are inexpensive, almost without cost, because some other agency, with other aims and resources, pays for them. Furthermore, they are often detailed spatially, and also detailed temporally, timely, and they are kept up-to-date. They have been used in several Scandinavian countries to replace their population counts. However for two chief reasons, most countries cannot use administrative registers to replace censuses. First, for lack of the conditions that facilitate the successes of Scandinavian registers: a highly educated and cooperative society, which is highly motivated to register promptly their own changes of residence. Second, no registers, not even the Scandinavian registers, have ever obtained the richer data (beyond a few lines) that modern censuses need. In addition, some statisticians fear the misuse of registers by careless, or malevolent, governments and societies.

5. Future Developments

Modern censuses face some gravely conflicting demands: higher quality and better coverage of the population, but with reduction of mounting costs. We need spatial detail, but also temporal detail and timeliness. Censuses yield more spatial detail, but sample surveys are superior in all of the three other aspects. The greatest need is for more timeliness, because decennial data do not satisfy modern needs, especially for annual data with spatial details. At the other extreme the monthly surveys provide adequate national statistics and satisfy the other requirements, but they yield no spatial detail for local needs. This conflict gave rise to designs of 'cumulative representative samples' and then to 'rolling samples,' in the last few years. The National Household Health Survey in the USA yields separate samples of about 1,000 households each week, and they are cumulated into 52,000 households yearly, with health data on about 150,000 persons. Thus the yearly cumulations yield data for even moderately rare diseases and infirmities. Furthermore, the American Community Survey of the US Census Bureau is conducting a large pilot study for a 'rolling sample' by AD 2003, which may replace the long form of the US Census of 2010 (Alexander 1996, Kish 1998). Many statisticians in AD 2000 felt that the greatest need generally is for regular, standardized annual surveys (sample or census) that are harmonized internationally, and also large enough to yield reliable data for small domains. It is likely that the censuses of the twenty-first century will be quite different from those of the twentieth century.

Statistical Systems: Crime

1. Crime Statistics

Crime statistics are largely generated from three avenues—administrative data, surveys, and ethnographic studies. Administrative data are often referred to as the 'official' statistics as they are drawn most often from the records kept by state institutions. The

first official statistics were published in France in 1827 (Coleman and Moynihan 1996). Self-report surveys are the other major source of crime data or statistics and involve interviewing perpetrators and victims of crime. In general ethnographic studies do not result in 'statistics' as such. They are based on small samples that are usually unrepresentative of the population. However, such rich materials play an important role in understanding what lies behind the numbers used by crime analysts.

The collection and monitoring of official crime statistics has largely been taken over by government and government sponsored agencies such as the US Bureau of Justice Statistics or the UK Home Office (Coleman and Moynihan 1996). These agencies draw on the major criminal justice institutions such as the police, prisons, and the courts for these official statistics. On the surface the collection of such data might appear straightforward and relatively uncontentious yet in reality it remains one of the most controversial areas in the analysis of crime. Official crime statistics have been subject to critique since the mid-nineteenth century through to the present, the beginning of the twenty-first century (Coleman and Moynihan 1996).

There are a variety of factors that contribute toward this controversy (Kempf 1990, Jackson 1990). Some of the more important reasons include:

(a) The study of crime itself is often controversial.
(b) What is defined as a 'crime' is a social construction and not an empirical fact.
(c) There is not always consensus on how to collect crime statistics.
(d) There is no one data source that can address all the issues raised in the study of crime.

2. *Official Crime Statistics*

Administrative databases are used to generate official crime statistics yet they are first and foremost a management tool. As a result, using data generated from this system as the sole source of crime statistics is problematic. Unlike many other economic and social activities, the act of committing a crime can result in the loss of liberty and in some cases the loss of life. Understandably, most people do not admit to committing crime. As a consequence detection of crime is dependent on victims reporting such activities to the police, and the police successfully apprehending the suspects. Police make decisions about whether to proceed with charges, then prosecutors make decisions about whether to continue with the charge and if so which charges they will pursue. Finally, the courts then make a determination as to guilt or innocence. There are many factors that intervene at different points in this process ultimately affecting the 'numbers' that appear in official statistical collections. Because of the potential for error at various stages through the recording process official homicide statistics are largely regarded as having the most credibility.

3. *Police Data*

Counting rules used by the collection agencies complicates interpretation of police statistics. Data can be confusing to the novice as it can on occasion refer to the offences/incidents and at other times to the offenders and victims. For example, one offender may be responsible for 50 offences. Similarly, five people may be involved in one offence (e.g., a bank robbery by a group of people). Where an individual has committed a range of offences often only the most serious offence is recorded for statistical purposes. For example, prison statistics in Australia are based on the most serious offence of the prisoner. Thus if an individual is convicted on a range of offences on a particular day only the most serious offence is recorded. As a result official statistics can under-report the extent of crime in the community. Police data are limited by:

(a) Definitions of what constitutes a crime.
(b) Variability in reporting by citizens.
(c) Law enforcement organizational structures.
(d) Variations in counting rules across jurisdictions.
(e) Low rates of detection and clearance.

4. *Court and Corrections Data*

These particular administrative databases represent a subset of police data for they record crimes that have been processed further down the criminal justice chain. For example only one in 20 people who appear before the criminal courts in Australia serve time in prison. Data from these systems are used to produce crime statistics on matters relating to sentencing, prison composition, recidivism, probation, and parole. However, as with police databases they are highly restrictive in terms of the limited nature of the data recorded. Usually only the most basic demographic and arrest characteristics are collected. Counting rules also vary across the courts. In Australia, for example, the unit of count is the charges or appearances in the lower court while in the higher court it is distinct persons. Crime statistics from these databases will be biased as they are based on those who represent the most serious offenders and offences.

5. *Improvements in Official Statistics*

Despite these limitations there have been significant advances in the recording of crime within administrative systems. Many countries have moved or are moving toward collating national data on crime that is comparable across areas by standardizing definitions and counting rules (UNAFEI and AIC 1990). In addition jurisdictions are seeking to link data across

criminal justice institutions so that a more complete picture of crime, offending, and offenders can be determined. Improved and cheaper technologies, and the development of statistical packages, have meant that analysts and researchers are demanding unit record files (URF) rather than aggregated statistics. As a result new administrative databases are being established to provide greater detail in response to research and policy demands. A major development has been the National Incident-Based Reporting System by the United States Federal Bureau of Investigation (Maxfield 1999).

There are three major factors that are driving improvements in crime statistics. The first is the demand for accountability by governments for the way in which scarce public money is spent. To justify their activities criminal justice institutions are increasingly relying on statistics to support their assertions and resource allocations. This results in both a greater awareness of statistics and a greater scrutiny of these same statistics. The second major factor has been the critical scrutiny of these data particularly by independent academic researchers. The third has been the development of technology that enables the cost-effective storage and retrieval of data.

6. *Crime Victim Surveys*

Researchers have long been concerned about a 'hidden figure' of crime that represents a large proportion of unrecorded crimes and criminals. Crime victims' surveys from a range of countries have shown that the majority of people do not, for a variety of reasons, report crimes to the police. There are other biases in the official statistics. White-collar crime is rarely recorded or dealt with under criminal law (Sutherland 1949). Some researchers argue that the important feature of crime data is the long-term trend in crime and not the overall amount of crime.

Others have argued that even the long-term trends are difficult to interpret—is crime really increasing or is it a reflection of other things? For example, changes in police practices and priorities, or changes in the interpretation and classification of particular offences can help to explain changes in crime statistics. There have also been changes in the police management/processing of some forms of crime, such as rape and domestic violence, that have impacted on the number of recorded crimes.

Given the sustained criticism of official statistics governments and academics have sought ways to improve upon their collections. To address the issue of under-reporting of crime to police, crime victim surveys are routinely undertaken in many countries. Individuals within households are randomly selected and asked about their experience of crime and victimization. From this source of information the nature and extent of crime has been shown to consistently be more prevalent than appears from 'official' statistics. However, such surveys have also been criticized on a number of grounds including (Koffman 1996, Coleman and Moynihan 1996, Skogan 1981):

(a) The definition of what constitutes a 'crime' in the survey instrument does not always match the legal definition in the official statistics making comparisons difficult.

(b) Particular subgroups are either more or less likely to self-report particular crimes affecting the reliability of the estimates. For example, those with higher levels of education are more likely to report assault, while women are less likely to report rape/domestic violence.

(c) Memory failure is a problem with respondents being more likely to recall incidents where the offender was not known to them than where the offender was known or related. There are also potential problems in terms of ignorance of events, deception, and 'forward and backward telescoping.'

(d) Methodological problems include who should be interviewed in the household and the phrasing and order of questions.

7. *Self-report Surveys*

In addition to victimization surveys there has been increasing use of self-report data from offenders. Dissatisfaction with official crime statistics has been a major factor in the development of offender surveys. This source of information has tended to be dominated by academics rather than government statistical collection agencies. One of the reasons is because these data need to be more carefully informed by theoretical models that can only come from an in-depth understanding of the substantive material. Self-reports are now regarded as the most common methodology for collecting data on crime statistics and large scale self-reported studies have taken place in a range of countries (see Junger-Tas and Marshall 1999).

Self-report data have generally confirmed that official data underestimates the level of crime in the community as described in official statistics. This particularly applies to victimless crime such as prostitution and illegal drug use. It is in the area of deviant behavior that self-reported crime statistics are superior to official statistics and these behaviors, if defined as illegal, are rarely reported to the police. Hence, self-report data are widely used to provide more accurate statistics on the prevalence and incidence of engagement in criminal activities by offenders. In addition self-report data have been used to:

(a) examine the correlates of offending;

(b) test theoretical models of criminal behavior; and

(c) evaluate intervention programs (Junger-Tas and Marshall 1999).

However, biases also apply to many self-report studies. Unless extraordinarily large sample sizes are obtained in population surveys the capacity to examine the correlates of offending or test theoretical models is limited by the highly skewed distribution of criminal behavior; this form of deviance is a rare event. For example, less than half a percent of the general population self-report having tried heroin in the past 12 months in household surveys in the USA and Australia.

To generate 100 people who have used heroin in the past 12 months would require a sample of 20,000 people. In addition most household surveys tend to under-represent those engaged in criminal activity; this is partly due to the sampling frame and partly due to the differential participation amongst particular groups (Weis 1986).

One solution to overcoming the problem of large sampling error is to use disproportionate stratified samples or to focus on specific groups such as incarcerated offenders. The latter will ensure that the sample has the desired characteristics but generalizability is severely limited.

Given the different methodologies employed to obtain crime statistics it is not surprising that the absolute rates vary between official and self-report data from offenders and victims. Consequently, researchers have advocated that relative rates should be used in making comparisons (see Junger-Tas and Marshall 1999). When this is done there is considerable consistency between the statistical sources from a range of difference countries (Junger-Tas et al. 1994).

8. Impediments to the Improvement of Crime Statistics

There are three major impediments to the improved development of crime statistics:

(a) the application of ethics/privacy/informed consent provisions;

(b) access to primary or unit record data; and

(c) the rising costs of undertaking major research studies.

The movement toward increased ethics (or human) oversight of projects can be problematic particularly in the area of crime. In practice the self-report methodology asks people to incriminate themselves. This poses real dilemmas for ethics committees, many of who are not trained in the discipline. As a result committees may be reluctant to give ethics approval. It also poses problems for researchers who in many countries and jurisdictions do not have protection under the law; they may be legally required to release information that was gained under assurances of confidentiality to the informant. Instigating informed consent forms, particularly when it requires a signature may conflict with assurances of confidentiality or anonymity thus affecting response rates. Junger-Tas and Marshall (1999) allude to the problem of informed consent on participation rates for delinquency studies. These issues militate against the study of crime and could well reduce the empirical study of crime and the collection of crime data outside of the official statistics.

The major improvements to crime statistics have largely occurred because of academic scrutiny of published statistics and secondary analysis of unit record data. The USA has had a long tradition of sharing and releasing statistical data for secondary analysis; this is not the norm. Access to official data collections for secondary analysis is often difficult and highly controlled by state institutions in many countries, like Australia. Until state institutions release full unit record data for secondary analysis this situation will continue to impede the improvement of national crime statistics.

Finally, funding constraints balanced alongside the increasing costs of data collection and research will affect both the government and nongovernment sectors in their ability to improve on their statistical collections. This is compounded by improvements in statistical methods that allow social scientists to undertake more sophisticated analysis. But this entails more sophisticated statistical collections and these are usually much more expensive.

Statistical Systems: Economic

'Economic statistics' in the widest sense of the term refers to those statistics the purpose of which is to describe the behavior of households, businesses, public sector enterprises, and government in the face of changes in the economic environment. Accordingly, economic statistics are about incomes and prices, production and distribution, industry and commerce, finance and international trade, capital assets and labor, technology, and research and development. Nowadays it is customary to include under economic statistics estimates of the value and quantity of stocks of natural assets and measurements of the state of the physical environment.

1. *Economic Statistics and Official Statistics*

In its strict sense the term economic statistics has a narrower scope as a distinction is drawn between economic statistics and economic accounts (as in the national or international accounts). Some statistics occupy a gray area—between social and economic statistics. They comprise measurements that play a role in describing social conditions and are used intensively in the making of social policies but at the same time relate intimately to the economic fabric of society. Examples are the statistics on income distribution commonly used for the measurement of poverty, the occupational make-up of the labor force, the expenditure patterns of households, and the structure of their income. For purposes of the present article the term 'economic statistics' excludes the national accounts but includes the statistics that are simultaneously used for economic and social purposes. Most of the references in this article apply to official statistics, i.e., those statistics that are either produced by government statistical agencies or by other bodies but are legitimized by being used by government. The usage adopted corresponds to the way in which government statistical offices are commonly organized.

2. *Directly Measured Statistics and Derived Statistics*

The term economic statistics is usually applied to statistics derived from direct measurement, i.e., either from surveys addressed to economic agents or from official administrative procedures that yield numerical data capable of being transformed into statistics. For example, the statistic on the national output of cement is usually derived by directly asking all (or a sample of) cement producers how much cement they produced over a defined period. The statistic on how many jobs were filled during a given period may be derived from the social security forms that employers are requested to send to the social security administration from time to time. This is different from the way in which the economic accounts of the nation are derived.

These are formed by combining all the existing economic (or basic) statistics through an interrelated system of accounting identities and from those inferring identity values that may not be available directly. They are also a means of assessing the strengths and weaknesses of economic statistics by noting how close they come into balance when the system of identities is applied to them. In other words, economic statistics are the raw material on the basis of which the economic or national accounts are compiled. The compilation of the national accounts in addition to summarizing and systematizing economic statistics plays the important role of showing up gaps in the range of economic statistics required to describe the functioning of the economic system (Table 1).

2.1 *Economic Statistics and Business Statistics*

The kernel of economic statistics is formed by statistics related to business and derived from questionnaires addressed to business, from questionnaires addressed to business employees, or from official records which businesses create in their dealings with government. Such statistics include descriptions of the business activity (what does the business produce, how does it produce it, for how much does it sell, what is the surplus generated by the sale once materials and labor are paid for, etc.) as well as of the nature of the factors engaged in production (structures and equipment used in production by type; labor employed by type of skill and occupation), and in addition statistics on the type of customers who purchase goods and services from businesses.

3. *How Economic Statistics Are Measured*

In spite of the increasing popularity of using administrative records as sources to generate economic statistics, on the whole, economic statistics are compiled mostly from surveys addressed to business. Generally speaking, the surveys consist of a list of respondents, a formal questionnaire—which can be used as basis for a personal interview (or an interview by telephone or Internet), a procedure followed when dealing with exceptional cases (not finding the right person to whom the questions should be addressed, finding that the business is not in the expected activity, or that the answers are incomprehensible or contradictory)—and a set of steps designed to aggregate individual answers so as to produce statistical totals, averages, or measures of distribution.

3.1 *Problems of Defining What Is a Business*

Part of the process of conducting a business survey consists in locating the addressees—either all the

Table 1
Types of economic statistics and sources (in italics) from which they are derived

Economic agent	Production	Distribution	Resources employed	Prices
Households	Household income/*surveys of household income*	Wages and salaries/*surveys of household income*, *labor force surveys*	Current population estimates, participation in labor force, employment/ *labor force surveys*	Consumer prices and consumer price index/ *surveys of prices*
Business	Value and amount of production; production by type of activity and by goods and services produced, orders and deliveries/*censuses and surveys of business activity*	Value and amount of sales; stocks of finished goods, materials and goods in process; sales by activity of seller and by product sold; sales by type of customer (exports and imports)/ *censuses and surveys of business activity; customs records*	Numbers employed by occupation; remuneration of labor employed; capital assets used; depreciation; profits; loans and equity borrowing/ *censuses and specialized business surveys; company balance sheets*	Producer prices, unit values in manufacturing, producer price index/*surveys of industrial prices, surveys of service activities, current agricultural surveys, customs records*
Government (central and local, public sector corporations, etc.)	Government expenditures and revenues by function and by source/*public sector accounts*	Public sector sales of goods and services/ *public sector accounts*	Public sector employment; public sector wages and salaries/*public sector reports; budget and supporting accounts*	Prices subject to regulation/ *special price surveys*
Other (nonprofit organizations, labor unions, employers confederations, etc.)	Income and expenditure of nonprofit sector/ *special surveys*		Employment in nonprofit sector; wages in nonprofit sector/ *special surveys*	

addressees in the survey universe if the survey is of a census type or some of the addressees if it is a sample survey. In either case two issues must be settled beforehand: (a) that all the addressees conduct the activity they are supposed to and (b) that there is no one else who conducts the targeted activity and has been left out. A related question has to do with what is a business. The 'business' can be defined as the entity that is liable under the law to pay taxes; that has a management capable of deciding its scale of operations and how those operations should be financed; and that *inter alia* conducts the activity that is germane to the survey. An alternative definition is one that seeks that part of the business (and only that part) that engages in the target activity directly and excludes all other parts of the business. In either case it is important that the respondents to the survey understand the scope of the questions and are capable of answering them out of records available to the business's management.

3.2 Business Records

Businesses tend to keep all the records they require to ensure informed management in addition to what they have to keep in order to comply with tax authorities and any other regulatory bodies that affect them. Usually those records fall into five categories: tax related; social insurance; engineering records on the performance of physical production; personnel and

safety records; and environmental records if the productive activity is of sufficient importance and of a kind that may detrimentally affect the physical environment. The efficiency of statistical surveys is measured partly by the ability of the statistical agency to request that information, but mostly by that information which is readily available from the records the business tends to keep anyway.

3.3 Household Surveys

Usually the major surveys addressed to households include a survey of households and how their members relate to the labor force and a survey of family income and expenditure. The former is the basis upon which statistics on the percentage of the labor force that is unemployed are calculated. The latter usually produces two key statistics: income distribution and structure of household expenditure. The latter is used to determine the various proportions of expenditure, which in turn are used in the compilation of the consumer price index. The surveys about household behavior—variation in the structure of expenditure and savings according to income, location of residence, family size, and age distribution—also provide key social statistics.

3.4 Public Accounts and Administrative Records

There are at least two categories of records that make explicit survey taking redundant: reports on public accounts and administrative registers created as a result of regular and comprehensive administrative procedures. The two have different properties. The accounts of the public sector (and of para-public enterprises such as nationalized industries or public corporations) are usually made available to the public as a means of displaying transparency and accountability. If the statistical requirement is limited to the displaying of aggregate information, what is published is usually sufficient as a description of the income, expenditure, and balance sheet of all public sector entities. In addition, all operations relative to the collection of taxes generate comprehensive records, susceptible to replace statistics to the extent the latter target the same variables. For example, the collection of income tax generates statistics on the income structure of all households (or individuals) liable to pay tax. The collection of VAT-type taxes generates records on the amount of sales, the nature of the seller, and in many cases the broad economic sector to which the buyer belongs. Social security records tend to generate information on the nature of the worker from whom amounts for social insurance are withheld, their place of work, the hourly, daily, or weekly remuneration that serves as a basis for the estimation of the amount withheld, etc. And of course, the oldest and most universal administrative operation of all—that connected with the activity of customs administrations—generates comprehensive information on the value, composition, conveyance used, origin, and destination of merchandise that either enters or leaves the national territory. This information, also known as merchandise exports and import statistics, is to be found amongst the earliest collections of numerical data of relevance to the administration of a country. To the extent that these administrative records are accessible to the compilers of statistics they tend to constitute acceptable replacements for estimates derived from surveys or from censuses.

4. Economic Classifications and Conceptual Frameworks

Economic statistics—like any other kind of descriptive statistics—are usually presented within the framework of standard classifications. In addition to geographic classifications, the most popular of these classifications are the Standard Industrial Classification (the SIC, or in its international version, the ISIC) and the Standard Product Classification (the SPC or, in its international version, the Standard International Trade Classification or currently the Central Product Classification). The SIC refers to the activity (or production technique) used to produce a specified list of goods and services. Similar (or homogeneous) production techniques are grouped into industries. The overall result of these groupings is a classification that views economic activity from the supply side. The SPC groups goods and services by their intrinsic characteristics rather than by the way in which they were produced. It is a classification that views the results of economic activity from the demand side. The use of international classifications is vital to ensure intercountry comparability of economic statistics.

The history of international cooperation in economic statistics is inextricably bound with the history of the two major economic classifications. Thus, the United Nations Statistics Commission, at its first meeting immediately after the end of World War II, commissioned the Secretariat to produce a classification of economic activities and shortly afterwards requested the development of a classification of the goods that entered into international exchanges (imports and exports). The Committee on Statistics of the League of Nations had worked on an initial version of such a classification. Almost immediately after the war the Statistics Commission approved the International Standard Industrial Classification of Economic Activities (ISIC) and the Standard International Trade Classification (SITC). Today, both classifica-

tions are into their fourth version (ISIC Rev. 3 and SITC Rev. 3, respectively).

Currently, the economic statistics of the members of the European Union and of many central and eastern European countries are classified by the NACE (Nomenclature des Activités économiques dans les Communautés Européennes). The three North American countries have their own system of economic classifications (North American Industrial Classification System—NAICS). Most other countries use one or another of the various versions of the ISIC.

The classification of goods was taken over by the body created to co-ordinate the activities of customs administrations worldwide (the Customs Co-ordination Council) and ended up as the Harmonized Commodity Description and Coding System (HS). As such it has been adopted for international trade statistics by the overwhelming majority of countries. Indeed, a number of them use the same classification for purposes of presenting their commodity output in the context of their industrial statistics. The requirement to develop an international classification of services prompted—again at the request of the United Nations Statistical Commission—the development of the Central Product Classification (CPC) which is being increasingly used to compare statistics on international trade in services with the internal production of and commerce in services.

4.1 Other Classifications

These apply to a variety of economic statistics but they (with the possible exception of the International Standard Classification of Occupations (ISCO)) are neither as well developed as the ones on activity and product nor are they at this stage the subject of international agreement. There are several examples of such classifications. In the case of capital assets there is still the question of whether a classification of assets ought to be embedded in the standard classifications of goods or whether it should be *sui generis*. There is no suitable classification of intangible assets. In the realm of labor inputs, recent innovations in the contractual relationship between employers and employees have produced a variety of forms of employment, none of which has so far found its way into an accepted classification.

4.2 Conceptual Frameworks

The conceptual framework for economic statistics is a hybrid, somewhere between business accounting and the system of national accounts. But, because economic statistics are the prime ingredient for the compilation of the national accounts, an explicit reconciliation between the former and the latter is required. Current trends suggest that because of pressures to keep government generated paperwork down, economic statistics tend to follow the patterns of business records. Where required, supplementary information is collected so that the basic statistics may be reconciled to the requirements of the national accounts compilers. But typically the necessary adjustments are conducted within the statistical agency. This is usually the case for key balances such as profits.

5. The Evolution of Economic Statistics as a System

The traditional manner in which economic statistics were derived was by the periodic taking of an economic census. Indeed in earlier times the census of population was taken together with the economic census. More recently, the economic census is addressed at businesses and retrieves information on their activity, location, legal form of organization, and on how many and what kind of people they employ. Supplementary information is usually obtained through lengthier questionnaires addressed not to all businesses but rather to a selection, usually above a certain size but sometimes to a randomly selected fraction of all those in the scope of the census.

5.1 Censuses and Registers

Economic censuses have become steadily less popular, largely due to their cost, the time it takes to process them, and the fact that, because of rapid changes in the size, make up, and even activity of businesses, census information loses much of its value shortly after it is compiled (see *Statistical Systems: Censuses of Population*). Instead, there has been an equally steady increase in the popularity of registers of businesses, usually derived from administrative data and used for much the same purposes as censuses but updated far more frequently. Indeed, in a number of cases, the introduction of new administrative procedures connected with tax gathering has been managed bearing in mind possible requirements of importance to the government's statistical agency.

The lists of businesses derived from administrative or tax-gathering procedures, commonly referred to as 'business registers,' are used mostly in two modes: as sampling frames and as a basis for indicators of economic performance such as 'net business formation' (the difference between the numbers of businesses created and the number of businesses closed down in a given period of time). As sampling frames, business registers are invaluable to support *ad hoc* inquiries into the state of the economy, usually conducted by contacting a randomly chosen group of businesses and gauging the opinion of their chief executive officers.

There are several requirements that must be satisfied for the modern approach to the compilation of business statistics to work. In particular, the source of information for the register must be comprehensive; it must be kept up to date as a result of the administrative procedures on which it is based; and the statistical agency must have unrestricted access to the source. The benefits that accrue to a statistical office from a business register are that: (a) it can dispense with the task of conducting a periodic census; (b) it can conduct a coherent set of sample surveys and link the resulting information so as to form a composite picture of the economy and its performance; and (c) it can control the paper burden that it imposes on individual business respondents through its multiple surveys.

5.2 *Applications of Business Registers*

Business registers are maintained at two distinct levels. There is a list of all businesses through their registration with some government department (usually the tax authority). This list conveys no more than there is a possible business behind a tax account. The physical counterpart of the tax account is usually determined by direct contact once it is established that the business is more than just a legal entity. The relationships between businesses as legal entities and the establishments, mines, mills, warehouses, rail depots, etc. that comprise them are a source of interesting information, but they are also the most difficult part of the management of a business register.

6. *Current Economic Indicators*

Under the impulse of macroeconomic stabilization policies and the belief in policy makers' ability to fine tune effective demand, the early 1960s saw a worldwide push to develop current economic indicators of demand by sector. A great deal of the empirical work had been done in the US, spearheaded by the National Bureau of Economic Research and resulting in a classification of short term economic statistics according to whether they lead, coincided, or lagged behind the 'reference' economic cycle. Most attention was placed on the performance of manufacturing industry, particularly on the output of equipment for/of fixed investment as well as for export; on the construction of plant and of other nonresidential structures; and in general on leading indicators of capital formation. At the same time considerable effort was made to improve the reliability and the timeliness of the key variables for purposes of economic stabilization: the rate of unemployment and the change in the consumer price index. Lastly, the balances in the main markets of the economy were looked at through quarterly national accounts, which in turn demanded major developments in the quality and the quantity of basic economic statistics.

7. *Today's Array of Economic Statistics*

In today's array of economic statistics the following would be the expected components in the more advanced statistical agencies: (a) statistics on the structure of the economy derived from either an economic census or from administrative data complemented by a survey on structural data (type of activity, breakdown of production costs, capital stock etc.); (b) exports and imports of goods and services, with the goods part broken down by commodity, country of origin and destination; (c) producer and consumer prices and indexes thereof; (d) short term indicators of economic change such as order books, deliveries of manufacturing goods and stocks thereof; (e) monthly physical output of key commodities and an index of industrial production; (f) business balance sheets (income, profit and loss, financial) and employment and unemployment as well as household income and expenditure. In addition, a statistical version of the accounts of the public sector would be an expected component.

In order to support these statistics, statistical agencies would maintain an up-to-date version of a classification by economic activity, usually an internationally agreed classification with a national supplement, and a classification of goods and services. They would also have their own or an international version of the classification of occupational employment.

Statistical Systems: Education

Educational activities of some kind occur in every human system such as the family, workplace, and governmental organizations such as schools and colleges. The statistical systems available to provide measurements of educational activities, such as individual learning and institutional support, are found in the institutions that administer those activities: schools and local, state, and federal government agencies. This article will describe the status of statistical information about the US educational system and educational attainment of individuals at the year 2000. It will discuss types of information collected by state and federal agencies, international agencies, and education associations. These agencies provide the basic statistical resources for many forms of social science analysis of educational practices and outcomes.

The educational statistical system was originally created to provide measurement of administrative capacity, such as the distribution of financial resources, rather than the capacity of individuals, such as what is learned by individuals. In recent years, national policies about education have shifted from providing access to resources to encouraging greater accountability by the school organizations themselves. Thus, the statistical system concentrated more attention between 1965 and 1999 on measures of student achievement and its correlates. The complete system of education statistics includes information about students, teachers, administrators, the general population, and finances.

1. *Organization of National and International Education Statistics*

For the United States, the constitutional power and responsibility for providing schooling for children resides in the laws of each state. Local school systems and colleges and universities collect some forms of statistical information about themselves to administer their own programs. Each school system and state education agency or college and university assembles basic facts about itself such as numbers of students enrolled, number of teaching staff, number of graduates, and amount of financial resources available. Since the nineteenth century, the federal government has been given authority to assemble aspects of school system statistics into national summaries at a central agency, such as the Department of Education, to provide for national trends in finance, enrollment, and completions of schooling and for monitoring the administration of programs in education. Standard definitions are assembled by the National Center for Education Statistics (NCES) of the US Department of Education to assist local agencies, states, and colleges and universities develop common statistical measures (NCES 1999c).

International organizations that provide central functions for the reporting of educational statistics include the Organization for Economic Co-operation and Development (OECD) and UNESCO. International standards were created in the 1970s by UNESCO to enable worldwide assembly of statistics of these basic enrollments, graduates, and financial accounts into a single report (UNESCO 1998). Statistics collected under these procedures were published annually in the UNESCO *Statistical Yearbook* until 1998 but may be discontinued after that year (UNESCO 1998). The ISCED definitions are used also by the OECD for the collection of educational statistics for its member countries which include Europe, Japan, Korea, Australia, New Zealand, Mexico, Turkey, and the United States (OECD 1999). OECD publishes an annual report, *Education at a Glance*, that provides comparable statistics across countries on demographic, financial resources, school participation, school environment, graduate output, student achievement, and labor market outcomes (OECD 1997).

The Office of Management and Budget (OMB) provides general oversight of the federal statistical agencies in the US government by evaluating their programs and establishing funding priorities. It also oversees and coordinates the administration's information and regulatory policies to develop better performance measures and to reduce burdens on the public. Survey instruments of the population proposed by federal agencies are evaluated by the OMB offices to insure that survey questions are not asked of the general public unnecessarily.

2. *US Department of Education*

In recognition that local schools and states needed to be able to monitor their own performance in enrollments in schools by comparing themselves with other states, a US Department of Education was originally created in 1867 for the purpose of collecting information on schools and teaching that would help the states establish efficient school systems. The most recent US Department of Education was created in 1979 by the Department of Education Organization Act (93 Stat. 668; 20 USC 3401). The responsibility for education statistics belongs to an agency within the Department of Education: The National Center for Education Statistics (NCES). The General Education

Provision act says, 'The purpose of the Center shall be to collect, and analyze, and disseminate statistics and other data related to education in the United States and in other nations' (20 U.S.C. 1221e-1, as amended). The programs of statistical data collection and reporting by NCES are described in their report *Programs and Plans* (NCES 1999c).

Congress allocates funds to NCES for the purpose of collecting, analyzing, reporting, and training persons to use educational statistics. These funds are then used in nationally competed contracts with companies that carry out survey collection and analysis functions for the government. The quality of the statistics are monitored by a staff of NCES to insure that unbiased collection procedures are followed and reported to all those who would use these statistical services. The agency conducts a few research studies of its own to improve, expand and modernize its techniques of statistical collection and reporting. Oversight of the agency is provided by a board of researchers from university settings and by other governmental agencies such as the Office of Management and Budget, which seeks to assure the public that data collection requests are not too heavily burdensome on the organizations that are required to provide the funds.

3. *The Census Bureau*

The first statistical information on schooling for the Nation was collected in the Census of 1840. The 1840 census required that 'the marshals and assistants should collect and return in statistical tables … all such information in relation to mines, agriculture, commerce, manufactures, and schools, as will exhibit a full view of the pursuits, industry, education, and resources of the country' (Wright 1900). This first report resulted in national statistics from school systems rather than from individuals and it resulted in a number of errors such that in some states more students were reported than children counted in the population. Beginning in 1850 individuals were asked whether they had 'attended school at any time during the year preceding the census' (Folger and Nam 1967 p. 2). Censuses during the twentieth century continued to ask individuals whether they were enrolled in school, but did not ask about grade of enrollment until 1940. The censuses since 1940 all contained grade of enrollment by demographic characteristics such as residence, sex, and race.

The census of 1840 also initiated a series of questions for adults on the ability to read and write. The reliability of this item was said to be weak, and to be reported for whites only. Approximately 1 in 5 persons in 1840 answered the census takers that they were illiterate (Folger and Nam 1967). A question on ability to read and write was continued in the censuses until 1930. But, by 1940 illiteracy rates had dropped to about 3 percent and adults were asked how many years of school they had completed (Folger and Nam 1967 p. 131). This question has continued until the census of 2000 which has modifications to expand the categories of persons with more than a high school education. A complete description of the actual census items used in measuring educational levels is contained in *200 Years of U.S. Census Taking* (US Bureau of the Census 1989).

The Census Bureau conducts monthly surveys of employment for the Bureau of Labor Statistics and includes items on educational attainment and school enrollment regularly so that analysis of changes in employment patterns, income, marriage, voting, and mobility might be examined for persons of different educational levels. The March Current Population Survey which collects information on income for all respondents contains questions about years of school completed. Statistics on these factors are reported in the annual series of reports on the Current Population Survey and are included in the public use tapes available to researchers. Occasionally, at the request of other agencies, the Census Bureau asks its respondents expanded questions about their education, such as their field of study (US Bureau of the Census 1999). The measure of educational levels was changed to type of degree rather than years of school completed in 1993.

4. *National Science Foundation and National Academy of Sciences*

The National Science Foundation monitors the production of scientists and engineers through the collection and analysis of surveys on doctorates and of financial support for basic research by government agencies as well as by private businesses. A summary of these statistical studies are reported every two years in a report titled, *Science & Engineering Indicators* (National Science Board 2000). NSF also provides survey data to researchers intended to study issues in academic science and engineering resources (such as the production, employment, and funding of scientists) in publicly available databases. Or by accessing the website (http://www.nsf.gov/sbe/srs/stats.htm) some of the statistical data sources can be accessed directly.

The National Academy of Sciences is a non-governmental organization established by President Lincoln to provide the Federal Government with the best advice of scholars throughout the country. It receives funding from federal agencies to conduct studies on specific issues, including the quality of statistical data collection activities of the government and the interpretation of statistical reports on student achievement and international comparisons. Thus, discussions and reports by the National Academy of Sciences indirectly influence the policies of the government in procedures for their statistical system. Reports

of the National Academy are publicly available through their website (http://www.nas.edu).

5. School Participation and Graduation

The number and percentage of the population attending schools of different kinds was a significant indicator of changes in institutional support for education during the nineteenth and twentieth centuries when the education system was expanding. In more recent years, a more significant indicator of educational levels is the completion of secondary school, of college, and field of study of graduates. Information about enrollments and graduates has been collected in household surveys, the census of population, and from reports of schools and colleges to the Commissioner of Education Statistics since 1840 and are summarized annually in the Digest of Education Statistics (NCES 1999a). The federal statistical agencies provide aggregate summaries of local, state, and household reports into a national summary.

Such descriptive statistics are of more interest to historian's analysis of changes in American institutions than to social science analysis of individual differences in progress through the education system. The study of personal choice within a school setting is conducted in a series of studies that follow a sample of students through school with paper and pencil questionnaires. Many such longitudinal studies are carried out by federal agencies in education, labor, and health for the purpose of analyzing consequences of student performance and choices made at an early age on later life chances (West et al. 1998). Many of these studies are conducted by joint participation of researchers and government agencies for the design and support of the analysis of significant issues in education and educational policy. Beginning in the1990s, most of this information is made available through agency websites.

6. Student Achievement

Every classroom in the United States evaluates student performance directly or indirectly. A national system of testing companies measuring student performance has grown since World War II to provide school teachers and administrators with professionally developed assessment instruments to evaluate the performance of whole schools compared with national averages or for individual student scores used for screening for college entry. Because of concerns that student performance as measured by college entrance exams appeared to be declining during the 1960s, but that the national estimates were not reliable, the Federal government created the National Assessment of Education Progress (NAEP) in 1966 as an independent measure of changes in student performance of the country. The National Assessment surveys and reporting of statistics has been supported and managed by NCES and results of the assessments for mathematics, science, reading, writing, and civics can be found in their annual publications. Establishing national standards for education performance and developing a methodology for conducting national assessments was made the responsibility of the National Assessment Governing Board by Congress in 1988 (see http://www.NAGBE.org). Planning and research to develop international comparisons of student performance was first initiated in 1958 and first conducted among 14 year-old students in mathematics in 1965 (Husen 1967). The countries that participate in these international comparisons formed an informal network of research institutes called the International Organization for the Evaluation of Educational Achievement (IEA). Several international studies of student performance in science, civics, writing, science, and mathematics were conducted between 1970 and 1999 (Medrich and Griffith 1992, OECD 2000). The US government, through the NCES and NSF, has provided support and monitoring of these studies because the results of the studies have received significant national publicity and have been effective in mobilizing local school districts to pay greater attention to student performance levels. The growth of the American form of testing in many other countries can be seen in the large number of countries that participated in the Third International Study of Mathematics and Science in 1995 when 50 countries participated in some aspects of the study and new countries were added to the assessment carried out in 1999. New international studies will be carried out after the year 2000 that use European definitions of the end of secondary schooling and measure student performance on skills and knowledge of mathematics, science, and reading literacy (OECD 2000).

Federal agencies conduct a number of studies that are intended to inform the general public about knowledge and attitudes held by adults. For example, the International Adult Literacy Survey was conducted in member countries of the OECD in 1994 to describe the literacy and numeracy of the adult populations in those countries (http://nces.ed.gov/pubs98/98053.pdf). A new survey of adults called the 'Life Skills Survey' is being planned for the year 2002 that will include national and international comparisons to identify and measure adult skills linked to social and economic success. The survey items in this survey will be based on a framework derived from American theories of intelligence and intends to create paper and pencil tests that would demonstrate the distribution of these skills in the population (NCES). This study and another study conducted for the National Science Foundation seeks to identify the distribution of knowledge and attitudes about science (science literacy) among adults in the United States and other countries (National Science Board 2000). Each of these surveys serves to

provide policymakers with information about the level of information held by adults.

Studies and reports about methods for assessing student performance are conducted by the National Academy of Sciences in its Board on Testing and Assessment and the Board on International Comparative Studies in Education. These committee members are selected from academic researchers who have written about student assessment procedures. Their discussions and reports raise questions in their meetings about the statistical quality of the intended and unintended affects of reporting of student assessment by statistical agencies and thus provide helpful guidance to federal policies about data collection.

7. *Teachers, Teaching, and Curriculum and Instruction*

A complete system of statistics for measuring changes in the US educational system would have to include aspects of the educational processes itself: teaching, curriculum, and instruction (Shavelson et al. 1989). Jeannie Oakes and Neil Carey say,

> Curriculum is the what of science and mathematics education. Curriculum in content—the topics, concepts, processes and skills that students learn in science and mathematics classes—but it includes more than that. It includes the depth to which students explore content; the way teachers organize, sequence, and present it; and the textbooks and materials schools use (Shavelson et al. 1989, p. 96).

International studies have helped introduce the methods of measuring the content of education systems. However, the statistical system has yet to put together all of the elements of this system in one place so that the operating events in schools can be compared and contrasted. Surveys are separately conducted about student achievement, teacher characteristics, curriculum, and teaching practices (National Science Board 2000).

Little consensus has been reached among education researchers about the most significant events in schools. Studies are conducted of pedagogy, curriculum content, and home environment (The Coleman Report 1966). The statistical system produces statistical studies that permit the analysis of social characteristics of students and parents as well as some of the classroom. But no single survey itself can summarize all of the elements essential to describing the processes and outcomes of the educational system.

8. *School Finance*

Differences in community capacity to support school systems results in large differences across the United States in revenues for public elementary and secondary schools. Since the differences may result from either differences in cost of living or in unequal spending, the collection and analysis of statistics on school finance of public elementary and secondary school systems is a major activity for NCES (NCES 1999c). In higher education, the methods that students and families use for payment of their tuition and living expenses while in college are a national policy concern and a subject of intense data collection and analysis (NCES 1999c). Surveys are conducted to determine what the effect of federal policy on the subsidies for tuition is to individuals and institutions.

The connection between educational level of individuals and personal income is a subject of data collection in surveys by the US Census Bureau where individuals are asked to report both their educational levels and income. In only a few instances has personal income been associated with measurement of specific educational experiences, such as field of study in college in Census Bureau surveys.

9. *Statistics and the Internet*

The results of education statistical studies are being disseminated more rapidly and thoroughly through the Internet than in previous years. All federal and many state education agencies are making available on their Websites statistical tables and analytical reports. Also, the databases themselves can be addressed over the Internet. In some instances, it is possible to request a specific table by electronic mail from a particular survey that generates the specific summaries. These changes in production and distribution of statistical materials have revolutionized the availability of statistics and makes their use much more likely to occur in many reports.

10. *Statistics and Public Policy*

School systems of all kinds have been undertaking reform of their practices of teaching and instruction for a number of years. Statistical measurement of the outcomes of schooling is important for the public discussion of the purposes and directions of these reforms. For example, the results of the Third International Mathematics and Science Study which reported that US students compared well with other countries in the 4th grade, less well at the 8th grade, and were much lower than other countries in the 12th grade attracted the attention of the President and many members of Congress. The production of statistical studies have affected deliberations about the importance of legislation regarding the improvement of education in the United States.

Statistical Systems: Health

Statistics is the science of collecting, analyzing, presenting, and interpreting data. A statistic is an item of quantitative data and so the term statistics can also mean a collection of quantitative data i.e., the results of collecting and analyzing data.

The term health statistics system can be used to describe any organized or structured mechanism that involves health statistics. It can therefore include systems that are used for collecting, analyzing, interpreting, and making available quantitative data in relation to health status or health services activity, as well as referring to the actual collections of quantitative health related data. Increasingly these statistics systems are computerized, and the increased availability and ease of access of information technology means that this trend towards computerization of health statistics systems is likely to continue in the future. However in many countries, paper based systems are still used for the collection of health statistics and, in some cases, the aggregation and dissemination of these health statistics are also not computerized. Therefore focusing solely on computerized health statistics systems, when looking for health information can mean that much valuable information is missed.

Decisions about health and health care, whether made by policy makers, by health professionals or by the public, are influenced by the information that is available. Much of this information is derived from official and other health statistics. Effective health care is therefore dependent on the process of gathering, analyzing, and disseminating timely and appropriate information. The quality and accessibility of the health statistics systems, from which this information is derived, can have a major influence on how health and health care systems are run and used.

When discussing statistical systems the terms data and information are often used interchangeably, but it is important to recognize the differences. Data are specific facts recorded in some way for possible future use, for example, the annual expenditure for a specific department in a hospital. Data becomes information when it is has meaning, usually by putting it in some relationship with other data. For example, relating expenditure for a hospital department to the services provided by that department and comparing this with the data for similar departments in other hospitals, provides information on how expensive it is to deliver the service in the hospital concerned compared to other hospitals. Health statistics are derived from data, and should provide information.

Another term that is increasingly used in relation to health information is knowledge. By putting information in the context of other information, including both quantitative data and textual information, deductions can be made that increase knowledge. Knowledge provides the basis for making decisions in a rational way. Knowledge, based on information, allows appropriate actions to be selected in order to achieve specific objectives. This is often referred to as evidence based decision-making. This is one of the main purposes of gathering data and producing health statistics.

1. Scope of Health Statistics

In some respects, the terms health information system and health statistics system can be used inter-

changeably. Where the focus is on the collection of the data, or on the statistical calculations that need to be carried out on the data to produce useful information, then the term health statistics may be used more often. However, if the focus is on the results of this data collection and analysis, and on making this information available, then the term health information is used more often. The use of telemedicine is expanding the scope of health care information, and so the definition of health information is growing to include not just health statistics but also multimedia audio, video, and high-resolution still images (Balch and Tichenor 1997).

The scope of what health statistics systems cover can be defined in several ways:

(a) by the type of data and information included;

(b) by where the data are produced;

(c) by where and how the information is held and made available; and

(d) by the purposes for which the information is used.

A narrow definition of health statistics could conclude that the purpose for collecting statistical information should be primarily to satisfy the needs of government. This would mean that health statistics systems would just cover those systems designed to produce official health statistics for government use. However, the current view in many countries, and of many of the producers of official statistics, is that the statistics are produced to serve not only government but also the wider community. The members of this wider community of health statistics users come from different organizational backgrounds, including legislative bodies, government departments, health service organizations, researchers, voluntary organizations, and patients, as well as the public in general. The health service organizations that need to use health statistics can also be wide ranging, depending on the health system in operation in the country concerned. They are likely to include both the public and private sector, and both providers of health care services and purchasing organizations.

This broader view of health statistics users is both driven by, and enabled by, the rapid spread of the use of the Internet and the World Wide Web. Familiarity with accessing information via the web has raised the expectations of both health professionals and the public in relation to the availability of health information. Increasingly producers of health statistics have started to respond to this by making the information they produce available in different formats and through different mechanisms to suit the differing needs of the user community.

The widespread use of the Internet has meant that this is now used as a common method of disseminating information about statistics, as well as providing access to the actual data in some cases. Access to statistics held on data archives, many of which include health statistics, is also possible via the web. Web-based approaches can also allow information from different systems to be brought together, either by making these available via a web site, or by using web based technologies to access information held on different systems.

The design and coverage of health statistics systems, described later in this article, therefore needs to be seen as being currently very much in a transitional stage. For many systems, developments are ongoing which will take advantage of the opportunities, and also meet the challenges, of the technology that is now available for bringing together information from different sources and for providing wider access to this information (Sandiford et al. 1992).

2. *Use of Health Statistics*

There are many different individuals and organizations involved in planning, managing, running, investigating, and using the health care system. Health statistics systems should ideally be designed to meet the information requirements of this health care community. Some of the main uses of health statistics are summarized in Sect. 2.1 to 2.9.

2.1 Information for Policy Makers and for the Management of Health Care Delivery

Policy makers at both national and local level need information to support decisions on planning and funding of services. This applies both to policy makers responsible for publicly funded services, and to organizations such as health insurance companies involved in the funding and provision of private health care services (Roos 1999, Roos et al. 1999). Health information systems can provide decision-makers with the capability to:

(a) Make critical comparisons across regions and subregions of residents' health status, socioeconomic risk characteristics, use of hospitals, nursing homes, and physicians.

(b) Carry out analyses, in relation to the population served, of demographic changes, expenditure patterns, and hospital performance.

(c) Carry out outcome research across hospitals and countries to support recommendations on effective treatments,

(d) Make comparisons of expenditure relative to outcomes to support purchasing decisions

(e) Carry out longitudinal research on the impact of health policy changes.

This information helps to answer questions such as what health care services do particular population groups need and, by comparing this need to the current service provision, which populations need more services and which need less? (See Slater 1999, Azubuike and Ehiri 1999, De Kadt 1989.)

In addition, health information systems are important support tools in the management and im-

provement of the delivery of health care services. Experience in several countries suggests that comparison of hospital-specific data influence hospital performance. If statistics on provider performance are made available this ensures not only prudent and cost-effective health care purchasing, but also it gives health care providers comparable information to enable them to improve the care they deliver.

2.2 Health Surveillance Systems

In health terms, surveillance is the close monitoring of the occurrence of selected health events in the population. This implies that the events to be monitored can be specified in advance. This may include setting up a notification system for the health event, to supplement data available from routine health data collection systems, for example in the case of infectious diseases such as tuberculosis. However, the events monitored can also include certain signs and symptoms which can be seen as 'indicator events', to give warning of unforeseen problems.

Surveillance methods have been developed as part of efforts to prevent or control specific health events. Surveillance systems are therefore dynamic, in contrast to archival health information, which can be used for epidemiological analysis. The events that can be controlled in surveillance systems include infectious diseases, maternal and child health, chronic non-infectious diseases, injuries, and the effects of exposure to occupational or environmental risk factors.

2.3 Types of Health Information

The ultimate aim of any statistical work in the health sector should be to assist in the maintenance and improvement of the health of the population and in the delivery of health care services. Health information can therefore be defined as any information that is needed to support these activities.

It is important to be able to access both health service and non-health service data when looking at health needs, since the determinants of health often lie outside the health service. Work in relation to prevention of illness and the promotion of good health therefore require access to data from a wide range of sources. In response to this requirement health statistics systems need to cover, or provide access to, information not only on all aspects of the health care systems, but also on factors that influence health and the availability and use of health care.

There are different models of health systems used in different countries, and these have an impact on the health statistics systems, both in terms of the data collected, and hence the information potentially available, and in terms of where the information is held and who has responsibility for it. There may also be variations in the organization of health care, hospitals and hospital information systems within a given national environment (Saltman and Figueras 1997). However, the differences in health system models usually relate mainly to funding mechanisms, rather than to the basic activities that need to be carried within the health sector. This means that the types of information held are usually similar, even if the organizations involved are different.

The types of information covered usually include:

(a) Health status
—Health of the population
—Vital statistics (births, deaths)
—Health surveillance—for both infectious and non infectious diseases

(b) Registers
—Patient registers e.g., persons insured, persons registered with a family doctor
—Disease registers e.g., cancer

(c) Health service resources
—Health care facilities
—Health care staff
—Other resources e.g., medical equipment, drugs

(d) Health service activity
—Hospital and other secondary care activity
—Primary care activity
—Financial information

(e) Explanatory factors
—Economic information
—Sociodemographic information
—Environmental information

(f) Other related data (often government or public sector statistics)
—Social care sector activity
—Police—crime figures, road traffic accidents
—Education

Some of the main types of information listed are discussed in more detail in later sections. In addition to the quantitative data listed in Sect. 2.3, the interpretation of information from health statistics systems often requires reference to textual information in relation to current policies and guidance, and also to research findings.

Some of the information is obtained using administrative data, which are routinely collected as part of the process of running and monitoring the health system. In addition information is available from censuses, either using data from national population censuses or from censuses of specific groups, e.g., census of patients in hospital at a particular time. Health statistics are also available from a wide range of survey data. These can be international, national, regional, or local surveys, and can include surveys that are part of a regular survey program as well as 'one off' surveys carried out for a specific research or policy analysis study.

The increased use of computerization in health statistics systems has already been mentioned. Computers can store large volumes of data and can process them quickly. This means that if data are entered on to

a computer at source it may not be necessary to summarize data before onward transmission. For example, every patient's record can be stored and sent rather than just counts of patients with particular diseases. Consequently converting data into information can be postponed until a specific issue raises the need for a particular piece of information. Much more flexibility is therefore available in how the data are aggregated to create information.

Also data held in electronic form is no longer confined to being in one place at a time. Several people can simultaneously be reading the same record in quite different locations. This creates possibilities for sharing information, which were never feasible with paper systems. However it also increases the risk of unauthorized access to data, and data confidentiality issues in relation to health statistics systems are discussed in a later section.

2.4 Health of the Population

Health monitoring requires measures of incidence, prevalence, and severity of illnesses, and the consequences of illness, classified by age, sex, socio-economic, and geographical characteristics of the population. There are no ideal measures, and several sources need to be used in combination, for example using both health surveys and information about patients in hospital. The varied sources of population health information provide different pieces of the overall health picture.

Ultimately the objective of health care expenditure is to improve the health of the population not for its own sake but so that people can live happier more prosperous lives. Gains in health status might be regarded as the ultimate measure of a health program's success. Composite measures of health status such as the DALY (Disability Adjusted Life Year) and the QALY (Quality Adjusted Life Year), although developed from different disciplinary backgrounds, both attempt to summarize the potential gains from medical interventions (Williams 1999, Jenkinson 1994). Whereas health economists developed QALYs, DALYs have their roots in epidemiology. As a consequence, the perspective of the first is based on patient assessment of pain and suffering while the second is disease driven with a medical assessment of the amount of suffering.

2.5 Vital Statistics—Mortality Data

The most absolute measure of ill health is death, and mortality statistics are one of the principal sources of information about the changing patterns of disease and the differences in these patterns between countries. Since mortality statistics are widely available death rates have traditionally been used as crude, but often effective, surrogates for more comprehensive measures of disease. This is often justified by the fact that death is unambiguous and the data collection is complete. However use of mortality data alone can provide misleading impressions of the burdens of disease in society. For example, in certain parts of the world, musculoskeletal disorders (including rheumatism and arthritis) are the most important current causes of limiting long-standing illness but are one of the least prevalent causes of death.

Death rates vary by age and by sex and so, if comparisons are to be made between populations with different age and sex composition then some adjustments are needed. A common approach is to use age standardized rates and ratios (often referred to as Standardized Mortality Ratios or SMRs). These are calculated by applying the rates found for a particular population to an agreed standard population. Standardization is also used when comparing other measures, such as hospitalization rates, which are likely to be affected by the age and sex structure of the population. Another measure commonly used when considering premature mortality or avoidable deaths is Potential Years of Life Lost (PYLL). This highlights the loss to society as a result of early deaths (for example, below age 65 or 75). The figure is the sum, over all persons dying from that cause, of the years that those persons would have lived had they survived to the stated age (e.g., 65).

2.6 Vital Statistics—Births Data

Although systems vary between countries, the systems from which birth and maternity data can be derived are likely to include civil registration of births, the notification of births, and hospital-based data collection systems. Birth registration is the oldest source of data about births. In most countries the primary reason for setting up systems for registering births, marriages, and deaths was to provide civil documents to record the events for legal purposes. To obtain a full picture of birth and maternity care, data also needs to be collected about facilities and staffing of the maternity services and about the socio-economic context in which childbirth occurs.

2.7 Patient Registers

Where health insurance systems are in operation, there will be registers for the population covered by the schemes. These registers are likely to include information such the individual's insurance status, name, date of birth, address, and identification number, plus possibly other socio-economic or medical status data, e.g., whether the person is a diabetic. Other data related to individuals would be the health insurance contributions made on their behalf from employers or through other mechanisms. Information on dependents covered by an employed person's contributions may also be included.

In many health systems patients will be registered with a family doctor or primary care center. These registers are likely to include some of the same basic patient information as for the health insurance registers, as well as some health status information. Records of preventive services such as immunizations carried out by family doctors may also be included.

2.8 Disease Registers

Separate registers are often kept, usually at local or regional level, for patients with specific diseases, and cancer registration is an important example of this. Since, in many parts of the world, cancer-related services are consuming ever-increasing health resources; the information from cancer registries is important in helping health care planners, researchers, and policy-makers formulate strategies to meet this challenge.

Cancer registration is the collection and classification of data on all cases of cancer occurring within a defined territory. The primary source of data on which cancer registration is based is the patient's clinical case notes. This holds true whether the information is derived from hospital departments, primary or community care, or the private sector.

Cancer registration is a worldwide process. The longest established cancer registries are in Europe and North America, but increasingly they are being developed in the countries of Asia, Africa, and South America. Attempts to record comprehensive information on the incidence and distribution of cancer have been made as part of individual censuses and studies since the last century, but it was not until the late 1940s that cancer registration really got underway. In 1959 the World Health Organization (WHO) produced recommendations for the establishment of cancer registries, and, in 1965 the International Agency for Research on Cancer (IARC) was established as a specialist research center of WHO.

2.9 Hospital Data

A wide variety of data is available from hospitals for the purpose of health service analysis and performance monitoring. Where computerized systems are not available, much of this is obtained as aggregate counts of patients, and of resources used, falling into predefined categories. However, where computerized health information systems are in operation, individual records of care can be accessed for each patient which contain wide ranging details of the diagnoses, the treatments delivered, and the resources used.

2.10 Non-health Service Data

As has already been mentioned, it is important to be able to access non-health service data when looking at health needs, and when comparing statistics on health service activity. In many countries there is also an increasing emphasis within the health sector on partnership working with other agencies, and the need to share information on common and related issues. Health and health care activities can be affected by activities in other sectors, and monitoring and planning of health services activity need to take this into account.

Non-health service data sources include population estimates, vital statistics, and census data. Vital statistics covering data on births and deaths have already been mentioned. Population estimates and census data are discussed elsewhere in this publication. Various deprivation indices, some of which are derived from Census data, are also used when analyzing and interpreting statistics relating to the health sector.

The links between housing and health have been well established. Some data on housing can usually be obtained from population censuses, and information about housing stock may also be available from local government statistical systems. Poor air quality is also considered to be detrimental to health. Once again some information may be available from government statistical systems supplemented by special studies. Other statistics relevant to health that may be available from government sources include information on education, income, unemployment, transport, and crime.

3. Standard Coding/Classification Systems

If health statistics are to be compared across different organizations, regions, and countries, it is important that common coding and classification systems are used throughout the health sector and that they are used consistently. The WHO International Classification of Diseases is a classification of specific medical conditions and groups of conditions which is determined by an internationally representative group of experts who advise the World Health Organization (WHO), which publishes periodic revisions. It was first introduced a hundred years ago and the version in current use worldwide is the tenth revision (ICD 10).

In addition to the use of international classifications such as ICD10, many countries and international communities have undertaken initiatives to standardize the health data they collect in order to facilitate comparisons across countries. An example of this is the European Union's program 'Community Action on Health Monitoring' that was adopted for a five-year period with effect from 1 January 1997 (for EU health information projects, see CORDIS website). Its stated objective was to contribute to the establishment of a Community health monitoring system that makes it possible to:

(a) Measure health status, trends and determinants throughout the Community.

(b) Facilitate the planning, monitoring and evaluation of Community programs and actions.

(c) Provide member states with appropriate health information to make comparisons and to support their national health policies.

(d) Develop methods and tools necessary for analysis and reporting on health status, the effect of policies on health and on trends and determinants in the field of health.

The program is structured in three pillars as follows:

(a) Pillar A deals with the establishment of Community health indicators and with conceptual and methodological work related to the process of making the data comparable and for identifying and developing suitable indicators;

(b) Pillar B deals with the development of a Community wide network for the sharing and transferring of health data between member states, the European Commission and international organizations;

(c) Pillar C deals with the development of methods and tools necessary for analysis and reporting and the support of analyses and reporting on health status, trends and determinants and on the effect of policies on health.

These activities are being carried out in close cooperation with the member states and also with institutions and organizations which are active in the field of health monitoring, in particular: the World Health Organization, the Organization for Economic Cooperation and Development, the International Labor Organization (OECD Health Data, WHO Health for All Database, WHO World Health Report 2000, WHO Health in Transition profiles).

4. *Managing Confidentiality*

One important aspect of health information, and therefore of the systems that relate to health information, is confidentiality. This is because the information held may relate to identifiable individuals. Many countries, as well as international communities such as the European Union, have strict laws requiring organizations, including government agencies, to register the types of personal information they hold, the purposes they use it for and who they share it with. The law gives people the rights to inspect the data which organizations hold about them and to challenge inaccuracy and mis-use. Information systems and data flows have to be designed to respect privacy with personal identifier data removed when it is not needed and security precautions in place when it is needed.

Some principles that commonly apply to collecting, holding, and using health data are that:

(a) Health authorities should justify the collection of personally identifiable information,

(b) Patients should be given basic information about data practices,

(c) Data should be held and used in accordance with fair information practices,

(d) Legally binding privacy and security assurances should attach to identifiable health information with significant penalties for breach of these assurances,

(e) Disclosure of data should be made only for purposes consistent with the original collection,

(f) Secondary uses beyond those originally intended by the data collector should be permitted only with informed consent.

5. *Recent Developments*

Some of the trends in technology affecting health information systems have already been described. Another feature of planned developments in systems is a move towards integrated, patient-centered computing. Currently information is often collected according to the activity carried out e.g., by hospital department, which can make it difficult to obtain a complete set of information for an individual patient, or group of patients. The patient centered approach means that the computer systems and files are designed around capturing information along the whole continuum of care for a patient (Nold 1997).

It is also expected that health statistics systems will move towards higher-speed data transmission, and greater network capacity, following national and international computing standards. This will allow more rapid access to health statistics, as well as facilitating the bringing together of information from different sources—leading to improved information and greater knowledge about population health and health care (Mendelson and Salinsky 1997).

D. Leadbeter

Statistical Systems: Labor

Labor statistics represent a large body of information relevant to many of the social and economic issues of our time. They are used as indicators of how well the general economy is functioning and also as a basis for designing, implementing, and monitoring employment and social programs and policies. Labor statistics are generally part of a national statistical program and are interrelated with statistics in other fields, for example, with statistics on education, health, and production. International comparisons of labor statistics can help in assessing a country's economic performance relative to other countries (for example, by comparing unemployment rates and employment growth) and in evaluating the competitive position of a country in international trade (for example, by comparing productivity and labor cost trends).

1. *Topics and Classifications*

Article 1 of Labor Statistics Convention Number 160 of the International Labor Office (ILO) established in 1985 a minimum set of topics to be covered in official national labor statistics programs (ILO 2000). The list is as follows.

(a) Economically active population, employment, where relevant unemployment, and, where possible, visible underemployment.

(b) Structure and distribution of the economically active population, for detailed analysis and to serve as benchmark data.

(c) Average earnings and hours of work (hours actually worked or hours paid for) and, where appropriate, time rates of wages and normal hours of work.

(d) Wage structure and distribution.

(e) Labor cost.

(f) Consumer price indices.

(g) Household expenditure or, where appropriate, family expenditure and, where possible, household income or, where appropriate, family income.

(h) Occupational injuries and, as far as possible, occupational diseases.

(i) Industrial disputes.

ILO convention 160 recommends that each member state (almost all countries are members of the ILO) 'collect, compile, and publish basic labor statistics, which shall be progressively expanded in accordance with its resources to cover [these] subjects.' The USA and most other developed nations collect and publish data for all subjects listed in Article 1. On the other hand, developing nations often do not yet have the full array of labor statistics. The publication *Key Indicators of the Labour Market* (Johnson et al. 1999) provides information about the availability of many of the basic labor statistics in almost all countries of the world. Deficiencies in the availability and timeliness of labor statistics are particularly apparent in Africa and parts of Asia.

1.1 *National Classifications*

The presentation of labor statistics requires many distinctions or categories such as occupations and branch of economic activity. In order to facilitate data collection and analysis, these categories are organized into classifications. These are instruments that group together units of a similar kind, often in hierarchies, thus allowing for different degrees of detail to describe the characteristics in a systematic and simplified way. For example, in the USA, the Standard Occupational Classification and the Standard Industrial Classification have been the structures that define occupations and industries for many years. Such systems need periodic revision to keep up with the changing economy and to accommodate new industries and occupations. *Revising the Standard Occupational Classification System* (1999) provides an account of the 1998 revision to the US occupational classification as well as a brief history of the industrial classification system.

The North American Industry Classification System (NAICS) represents a complete restructuring of the

US industrial classification (1997). This system was prepared jointly because the North American Free Trade Agreement of 1994 increased the need for comparable statistics from the USA, Canada, and Mexico. Each country can individualize the new system to meet its own needs, as long as data can be aggregated to the standard NAICS categories.

1.2 Other International Classifications

International standard classifications serve to enhance cross-national comparisons. The International Standard Industrial Classification of all Economic Activities was established under the auspices of the United Nations, and the latest International Standard Classification of Occupations was established by the ILO's 14th International Conference of Labor Statisticians in 1987. Summaries of these classifications appear in the appendices to the ILO's *Yearbook of Labour Statistics* (1999). Countries often prepare concordances or 'crosswalks' that allow their national classifications to mesh with the international classifications.

1.3 International Concepts

The ILO's periodic Conferences of Labor Statisticians have established guidelines for the measurement of many aspects of labor statistics (ILO 2000). These guidelines serve as a model for countries trying to develop national statistics on the topic concerned and they also provide, to some extent, a benchmark for international comparisons. For example, ILO standards for measuring labor force, employment, and unemployment are followed by many countries. Varying interpretations of these guidelines, however, particularly with regard to different aspects of unemployment, create differences across countries that require adjustments to enhance comparability of unemployment rates (Sorrentino 2000).

2. Institutional Framework

Labor statistics are primarily collected by governments rather than the private sector, although in some countries there has been a movement toward privatizing some data collections. In the USA, which has a decentralized statistical system, over 70 Federal agencies are engaged in the collection of statistics. The Bureau of Labor Statistics (BLS) in the US Department of Labor is the principal data-gathering agency of the US Federal Government in the broad field of labor economics. Most of the Bureau's data come from voluntary responses to surveys of businesses or households conducted by BLS staff, by the Bureau of the Census (under contract to BLS), or in conjunction with cooperating State and Federal agencies.

Unlike the decentralized system of the USA, other countries tend to have central statistical offices, and the collection of labor statistics is accomplished within these national agencies. However, labor ministries often also play a role in the collection of labor statistics abroad.

Several international organizations work in the realm of labor statistics, obtaining and publishing labor information from countries, providing technical assistance to member countries, and establishing conceptual guidelines. National agencies cooperate with the international organizations by transmitting the data requested on a regular basis and also for *ad hoc* studies. Major international organizations involved in labor statistics are discussed in Sect. 6.

3. Sources of Labor Statistics

Labor statistics are generally collected in censuses or sample surveys of households or business establishments, or processed on the basis of data resulting from administrative procedures of public agencies. Many of the major programs of the US BLS are based on sample surveys. For instance, the Current Population Survey (CPS) is a monthly survey based on a sample of about 50,000 households; data are collected by computer-assisted personal and telephone interviews. The survey is conducted by the Bureau of the Census for BLS and is the source of national statistics on the labor force, employment, and unemployment. About 70 countries conduct regular labor force surveys, on an annual, quarterly, or monthly basis.

Another major survey of BLS is the monthly Current Employment Statistics Survey. This survey is a sample of almost 400,000 establishments conducted by State employment security agencies in cooperation with BLS, and it provides employment, hours, and earnings data collected from payroll records of business establishments. Similar surveys are conducted by many other countries.

Labor statistics may also be based on administrative records. Although the primary purpose of administrative records is not the production of statistics, these systems provide a rich information source that has been exploited to varying degrees in different countries. Among the uses in the USA, administrative data from the Unemployment Insurance system are used in combination with CPS data to produce unemployment data for States, labor market areas, counties, and cities. In several European countries, employment office registrations are the primary monthly indicator of the labor market. This is likely to be the case in countries that do not have a monthly household survey as a source for unemployment statistics.

Some labor statistics are constructed by combining data from different sources. For example, industry

labor productivity data (output per employee or per hour) require data on both labor input and business output. The labor input measures are generally constructed from a combination of hours data from labor force and establishment surveys, while the output components typically are based on national income and product accounts which are derived from business establishment surveys.

4. Dissemination of Labor Statistics

Disseminating statistics means presenting and distributing the data to users in various forms and preparing analyses of the data. The BLS makes available the information it produces through a broad publication program that includes news releases, periodicals, reports, and bulletins. Articles in the *Monthly Labor Review* present analyses of labor data. Some BLS material is available on magnetic tape, computer diskette, CD-ROM, and microfiche. Current BLS data, publications, and articles are also made available through the Internet. Other countries use similar methods of data dissemination.

The publications *Major Programs of the Bureau of Labor Statistics* (1998) and the *Handbook of Methods* (1997), as well as the BLS web site noted in the bibliography, provide further information on the Bureau's programs and how to obtain BLS data. Links to the statistical offices of other countries as well as to international organizations are included on the BLS web site.

In 1996, the International Monetary Fund established a Dissemination Standards Bulletin Board on a web site (IMF DSBB) to assist countries in following the best practices of dissemination of economic and financial data to the public. One of the aspects of this, the General Data Dissemination System (GDDS), guides countries in the provision of comprehensive, timely, accessible, and reliable data, and the site provides information on data produced and disseminated by participating member countries. The GDDS system is built around four dimensions—data characteristics, quality, access, and integrity. Information on the formats and titles of national statistical publications is included. The GDDS is a source of metadata (that is, descriptions of current practices on data concepts, sources, and methods) on labor statistics as well as on other types of economic statistics. The detailed metadata provide users with a tool to better assess the usefulness of the data for their own particular purposes.

5. International Comparisons

An international perspective can often enrich analysis of national labor markets, but such comparisons must be made with caution because statistical concepts and methods vary from country to country. Simply comparing national data across countries could lead to erroneous conclusions. The BLS and several international organizations derive meaningful comparisons by selecting a conceptual framework for comparative purposes; analyzing foreign statistical series and selecting those that most nearly match the desired concepts; and adjusting statistical series, where necessary and feasible, for greater inter-country comparability.

The BLS comparisons generally are based on US concepts so that they will be on the conceptual basis most familiar to US data users. Comparisons made by international organizations frequently are based on the international standards recommended by the ILO, discussed in section 2.3. Brief descriptions of the comparative programs of the BLS, three international organizations, and a unique international micro-database follow. Further information is available from their respective web sites, cited in the bibliography.

5.1 Bureau of Labor Statistics

From its inception, BLS has published comparative information on labor conditions and developments abroad. Foreign labor research and statistical analyses have been undertaken because: (a) comparisons between US and foreign labor conditions shed light on US economic performance relative to other nations; (b) comparisons provide information on the competitive position of the USA in foreign trade, which has an important influence on the US economy and employment; (c) information on labor conditions published by a majority of foreign countries is not readily available to US labor representatives, employers, Government officials, and others, and frequently is not available in English; and (d) often, only an expert can judge the quality and comparability of foreign statistical data.

The BLS comparisons program currently covers three key areas: (a) labor force, employment, and unemployment; (b) manufacturing productivity and labor costs; and (c) manufacturing hourly compensation costs. Only major developed countries are covered in the labor force and productivity comparisons, whereas the hourly compensation comparisons cover 28 countries at various stages of development. Outside the USA, national statistical agencies generally do not produce their own international comparisons. They depend on the comparative work of the BLS as well as that of international bodies such as those described below.

5.2 International Labor Office

The ILO in Geneva plays a major role in the arena of international labor statistics. This agency's role has already been mentioned in terms of promoting the

production of labor statistics and setting international standards for statistics. The worldwide scope of the ILO's membership ensures that this organization provides the most comprehensive geographic coverage among the international organizations involved in labor statistics.

The ILO has several publications or programs that provide varying degrees of comparable labor statistics. The annual *Yearbook of Labour Statistics* (ILO 1999) is the most comprehensive source for worldwide labor statistics. The *Yearbook* compiles national labor data according to international classifications of industry and occupation, with annotations concerning deviations from these classifications, coverage, and sources. However, no adjustments are made for conceptual differences in labor force measures. All data are supplied by the national statistical authorities. The *Yearbook* contains data on labor force, employment, unemployment, hours of work, wages, labor cost, consumer prices, occupational injuries, and strikes and lockouts. Some statistics are presented as time series, others are provided for only the latest year.

The ILO's program of ILO-Comparable labor force statistics takes the process a step further by making adjustments of the labor force and unemployment data to ILO concepts for over 30 countries. Data from the ILO-Comparable program are available online (Lawrence 1999) and are also used in the publication *Key Indicators of the Labour Market* (Johnson et al 1999). The latter publication is well annotated concerning comparability issues for all of the 18 indicators provided.

5.3 Organization for Economic Cooperation and Development (OECD)

The Paris-based OECD comprises 29 member countries, most of which are the advanced countries in North America and Western Europe, as well as Australia, New Zealand, and Japan. In addition, some of the transition countries of Eastern and Central Europe, Mexico, and Korea became members of the OECD in the 1990s. Most OECD labor statistics cover the member countries only, but some series are being expanded to cover non-member Asian and Latin American countries.

The main labor-related publications of the OECD are the annual and quarterly editions of *Labour Force Statistics* (1999). The annual publication compiles two decades of statistics, while the quarterly editions show selected data for the past five years. These publications provide statistics on key elements of the labor force, rather than on the broader range of labor statistics contained in the ILO *Yearbook*. Through the OECD's provision of extended time series, it is possible to identify structural changes that have taken place in the labor force of the countries with respect to gender, age, and economic activities. Data on part-time employment and duration of unemployment are included. The detailed statistics on employment are generally in conformity with the International Standard Industrial Classification.

Another program of the OECD, the Standardized Unemployment Rates, provides unemployment rates adjusted to ILO concepts for 24 member countries. The Standardized Rates are published in an annex to the aforementioned quarterly editions and they also are available from the OECD web site.

Additional labor statistics are published in the annual *OECD Employment Outlook*, expanding the range considerably to include special international analyses of training statistics, indicators of the degree of employment protection and regulation, trends in self employment, income distribution, minimum wages and poverty, the transition from education to the labor market, trends in working hours, and workforce aging, to name some of the special studies. The OECD analyses pay careful attention to comparability and often contain annexes that explain the data comparison issues in detail.

5.4 Statistical Office of the European Communities (Eurostat)

Eurostat's main role is to process and publish comparable statistical information for the 15 member countries of the European Union. Eurostat tries to arrive at a common statistical language that embraces concepts, methods, and statistical and technical standards. A significant portion of Eurostat's statistics relates to labor. The *Labor Force Survey* (1998) is a joint effort by member states to coordinate their national surveys. The result is a detailed set of comparative data on employment, working time, and unemployment. Eurostat also publishes monthly harmonized unemployment rates for all member countries. Comparable data are critically important for the European Union because the Community's social funds are distributed according to a formula that includes unemployment as a significant component.

Eurostat's Harmonized Indices of Consumer Prices (HICPs) are designed for international comparisons of consumer price inflation. The HICPs are the result of the collaboration between Eurostat and national statistical offices of member states on harmonizing the different methods used to compile price indices. The harmonization process has resulted in an improved quality of the indices. HICPs are not intended to replace national consumer price indices (CPIs).

Besides the labor force survey and CPI statistics, Eurostat also publishes results from its harmonized labor cost surveys and conducts a European household panel that allows for analysis of income, employment, social exclusion, health, education, and many other topics.

5.5 Luxembourg Income Study (LIS)

The LIS, begun in 1983, is a unique cooperative international research project with a membership that includes 25 countries on four continents. The project is funded mainly by the national science and social science research foundations of its member countries. LIS comprises a collection of household income survey sets of microdata (files of data on individual households) for cross-country research. A companion database established in 1993 is the Luxembourg Employment Study, or LES. The data sets of LIS and LES have been harmonized in order to facilitate comparative studies. LIS and LES have become a rich source for comparative research in the areas of poverty and income distribution as well as labor market behavior. Moreover, these databases foster interdisciplinary research in the fields of economics, sociology, and political science. Researchers in member countries may use the LIS and LES databases at no charge, after signing a confidentiality agreement. Copies of the studies based on these databases are available from the LIS web site.

Statistics as Legal Evidence

1. Introduction

The subject of statistics has sometimes been defined as decision-making in the face of uncertainty; from this perspective, the legal use of statistics is a natural rather than a surprising development. Indeed, probabilistic and statistical modes of reasoning and inference can be found in documents as old as the Talmud and the use of pseudo-quantitative degrees of proof is one element of medieval canon law. But all such attempts to introduce quantitative elements into the law remained necessarily informal until the rise of probability and statistics as formal mathematical disciplines.

Shortly after the birth of mathematical probability in the seventeenth century, mathematicians such as Leibniz and James Bernoulli examined the legal implications of the subject (the latter in his masterpiece, the *Ars conjectandi*) and, in the eighteenth and nineteenth centuries, analyses of the reliability of testimonial evidence became commonplace in the treatises of the day on mathematical probability. But it was only in the hands of the French mathematicians Condorcet, Laplace, and Poisson that models of jury deliberation were first proposed, analyzed, and fitted to data. The models of Condorcet and his successors became of renewed interest in the 1970s

when some United States jurisdictions considered permitting juries to either have fewer than 12 members, or non-unanimous verdicts. Subsequently, critics such as Comte and Bertrand in France and Mill and Venn in England questioned whether the subjective, qualitative, and individual could be analyzed by methods that were supposed to be objective, quantitative, and based on the collective; and in the end such academic discussions had little practical legal impact.

But in the twentieth century, and especially in the years following World War II, when the uses and applications of statistics found ubiquitous applications throughout science, commerce, government, and society, the law began to turn increasingly to the methods of statistical inference for assistance in a wide variety of fields. Such applications now range from sampling, proof of discrimination, and the determination of damages, to the establishment of paternity, human identification, and the prediction of future violent behavior. The applications that occur fall into two natural classes: in some cases, statistical methods are used to determine specific facts relevant to a particular case being decided (did this employer discriminate against that employee? did the defendant commit the offense charged?); in other cases, statistical methods are used are answer more general questions thought to be relevant to underlying law (does capital punishment deter homicides?).

2. *Sampling*

The use of sampling in civil and administrative cases represents a natural and early application of statistical methods. A company seeking a refund for overpaid taxes but wishing to avoid the time and expense of examining each and every sales receipt at issue, might instead draw a sample from the population of all receipts; a government regulatory agency, suspecting inappropriate behavior on the part of a company trading commodity futures might conduct an audit of a random selection of accounts, rather than examine and analyze potentially tens of thousands of such accounts; an insurance company engaged in an arbitrated dispute might agree to accept the results of a sample of policies drawn by a neutral third party. Such applications are natural and represent some of the earliest serious uses of statistics in the law precisely because the benefits were obvious and the methodology (if properly conducted) difficult to challenge.

3. *Random Selection*

A properly drawn scientific sample is accepted as representative because the randomness in question has been imposed by the statistician (using either a computer, random number table, pseudo-random number generator, or physical randomization). Sampling practitioners know however that true randomness is often difficult to achieve and that samples not drawn in accord with appropriate protocols may turn out to exhibit serious biases. Thus in some legal applications of statistics, whether or not a sample has been randomly drawn is itself the question of interest. Casinos reporting unusually low cash receipts during a year are sometimes challenged on the basis of a statistical analysis of possible variation in yearly revenue. Governments also resort to the use of random selection or lotteries, for example, in jury selection, the military draft, random audits of tax returns, and spot checks of baggage or individuals at airports, in ways that may be subjected to statistical scrutiny and legal challenge. One famous example of this is the 1968 United States draft lottery (which determined the order in which individuals were drafted into the army): individuals born later in the year were more likely to be drafted before individuals born earlier in the year. Sometimes the purpose of a government lottery is not just to achieve randomization, but also to ensure a popular perception of fairness. Aristotle, in his *Athenian Constitution*, describes a complex multistage procedure for juror selection that presumably satisfied both of these functions.

Even if the mechanism for selection of a jury or grand jury does not employ randomization, there may be a legal requirement that the results of whatever method of selection has been used should at least appear to be random. In any discussion of random selection, it is important to distinguish between the process used to generate an outcome, and the absence of pattern in the outcome. The process may employ a true element of physical randomness, yet the outcome might by chance display some form of pattern; while the output of some deterministic processes, such as a pseudo-random number generator, may appear to be pattern free. Thus in the United States, for example, juror pools are often based on samples of administrative convenience but may, as a matter of law, be required, however selected, to be a representative cross-section of the population. Jury verdicts are therefore sometimes challenged on the ground of possible discrimination in the selection of the jury, it being alleged that either minorities or other groups had been excluded or underrepresented. Thus, for example, in the trial of Dr. Benjamin Spock for advocating resistance to the draft, his attorneys (believing that women would be more favorably disposed towards their client) appealed his conviction in part on the ground that women had been disproportionately excluded during one stage in the jury selection process and based this contention on a statistical analysis.

4. *Employment Discrimination*

In scientific sampling, the model of random selection arises from the actions of the statistician and, in jury selection, the randomness of the outcome may be a

legal requirement. But in some instances the model of random selection is a benchmark imposed by the analyst. In employment discrimination cases, for example, it may be claimed that racial, ethnic, sexual, or age discrimination took place in the hiring, promotion, or termination of individuals. In the workplace, such discrimination, if it does take place, is seldom explicit today and resort is often made to statistical methods of proof to document the underrepresentation of a protected class.

In the United States, the law distinguishes two basic classes of employment discrimination: disparate treatment and disparate impact. In disparate treatment, intentional discrimination on the part of the employer is charged and statistical proof of underrepresentation may be introduced to support such a claim. In disparate impact cases, in contrast, the intent of the employer is not at issue: it is charged that, for whatever reason, the hiring, promotion, or termination practices of the employer impact to a greater extent on one or more protected classes, for example, Hispanics and African-Americans, than others. Rulings of the US Supreme Court in the 1970s found that, in certain circumstances, disparate impact was enough to sustain a finding of discrimination, unless the employer can defend the practice at issue on the grounds of 'business necessity'; for example, a promotional examination may have a disparate impact but test for a necessary job skill. Such rulings were of great importance: by creating a purely statistical category of employment discrimination, they resulted in a rapid assimilation of statistical methods into the law, including many areas other than employment discrimination, due in large measure to the imprimatur given them by the Supreme Court.

After statistical methods of proof of employment discrimination became routinely accepted in US courts, increasingly sophisticated methods began to be introduced. In cases of salary discrimination, for example, complex regression models are sometimes used in an attempt to argue that a minority group or other protected class is being underpaid even after the salary of the individual is adjusted for all variables (such as experience, skill, and credentials). Because both the hiring and promotion of individuals and the salaries they are paid are not the outcome of a lottery but the result of human choice and agency, the appropriateness of using as a yardstick the random selection model underlying all such statistical models has been questioned. One serious concern is that as the methods used become more complex and in consequence more removed from the intuition of the lay trier of fact, the potential for misunderstanding and misuse increases. One illustration of this is the not uncommon interpretation of a mere finding of statistical significance as being a direct proxy for one of substantive significance.

It is not always obvious at what level an analysis should take place in a discrimination case. Simpson's paradox refers to situations where a disparity between two groups is found at one level of analysis, but disappears at another. For example, in the 1960s, the Graduate School of the University of California at Berkeley discovered that a substantially higher percentage of men than women were being admitted for graduate studies. In an attempt to identify those departments responsible for the disparity, the Graduate School examined the records of individual departments and found that in each department women were doing at least as well as, and sometimes better than, their male counterparts. There is a simple explanation for the phenomenon in this case: women were applying preferentially to departments that had a lower admission rate, men were applying preferentially to departments that had a higher admission rate.

5. *Forensic Applications*

Much of forensic science is devoted to the identification of substances or individuals, and in both cases important statistical issues arise. Classical gunpowder residue, blood alcohol level, and drug tests, three examples of tests for the suspected presence of substances, must all take into account the statistical variability inherent in the testing process. In the case of human identification, additional issues arise. The determination of human identity has classically exhibited two extremes. In fingerprint analysis, it is usually accepted that an adequate fingerprint exhibiting enough characteristics suffices to uniquely identify its source. In classical serological testing, in contrast, determining the ABO type of a biological specimen (usually blood, saliva, or semen) merely suffices to narrow down the class of possible donors to perhaps 25 percent to 1 percent of the population. Such evidence, although probative, obviously cannot by itself establish identity. It is only recently, with the advent of sophisticated methods of DNA testing, that the potential for human identification has dramatically increased.

In a DNA profile, one or more locations (loci) on the human chromosome are examined and typed. Because human chromosomes come in pairs, two alleles are present for each locus and the list of allele pairs for each locus constitutes the DNA profile for the individual. Because the loci used in forensic applications are typically hypervariable (many possible alleles can occur at each locus), the resulting DNA profiles can be highly discriminating (few individuals in the population will have the same profile) and the typical profile may have a frequency in the population ranging from 1 in several thousand, to 1 in several million, billion, or more (depending on the system used). Such impressive frequency estimates necessarily make certain statistical or population genetic assumptions (independence of alleles within and between loci,

sometimes termed either 'gametic' and 'zygotic,' or 'Hardy-Weinberg' and 'linkage' equilibrium), assumptions whose validity must be tested and may vary substantially from one population to another. More sophisticated approaches estimate parameters that attempt to correct for the presence of possible subpopulations.

Initially the introduction of such frequency estimates was attended by considerable controversy, but the introduction of polymerase chain reaction (PCR) methods in recent years has resulted in the ability to type increasing numbers of loci. At first, the FBI laboratory only typed four restriction fragment length polymorphism (RFLP) loci but in the not too distant future, the resulting DNA profiles may well come to be viewed as essentially establishing identity.

Nevertheless, even in situations where the computation of a profile frequency is not regarded as being by itself controversial, a number of statistical complexities still arise:

(a) the calculation of profile frequencies requires knowledge of the underlying allele frequencies, and knowledge of these requires either a true random sample, or at least, if a sample of convenience is used, one thought to be representative of the population,

(b) profile frequencies can vary considerably from one racial or ethnic group to another and information for some population subgroups may not be readily available (for example, some American Indian populations),

(c) in some cases, especially sexual assaults, a mixture of two or more sources of DNA may be present and such complex mixture cases can present formidable difficulties in both interpretation and appropriate statistical analysis,

(d) if a DNA profile is identified by searching through a large databank of such profiles (for example, profiles of convicted felons), the statistical weight afforded to such a match needs to take this into account. (From a frequentist perspective, it is sometimes argued that this should be done by adjusting for the multiple comparisons being performed; from a Bayesian perspective, the adjustment would reflect the differing priors in a situation where a suspect is in hand and a suspectless crime resulting in a databank search.)

(e) matching DNA profiles are much more common among relatives than unrelated individuals in a population, the computation of profile frequencies for relatives leads naturally to another important application of DNA testing.

6. *Paternity Testing*

Closely related to its use in criminal forensics, DNA profiles are also used in establishing paternity. Suppose the profiles of a child, mother, and putative father have been determined. If the putative father is not excluded as a possible father, then two statistics are commonly encountered to measure how unusual such a failure to exclude is. One statistic, termed the 'random man not excluded' (RMNE), computes what fraction of the male population would similarly not be excluded if their DNA profiles were also tested. The second statistic, termed the 'paternity index,' computes the likelihood ratio for two hypotheses conditional on the observed evidence (the three profiles): the first hypothesis, that the putative father is indeed the father; the second, that the true father is a random member of the population. Such calculations were initially performed using knowledge of the ABO and other blood groups, but in the current era of DNA testing often suffice to effectively establish paternity.

There are a number of variant calculations that can also be performed. One can compute paternity indices if the profile of the mother is unknown or in more complex situations where the profiles of relatives other than the mother are known. Or one can attempt to identify the source of biological material when the profile of the individual is unavailable but the profiles of relatives are available. This is often the case in body identification, in particular when mass disasters are involved.

7. *Violence Prediction*

Society often has a stake in attempting to predict future violent behavior: are there adequate grounds for confining a mentally ill person on the grounds that they pose a significant risk if left at liberty; if a prison inmate is paroled, is it likely that they will commit another crime after release; if a sexual predator is released after their prison sentence is completed, how likely is it that they will commit another sexually violent offense after their release? Such predictions, especially in the last category, have traditionally suffered from the same difficulties as testing for a rare disease: even if a test for a disease has both high sensitivity and specificity, when the disease is rare enough, most of the positives are false positives. Despite such difficulties, in recent years some psychologists have attempted to construct predictive 'instruments' (tests) using complex logistic regression models, and have analyzed their performance using survival analysis techniques.

8. *Interpretation*

Statistical analyses may be performed by highly competent individuals but their results must be interpreted and used by persons lacking formal training or quantitative understanding. This presents challenges both in successful presentation and in meeting the important responsibilities placed on the statistician to

ensure that his results are not overvalued. Terms such as 'statistical significance' are easily and frequently misunderstood to imply a finding of practical significance; levels of significance are all too often interpreted as posterior probabilities, for example, in the guise that, if a DNA profile occurs only 1 in 10,000 times, then the chances are 9,999 to 1 that an individual having a matching profile is the source of the profile. As a result, individuals may tend to focus on the quantitative elements of a case, thereby overlooking qualitative elements that may in fact be more germane or relevant.

9. Other Applications

The last decades of the twentieth century saw a remarkable variety of legal applications of statistics: attempting to determine the possible deterrent effects of capital punishment, estimating damages in antitrust litigation, epidemiological questions of the type raised in the book and movie *A Civil Action*. Some of the books listed in the bibliography discuss a number of these.

Statistics, History of

The word 'statistics' today has several different meanings. For the public, and even for many people specializing in social studies, it designates numbers and measurements relating to the social world: population, gross national product, and unemployment, for instance. For academics in 'Statistics Departments,' however, it designates a branch of applied mathematics making it possible to build models in any area featuring large numbers, not necessarily dealing with society. History alone can explain this dual meaning. Statistics appeared at the beginning of the nineteenth century as meaning a 'quantified description of human–community characteristics.' It brought together two previous traditions: that of German '*Statistik*' and that of English *political arithmetic* (Lazarsfeld 1977).

When it originated in Germany in the seventeenth and eighteenth centuries, the *Statistik* of Hermann Conring (1606–81) and Gottfried Achenwall (1719–79) was a means for classifying the knowledge needed by kings. This 'science of the state' included history, law, political science, economics, and geography, that is, a major part of what later became the subjects of 'social studies,' but presented from the point of view of their utility for the state. These various forms of knowledge did not necessarily entail quantitative measurements: they were basically associated with the description of specific territories in all their aspects. This territorial connotation of the word 'statistics' would subsist for a long time in the nineteenth century.

Independently of the German *Statistik*, the English tradition of political arithmetic had developed methods for analyzing numbers and calculations, on the basis of parochial records of baptisms, marriages, and deaths. Such methods, originally developed by John Graunt (1620–74) in his work on 'bills of mortality,' were then systematized by William Petty (1627–87). They were used, among others, to assess the population of a

kingdom and to draw up the first forms of life insurance. They constitute the origin of modern demography.

Nineteenth-century 'statistics' were therefore a fairly informal combination of these two traditions: taxonomy and numbering. At the beginning of the twentieth century, it further became a mathematical method for the analysis of facts (social or not) involving large numbers and for inference on the basis of such collections of facts. This branch of mathematics is generally associated with the *probability theory*, developed in the seventeenth and eighteenth centuries, which, in the nineteenth century, influenced many branches of both the social and natural sciences (Gigerenzer et al. 1989). The word 'statistics' is still used in both ways today and both of these uses are still related, of course, insofar as quantitative social studies use, in varied proportions, inference tools provided by mathematical statistics. The probability calculus, on its part, grounds the credibility of statistical measurements resulting from surveys, together with random sampling and confidence intervals.

The diversity of meanings of the word 'statistics,' maintained until today, has been heightened by the massive development, beginning in the 1830s, of *bureaus of statistics*, administrative institutions distinct from universities, in charge of collecting, processing, and transmitting quantified information on the population, the economy, employment, living conditions, etc. Starting in the 1940s, these bureaus of statistics became important 'data' suppliers for empirical social studies, then in full growth. Their history is therefore an integral part of these sciences, especially in the second half of the twentieth century, during which the mathematical methods developed by university statisticians were increasingly used by the so-called 'official' statisticians. Consequently the 'history of statistics' is a crossroads history connecting very different fields, which are covered in other articles of this encyclopedia: general problems of the 'quantification' of social studies (Theodore Porter), mathematical 'sampling' methods (Stephen E. Fienberg and J. M. Tanur), 'survey research' (Martin Bulmer), 'demography' (Simon Szreter), 'econometrics,' etc. The history of these different fields was the object of much research in the 1980s and 1990s, some examples of which are indicated in the Bibliography. Its main interest is to underscore the increasingly closer connections between the so-called 'internal' dimensions (history of the technical tools), the 'external' ones (history of the institutions), and those related to the construction of social studies 'objects,' born from the interaction between the three foci constituted by university research, administrations in charge of 'social problems,' and bureaus of statistics. This 'co-construction' of objects makes it possible to join historiographies that not long ago were distinct. Three key moments of this history will be mentioned here: Adolphe Quetelet and the average man (1830s), Karl Pearson and correlation (1890s), and the establishment of large systems for the production and processing of statistics.

1. *Quetelet, the Average Man, and Moral Statistics*

The cognitive history of statistics can be presented as that of the tension and sliding between two foci: the *measurement of uncertainty* (Stigler 1986), resulting from the work of eighteenth-century astronomers and physicists, and the *reduction of diversity*, which will be taken up by social studies. Statistics is a way of taming chance (Hacking 1990) in two different ways: chance and uncertainty related to protocols of observation, chance and dispersion related to the diversity and the indetermination of the world itself. The Belgian astronomer and statistician Adolphe Quetelet (1796–1874) is the essential character in the transition between the world of 'uncertain measurement' of the probability proponents (Carl Friedrich Gauss, Pierre Simone de Laplace) and that of the 'regularities' resulting from diversity, thanks to his having transferred, around 1830, the concept of average from the natural sciences to the human sciences, through the construction of a new being, the average man.

As early as the eighteenth century, specificities appeared from observations in large numbers: drawing balls out of urns, gambling, successive measurements of the position of a star, sex ratios (male and female births), or the mortality resulting from preventive smallpox inoculation, for instance. The radical innovation of this century was to connect these very different phenomena thanks to the common perspective provided by the 'law of large numbers' formulated by Jacques Bernoulli in 1713. If draws from a constant urn containing white and black balls are repeated a large number of times, the observed share of white balls 'converges' toward that actually contained by the urn. Considered by some as a mathematical theorem and by others as an experimental result, this 'law' was at the crossroads of the two currents in epistemological science: one 'hypothetical deductive,' the other 'empirical inductive.'

Beginning in the 1830s, the statistical description of 'observations in large numbers' became a regular activity of the state. Previously reserved for princes, this information henceforth available to 'enlightened men' was related to the population, to births, marriages, and deaths, to suicides and crimes, to epidemics, to foreign trade, schools, jails, and hospitals. It was generally a by-product of administration activity, not the result of special surveys. Only the population census, the showcase product of nineteenth-century statistics, was the object of regular surveys. These statistics were published in volumes with heterogeneous contents, but their very existence

suggests that the characteristics of society were henceforth a matter of scientific law and no longer of judicial law, that is, of observed regularity and not of the normative decisions of political power. Quetelet was the man who orchestrated this new way of thinking the social world. In the 1830s and 1840s, he set up administrative and social networks for the production of statistics and established—until the beginning of the twentieth century—how statistics were to be interpreted.

This interpretation is the result of the combination of two ideas developed from the law of large numbers: the generality of 'normal distribution' (or, in Quetelet's vocabulary: the 'law of possibilities') and the regularity of certain yearly statistics. As early as 1738, Abraham de Moivre, seeking to determine the convergence conditions for the law of large numbers, had formulated the mathematical expression of the future 'Gaussian law' as the limit of a binomial distribution. Then Laplace (1749–1827) had shown that this law constituted a good representation of the distribution of measurement errors in astronomy, hence the name that Quetelet and his contemporaries also used to designate it: the law of errors (the expression 'normal law,' under which it is known today, would not be introduced until the late nineteenth century by Karl Pearson).

Quetelet's daring intellectual masterstroke was to bring together two forms: on the one hand the law of errors in observation, and on the other, the law of distribution of certain body measurements of individuals in a population, such as the height of conscripts in a regiment. The likeness of the 'Gaussian' looks of these two forms of distribution justified the invention of a new being with a promise of notable posterity in social studies: the average man. Thus, Quetelet restricted the calculation and the legitimate use of averages to cases where the distribution of the observations had a Gaussian shape, analogous to that of the distribution of the astronomical observations of a star. Reasoning on that basis, just as previous to this distribution there was a real star (the 'cause' of the Gaussian-shaped distribution), previous to the equally Gaussian distribution of the height of conscripts there was a being of a reality comparable to the existence of the star. Quetelet's average man is also the 'constant cause,' previous to the observed controlled variability. He is a sort of model, of which specific individuals are imperfect copies.

The second part of this cognitive construction, which is so important in the ulterior uses of statistics in social studies, is the attention drawn by the 'remarkable regularity' of series of statistics, such as those of marriages, suicides, or crimes. Just as series of draws from an urn reveal a regularity in the observed frequency of white balls, the regularity in the rates of suicide or crime can be interpreted as resulting from series of draws from a population, some of the members of which are affected with a 'propensity' to suicide or crime. The average man is therefore endowed not only with physical attributes but also 'moral' ones, such as these propensities. Here again, just as the average heights of conscripts are stable, whereas individual heights are dispersed, crime or suicide rates are just as stable, whereas these acts are eminently individual and unpredictable. This form of statistics, then called 'moral,' signaled the beginning of sociology, a science of society radically distinct from a science of the individual, such as psychology (Porter 1986). Quetelet's reasoning would ground the one developed by Durkheim in *Suicide: A Study in Sociology* (1897).

This way of using statistical regularity to back the idea of the existence of a society ruled by specific 'laws,' distinct from those governing individual behavior, dominated nineteenth-century, and, in part, twentieth-century social studies. Around 1900, however, another approach appeared, this one centered on two ideas: the distribution (no longer just the average) of observations, and the correlation between two or several variables, observed in individuals (no longer just in groups, such as territories).

2. *Distribution, Correlation, and Causality*

This shift of interest from the average individual to the distributions and hierarchies among individuals, was connected to the rise, in late-century Victorian England, of a eugenicist and hereditarian current of thought inspired from Darwin (MacKenzie 1981). Its two advocates were Francis Galton (1822–1911), a cousin of Darwin, and Karl Pearson (1857–1936). In their attempt to measure biological heredity, which was central to their political construction, they created a radically new statistics tool that made it possible to conceive partial causality. Such causality had been absent from all previous forms of thought, for which A either is or is not the cause of B, but cannot be so somewhat or incompletely. Yet Galton's research on heredity led to such a formulation: the parents' height 'explains' the children's, but does not entirely 'determine' it. The taller fathers are, the taller are their sons *on average*, but, for a father's given height, the sons' height dispersion is great. This formalization of heredity led to the two related ideas of regression and correlation, later to be extensively used in social studies as symptoms of causality.

Pearson, however, greatly influenced by the antirealist philosophy of the physicist Ernst Mach, challenged the idea of 'causality,' which according to him was 'metaphysical,' and stuck to the one of 'correlation,' which he described with the help of 'contingency tables' (Pearson 1911, Chap. 5). For him, scientific laws are only summaries, brief descriptions in mental stenography, abridged formulas, a condensation of perception routines for future use and forecasting. Such formulas are the limits of observa-

tions that never perfectly respect the strict functional laws. The correlation coefficient makes it possible to measure the strength of the connection, between zero (independence) and one (strict dependence). Thus, in this conception of science associated by Pearson with the budding field of mathematical statistics, the reality of things can only be invoked for pragmatic ends and provided that the 'perception routines' are maintained. Similarly, 'causality' can only be insofar as it is a proven correlation, therefore predictable with a fairly high probability. Pearson's pointed formulations would constitute, in the early twentieth century, one of the foci of the epistemology of statistics applied to social studies. Others, in contrast, would seek to give new meaning to the concepts of reality and causality by defining them differently. These discussions were strongly related to the aims of the statistical work, strained between scientific knowledge and decisions.

Current mathematical statistics proceed from the works of Karl Pearson and his successors: his son Egon Pearson (1895–1980), the Polish mathematician Jerzy Neyman (1894–1981), the statistician pioneering in agricultural experimentation Ronald Fisher (1890–1962), and finally the engineer and beer brewer William Gosset, alias Student (1876–1937). These developments were the result of an increasingly thorough integration of so-called 'inferential' statistics into probabilistic models. The interpretation of these constructions is always stretched between two perspectives: the one of science, which aims to prove or test hypotheses, with truth as its goal, and the one of action, which aims to make the best decision, with efficiency as its goal. This tension explains a number of controversies that opposed the founders of inferential statistics in the 1930s. In effect, the essential innovations were often directly generated within the framework of research as applied to economic issues, for instance in the cases of Gosset and Fisher.

Gosset was employed in a brewery. He developed product quality-control techniques based on a small number of samples. He needed to appraise the variances and laws of distribution of parameters calculated on observations not complying with the supposed 'law of large numbers.' Fisher, who worked in an agricultural research center, could only carry out a limited number of controlled tests. He mitigated this limitation by artificially creating a randomness, itself controlled, for variables other than those for which he was trying to measure the effect. This 'randomization' technique thus introduced probabilistic chance into the very heart of the experimental process. Unlike Karl Pearson, Gosset and Fisher used distinct notations to designate, on the one hand, the theoretical parameter of a probability distribution (a mean, a variance, a correlation) and on the other, the estimate of this parameter, calculated on the basis of observations so insufficient in number that it was possible to disregard the gap between these two values, theoretical and estimated.

This new system of notation marked a decisive turning point: it enabled an inferential statistics based on probabilistic models. This form of statistics was developed in two directions. The estimation of parameters, which took into account a set of recorded data, presupposed that the model was true. The information produced by the model was combined with the data, but nothing indicated whether the model and the data were in agreement. In contrast, the hypothesis tests allowed this agreement to be tested and if necessary to modify the model: this was the inventive part of inferential statistics. In wondering whether a set of events could plausibly have occurred if a model were true, one compared these events—explicitly or otherwise—to those that would have occurred if the model were true, and made a judgment about the gap between these two sets of events.

This judgment could itself be made according to two different perspectives, which were the object of vivid controversy between Fisher on the one hand, and Neyman and Egon Pearson on the other. Fisher's test was placed in a perspective of truth and science: a theoretical hypothesis was judged plausible or was rejected, after consideration of the observed data. Neyman and Pearson's test, in contrast, was aimed at decision making and action. One evaluated the respective costs of accepting a false hypothesis and of rejecting a true one, described as errors of Type I and II. These two different aims—truth and economy—although supported by close probabilistic formalism, led to practically incommensurable argumentative worlds, as was shown by the dialogue of the deaf between Fisher on one side, and Neyman and Pearson on the other (Gigerenzer et al. 1989, pp. 90–109).

3. *Official Statistics and the Construction of the State*

At the same time as mathematical statistics were developing, so-called 'official' statistics were also being developed in 'bureaus of statistics,' for a long time on an independent course. These latter did not use the new mathematical tools until the 1930s in the United States and the 1950s in Europe, in particular when the random sample-survey method was used to study employment or household budgets. Yet in the 1840s, Quetelet had already actively pushed for such bureaus to be set up in different countries, and for their 'scientification' with the tools of the time. In 1853, he had begun organizing meetings of the 'International Congress of Statistics,' which led to the establishment in 1885 of the 'International Statistical Institute' (which still exists and includes mathematicians and official statisticians). One could write the history of these bureaus as an aspect of the more general history of the construction of the state, insofar as they developed and legitimized a common language specifically combining the authority of science and that of

the state (Anderson 1988, Desrosières 1998, Patriarca 1996).

More precisely, every period of the history of a state could be characterized by the list of 'socially judged social' questions that were consequently put on the agenda of official statistics. So were co-constructed three interdependent foci: representation, action, and statistics—a way of describing and interpreting social phenomena (to which social studies would increasingly contribute), a method for determining state intervention and public action, and finally, a list of statistical 'variables' and procedures aimed at measuring them.

Thus for example in England in the second third of the nineteenth century, poverty, mortality, and epidemic morbidity were followed closely in terms of a detailed geographical distribution (counties) by the General Register Office (GRO), set up by William Farr in 1837. England's economic liberalism and the Poor Law Amendment Act of 1834 (which led to the creation of workhouses) were consistent with this form of statistics. In the 1880s and 1890s, Galton and Pearson's hereditarian eugenics would compete with this 'environmentalism,' which explained poverty in terms of the social and territorial contexts. This new 'social philosophy' was reflected in news forms of political action, and of statistics. Thus the 'social classification' in five differentiated groups used by British statisticians throughout the twentieth century is marked by the political and cognitive configuration of the beginning of the century (Szreter 1996).

In all the important countries (including Great Britain) of the 1890s and 1900s, however, the work of the bureaus of statistics was guided by labor-related issues: employment, wages, workers' budgets, subsistence costs, etc. The modern idea of unemployment emerged, but its definition and its measurement were not standardized yet. This interest in labor statistics was linked to the fairly general development of a specific 'labor law' and the first so-called 'social welfare' legislation, such as Bismarck's in Germany, or that developed in the Nordic countries in the 1890s. It is significant that the application of the sample survey method (then called 'representative' survey) was first tested in Norway in 1895, precisely in view of preparing a new law enacting general pension funds and invalidity insurance: this suggests the consistency of the political, technical, and cognitive dimensions of this co-construction.

These forms of consistency are found in the statistics systems that were extensively developed, at a different scale, after 1945. At that time, public policies were governed by a number of issues: the regulation of the macroeconomic balance as seen through the Keynesian model, the reduction of social inequalities and the struggle against unemployment thanks to social-welfare systems, the democratization of school, etc. Some people then spoke of 'revolution' in government statistics (Duncan and Shelton 1978), and underscored its four components, which have largely shaped the present statistics systems. National accounting, a vast construction integrating a large number of statistics from different sources, was the instrument on which the macroeconomic models resulting from the Keynesian analysis were based. Sample surveys made it possible to study a much broader range of issues and to accumulate quantitative descriptions of the social world, which were unthinkable at a time when the observation techniques were limited to censuses and monographs. Statistical coordination, an apparently strictly administrative affair, was indispensable to make consistent the observations resulting from different fields. Finally, beginning in 1960, the generalization of computer data processing radically transformed the activity of bureaux of statistics.

So, 'official statistics,' placed at the junction between social studies, mathematics, and information on public policies, has become an important research component in the social studies. Given, however, that from the institutional standpoint it is generally placed outside, it is often hardly perceived by those who seek to draw up a panorama of these sciences. In fact, the way bureaus of statistics operate and are integrated into administrative and scientific contexts varies a lot from one country to another, so a history and a sociology of social studies cannot omit examining these institutions, which are often perceived as mere suppliers of data assumed to 'reflect reality,' when they are actually places where this 'reality' is instituted through co-constructed operations of social representation, public action, and statistical measurement.

Statistics: The Field

Statistics is a term used to refer to both a field of scientific inquiry and a body of quantitative methods. The field of statistics has a 350-year intellectual history rooted in the origins of probability and the rudimentary tools of political arithmetic of the seventeenth century. Statistics came of age as a separate discipline with the development of formal inferential theories in the twentieth century. This article briefly traces some of this historical development and discusses current methodological and inferential approaches as well as some cross-cutting themes in the development of new statistical methods.

1. Introduction

Statistics is a body of quantitative methods associated with empirical observation. A primary goal of these methods is coping with uncertainty. Most formal statistical methods rely on probability theory to express this uncertainty and to provide a formal mathematical basis for data description and for analysis. The notion of variability associated with data, expressed through probability, plays a fundamental role in this theory. As a consequence, much statistical effort is focused on how to control and measure variability and or how to assign it to its sources.

Almost all characterizations of statistics as a field include the following elements:

(a) Designing experiments, surveys, and other systematic forms of empirical study.

(b) Summarizing and extracting information from data.

(c) Drawing formal inferences from empirical data through the use of probability.

(d) Communicating the results of statistical investigations to others, including scientists, policy makers, and the public.

This article describes a number of these elements, and the historical context out of which they grew. It provides a broad overview of the field, that can serve as a starting point to many of the other statistical entries in this encyclopedia.

2. The Origins of the Field

The word 'statistics' is related to the word 'state' and the original activity that was labeled as statistics was social in nature and related to elements of society through the organization of economic, demographic, and political facts. Paralleling this work to some extent was the development of the probability calculus and the theory of errors, typically associated with the physical sciences (see *Statistical Methods, History of: Pre-1900*). These traditions came together in the nineteenth century and led to the notion of statistics as a collection of methods for the analysis of scientific data and the drawing of inferences therefrom.

As Hacking (1990) has noted: 'By the end of the century chance had attained the respectability of a Victorian valet, ready to be the logical servant of the natural, biological and social sciences' (p. 2). At the beginning of the twentieth century, we see the emergence of statistics as a field under the leadership of Karl Pearson, George Udny Yule, Francis Y. Edgeworth, and others of the 'English' statistical school. As Stigler (1986) suggests:

> Before 1900 we see many scientists of different fields developing and using techniques we now recognize as belonging to modern statistics. After 1900 we begin to see identifiable statisticians developing such techniques into a unified logic of empirical science that goes far beyond its component parts. There was no sharp moment of birth; but with Pearson and Yule and the growing number of students in Pearson's laboratory, the infant discipline may be said to have arrived. (p. 361)

Pearson's laboratory at University College, London quickly became the first statistics department in the world and it was to influence subsequent developments in a profound fashion for the next three decades. Pearson and his colleagues founded the first methodologically-oriented statistics journal, *Biometrika*, and they stimulated the development of new approaches to statistical methods. What remained before statistics could legitimately take on the mantle of a field of inquiry, separate from mathematics or the use of statistical approaches in other fields, was the development of the formal foundations of theories of inference from observations, rooted in an axiomatic theory of probability.

Beginning at least with the Rev. Thomas Bayes and Pierre Simon Laplace in the eighteenth century, most early efforts at statistical inference used what was known as the method of inverse probability to update a prior probability using the observed data in what we now refer to as Bayes' Theorem. (For a discussion of who really invented Bayes' Theorem, see Stigler 1999, Chap. 15). Inverse probability came under challenge in the nineteenth century (see *Statistical Methods, History of: Pre-1900*), but viable alternative approaches gained little currency. It was only with the work of R. A. Fisher on statistical models, estimation, and significance tests, and Jerzy Neyman and Egon Pearson, in the 1920s and 1930s, on tests of hypotheses, that alternative approaches were fully articulated and given a formal foundation. Neyman's advocacy of the role of probability in the structuring of a frequency-based approach to sample surveys in 1934 and his development of confidence intervals further consolidated this effort at the development of a foundation for inference (cf. *Statistical Methods, History of: Post-1900* and the discussion of 'The inference experts' in Gigerenzer et al. 1989).

At about the same time Kolmogorov presented his famous axiomatic treatment of probability, and thus by the end of the 1930s, all of the requisite elements were finally in place for the identification of statistics as a field. Not coincidentally, the first statistical society devoted to the mathematical underpinnings of the field, The Institute of Mathematical Statistics, was created in the United States in the mid-1930s. It was during this same period that departments of statistics and statistical laboratories and groups were first formed in universities in the United States.

3. Emergence of Statistics as a Field

3.1 The Role of World War II

Perhaps the greatest catalysts to the emergence of statistics as a field were two major social events: the Great Depression of the 1930s and World War II. In the United States, one of the responses to the depression was the development of large-scale probability-based surveys to measure employment and unemployment. This was followed by the institutionalization of sampling as part of the 1940 US decennial census. But with World War II raging in Europe and in Asia, mathematicians and statisticians were drawn into the war effort, and as a consequence they turned their attention to a broad array of new problems. In particular, multiple statistical groups were established in both England and the US specifically to develop new methods and to provide consulting. (See Wallis 1980, on statistical groups in the US; Barnard and Plackett 1985, for related efforts in the United Kingdom; and Fienberg 1985). These groups not only created imaginative new techniques such as sequential analysis and statistical decision theory, but they also developed a shared research agenda. That agenda led to a blossoming of statistics after the war, and in the 1950s and 1960s to the creation of departments of statistics at universities—from coast to coast in the US, and to a lesser extent in England and elsewhere.

3.2 The Neo-Bayesian Revival

Although inverse probability came under challenge in the 1920s and 1930s, it was not totally abandoned. John Maynard Keynes (1921) wrote *A Treatise on Probability* that was rooted in this tradition, and Frank Ramsey (1926) provided an early effort at justifying the subjective nature of prior distributions and suggested the importance of utility functions as an adjunct to statistical inference. Bruno de Finetti provided further development of these ideas in the 1930s, while Harold Jeffreys (1938) created a separate 'objective' development of these and other statistical ideas on inverse probability.

Yet as statistics flourished in the post-World War II era, it was largely based on the developments of Fisher, Neyman and Pearson, as well as the decision theory methods of Abraham Wald (1950). L. J. Savage revived interest in the inverse probability approach with *The Foundations of Statistics* (1954) in which he attempted to provide the axiomatic foundation from the subjective perspective. In an essentially independent effort, Raiffa and Schlaifer (1961) attempted to provide inverse probability counterparts to many of the then existing frequentist tools, referring to these alternatives as 'Bayesian.' By 1960, the term 'Bayesian inference' had become standard usage in the statistical literature, the theoretical interest in the development of Bayesian approaches began to take hold, and the neo-Bayesian revival was underway. But the movement from Bayesian theory to statistical practice was slow, in large part because the computations associated with posterior distributions were an overwhelming stumbling block for those who were interested in the methods. Only in the 1980s and 1990s did new computational approaches revolutionize both Bayesian methods, and the interest in them, in a broad array of areas of application.

3.3 The Role of Computation in Statistics

From the days of Pearson and Fisher, computation played a crucial role in the development and application of statistics. Pearson's laboratory employed dozens of women who used mechanical devices to carry out the careful and painstaking calculations required to tabulate values from various probability distributions. This effort ultimately led to the creation of the *Biometrika Tables for Statisticians* that were so widely used by others applying tools such as chi-square tests and the like. Similarly, Fisher also

developed his own set of statistical tables with Frank Yates when he worked at Rothamsted Experiment Station in the 1920s and 1930s. One of the most famous pictures of Fisher shows him seated at Whittingehame Lodge, working at his desk calculator (see Box 1978).

The development of the modern computer revolutionized statistical calculation and practice, beginning with the creation of the first statistical packages in the 1960s—such as the BMDP package for biological and medical applications, and Datatext for statistical work in the social sciences. Other packages soon followed—such as SAS and SPSS for both data management and production-like statistical analyses, and MINITAB for the teaching of statistics. In 2001, in the era of the desktop personal computer, almost everyone has easy access to interactive statistical programs that can implement complex statistical procedures and produce publication-quality graphics. And there is a new generation of statistical tools that rely upon statistical simulation such as the bootstrap and Markov Chain Monte Carlo methods. Complementing the traditional production-like packages for statistical analysis are more methodologically oriented languages such as S and S-PLUS, and symbolic and algebraic calculation packages. Statistical journals and those in various fields of application devote considerable space to descriptions of such tools.

4. *Statistics at the End of the Twentieth Century*

It is widely recognized that any statistical analysis can only be as good as the underlying data. Consequently, statisticians take great care in the the design of methods for data collection and in their actual implementation. Some of the most important modes of statistical data collection include *censuses*, *experiments*, *observational studies*, and *sample surveys*, all of which are discussed elsewhere in this encyclopedia. Statistical experiments gain their strength and validity both through the random assignment of treatments to units and through the control of nontreatment variables. Similarly sample surveys gain their validity for generalization through the careful design of survey questionnaires and probability methods used for the selection of the sample units. Approaches to cope with the failure to fully implement randomization in experiments or random selection in sample surveys are discussed in *Experimental Design: Compliance* and *Nonsampling Errors*.

Data in some statistical studies are collected essentially at a single point in time (cross-sectional studies), while in others they are collected repeatedly at several time points or even continuously, while in yet others observations are collected sequentially, until sufficient information is available for inferential purposes. Different entries discuss these options and their strengths and weaknesses.

After a century of formal development, statistics as a field has developed a number of different approaches that rely on probability theory as a mathematical basis for description, analysis, and statistical inference. We provide an overview of some of these in the remainder of this section and provide some links to other entries in this encyclopedia.

4.1 *Data Analysis*

The least formal approach to inference is often the first employed. Its name stems from a famous article by John Tukey (1962), but it is rooted in the more traditional forms of descriptive statistical methods used for centuries.

Today, data analysis relies heavily on graphical methods and there are different traditions, such as those associated with

(a) The 'exploratory data analysis' methods suggested by Tukey and others (see *Exploratory Data Analysis: Univariate Methods*).

(b) The more stylized correspondence analysis techniques of Benzecri and the French school (see *Scaling: Correspondence Analysis*).

(c) The alphabet soup of computer-based multivariate methods that have emerged over the past decade such as ACE, MARS, CART, etc. (see *Exploratory Data Analysis: Univariate Methods*).

No matter which 'school' of data analysis someone adheres to, the spirit of the methods is typically to encourage the data to 'speak for themselves.' While no theory of data analysis has emerged, and perhaps none is to be expected, the flexibility of thought and method embodied in the data analytic ideas have influenced all of the other approaches.

4.2 *Frequentism*

The name of this group of methods refers to a hypothetical infinite sequence of data sets generated as was the data set in question. Inferences are to be made with respect to this hypothetical infinite sequence. (For details, see *Frequentist Inference*).

One of the leading frequentist methods is significance testing, formalized initially by R. A. Fisher (1925) and subsequently elaborated upon and extended by Neyman and Pearson and others (see below). Here a null hypothesis is chosen, for example, that the mean, μ, of a normally distributed set of observations is 0. Fisher suggested the choice of a test statistic, e.g., based on the sample mean, $\bar{x}$, and the calculation of the likelihood of observing an outcome as or more extreme as $\bar{x}$ is from $\mu = 0$, a quantity usually labeled as the p-value. When p is small (e.g., less than 5 percent), either a rare event has occurred or the null hypothesis is false. Within this theory, no probability can be given for which of these two conclusions is the case.

A related set of methods is testing hypotheses, as proposed by Neyman and Pearson (1928, 1932). In this approach, procedures are sought having the property that, for an infinite sequence of such sets, in only (say) 5 percent for would the null hypothesis be rejected if the null hypothesis were true. Often the infinite sequence is restricted to sets having the same sample size, but this is unnecessary. Here, in addition to the null hypothesis, an alternative hypothesis is specified. This permits the definition of a power curve, reflecting the frequency of rejecting the null hypothesis when the specified alternative is the case. But, as with the Fisherian approach, no probability can be given to either the null or the alternative hypotheses (see *Hypothesis Testing in Statistics*).

The construction of confidence intervals, following the proposal of Neyman (1934), is intimately related to testing hypotheses; indeed a 95 percent confidence interval may be regarded as the set of null hypotheses which, had they been tested at the 5 percent level of significance, would not have been rejected. A confidence interval is a random interval, having the property that the specified proportion (say 95 percent) of the infinite sequence, of random intervals would have covered the true value. For example, an interval that 95 percent of the time (by auxiliary randomization) is the whole real line, and 5 percent of the time is the empty set, is a valid 95 percent confidence interval.

Estimation of parameters—i.e., choosing a single value of the parameters that is in some sense best—is also an important frequentist method. Many methods have been proposed, both for particular models and as general approaches regardless of model, and their frequentist properties explored. These methods usually extended to intervals of values through inversion of test statistics or via other related devices (see e.g., *Fiducial and Structural Statistical Inference*). The resulting confidence intervals share many of the frequentist theoretical properties of the corresponding test procedures (see *Estimation: Point and Interval*).

Frequentist statisticians have explored a number of general properties thought to be desirable in a procedure, such as invariance, unbiasedness, sufficiency, conditioning on ancillary statistics, etc. (see *Invariance in Statistics*, *Estimation*: *Point and Interval*, *Statistical Sufficiency*). While each of these properties has examples in which it appears to produce satisfactory recommendations, there are others in which it does not. Additionally, these properties can conflict with each other. No general frequentist theory has emerged that proposes a hierarchy of desirable properties, leaving a frequentist without guidance in facing a new problem.

4.3 Likelihood Methods

The likelihood function (first studied systematically by R. A. Fisher) is the probability density of the data, viewed as a function of the parameters. It occupies an interesting middle ground in the philosophical debate, as it is used both by frequentists (as in maximum likelihood estimation) and by Bayesians in the transition from prior distributions to posterior distributions. A small group of scholars (among them G. A. Barnard, A. W. F. Edwards, R. Royall, D. Sprott) have proposed the likelihood function as an independent basis for inference (see *Likelihood in Statistics*). The issue of nuisance parameters has perplexed this group, since maximization, as would be consistent with maximum likelihood estimation, leads to different results in general than does integration, which would be consistent with Bayesian ideas.

4.4 Bayesian Methods

Both frequentists and Bayesians accept Bayes' Theorem as correct, but Bayesians use it far more heavily (see *Bayesian Statistics*). Bayesian analysis proceeds from the idea that probability is personal (see *Probability: Interpretations*) or subjective, reflecting the views of a particular person at a particular point in time. These views are summarized in the prior distribution over the parameter space. Together the prior distribution and the likelihood function define the joint distribution of the parameters and the data. This joint distribution can alternatively be factored as the product of the posterior distribution of the parameter given the data times the predictive distribution of the data.

In the past, Bayesian methods were deemed to be controversial because of the avowedly subjective nature of the prior distribution. But the controversy surrounding their use has lessened as recognition of the subjective nature of the likelihood has spread. Unlike frequentist methods, Bayesian methods are, in principle, free of the paradoxes and counterexamples that make classical statistics so perplexing. The development of hierarchical modeling and Markov Chain Monte Carlo (MCMC) methods have further added to the current popularity of the Bayesian approach, as they allow analyses of models that would otherwise be intractable (see *Monte Carlo Methods and Bayesian Computation: Overview* and *Markov Chain Monte Carlo Methods*).

Bayesian decision theory, which interacts closely with Bayesian statistical methods, is a useful way of modeling and addressing decision problems of experimental designs and data analysis and inference (see *Decision Theory: Bayesian*). It introduces the notion of utilities and the optimum decision combines probabilities of events with utilities by the calculation of expected utility and maximizing the latter (e.g., see the discussion in Lindley 2000).

Current research is attempting to use the Bayesian approach to hypothesis testing to provide tests and p-values with good frequentist properties (see Bayarri and Berger 2000).

4.5 Broad Models: Nonparametrics and Semiparametrics

These models include parameter spaces of infinite dimensions, whether addressed in a frequentist or Bayesian manner. In a sense, these models put more inferential weight on the assumption of conditional independence than does an ordinary parametric model. Methods and properties of these models are still being developed and some of these are described in various entries of this encyclopedia (see *Exploratory Data Analysis: Multivariate Approaches (Nonparametric Regression)*, *Nonparametric Statistics: Rank-based Methods*, *Semiparametric Models*).

4.6 Some Cross-cutting Themes

Often different fields of application of statistics need to address similar issues. For example, dimensionality of the parameter space is often a problem. As more parameters are added, the model will in general fit better (at least no worse). Is the apparent gain in accuracy worth the reduction in parsimony? There are many different ways to address this question in the various applied areas of statistics.

Another common theme, in some sense the obverse of the previous one, is the question of model selection and goodness of fit. In what sense can one say that a set of observations is well-approximated by a particular distribution? (cf. *Goodness of Fit: Overview*). All statistical theory relies at some level on the use of formal models, and the appropriateness of those models and their detailed specification are of concern to users of statistical methods, no matter which school of statistical inference they choose to work within.

5. Statistics in the Twenty-first Century

5.1 Adapting and Generalizing Methodology

Statistics as a field provides scientists with the basis for dealing with uncertainty, and, among other things, for generalizing from a sample to a population. There is a parallel sense in which statistics provides a basis for generalization: when similar tools are developed within specific substantive fields, such as experimental design methodology in agriculture and medicine, and sample surveys in economics and sociology. Statisticians have long recognized the common elements of such methodologies and have sought to develop generalized tools and theories to deal with these separate approaches (see e.g., Fienberg and Tanur 1989).

One hallmark of modern statistical science is the development of general frameworks that unify methodology. Thus the tools of Generalized Linear Models draw together methods for linear regression and analysis of various models with normal errors and those log-linear and logistic models for categorical data, in a broader and richer framework. Similarly, graphical models developed in the 1970s and 1980s use concepts of independence to integrate work in covariance section, decomposable log-linear models, and Markov random field models, and produce new methodology as a consequence. And the latent variable approaches from psychometrics and sociology have been tied with simultaneous equation and measurement error models from econometrics into a broader theory of covariance analysis and structural equations models.

Another hallmark of modern statistical science is the borrowing of methods in one field for application in another. One example is provided by Markov Chain Monte Carlo methods, now used widely in Bayesian statistics, which were first used in physics. Survival analysis, used in biostatistics to model the disease-free time or time-to-mortality of medical patients, and analyzed as reliability in quality control studies, are now used in econometrics to measure the time until an unemployed person gets a job. We anticipate that this trend of methodological borrowing will continue across fields of application.

5.2 Where Will New Statistical Developments be Focused?

In the issues of its year 2000 volume, the *Journal of the American Statistical Association* explored both the state of the art of statistics in diverse areas of application, and that of theory and methods, through a series of vignettes or short articles. These essays provide an excellent supplement to the entries of this encyclopedia on a wide range of topics, not only presenting a snapshot of the current state of play in selected areas of the field but also affecting some speculation on the next generation of developments. In an afterword to the last set of these vignettes, Casella (2000) summarizes five overarching themes that he observed in reading through the entire collection:

(a) Large datasets.
(b) High-dimensional/nonparametric models.
(c) Accessible computing.
(d) Bayes/frequentist/who cares?
(e) Theory/applied/why differentiate?

Not surprisingly, these themes fit well those that one can read into the statistical entries in this encyclopedia. The coming together of Bayesian and frequentist methods, for example, is illustrated by the movement of frequentists towards the use of hierarchical models (see *Hierarchical Models: Random and Fixed Effects*) and the regular consideration of frequentist properties of Bayesian procedures (e.g., Bayarri and Berger 2000). Similarly, MCMC methods are being widely used in non-Bayesian settings and, because they focus

on long-run sequences of dependent draws from multivariate probability distributions, there are frequentist elements that are brought to bear in the study of the convergence of MCMC procedures. Thus the oft-made distinction between the different schools of statistical inference (suggested in the preceding section) is not always clear in the context of real applications.

5.3 The Growing Importance of Statistics Across the Social and Behavioral Sciences

Statistics touches on an increasing number of fields of application, in the social sciences as in other areas of scholarship. Historically, the closest links have been with economics; together these fields share parentage of econometrics. There are now vigorous interactions with political science, law, sociology, psychology, anthropology, archeology, history, and many others.

In some fields, the development of statistical methods has not been universally welcomed. Using these methods well and knowledgeably requires an understanding both of the substantive field and of statistical methods. Sometimes this combination of skills has been difficult to develop.

Statistical methods are having increasing success in addressing questions throughout the social and behavioral sciences. Data are being collected and analyzed on an increasing variety of subjects, and the analyses are becoming increasingly sharply focused on the issues of interest.

We do not anticipate, nor would we find desirable, a future in which only statistical evidence was accepted in the social and behavioral sciences. There is room for, and need for, many different approaches. Nonetheless, we expect the excellent progress made in statistical methods in the social and behavioral sciences in recent decades to continue and intensify.

Status and Role, Social Psychology of

The social psychology of status and role refers to the study of the social interactive processes that involve people in displaying, creating, and changing statuses and roles. Status and role link individuals to society, to institutional structures, social groups, etc.

1. History of Status and Role

Status is a term originally referring to legally enforceable rights related to societal positions, such as the rights implied in the expression 'the status of citizens.' In the social sciences it has been used to refer to societal positions, such as ascribed (race, gender, age) and achieved (occupational) statuses. Historically different societal positions have been attributed vary-

ing degrees of legal rights (slaves, women, peasants); thus the term status carries with it an invidiousness. This connotation has been conceptualized as amounts of societal honor, esteem, and resources attributed to individuals or groups. The social psychological conception of role is derived from the theater applied to everyday life; individuals are conceived as playing roles in society similar to actors upon a stage. Role also has more than one meaning. Role is conceptualized as cultural norms, prescriptions, and expectations associated with statuses such as those of fulfilling the achieved status of physician or the ascribed status of woman. Role also has been formulated as the real practices associated with a status.

Both concepts have long histories. What is now termed symbolic interaction, a form of social psychology associated with the University of Chicago early in the twentieth century employed the concept of role as developed by George Herbert Mead and Robert E. Park (Stryker and Statham 1985). Mead's (1934) conceptions of 'role-playing' or 'taking the role of the other' are normative formulations used to theorize social processes such as the socialization of children, the development and evolution of self in interactions with others, and the acquisition of meanings in conversations. Park formulated roles as ubiquitous public performances in which people engage to construct the social organizations of society (Turner 1968). It was the anthropologist Ralph Linton who explicitly linked status to role. Linton theorized statuses as ascribed and achieved societal positions. Attached to each status is a role described as normative prescriptions (i.e., rights and duties, Linton 1936, p. 113) expressing expected behaviors associated with the status that the role incumbent is obliged and committed to fulfill. For Linton status is a structural unit of society separate from the individual who fills it and role is social process ('A *role* represents the dynamic aspect of a status' Linton 1936, p.114). Linton illustrates these by describing age and gender (he uses the word sex) as ascribed statuses associating these with culture-specific behaviors that constitute these roles in different societies.

2. *Elaborating the Social Psychology of Status and Role: 1940s to 1970s*

In the period following World War II Theodore Sarbin, a social psychologist, along with two sociologists, Erving Goffman and Ralph H. Turner, shaped the social psychological discourse of status and role as social processes. Sarbin moved Linton's focus from cultural prescriptions embedded in status shaping role incumbents' behavior to factors for effectively accomplishing roles. Goffman elaborated the metaphor of social life as theater, focusing on the processes of role playing in creating selves and definitions of the situations. Turner conceptualized indeterminacy and individuals' agency in status-role playing. Despite their different focuses the authors share intellectual heritages in Park and G. H. Mead.

In 1943, 1954, and 1968 Theodore Sarbin provided extended statements on role theory. The 1954 and 1968 essays were published in the influential *Handbook of Social Psychology*. In the 1954 essay Sarbin used, but collapsed, the terminology of status and role, conceiving of roles as simultaneously normative obligations ('expectations,' 'rights and obligations,' Sarbin 1954, p. 226) and as social positions ('We define position as a system of role expectations, p. 223). This formulation framed an evolving trend for these three interactively inclined authors; the concept of status became muted as the dynamic processes of role were moved center stage in their analyses.

In the late 1960s Sarbin and Allen formulated role enactment (1968, p. 497) as a dependent variable, analyzing the influences of independent variables that enhance or inhibit the effectiveness of a role's display. By effectiveness the authors mean motor and linguistic actions expressed in roles that are congruent with roles' prescriptions and expectations (1968, p. 550). Sarbin and Allen provide six independent variables that impact upon the effectiveness of role enactment. The variables (1968, pp. 546–7) are: (a) role expectations (validity of role expectations held by the actor); (b) role location (accuracy locating others and the self in the proper role system); (c) role demands (sensitivity to situationally generated role demands); (d) role skills (available general and specific skills for role performances); (e) self-role congruence (congruence of self-conception with the role); (f) audience effects (role reinforcement properties of the audience). Detailed analyses of the six variables indicate that role incumbents possess differing linguistic, motor, and emotional capacities furnishing them with the wherewithal to perform roles more or less effectively (i.e., convincingly, appropriately, authentically—1968, p. 490). Although Sarbin emphasizes individuals' capacities for effective role enactments, his role theorizing is interactive (e.g., 'role enactment always occurs in the social context of complementary roles,' p. 545) as evidenced by the concern with the causes, personal and social, for variation in role performances in social settings. In a closing section of the 1968 essay the authors turn their analysis around asking how role enactments, treated as independent variables, affect the creation, evolution, and change of role incumbents' social identities; this analysis of social identities parallels Goffman's conception of the construction of self in interaction.

Sarbin insists that his portrayal of status and role is within the context of a dramaturgical (social life as theater) metaphor (Sarbin and Allen 1968, pp. 488–9, Sarbin 1968, p. 546). That metaphor is even more appropriately applied to Erving Goffman's theorizing. In the preface to his *The Presentation of Self in Everyday Life* Goffman (1959, p. xi) so anoints his approach, and in the remainder of the book he

elaborates the metaphor. However, the focal concept of the book and of Goffman's corpus is the self. Goffman has devoted much less space to theorizing status and role than he has to the self. However, it is individual role players' actual public accomplishments in interactive performances that construct selves for others and self (Goffman 1959, pp. 252–3). Goffman defines role similarly to Linton as cultural prescriptions situated in statuses but also as typical real activities in which role players engage (i.e., role enactments, Goffman 1961, pp. 85, 93); he conceives of status as social position related to other positions and as honors and resources attached to the status.

Within the context of the dramaturgical metaphor Goffman theorizes a conception of interactive performances in which every rule and practice used to construct selves and define situations are sociological features of role playing. Goffman describes two settings in which role playing occurs: focused and unfocused interactions. The latter refers to the myriad trivial interchanges of daily life such as those between shoppers and supermarket cashiers, or among a group of unacquainted passengers riding an elevator (Goffman 1963). Sustained interactions are focused and particularly relevant; among these are organized work settings. Institutionalized work teams interest Goffman because role playing in these are staged in bounded structural and interactive circumstances that are specifiable precisely for analysis.

It is from the work setting of doctors and nurses as a hospital surgical team that Goffman formulates a theory of the processes of status and role (Goffman 1961). Goffman frames the essay by distinguishing between role embracing and distancing. 'To embrace a role is to disappear completely into the virtual self available in the situation' …, (Goffman 1961, p.106). It is the role incumbent engaged as Linton might describe '… to act solely in terms of the normative demands upon someone in his position' (p. 85). In contrast role distancing suggests that the role incumbent, while engaging in the normative performances of the role will also perform activities that are not part of, or may even be inconsistent with, the role in order to perpetuate the organization's work functions (pp. 108, 114–15).

Nowhere should role incumbents more totally embrace their roles than among doctors and nurses engaged in the serious work of surgery. Yet in typical ways doctors and nurses exhibit role-distancing activities in the operating theater. In addition to performing surgery a chief surgeon may find that he or she must act as 'team manager' expending status resources (e.g., their dignity) by playing the role of 'nice guy or gal' in order to reduce neophyte team members' anxieties, increasing their poise and communication during the surgery (Goffman 1961, p.122). Surgeons may mimic, jest, joke, sing, or discuss recent personal and news events to dispel tension. Surgeons may perform tasks not associated with their role and beneath their status (again expending status honor) to maintain the team's solidarity and commitments to the tasks. These role-distancing activities, Goffman suggests, are systemic and typical because they are derived from the sociological role-set in which surgeons are embedded. Some distancing activities evolve from the surgeon's ties to the hospital administration, others from their status as instructor and mentor to interns, still others from connections with patients and their family, and even the surgeon's own family may be the source for role-distancing performances. No matter where they originate from, these distancings are endemic to the surgical theater; they are performed to preserve and perpetuate the ordered functions of the team and its effective accomplishment of the surgical task.

Goffman argues that Linton's conception of the structural determination of roles (an embracing of role norms) is anomalous. He insists that adequate theorizing requires integrating normative role obligations with situationally required role distancing. Only such a complementary formulation proffers an empirically sound theory for the effective accomplishment of institutional tasks.

Turner does not emphasize the dramaturgical metaphor; instead he methodically and systematically theorizes and investigates the processes of status and role. Turner centers interactional, in contrast to structural, determination of status and role. Linton's structural conceptualization of role behavior determined by status did not sit well with Turner's epistemic roots in the Meadian tradition. Early in his career Turner published 'The Navy Disbursing Officer as Bureaucrat' (1947) addressed to this issue. In that essay Turner suggests that some status incumbents performed the role consistent with its bureaucratic normative role prescriptions, but others were capable of creating alternate solutions for the Navy Disbursing Officer role. These officers constructed novel, better adapted, more effective courses of action, innovating upon the cultural, structural, and personal constraints placed upon them as role incumbents.

This early essay indicated Turner's inclinations toward interactive determination. His subsequent writings became more ardently so inclined. Thus, he ultimately theorized that even role performances that publically conform to normatively expected behaviors may not be taken for granted as structurally determined. Instead, Turner conceives of status occupants as interactively engaged in constructing their roles and positions. For example, Turner argues that Sarbin's and Goffman's conceptions of 'appearances and props,' such as a military uniform or the spacial arrangement in classrooms such as the teacher's position at the head of class, do not assure incumbents' statuses nor their role performances. Turner advocates that in every instance it is the role performances, interactively achieved, that create an incumbent's right to claim a status and to play a role (Turner 1985).

Turner's conception of status and role is that they are volitionally constructed within the constraints of social settings. Paraphrasing his language, incumbents engage in processes of interactively creating their statuses and roles; they engage in role making (an intractable aspect of role playing) as well as role taking (Turner 1962).

While Turner assumes normatively prescribed roles exist, their prescriptions are general propositions (*gestalts* regarding such as values, goals, sentiments, styles, etc., Turner 1985), not specific dictates to behaviors, and therefore they are indeterminate. Individuals use these gestalts as schema to organize and interpret their own and others' behaviors. It is individuals' interpretations of these gestalts, within specific social contexts, that guide their performances. This proposition involved Turner in an epistemic coherent 'inductive' approach to the study of a variety of related topics on statuses and roles. However, after three decades of such publications Turner moved to unify his social psychology of status and role.

As the 1970s ended, a theoretical language to study the processes of status and role had evolved. The language assumed that while status and role exist as structural and normative features of society their enactment is determined by individual incumbents' qualities and accomplishments in situated interactions. The language formulated the possibilities not only for individuals' recapitulation of culturally prescribed status and role but also for actors' fashioning and performing differentiated variations of them. Status and role are linked to the development and character of selves and identities, as well as to definitions of situations, social organizations, and institutions. The language proffered an empirically grounded interactive theory of status and role social processes. While the theoretical language was bold, it was also preliminary. Nevertheless, as a series of loosely connected propositions and hypotheses it stimulated an array of empirical and theoretical topics, from status and role enactment, to status and role strain and conflict, differentiation and change, etc. The social psychology of status and role had progressed a long way from its initial formulations delivered by Mead, Park, and Linton.

3. *Consolidations in the 1980s*

The 1980s began a period of critical review and theoretical consolidation. Of the three influential social scientists, only Turner remained involved with the topic. Turner provides a unique effort at consolidating the social psychology of status and role. He, and his colleague Paul Colomy, introduced axioms to explain role processes (Turner and Colomy 1988, Turner 1990). The essays focus on the processes of role allocation, differentiation, and change. Three axioms determine these processes. They are: (a) functional efficiency of roles, (b) costs and benefits for role incumbency, and (c) positive and negative cultural representation of roles. Each of these three axioms separately and in combination explain the processes of role allocation and differentiation. Turner provides a similar but more complex analysis for role change (Turner 1990). The intent of these essays is to integrate role theory using a small, limited set of explanatory axiomatic factors. At the same time it is an effort to coherently integrate macro structural features to role processes (Turner 1990, pp. 106–8). The authors provide remarkably incisive models. However, their commitment to indeterminacy in the construction of statues and roles deters them from achieving theoretical closure. The models also still require empirical substantiation.

A second form of consolidation is the attempt to synthesize interactive and structural approaches (earlier attempts are in Coser 1966 and Merton 1975.) In the 1980s 'impartial' scholars tried to resolve the differences between the approaches in an effort to provide a unified theory. An underlying theme in these endeavors is that both approaches had advanced theoretically to where they were no longer in opposition with one another.

Warren Handel, in a cautiously reasoned essay (1979), suggests that interactive and structural approaches are 'compatible and complementary.' Structural approaches' increasing theoretical emphasis on role conflict undermines a previously held core conception of role incumbents' conformity to internalized norms permitting stability and variation in status and role performances. Handel suggests that interactive approaches' conception of negotiated meanings do not undermine structural conceptions of patterned conduct. Negotiated meanings may coexist within a working consensus among interacting individuals in a particular situation. Handel concludes by legitimating his synthetic formulation, suggesting it has been designed in accord with Mead's interactive theorizing. Jerold Heiss provides a similar synthesis between the two approaches. His reasoning is more ad hoc than is Handel's but it comes to a similar conclusion, 'The *general* role theory that I foresee for the future will combine the macroanalyses of the structuralists with the microanalyses of the interactionists' (Heiss 1981, p. 101, emphasis in the original).

In a third form of consolidation Sheldon Stryker attempts to develop a unified theory of roles by integrating interaction and structure. The framework is entitled a 'structural symbolic interactionism' (Stryker 1983, Stryker and Statham 1985), for some an oxymoron. The theory assumes that macro and micro social structures may constrain role improvisation. Among the micro and macro structures that do so are: persons' selves and identities, expectations embedded in roles, others' potential sanctions, structural closure and openness, cultural symbols' impositions. Each is a variable, thus its constraint of improvisation depends

on the relative capacity to impose itself upon role incumbents. Stryker generalizes that in interactions when role incumbents' selves and identities and their goals and interests are satisfied they will conform to the role expectations. In contrast, disruptive social circumstances will encourage role improvisation. Stryker's commitment to Mead's symbolic interaction inspires him also to suggest that the same structural conditions (e.g., high employee turnover) may provoke antithetical interpretations simultaneously suggesting opportunities for role innovation and demands for conformity. Stryker suggests that his theory is a work in progress which 'to this point has produced only a few reasonably rigorous theories. It largely consists of a set of assumptions and concepts ...' (Stryker and Statham 1985, p. 368).

4. Conclusion: To the Millennium and Beyond

The theoretical link between status and role was severed soon after World War II. The structural conception of status is now confined to such as 'status attainment studies,' i.e., investigations of individuals' and groups' relative position in stratification systems that are the result of acquired resources such as income, education, occupation. Status in social psychology is conceived as individuals' or groups' relative societal evaluation, thus referring to degrees of honor, esteem, or resources. Status in this form is used as an independent variable, analyzing its effects upon other social processes.

A second fault line, already discussed, occurred between structural and interactive approaches. Despite their controversy, both camps reduced the use of the term status; a situation particularly accented among interactionists who came to use role as both societal position and its cultural norms. The social psychology of status and role is now tantamount to the social psychology of roles. Additionally, recent studies of status and roles have relied upon and elaborated established theory rather than created theory anew.

Baker and Faulkner's (1991) conception of roles as employed by persons to acquire resources and combine into concrete positions is exemplary of the terminological and theoretical uses of contemporary role theory. Their study of Hollywood film producers, directors, and screen writers refers to these as roles and not as social positions or statuses. Their analysis then focuses upon combinational relations among the three roles before and after the rise of the movie blockbuster. It relates films' financial successes to innovative role combinations. In the production of films the stereotypical organization is functional specificity with three different persons playing the three roles. However, Baker and Faulkner find that functional specificity of producer and functional dedifferentiation of director-screen writer was the most effective arrangement for achieving financial successes during the blockbuster era. The authors present quotes from secondary sources to illustrate that role participants were aware of the advantages of this organizational arrangement. Although their study is primarily focused at the structural level the authors assume that organization is the result of persons' volitional activities, and they attribute the structural reorganization to movie industry leaders' personal agency. Neither in theory nor in practice is there a division between structural and interactive determination of roles and organization for the authors. This position permits the authors to conclude that role innovations may be used as organizational resources.

Each of the first three editions of the *Handbook of Social Psychology* (1954, 1968, 1985) devoted a chapter to role theory. The fourth edition of the *Handbook*, published in 1998, contains no chapter exclusive to roles. Instead role is introduced throughout the fourth edition in relation to its functions and displays in groups, gender, race, stereotyping, distributive justice and so forth. Although the language is still not unified, role and status are now part of the social science lexicon and are employed conceptually when empirical issues appropriately call for their use.

Status and Role: Structural Aspects

The closely connected concepts of 'status' and 'role' have a long and complex history in a number of different traditions of social thought, but their contemporary meanings developed during the first half of the twentieth century. Despite it having been Shakespeare who claimed that 'all the world's a stage,' it was the social psychologists of the early twentieth century who systematically employed the concept of role and so paved the way for later 'dramaturgical' approaches to social life. This work also prepared the way for those who would develop the idea of status as the structural position corresponding to a role. The term status, however, has been used in two quite different ways, only one of which is directly relevant to this discussion. One usage has referred to hierarchical differences of prestige and social honor in systems of social stratification (see *Social Stratification*); the other has referred, more generally, to any structural position or location in a social system. It is the second sense that will be discussed in this article.

1. Status as Structural Position

The hierarchical concept of status was popularized by Max Weber, who contrasted stratification by status with stratification by class (Scott 1996). In the 1930s, however, cultural anthropologists introduced the idea of status as a position or location in a social structure (Linton 1936). This usage was rapidly adopted by structural functionalist sociologists. While this initially led to some confusion about whether or not particular statuses were hierarchically ranked, the new usage soon became established (Parsons 1942b). Some resolved this confusion by using 'position' or 'location' in preference to status (Warner 1952, p. 46), and this practice will be followed in this article.

The idea of status as structural position originated in the idea that social structure consisted of culturally defined institutions. This had its origins in Durkheim, but it was the development of a clear understanding of culture by American anthropologists (Kroeber 1917, Kluckhohn 1954) that gave the idea its contemporary form. It became a central concept in sociological analysis (Parsons 1951).

It was held that the culture of a society establishes a set of social institutions. These are standardized normative patterns that people are expected to follow in their social actions. They regulate individual and group behavior by defining the nature of their social relations. Institutions define 'proper, legitimate or expected modes of action or of social relationship' (Parsons 1940, p. 53), and so guide and channel behavior. Parsons defined social structure as 'a patterned system of social relationships of actors' (Parsons 1945, p. 230).

The institutionalized expectations that people share define their social positions relative to other positions, and to the performances of the individuals who occupy these (Parsons 1942b, p. 143). This knowledge of social positions provides people with the conceptual maps that they use to organize their social actions. Like all ideas, they are contained in individual minds. However, because they are *shared*, there is a reciprocity of expectations that solidifies them into distinctively collective representations (Davis 1948, p. 87). Social positions are Durkheimian social facts with the power to constrain the behavior of individuals. We do not simply 'know' the social positions that make up our society, we experience social pressure to conform to the expectations they involve.

These pressures are felt through role expectations. Roles define the specific rights and obligations that are

entailed in a social position (Dahrendorf 1958, p. 36). They tell us what to do and what to expect others to do (Parsons 1940, p. 54). They provide us with a definition of the situation that sets the limits within which we may legitimately act (Williams 1960).

Some writers used the concept of role to describe the *actual* behavior associated with a position, but most have recognized that a normative focus requires a concern for *expected* behavior (Levy 1952, pp. 158–60). The relationship between expected behavior and actual behavior is very complex, and there is no one-to-one correspondence between norms and behavior. Roles are definitions of what people are expected to do in different situations. They define the goals, the means, and the attitudes that are culturally recognized as legitimate for those who occupy particular social positions.

2. *Role Theory*

These ideas were taken up during the 1950s as the basis of a 'role theory' that tried to set out a comprehensive paradigm for role analysis. The most influential formulation of this was that of Gross et al. (1958), who used it to explore the behavior of school superintendents. They did this using Merton's (1957) argument that each social position is associated with an array of role-specific forms of behavior that together comprise a 'role set.' A medical student, for example, must act as a student not only in relation to other students, but also in relation to teachers, doctors, nurses, social workers, patients, medical technicians, and so on. In each of these relations, the student is likely to encounter different expectations about her or his behavior (Merton 1957, p. 112).

Gross et al. showed that the school superintendent had to negotiate the conflicting expectations held by teachers, parents, children, governors, and ancillary staff. They recognized that this produces varying degrees of strain or conflict in role expectations. The concept of 'role conflict' has been central to many applications of role theory.

While this work concentrated on the structural aspects of position and role, it was complemented by those who worked on a social psychology of roles (Newcomb 1950). These writers explored the learning processes through which roles are acquired and the social pressures to conformity that exist in face-to-face situations. Socialization and conformity were central principles for role theorists, and their views have been subject to persistent criticism.

3. *Socialization and Conformity*

Role theorists see the norms that define social positions as learned through a process of socialization. The expectations of others are *internalized* in the personality as it is formed. They become objects of moral commitment, and individuals are likely to be strongly attached to them. They tend to regard conformity as a duty (Parsons 1940).

This is associated with the argument that there is consensus over social norms. Members of a society share their moral commitments and so violations are met with guilt or shame in the violator and indignation or condemnation in those whom the deviance affects. Deviance from these shared norms is likely to result in 'corrective forces' or sanctions that may vary from mild disapproval to overt coercion. For many, this led to the conclusion that deviance was both infrequent and automatically corrected. Societies were seen as self-regulating systems in which actors had little choice but to conform.

The degree of consensus in a society rarely reaches this level, however, and individuals are never perfectly socialized (Wrong 1961). These points were especially forcefully raised against Parsons, but even he recognized that the 'completely institutionalized' social relationship was a rarity. Although broad descriptive contrasts could be drawn between societies in terms of their common values, 'when dynamic problems of directions and processes of change are at issue, it is essential to give specific attention to the elements of malintegration, tension and strain in the social structure' (Parsons 1942a, p. 117). Nevertheless, the mainstream of role theory overemphasized both consensus and internalization. It was conflict theorists such as Dahrendorf (1958) who showed that role expectations have to be seen in relation to the distribution of power and that this can give them a solidity that does not depend on a consensus of opinion.

What passes for consensus may be the ideas of a dominant or powerful group (Rex 1961, Shils 1961). A minority may be able to use its resources to institutionalize its own norms for the population as a whole. This may be especially effective where the majority of the population forms a relatively unorganized mass without strong counterinstitutions of its own.

4. *Role-taking and Role-making*

Structural functional and conflict theories of position and role, supported by social psychological theories of socialization and conformity, lay at the heart of mainstream sociology from the 1940s to the 1960s. During the 1960s, however, radical and forceful objections were raised against this (see *Action Theory: Psychological*). The immediate origin of the sociological concept of role had been Mead's (1927) account of taking the role of the other, and critics of the mainstream turned to Mead for support. They questioned cultural determinism and its oversocialized image of the actor that saw people as the mere puppets of structural forces. Blumer (1962, p. 189) held that a

structure of positions is simply a 'framework inside of which action takes place.' It is a conceptual guide for action, not an external, substantial entity or an independent coercive power.

Turner (1962) took this argument to the heart of role theory. He held that the emphasis on conformity gave only a partial view of role behavior. It stressed imitation and ignored innovation, failing to recognize that role-takers were also 'role-makers.' Individuals do not simply take over roles as templates for conformist behavior. Turner held that role-taking always required improvisory behavior. The role knowledge that individuals learn during their primary and secondary socialization does not give them precise, programmed instructions for behavior in all the many unique and unpredictable circumstances in which they are likely to find themselves. Individuals tentatively interpret and reinterpret each other's actions in the situations that they encounter, recreating their roles from the raw materials provided to them during socialization (Turner 1962, p. 23). Shared knowledge of social positions sets the general conditions for action, but it does not fully determine it (Blumer 1962, p. 190). The normative functionalist approach to role-taking has to be broadened into a more comprehensive account.

The fullest development of this view was that of Erving Goffman (1959, 1963), who explored the ways in which individuals actively and creatively construct the images that they present in their role behavior. Goffman systematically employed the theatrical metaphor of role-playing, holding that individuals are never merely actors following a script, but are authors as well. Using such ideas as props, scenery, front stage, and back stage, Goffman showed how public performances depend on the more private situations to which individuals can withdraw. He introduced a number of novel concepts, most notably 'role distance.'

5. *A Sense of Social Structure*

The criticisms made by the symbolic interactionists added a whole new dimension to the analysis of position and role. While some of the critics of mainstream views saw this role as a complete alternative to the orthodoxy, others saw it as complementing the structural account. These differences persist, and have been compounded by a newer and more radical line of argument. Influenced by phenomenology and ethnomethodology, Aaron Cicourel has produced the most systematic statement of this critique.

Cicourel asked the fundamental question: how is role-taking possible? His answer was that the taking and making of roles rests on a set of cognitive processes through which actors give meaning to the world and so sustain a 'sense of social structure' (Cicourel 1972, p. 11). People do carry role information in their heads, but they must also be able to recognize when one particular position or role is relevant, and they must be able to infer what expectations others have of their behavior. They cannot make sense of their social world simply by drawing on the role and positional knowledge that they have learned during their socialization. Before they can apply norms in particular situations, they must arrive at some kind of understanding of what kind of situation it is. This means that 'members of a society must acquire the competence to assign meaning to their environment so that surface rules and their articulation with particular cases can be made' (Cicourel 1968, p. 52). This ability to infer and to impute meaning to situations is a practical skill that is an essential condition for any social life at all. Cicourel sees this skill as an interactional competence, making explicit parallels with Chomsky's concept of linguistic competence. Though he does not adopt Chomsky's own rationalist theory of the mind, Cicourel does take over his stress on the generative capacities that are provided by human competences. It is their practical, meaning-making skills that allow people to use their knowledge of social norms to generate appropriate role behavior. The structural aspects of positions and roles, therefore, are seen by Cicourel as resting on the possession of a complex set of cognitive procedures (also termed inductive, interpretive, or inference procedures) that operate in the same way as the deep structure grammatical rules of a language.

Cicourel illustrated these cognitive procedures by drawing on Alfred Schutz' discussion of the assumptions that people must make for social interaction to be possible. Schutz held that individuals must assume a reciprocity of perspectives between themselves and their potential partners, they must fill in the gaps in their knowledge through the *et cetera* principle, and they must assume that things occur as 'normal form.' These and similar cognitive procedures constitute the mental module that makes it possible for actors to generate appropriate but innovative responses in changing circumstances, despite the fact that they have only fragmentary and uncertain evidence available to them. They allow people to assign meaning and relevance to the objects in their environment and to construct definitions of the situation that allow them to infer which of the norms stored in their memories are relevant. People build a sense of social structure that allows them to orient themselves appropriately in the various situations that they encounter. Once the meaning of a situation has been decided, norms can be invoked on the assumption that there is a consensus among those with whom they interact and that these are, indeed, the appropriate norms. Normative order and role behavior, therefore, are negotiated and constructed on the basis of the underlying sense of social structure that interactional competence makes possible.

6. Conclusion

Status—or position—and role remain central concepts in the normative account of social structure. This normative account does not tell us everything that we need to know about social structure (Lockwood 1956, 1964), but it is an essential aspect of any structural account. The use of these normative concepts, however, must incorporate an awareness of the creative and innovative role-making activities that are integral to all role behavior. It is important to recognize that improvisation and negotiation are essential features of the construction of social action. It is also important to recognize, however, that these processes are possible only because individuals possess certain cognitive skills that allow them to infer the meaning of social situations and to build a sense of the social structures in which they must act. Structural positions and roles are human accomplishments, but they have real consequences for the people who occupy them.

Statutes of Limitations

1. Definition

Statutes of limitations are procedural rules that limit legal actions on the basis of time. They derive from both legislative and judicial sources and exist in many continental and non-continental legal systems. Specifically, they regulate the amount of time that a potential plaintiff has to initiate a formal legal claim. In general, once a statute of limitation expires, a plaintiff cannot press a particular legal claim, regardless of its underlying substantive merits.

It is important to distinguish statutes of limitations from the closely related yet distinct common law doctrine of 'laches.' The doctrine of laches vests courts with discretionary authority to determine whether a plaintiff, while commencing a legal action within the

time requirements set forth by the relevant statute of limitations, nonetheless has unreasonably delayed bringing a lawsuit to the detriment of a defendant (Heriot 1992). Both statutes of limitations and the doctrine of laches limit a plaintiff's access to court.

2. *Purposes*

Statutes of limitations seek to reconcile numerous individual and social interests. These interests, broadly construed, include a desire for an orderly legal system that resolves claims promptly, efficiently, and equitably and also promotes legal stability.

Within the context of litigation, these general interests become more individualized, acute, and particularized. Plaintiffs benefit from having a reasonable amount of time within which to press a legal claim. Some amount of time is necessary so that a potential plaintiff can contemplate possible litigation and gather and assess evidence that will inform a decision about whether to pursue formal legal remedies. Statutes of limitations induce plaintiffs to pursue legal claims diligently and promptly by punishing those who do not by foreclosing the opportunity to pursue a legal claim. Also, defendants have a legitimate interest in repose as well as not having to defend against 'stale' claims. Moreover, defendants should not be disadvantaged in court due to lost evidence, faded memories, and the disappearance of witnesses—all possibilities that increase with the passage of time.

Numerous social interests cut in different directions. It is, of course, well known that societies benefit when their judicial systems vindicate their members' legal rights. Other social interests include a desire for a secure and stable legal system. Moreover, a desire to minimize court congestion is shared by many. Finally, the probability of legal error increases when plaintiffs wait too long before commencing legal action and degrade components critical to a fair, just, and thorough trial.

3. *History and Development*

Statutes of limitations have existed for centuries; scholars trace the origins of statutes of limitations to the early days of Roman Law (Lowenthal 1950). By 1236 in England, statutes of limitations governing the transfer of property were enacted (Pollock and Maitland 1898). During the reign of Henry VIII, Parliament passed legislation establishing some time limits that affected real property transfers (Heriot 1992). The Limitation Act of 1623 marks the advent of the first systematic and reasonably effective rules governing time limitations for commencing legal actions. Notably, the Act expressly tolled limits for, among others, infants as well as the aged, imprisoned, and infirm. In addition, the Act codified the common law doctrine of adverse possession which generally provides an individual with legal title to property that the individual has occupied openly, notoriously, and continuously for a prescribed period of time. The Act also marks the beginning of the modern law of limitations governing personal actions in common law (Lowenthal 1950) and served as the model adopted by many American legislatures (Heriot 1992).

Statutes of limitations are found in many common law and non-common law settings. In common law settings, such as the United States, a recent survey of California law uncovered more than 32,000 statutes of limitations (or time-limiting bars) in that state alone (Montoya 1996). These enactments provide insights into a legal system's moral and ethical orientation, and in particular, their preference for human life issues over legal claims relating to other issues. In California, for example, statutes of limitations for slander or libel claims typically prevent any such claim being initiated more than one year after the action. On the other hand, there is no statutory limit whatsoever for murder.

Statutes of limitations are found in non-common law settings as well. For example, general 30-year statutes of limitation for civil actions operate in France and Germany (Martindale-Hubbell 2000). Of course, deviations from the general rule peculiar to each country also exist. In Germany, a general four-year statute of limitation governs certain business claims; three years for tort actions (Martindale-Hubbell 2000). In France, a ten-year limit governs most tort actions; a two-year limitation bounds claims on most insurance policies (Martindale-Hubbell 2000).

4. *Rationale*

Reflecting statutes of limitations' effort to reconcile conflicting principles, rationales advanced by scholars justifying such statutes vary. Both efficiency and equity (or 'fairness') emerge in the literature as common rationales for statutes of limitations (see, for example, Lowenthal 1950). Epstein (1986) advances a utilitarian justification that, in a world where everyone has an equal probability of being a plaintiff or defendant, the application of statutes of limitations and the resulting reduction in legal error, administrative and transaction costs bring about a net gain for the benefit of all.

5. *Criticisms*

Most critics of statutes of limitations focus on three points. One critique dwells on the particular time limits imposed on particular legal claims (see, for example, Bibas 1994, Thomas 1991). A second critique focuses on the operation of statutes of limitations,

especially on when time limits begin to run against a possible plaintiff (see, for example, Glimcher 1982). A third, broader critique flows from the courts' application of time limits in a 'rule-like' manner. Some critics of the rule-like application of statutes of limitations advance as one alternative administration by judges on a case-by-case basis (see, for example, Richardson 1997).

However, even most critics recognize that a rule-like application of statutes of limitations yields certain advantages. Such an application provides benefits from the fact that it is comparatively easy to administer, since decisions depend on a limited number of ascertainable facts and results can often be predicted *ex ante*. Moreover, well-crafted statutes convey in advance clear requirements for those contemplating pressing legal claims. Finally, a rule-like application of statutes of limitations reduces the potential for judicial abuse of discretionary powers.

Problems with statutes of limitations arise when the application of rules generates difficult or inequitable results. Critics point to such results as evidence for a more flexible application of statutes of limitations and for a close examination, case-by-case, of the way in which a particular application advances or impedes the underlying rationale for the time limits.

A case-by-case or individualized (i.e., non-rule-based) approach to applying statutes of limitations possesses certain advantages. Principally, this discretionary approach permits a closer examination of whether a specific claim falls within the range of difficulties that statutes of limitations were designed to address. Judicial discretion can reduce the possibility of injustice generated by a mechanical application of a statute of limitation. Ironically, greater judicial discretion in the application of such rules as statutes of limitations entails costs as well as benefits, because they generate greater uncertainty and thus increase the danger of judicial abuse.

Over one hundred years ago, Justice Oliver Wendell Holmes (1897) asked, 'What is the justification for depriving a man of his rights, a pure evil as far as it goes, in consequence of the lapse of time?' Justice Holmes' rhetorical question highlights a general ambivalence surrounding statutes of limitations and their applications (Ochoa and Winstrich 1997).

Benefits flowing from the application of statutes of limitations are frequently long-term and sometimes difficult to discern. In contrast, the costs imposed by statutes of limitations are short-term and more immediate and visceral. By seeking to reconcile critical principles that sometimes collide in litigation, statutes of limitations generate ambivalence and unease which weakens—but by no means dislodges—their secure and long-standing position in many—if not most—legal systems.

Stereotypes, Social Psychology of

1. Origin and History

Introduced to the social sciences by Lippmann in his book *Public Opinion* (1922), the concept of stereotype refers to beliefs, knowledge, and expectations of social groups. To capture the idea of a stereotype, Lippmann made famous the phrase 'pictures in our heads' to refer to an internal, mental representation of social groups in contrast to their external reality. At a time when mental constructs of any type were undeveloped and soon to be frowned upon in American psychological discourse, it is especially remarkable that Lippman and other early theorists detected and described the psychological importance of stereotypes. Not only was such a possibility theorized, the results of empirical tests of stereotypes were made available by Katz and Braly (1933). Their checklist method of asking respondents to assign trait adjectives (e.g., intelligent, dishonest) to ethnic and national groups (e.g., Jews, Germans) dominated the field, and in modified form, remains in use even today. With the exception of a hiatus in research on stereotypes at mid-century, the concept of stereotype has occupied a dominant position in psychology since the 1920s.

Reviews of historical and contemporary research on stereotypes are liberally available (see Fiske 1998).

The concept of stereotype, in many ways, remains largely in keeping with its original formulation, although some shifts in definition and emphasis are worth noting. In the earliest proposals, stereotypes were regarded to be inaccurate assessments of groups; in fact, according to Lippmann, a stereotype was a 'pseudoenvironment' or 'fiction' and according to Katz and Braly (1933) it was an unjustified and contradictory reaction to an outgroup. In contemporary psychology, the accuracy with which a stereotype captures the essence of a social group is not of central theoretical interest. The belief that 'Many X's are Y' may well be accurate (e.g., many neurosurgeons are men) but if such a belief is applied in judging an individual member of a group (e.g., Female X is not, or cannot be, a neurosurgeon), a stereotype is seen to be in play. This process, by which an individual is given or denied an attribute because of membership in a group, is regarded to be of psychological and social interest. Such a shift is the result of a change in emphasis from examining beliefs about social groups per se (stereotype content), to an interest in the mental mechanics by which they influence interpersonal and intergroup perception and interaction (stereotype process). It is obvious that both aspects of stereotypes, their content and process, are critical to an understanding of their nature and function in social interaction. In fact, attention to implicit or automatic stereotypes in recent years has rekindled an interest in stereotype content and strength and in their relationship to related constructs such as explicit stereotypes, implicit and explicit prejudice, and group identity.

From the earliest use of the term in psychology, stereotypes have been regarded as the cognitive (thought) as opposed to the affective (feeling) component of mental representations of social groups. As such, the construct is tied to but differentiated from the concept of attitude, preference, or liking as well as the concept of discrimination. 'I do not like group X' is a verbal statement of an attitude or prejudice, while an act denying friendship or intimacy with a member of group X may be regarded as a behavioral indicator of prejudice. To say 'I believe group X to be incompetent' is to express a stereotype, while an act of denying employment to a member of group X based on such a belief is seen as the behavioral indicator of that stereotype.Of course, such arbitrary distinctions between mental and behavioral measures disappear when measures of brain activation are introduced. Verbal self-reports, bodily gestures, decisions about hiring are all viewed as behavioral, as opposed to brain indicators of stereotypes and prejudice. It is likely that just as measures of activation in particular sub-cortical structures like the amygdala have been shown to be associated with behavioral measures of prejudice (Phelps et al. 2000), the future will yield similar studies of stereotypes and their neural correlates. Such research has the potential to unify social, cognitive, and neural levels of analysis by demonstrating that the learning of stereotypes that culture and social environments make possible can be synchronously detected in observable behavior as well as in brain activation.

The lure of a cognitive analysis in psychology led to a preponderance of attention to stereotypes, to the exclusion of its sister concept, prejudice. Fiske notes a 5:1 ratio in published work on the two concepts between 1974 and 1995. That trend appears to be shifting with attention to both stereotype and prejudice in recent years and especially to their relationships as observed at both conscious and unconscious levels. In addition, research has focused on the role of mood states in dictating stereotype expression with the counterintuitive proposal that positive mood increases rather than decreases reliance on stereotypes (Bodenhausen et al. 1994). The relationship between stereotype (cognition) and prejudice (attitude) has been a complex one with early work linking the two concepts closely enough so as to regard them as synonymous. Today, the relationship between the two is an uneasy one, without a clear sense of the exact nature of the relationship between stereotypic thoughts and prejudicial feelings. It is assumed that stereotypes and prejudice need not be evaluatively compatible. Attitude (liking) can be dissociated from stereotypes (competence, respect, etc.).

When searching for large-scale theories of stereotypes or theories in which the role of stereotypes is central, one comes up relatively empty-handed. The focus of research appears not to have been on the development of broad theories, although two exceptions must be noted, in each of which stereotypes play a role in the larger framework: a psychodynamic, individual difference approach advancing the notion of an authoritarian personality to understand ethnocentrism (Adorno et al. 1950), and a social-cognitive approach based on social identity and self-categorization (Tajfel and Turner 1986) to understand individual–group relationships and their psychological and social consequences. The paucity of large-scale theories of stereotyping and prejudice is compensated by creative experiments that form the groundwork of what may in the future yield unified theories of stereotypes and related constructs of prejudice and discrimination. The last three decades are likely to be remembered for noteworthy experimental discoveries and diversity in the manner in which stereotypes have been measured, with special emphasis on the role of consciousness in thought and feeling about social groups.

2. *Categorization and Beyond*

To perceive is to differentiate, and social perception inherently involves the ability to see differentiation among groups, for example, to see women as dif-

ferentiated from men, elderly as differentiated from young, European as differentiated from Asian. Individual humans each belong to multiple social groups, with gender, age, race/ethnicity, class, religion, and nationality being the most obvious such categories and numerous other differentiations also easily perceived along dimensions such as political orientation, physical attractiveness, etc. A fundamental feature of social perception is the classification of individuals into groups, and the process by which such classification is achieved is assumed to be automatic (Fiske 1998). Once categorized, attributes believed to be associated with the group are generalized to individuals who qualify for group membership. Thus, for example, women may come to be seen as nurturant and nice, men as strong and competent whether they as individuals, deserve those ascriptions or not.

Stereotypes are fundamental to the ability to perceive, remember, plan, and act. Functionally, they may be regarded as mental helpers that operate in the form of heuristics or short-cuts. Historically, this view of stereotypes as devices that allow a sensible reading of a complex world marked a breakthrough in research on stereotypes. Advanced by Allport (1954) and Tajfel (1969), the idea that stereotypes were inherent to the act of social categorization now forms the basis of the modern view. As such, stereotypes are regarded to be ordinary in nature, in the sense that they are the byproducts of basic processes of perception and categorization, learning, and memory. This cognitive view of stereotypes has dominated the field since the early 1980s, and from this standpoint several noteworthy discoveries about the nature of stereotypes have emerged.

3. *Discoveries*

Early research in this cognitive tradition showed that within-group differences are minimized and between-group differences are exaggerated, with greater confusion, for example, in memory for within-race and within-gender comparisons than between group comparisons. Stereotypes can be generated through a misperception about the frequency with which an attribute is associated with a group. For example, perceivers may come to see an illusory correlation based on the shared distinctiveness of particular attributes. Specifically, when a doubly distinctive event occurs (e.g., when a statistical minority performs a low frequency behavior) such an event is overemphasized in memory and produces a bias in perception such that their occurrence is overestimated.

Hamilton and Gifford (1976) have shown how such a process can lead to the assessment that members of minority groups perform more evaluatively negative behaviors than is actually the case. Research in this tradition has also provided a good understanding of how stereotypes, in the form of expectancies of what social groups are capable of, can lead to a bias to confirm rather than disconfirm expectancies. Moreover, the targets who are stereotyped may themselves fulfill the expectancies the perceiver holds about them to complete the biased cycle of intergroup interaction. Stereotypes are the vehicles of essentialist thinking about social groups. Dispositional group attributions, or the belief that groups are inherently the way they are, can lead to the assessment that attributes associated with groups are stable and unchanging.

Stereotypes play their role from the earliest moments in the information processing sequence, giving preference to stereotype-consistent options. To date the evidence overwhelmingly suggests that stereotypes influence the manner in which information is sought, perceived, remembered, and judged. Stereotypes limit the amount of information that is required to make a judgment by giving meaning to partial and even degraded information, and they allow decisions to be reached even when time is short. Stereotypes facilitate initial identification of congruent information and disallow attention to incongruent information. Although research has focused on the role of stereotypes in thinking, they are viewed as serving a socially pragmatic function—as helping social interaction proceed smoothly and with ease (Fiske 1998).

From such research it may appear that the only judgments of individuals that ensue are those that rely entirely on knowledge of and beliefs about social groups. Yet, that is not the case. Depending on the context and the motivation of the perceiver, category-based stereotypic judgments may well yield to more individualized, person-based judgments (Brewer 1988, Fiske and Nuberg 1990). Indeed, experiments on the mechanisms of stereotype expression have regularly shown that stereotypes may or may not play a role depending on the extent to which such knowledge is seen as meaningful or justified (Banaji et al. 1993).

The routine simplification function of stereotypes can have far-reaching effects. In the work of Tajfel and co-workers, categorization of individuals into social groups was shown to produce a heightening of perceived differences, and these differences (even when the distinction between groups was arbitrary and minimal) created intergroup discrimination in the form of greater resource allocation to members of one's own than another group. Thus, emanating from ordinary categorization, stereotypes can play a crucial role in interpersonal and intergroup relations. Besides routine simplification, stereotypes are also regarded as serving the function of protecting a stable and psychologically justified view of the world and the place of humans, as members of social groups, in it. Jost and Banaji (1994) argued that holding negative stereotypes of another's group may serve not only an ego-protective function ('I am better than you') and a group-protective function ('My group is better than yours') but a system justifying function as well. The counterintuitive hypothesis from such a perspective is

that when status hierarchies relegate groups to relative positions of inferiority and superiority, members of disadvantaged groups may themselves come to hold negative beliefs about their groups in the service of a larger system in which social groups are arranged.

3.1 Implicit Stereotypes

With its roots in the ideas of Allport and Tajfel, the notion that stereotypes may operate without conscious awareness, conscious intention, and conscious control is hardly surprising. In fact, throughout the twentieth century, experiments have shown that in one form or another stereotypes emerge spontaneously from initial categorization and continue to have a life of their own independent of conscious will. Yet, it would be fair to say that a direct interest in implicit or unconscious social cognition is relatively recent, with theoretical input from theories of unconscious mental life and methodological input from the development of new measurement tools and techniques.

Contrast the following two measures of stereotypes. A respondent is asked to indicate, using a traditional verbal self-report scale, the extent to which African Americans are scholarly and athletic. Or, a respondent is asked to rapidly pair words like 'scholar' and 'athlete' with faces of African–Americans, and the time to do so is measured. The first measure assumes the ability to respond without self-presentational concerns, and more importantly, it assumes the ability to be able to adequately reflect on the content of one's thoughts and provide an accurate indication of the complex association between race and psychological attributes. The second measure, although not within the traditional view of stereotype assessment, provides a measure of the strength of association between the group and the attributes. Such a measure has been taken to be an indicator of the stereotype and its strength. To investigate the implicit or automatic manner in which stereotypes of social groups may express themselves, investigators have used a variety of techniques from measuring response latencies (i.e., the time to make a response), to examining errors in memory and biases in linguistic reports. The largest single body of work has used response latencies as indicators of automatic stereotypes and prejudice and the data from such measures have yielded several new results and debates about them (see Banaji 2001).

Stereotypes can be activated by the mere presentation of symbols of social group or group-related attributes. It appears that although conscious prejudice and stereotypes have changed, their less conscious, automatic expressions are strikingly strong. As measured by the Implicit Association Test (Greenwald et al. 1998) automatic stereotypes appear to exist in robust form; large effect sizes are the hallmark of automatic stereotypes (see Nosek et al. in press). A priming measure has also been widely utilized in which prime-target pairs are presented in close succession and response latency to the target serving as the measure of automatic stereotypes. For example, responses are reliably faster to female first names ('Jane') when the immediately preceding word is stereotypically consistent ('nurse') than inconsistent ('doctor'). Such effects are obtained with words and pictures and they generalize to a variety of social groups.

Given the socially significant consequences of stereotype use, investigations of the variability and malleability of automatic stereotypes have been examined. Research has focused on the relationship between conscious and unconscious expressions of stereotypes and prejudice. As Devine (1989) showed, evidence of automatic race stereotypes is present irrespective of the degree of conscious prejudice toward Black Americans. Additionally, Banaji and Hardin (1996) showed that automatic gender stereotypes were manifested irrespective of endorsement of conscious attitudes and beliefs about gender egalitarianism. Such results point to the dissociation between conscious and unconscious social stereotypes, but it is clear that a simple dissociation may not adequately or accurately capture this relationship. Rather, results are now available that indicate that those with higher levels of conscious prejudice may also show higher levels of automatic or implicit prejudice. It appears that studies using multiple measures of each stereotype and statistical tools to uncover latent factors will yield evidence in favor of a relationship between conscious and unconscious stereotypes, while also revealing their unique and non-overlapping nature.

Questions concerning the controllability of automatic stereotypes are hotly debated (Fiske 1998). It appears that a desire to believe that stereotypes can be controlled, perhaps because of their pernicious social consequences, can result in the wishful assessment that they are indeed controllable. Automatic stereotypes do not appear to be controllable by ordinary acts of conscious will. However, habitual patterns of thought, feeling, and behavior toward social groups that cohere with broader value systems and ideology appear to predict automatic responses. In addition, Greenwald et al. (in press) have shown that automatic identity with one's group can predict stereotypes held about the group and attitudes toward it and have put forth a unified theory of self, group stereotypes, and attitudes. In support, they have found that attitudes toward mathematics and science can be predicted by the strength of the automatic stereotype that math is male or masculine. Women who hold a stronger math = male stereotype also show more negative attitudes toward mathematics.

The effects of minor interventions to activate stereotype-incongruent associations (e.g., female–strong) can be detected in weaker automatic stereotypes (Blair et al. in press). Such findings point to the flexibility of the representations of social stereotypes. Although the category 'strong women' may be

counter-stereotypic, interventions that highlight this association can produce a lowering of the default stereotype of female = weak. The possibility of such strategies for inducing a shift in automatic stereotypes and the potential to track stereotypes through both behavioral and brain activation measures has the potential, in the future, to inform about stereotype representation, process, content, and mechanisms for social change.

Stevens, Stanley Smith (1906–73)

S. Smith Stevens (1906–73) was a leading figure in the field of experimental psychology during the middle part of the twentieth century. He is best known for his work in psychophysics and especially for the development of the psychophysical power law, but he also made important contributions to the study of hearing, and to an understanding of measurement theory and its role in psychology. Aside from his many research reports, his most influential publications include the classic *Hearing: its Psychology and Physiology* (1938) co-authored with Hallowell Davis, the *Handbook of Experimental Psychology* (1951), and *Psychophysics: Introduction to its Perceptual, Neural and Social Prospects* (1975) edited by his wife, Geraldine Stevens.

1. Beginnings

To understand fully the significance of any scientist's contribution, it is important to know the context in which it occurred. It is particularly useful to be acquainted both with the scientists who paved the way and with those who followed. Historians of experimental psychology have traced the beginnings of the field to the German scientist Wilhelm Wundt (1832–1920), who established the first laboratory for psychological research in 1879. Although other scientists had made important contributions to the emerging field, it was Wundt who first identified an entire range of questions in psychology amenable to laboratory inves-

tigation, and it was to his laboratory in Leipzig that students from many countries came for training in experimental psychology. Stevens, whose distinguished career culminated in his position as Professor of Psychophysics at Harvard University, stands in a direct line of scholarly descent from Wundt as a member of the fourth generation. He was trained by E. G. Boring (1886–1968) at Harvard, who in turn had studied at Cornell with E. B. Titchener (1867–1927), an Englishman who had received his degree in Leipzig from Wundt in 1892. And whereas Wundt may be considered the first to devote himself to Experimental Psychology, it may well be that Stevens was the last. His work marked and contributed to a transition from one era to another in the evolution of scientific psychology and an understanding of that transition makes an interesting story.

Stevens was born on November 4, 1906 in Ogden, Utah, home to the Mormon Church, and, following the customs of that institution, he departed at the age of 17 to spend 3 years as a missionary in Belgium and later in France despite a complete ignorance of the language. It seems likely that this experience contributed to the development of persistence and determination, traits that were to serve him well in his career as a scientist. On his return he entered the University of Utah and, after two years, transferred to Stanford, where he graduated in 1931 having taken such a wide variety of courses that the identification of a major was problematic. He was accepted by the Harvard Medical School but demurred on the grounds that the required payment of a $50 fee and the need to spend the summer taking a course in organic chemistry seemed equally unattractive. But he did decide to study at Harvard, and duly enrolled in the School of Education as the easiest (and most economical) path to Harvard's resources. The transforming experiences there were E. G. Boring's course on perception and service as Boring's unpaid research assistant. By the end of his second year, Stevens had earned a PhD in the Department of Philosophy (from which the Psychology Department emerged a year later). A year studying physiology under Hallowell Davis and another as a research fellow in physics led to appointment in 1936 as an instructor in the Psychology Department, where he remained until his death on January 18, 1973 in Vail, Colorado. By 1946 he achieved the rank of full professor, and in 1962 the University acceded to his request that he be named Professor of Psychophysics in honor of the field founded a century earlier by G. T. Fechner, whose theories, ironically, Stevens worked hard to refute.

2. *Stevens's Psychophysical Power Law*

Scholars familiar with his work quickly could agree in making a list of Stevens's major achievements, but could and do disagree about their relative importance and their lasting value. For some the single most important accomplishment was his discovery of the psychophysical power law that sometimes does and always should carry his name (Stevens 1957). He not only revived a view broached by some in the nineteenth century, but also created a body of evidence that firmly established what is sometimes called the Psychophysical Power Law and sometimes Stevens's Law. It concerns the relation between the strength of some form of energy, such as the sound pressure level of a tone, and the magnitude of the corresponding sensory experience, loudness in this example. It is easily discovered that sensation strength is nonlinearly related to stimulus intensity (two candles do not make a room seem twice as bright as one), but it is harder to say what that relation is. For over a century before Stevens approached the problem, the prevailing view, Fechner's Law, asserted that, as stimulus strength grew geometrically (by constant ratios), sensation strength increased arithmetically. This logarithmic relation had little supporting evidence but remained in many texts for lack of a good alternative. Stevens came to a different conclusion on the basis of data obtained by asking observers who were presented with stimuli varying in intensity to make numerical judgments of their subjective experience. In the case of loudness he found that judged loudness grew as a power function of sound pressure (with an exponent of about 0.6), not as the logarithmic relation predicted by Fechner (Stevens 1961). A similar relation was found to hold between judged brightness and luminance, and eventually, such a relation was found for dozens of other continua. In each case, as the amount or intensity of a stimulus grew by ratio steps, so too did the observer's estimate of his subjective experience of it. Stevens's Law seemed applicable to all intensive perceptual continua.

Equally interesting was the discovery that for each perceptual continuum, there was a distinctive value of the exponent relating numerical judgment to stimulus intensity. In hearing, for example, a huge range of sound pressures was compressed into a much smaller range of loudness, whereas for electric shock applied to the fingertips, a quite small range of currents between detectability and pain was expanded into a larger range of perceived intensities.

Although Stevens originally argued that the method of magnitude estimation provided a 'direct measure' of sensation (see *Sensation and Perception: Direct Scaling*) and that the power law described how energy in the environment was transformed through the relevant sensory apparatus into sensation, critics soon showed this assumption to be untenable. What remained was an empirical principle relating judgment to stimulus intensity.

Stevens went on to show that numerical magnitude estimation was a special case of a more general paradigm, cross-modal matching. If the observer is asked to match loudness, for example, by manipu-

lating the luminance of a light source until its brightness matches the level of the target loudness, the power relation is again the result. And, neatly enough, the exponent of that function is exactly predictable by the exponents identified through magnitude estimation of brightness and loudness alone (Stevens 1969). It is this ability of observers to match perceived magnitudes across many different perceptual attributes, and the discovery that in all cases the result is described by a power function, that are the two pillars on which Stevens's Law rests. Despite the many controversies over its meaning, this simple empirical principle stands securely on a mountain of evidence and must be accommodated by any theory of psychophysics.

3. *Scales of Measurement*

Others attach greater importance to Stevens's ideas about scales of measurement. In a seminal paper (1946) he created a taxonomy of measurement, which identified four classes of scales—nominal, ordinal, interval, and ratio—distinguishing among them on the basis of the operations that leave the form of the scale invariant. Nominal scales assigned numbers that serve only to distinguish one event or class of events from another (the classic example is the set of numbers used to identify each member of a team); any one-to-one substitution is permissible because player identity is preserved. Ordinal scales of measurement permit a rank ordering of measured events (relative hardness of materials, for example) and will remain invariant under monotonic increasing transformations. Interval scales entail a constant unit of measurement and so permit the calculation of differences between any two values (as for the common scales of temperature) and remain invariant under linear transformations. Ratio scales (the bread and butter of physics) also feature constant units of measurement, but in addition allow the expression of two values as a ratio, since a true zero exists; weight is a good example. Such a scale is invariant under a simple multiplicative transformation.

It is harder to assess the impact of this conceptualization of measurement than that of the work on cross-modal matching judgments. The latter was instrumental in creating new bodies of knowledge, especially in the field of sensory psychology, and continues to play an influential role in psychophysical theory and research. But Stevens's four-step hierarchy of measurement scales encountered an assortment of reactions that leaves its present status in some doubt.

Contemporary theorists find the nominal scale of little interest because it imposes no ordering on the measured entities. And several authorities have noted the omission of a log interval scale from what Stevens had proposed as an exhaustive listing. The relevance of this classification to the selection of statistical procedures was hotly debated (e.g., see Binder 1984). Stevens had argued that the type of measurement placed constraints on which statistics can be used, but statisticians were quick to cite seeming exceptions, and the usefulness of Stevens's measurement taxonomy as a guide to the selection of statistical techniques became uncertain.

But, for psychologists, his ideas about measurement were, and in some ways continue to be, of great importance. At a time when Stevens was trying to provide support for his newly-created scale of loudness, he felt it important to show that it met the same criteria of legitimacy as did the familiar scales of the more developed sciences. It was a time when the status of psychology as a science was a topic of lively debate, and Stevens was much involved in efforts to identify the critical features of science and the ways in which psychology shared them. During the 1940s and 1950s questions about the nature of science and psychology's place in it were discussed at length, and Stevens's analysis of measurement in general and the ways in which psychologists could use scales of measurement was very influential. The idea that a measurement scale—or, for that matter, any lawful relation—could be expressed in terms of the operations that left it invariant, played an important role in the thinking of his students, and no doubt for scientists in other disciplines as well. The work that Stevens began has now evolved into a mathematical specialty in its own right, yielding results that confirm some of what Stevens intuited, and disconfirming other aspects of his work. (It must be remembered that the ideas he was advancing lent themselves to mathematical formalization, though he himself did not provide it.) That his ideas about measurement have continued to be developed and refined by other scientists today may be the ultimate accolade for his pioneering work in this field (e.g., see Luce and Narens 1999).

4. *Hearing*

If Stevens had never established the psychophysical power law and had left the study of measurement untouched, he would still be known and remembered as a pioneer in the field of psychoacoustics, the scientific study of the perception of sound (e.g., see Scharf 1999). His collaboration with Hallowell Davis in the late 1930s resulted in *Hearing*, a book that for many years was the fundamental source on the subject and has been ranked by some scholars as second only to the work of Helmholtz in its originality and breadth. In addition to his measurements of loudness, he did important work on auditory localization, and on the relation of pitch to intensity. At the behest of the US Army Air Corps he established the Psycho-Acoustic Laboratory at Harvard in 1940 to study the effect of noise on pilot psychomotor efficiency. As its director

he was able to attract a group of students and colleagues of extraordinary ability, among them W. R. Garner, K. D. Kryter, J. C. R. Licklider, and G. A. Miller, all of whom made important contributions to psychoacoustics and beyond. It was an interesting aspect of his personality that, despite a rather gruff manner, he functioned as an intellectual magnet, attracting to his laboratory some of the most talented researchers in the world. Not the least of these was G. von Békésy, who spent almost 20 years in Stevens' basement lab and won a Nobel Prize during that period for his early work (in Budapest and Stockholm) on the ear.

Throughout his career there were several periods of intense activity as a laboratory scientist. But in the period before World War II he was also active in the discussion of philosophical questions about the nature of psychology. He was impressed by the work of the physicist P. W. Bridgman on the central role of operationism in science, and argued for its use in defining the concepts of psychology. And for a period he was associated closely with a group of logical and methodological positivists whose ideas about the nature of science seemed especially hospitable to a behaviorist psychology (Stevens 1939). Perhaps one manifestation of this outlook was a reluctance to extend his thinking very far beyond his data. In a period when many experimental psychologists were developing ever more complex theoretical systems, Stevens's own forays into the realm of theory were few and limited in scope. He seemed happiest examining his data (as well as those of others) to see what useful information could be extracted. Much of his time in the laboratory was spent plotting and replotting data in the pursuit of clarity and simplicity, and his research reports were models of both qualities.

5. *Impact on Experimental Psychology*

Two additional characteristics of his work deserve mention. While the majority of his contemporaries were engaged in a search for relevant variables (e.g., does 'meaningfulness' affect ease of remembering?), Stevens's goal was the discovery of functional relations, mathematical descriptions of the association of one factor with another, as epitomized by his psychophysical power law. A corollary of this belief was an attitude toward sampling theory and statistical testing that ranged from indifference to disdain. The object for him was not to see whether 80 dB tones received an average loudness judgment greater than did 60 dB tones (at the 5 percent level of significance), the equivalent of what most of his contemporaries were doing. What was important to Stevens was whether a lawful relation could be seen when data were plotted in a thoughtful way. Large numbers of experimental subjects were not needed to reveal the kind of robust relations he sought; a few colleagues or students recruited in the hallways were enough for most of his purposes.

A landmark publication for research psychologists in the 1950s was the *Handbook of Experimental Psychology* edited by Stevens (1951). It was, as he described it in the preface, 'a technical survey that would systematize, digest, and appraise the mid-century state of experimental psychology.' It was not the first of its kind, but it was the most recent, and thus defined for teachers and students alike the set of shared interests that constituted experimental psychology. It was a time still when one might be expert in one aspect of the field and fairly knowledgeable about many others. Since then the amount of knowledge in psychology has grown at an explosive rate, and now the achievement of competence in one area increasingly restricts knowledge of any other. At the beginning of the twenty-first century, the tent of 'experimental psychology' has few remaining occupants; there are instead cognitive scientists, brain researchers, vision scientists, and a host of others in specialized niches. Just as Stevens's mentor E. G. Boring may have been among the last to teach an all-inclusive account of psychology in a single course, so Stevens may have been among the last to view the phrase 'experimental psychology' as a useful rubric.

6. *Conclusion*

Stevens can be seen as a transitional figure in the evolution of psychological science, yet much of what he did continues to influence the way it is practiced today. His lasting contributions to the fields of psychoacoustics and psychophysics have been discussed here. But, in addition, he created a roadmap for much of modern sensory neurophysiology and for those who theorize in that area. Many of the phenomena for which today's brain researchers seek explanations were established by Stevens or by others using the methods he developed. Were he alive today, it seems likely that he would embrace the new technology and would be developing ingenious techniques for exploring the neural aspects of sensory events. Although an account of his influence remains an unfinished story, at the least he will be remembered as one who brought new and powerful ideas to the study of psychophysics, leaving it a field reinvigorated and evolving as a subject of great intrinsic interest and many useful applications (e.g., see Baird 1997, Norwich 1993, Stevens 1966).

R. Teghtsoonian

Stigler, George Joseph (1911–91)

1. Personal History

George Stigler, one of the great economists of all time, with a gift for writing matched among modern economists only by John Maynard Keynes, was born January 17, 1911 in Renton, Washington, a suburb of Seattle, the only child of Joseph and Elisabeth Stigler. His parents had separately migrated to the United States at the end of the nineteenth century, his father from Bavaria, his mother from what was then Austria-Hungary. Stigler went to public schools in Seattle, and then to the University of Washington, receiving a BA in 1931. Although he says that he had 'no thought of an academic career' when he graduated from college, he applied for and was awarded a fellowship at Northwestern University for graduate study in the business school, receiving an MBA in 1932 (Stigler 1988, p.15). More important, at Northwestern he developed an interest in economics as an object of study in its own right and decided on an academic career. After one further year of graduate study at the University of Washington, he moved to the University of Chicago where he found the intense intellectual atmosphere he sought. Chicago became his intellectual home for the rest of his life, as a student from 1933 to 1936, a faculty member from 1958 to his death in 1991, and a leading member of, and contributor to, the 'Chicago School' throughout. He received his PhD in 1938, with a thesis, now a classic, on the history of neoclassical theories of production and distribution (Stigler 1941).

At Chicago, Stigler was particularly influenced by Frank H. Knight, under whom he wrote his dissertation, Jacob Viner, who taught economic theory and international economics, John U. Nef, economic historian, and their younger colleague, Henry Simons, who became a close personal friend and whose *A Positive Program for Laissez Faire* greatly influenced many of Stigler's contemporaries.

'At least as important to me,' Stigler writes (1988, pp. 23–5), 'as the faculty were the remarkable students I met at Chicago,' and goes on to list W. Allen Wallis, Milton Friedman, Kenneth Boulding, and Robert Shone from Britain, Sune Carlson from Sweden, Paul Samuelson, and Albert G. Hart—all of whom subsequently had distinguished careers.

In 1936, Stigler was appointed an assistant professor at Iowa State College (now University), and shortly thereafter was married to Margaret Mack. The Stiglers had three sons: Stephen, a professor of statistics at the University of Chicago, David, a lawyer in private practice, and Joseph, a businessman. Mrs. Stigler died in 1970, tragically without any advance warning. George never remarried.

In 1938, Stigler accepted an appointment at the University of Minnesota, going on leave in 1942 to work first at the National Bureau of Economic Research and then at the Statistical Research Group of Columbia University, where he joined a group directed by W. Allen Wallis that was engaged in war research on behalf of the armed services. When the war ended in 1945, George returned to the University of Minnesota, but remained only one year, leaving in 1946 to accept a professorship at Brown University, where he also remained only one year before moving to Columbia University in 1947 and then, in 1958, to the University of Chicago where he remained the rest of his life. At Chicago, he became an editor of the *Journal of Political Economy*, established the Industrial Organization Workshop, which achieved recognition as the key testing ground for contributions to the field of industrial organization, and in 1977 founded the Center for the Study of Economy and the State, serving as its director until his death in Chicago on December 1, 1991.

Stigler served as President of the American Economic Association in 1964, and of the History of

Economics Society in 1977. He was elected to the National Academy of Sciences in 1975. He received the Alfred Nobel Memorial Prize in Economic Science in 1982 and the National Medal of Science in 1987.

Stigler's governmental activities included: serving as a member of the Attorney General's National Committee to Study the Antitrust Laws, 1954–5; Chairman, Federal Price Statistics Review Committee, 1960–1; member, Blue Ribbon Panel of the Department of Defense, 1969–70; Vice Chairman, Securities Investor Protection Corporation, 1970–3; Co-Chairman, Blue Ribbon Telecommunications Task Force, Illinois Commerce Commission. 1990–1.

2. *Scientific Contributions*

Stigler made important contributions to a wide range of economic areas: (a) history of thought, (b) price theory, (c) economics of information, (d) organization of industry, and (e) theory of economic regulation. In addition, (f) he wrote many influential essays and reviews, and was a long-time editor.

2.1 *Intellectual History*

Intellectual history was Stigler's first field of specialization and remained a continuing interest throughout his life. His doctoral dissertation, published as *Production and Distribution Theories*, was followed by a steady flow of perceptive, thoughtful, and beautifully written articles and books interpreting the contributions of his predecessors. Almost single-handedly, he kept the field alive, despite widespread lack of interest within the profession. More recently, he succeeded in bringing about a revival of interest in the field, which is currently flourishing. In the words of one of his students, 'The versatility of his work in [the history of economic thought] has been matched by its depth and insight—and unmatched by any other historian of economic thought' (Sowell 1987, p. 498; the rest of this paragraph draws from Sowell's excellent summary of 'Stigler as an Historian of Economic Thought'). In addition to analyzing the theories of particular economists, he examined particular concepts, such as perfect competition and utility, traced trends in the economics profession, considered the influence of economic theories on events and vice-versa, and the meaning of originality. Many of his important articles in this area are collected in a 1965 volume, *Essays in the History of Economics*.

The history of thought provided a rich seedbed for Stigler's wide-ranging scientific work. Stigler regarded economic theory, in the words of Alfred Marshall, as 'an engine for the discovery of concrete truth,' not as a subject of interest in its own right, a branch of mathematics. Few economists have so consistently and successfully combined economic theory with empirical analysis, or ranged so widely.

2.2 *Price Theory*

Stigler's first important publication after his doctoral thesis was a textbook, *The Theory of Competitive Price*, published in 1942, followed by four revised versions under the title *The Theory of Price* (1946, 1952, 1966, 1987). His textbook is unique among intermediate textbooks in price theory in its systematic linking of highly abstract theory to observable phenomena. It is unique also in its concise yet rigorous exposition.

One of his earliest papers (1939) broadened the concept of a short-run cost curve to accommodate the observation that firms faced with fluctuating demand could build flexibility into their fixed equipment at a cost of not achieving the lowest possible cost for a particular output.

Another early paper (1945) presented a formal analysis of determining the minimum cost of an adequate diet, supplemented by an empirical calculation of the minimum cost—one of the earliest applications of linear programming. 'The procedure,' he explained, 'is experimental because there does not appear to be any direct method of finding the minimum of a linear function subject to linear conditions' (p. 310). Two years later George Dantzig provided such a direct method, the simplex method, now widely used in many economic and industrial applications (1987).

Like these two examples, Stigler's many later contributions to price theory were a by-product of seeking to understand puzzling real world phenomena, and are best discussed in that context.

2.3 *Economics of Information*

'The Economics of Information' is the title of a seminal article, published in 1961. In his intellectual autobiography, Stigler termed it, 'My most important contribution to economic theory' (1988, pp. 79–80). The article begins, 'one should hardly have to tell academicians that information is a valuable resource: knowledge is power. And yet it occupies a slum dwelling in the town of economics. Mostly it is ignored' (Stigler 1961, p. 213).

This brief 12-page article is a splendid illustration of several of Stigler's unique virtues: creativity, which he defined as consisting 'of looking at familiar things or ideas in a new way'; the capacity to extract new insights about those seemingly familiar things; and the ability to state his main points in a provocative and eminently readable way.

Stigler illustrates the importance of subjecting information to economic analysis with two familiar observations—that there is generally no single 'market price' but a variety of prices that 'various sellers (or buyers) quote at any time' and that 'advertising … is an enormously powerful instrument for the elimination of ignorance … and is normally "paid" for by the seller.' In each case, he presents a sophisticated analysis that explains what determines the observed phenomena, an analysis that has empirical implications capable of being contradicted by observation. He concludes that 'The identification of sellers and the discovery of their prices are only one sample of the vast role of the search for information in economic life' (quotes from Stigler 1988, pp. 213, 220, 221, 224).

As occurred throughout his career in every field Stigler touched, this article was less important for the particular familiar observations that it analyzed than for giving birth to an essentially new area of study for economists. There followed an outpouring of further studies by him but even more by his students and others that have radically altered the accepted body of economic theory.

This aspect of his influence was stressed in the citation for his Nobel Prize, which noted that Stigler's 'studies of the forces which give rise to regulatory legislation have opened up a completely new area of economic research … Stigler is also recognized as the founder of "economics of information" and "economics of regulation," and one of the pioneers of research in the intersection of economics and law.'

2.4 *The Organization of Industry*

The Organization of Industry is the title of a book published in 1968. Its 'main content,' Stigler says in the preface, 'is a reprinting of 17 articles I have written over the past two decades [including the "Economics of Information"] in the area of industrial organization. Although the main topics in industrial organization are touched upon, the touch is often light. The ratio of hypotheses to reasonably persuasive confirmation is distressingly high in all of economic literature, and it must be my chief and meager defense that I am not the worst sinner in the congregation.' Far from being the worst sinner, Stigler's main contribution to the field, both in this book and later writing, was the use of empirical evidence to test hypotheses designed to explain features of industrial organization. Article after article combines subtle theoretical analysis with substantial nuggets of empirical evidence, presented so casually as to conceal the care with which the data were compiled and the effort that was expended to determine what data were both relevant and accessible. These articles record the shift in Stigler's views on antitrust—from initial support of an activist antitrust policy to skepticism about even a minimalist policy.

One of the most influential of the articles in the book was on 'The Economies of Scale' in which he introduced 'the survivor principle' as a way to use market data to determine the efficient size of an enterprise in a particular industry. The approach has since become widely accepted.

In 1962, he published an article, in collaboration with Claire Friedland, his long-time associate, entitled 'What Can Regulators Regulate? The Case of Electricity,' which concluded that regulation of electric utilities had produced no significant effect on rates charged. Schmalensee (1987, p. 499) notes that 'This essay stimulated a great deal of important empirical work on public regulation in the USA. It also posed a basic problem: if regulation does not generally achieve its stated objectives, why have so many agencies been established and kept in existence?'

2.5 *Economic Regulation*

'The Theory of Economic Regulation' (1971b) attempts to answer that question. It is one of a series of contributions by Stigler to what has since come to be called 'public choice' economics: the shift from viewing the political market as not susceptible to economic analysis, as one in which disinterested politicians and bureaucrats pursue the 'public interest,' to viewing it as one in which the participants are seeking, as in the economic market, to pursue their own interests, and hence subject to analysis with the usual tools of economics. The seminal work that deserves much of the credit for launching 'public choice,' *The Calculus of Consent*, by James Buchanan and Gordon Tullock (1962), appeared in the same year as the Stigler–Friedland article.

The 'central thesis of the article,' Stigler wrote, 'is that, as a rule, regulation is acquired by the industry and is designed and operated primarily for its benefit.' He notes that two 'alternative views of the regulation of industry are widely held. The first is that regulation is instituted primarily for the protection and benefit of the public at large or some large subdivision of the public. The second view is essentially that the political process defies rational explanation.' He then gives example after example to support his own thesis, which is, by now, the orthodox view in the profession, concluding: 'The idealistic view of public regulation is deeply imbedded in professional economic thought. The fundamental vice of such a [view] is that it misdirects attention'—to preaching to the regulators rather than changing their incentives (quotes from Stigler 1971b, p. 3).

'Smith's Travels on the Ship of State' (1971a), published in the same year as 'The Theory of Economic Regulation,' raises the same question on a broader scale. Smith gives self-interest pride of place in analyzing the economic market, but does not give it the same role in analyzing the political market. Smith's

failure to do so constitutes Stigler's main—indeed, nearly only—criticism of the *Wealth of Nations*, that 'stupendous palace erected upon the granite of self interest' (Rosenberg 1993, p. 835). The same theme pervades many of Stigler's later publications.

2.6 *Essays, Editorship, and Reviews*

In addition to his prolific academic publications, Stigler published a great many essays for a broader audience, many given as talks to a wide variety of audiences. The most important are collected in three volumes, *The Intellectuals and the Marketplace* (1963), *The Citizen and the State* (1975), and *The Economist as Preacher* (1982). 'There he (the intelligent layman) will find a potpourri of wit and seriousness blended with a high writing style' (Demsetz 1982, p. 656). 'For 19 years Stigler was a very successful editor of the *Journal of Political Economy*. Under his leadership this journal solidified its high reputation among economists' (Becker 1993, p. 765).

Stigler was also a prolific reviewer of books. His complete bibliography lists 73 reviews in 24 publications ranging from strictly professional, such as the *Journal of Political Economy* (22) and the *American Economic Review* (10) to the popular, such as the *Wall Street Journal* (5), and the *New York Times* (3), and dating from 1939 to 1989.

Stigler's last book, his intellectual autobiography, published in 1988, *Memoirs of an Unregulated Economist*, is a delight to read. As I described it at the time: 'Stigler's memoirs are a gem: in style, in wit, and above all, in substance, they reflect accurately his own engaging personality and his extraordinarily diverse contributions to our science.'

3. *Concluding Comments*

An evaluation of Stigler's scientific contribution would be incomplete without recognizing his role as a teacher and colleague. As teacher, he inspired his students by his own high standards, and instilled a respect for economics as a serious subject concerned with real problems. As one of his students, Thomas Sowell, wrote (1993, p. 788): 'What Stigler really taught, whether the course was industrial organization or the history of economic thought, was intellectual integrity, analytical rigor, respect for evidence—and skepticism toward the fashions and enthusiasms that come and go.'

Stigler supervised many doctoral dissertations at both Columbia and the University of Chicago. According to Claire Friedland, Stigler's associate for many years, he served on more than 40 thesis committees at Chicago, and perhaps 40 more at Columbia, and chaired a considerable fraction of those committees. His students come close to dominating the field of industrial organization.

Stigler was an extremely valuable colleague. He provided much of the energy and drive to the interaction among members of the Chicago economics department, business school, and law school that came to be known as 'The Chicago School.' His Workshop in Industrial Organization was an outgrowth of a law school seminar started by Aaron Director that Stigler cooperated in running when he came to Chicago. His relations were especially close with Aaron Director, Gary Becker, Richard Posner, Harold Demsetz, and myself, enhancing significantly the scientific productivity of all of us.

Stigma, Social Psychology of

A person who possesses an attribute that risks their full acceptance from others is said to possess a stigma. As a consequence, the individual is stigmatized, reduced in our minds from a whole and usual person to a tainted, discounted one (Goffman 1963). A person with a stigma may be described as possessing a failing, a shortcoming, or a handicap, be viewed as deviant or abnormal, and thus be subject to marginalization or oppression. Thus, stigmatized individuals are the targets of prejudice, stereotyping, and discrimination (see *Intergroup Relations, Social Psychology of*; *Stereotypes, Social Psychology of*). In order to cope with their situation, some stigmatized individuals may make use of a variety of psychological and behavioral coping strategies (see *Coping across the Lifespan*).

There are several categories of attributes in our culture that have been the basis for pervasive stigmatization (e.g., race, ethnicity, religion, physical ability, physical appearance, gender, and sexual orientation). Goffman (1963) described three general categories/types of stigma: abominations of the body (e.g., physical deformities), blemishes of individual character (e.g., criminal behavior, addiction, or sexual orientation), or tribal stigma (e.g., race, nation, religion, etc.). Most characterizations of stigma emphasize its relational nature: an attribute cannot be stigmatizing without another attribute being viewed as more usual or more acceptable. For example, an unusually tall woman may not feel stigmatized in the company of other very tall people, however, she might feel stigmatized in the company of average height people. Depending upon the context, we all have the potential to be stigmatized.

The nature of stigmas may vary across several dimensions. For instance, Jones et al. (1984) described six dimensions: concealability of the stigmatizing attribute, course (duration and permanence) of the stigmatizing attribute, disruptiveness of the stigmatizing attribute in social interactions, esthetic qualities of the stigmatizing trait, origin or cause of the stigmatizing trait, and perilousness of the stigmatizing trait to others. Crocker et al. (1998) argued that two of these traits are the most critical to understanding the experience of a stigmatized person: the visibility (or concealability) of the attribute, and the controllability of the attribute (or the origin, reason for the person's having that attribute; for example, personal choice vs. genetic inheritance).

1. *History of Research on Stigma*

Early research on stigma was very descriptive in nature, bringing the circumstances and concerns of stigmatized individuals to the attention of the social sciences. This early research typically focused on one particular stigmatizing trait (e.g., physical disability, mental illness, or criminal status) in single-study pieces, often conducted by sociologists or clinicians using qualitative methods such as interviews and intensive case studies. It was not until 1963 that this varied literature was integrated into a single theoretical review in Goffman's (1963) book *Stigma: Notes on the Management of Spoiled Identities*. His book provided a unifying theory of stigma, and insights into issues stigmatized people face in terms of their social and personal identity and their management of interactions with nonstigmatized people.

Early theorizing and research can be characterized as attempts to promote sympathy and understanding by emphasizing the perceived pitiable situation of stigmatized individuals. This is illustrated by Lewin's (1941/1948) discussion of self-hatred among Jews and Allport's (1954/1985) discussion of traits due to victimization. As Allport noted 'One's reputation, whether false or true, cannot be hammered, hammered, hammered, into one's head without doing something to one's character.' It was during this phase that the famous 'doll studies' were conducted in an attempt to show the damage to the self-concept caused by prejudice and segregation (e.g., Clark and Clark 1939). The conclusions often drawn from this research were that black children showed self-hatred by preferring white to black dolls whereas no such self-hatred was shown by white children. Although later refuted (see below), these doll studies were used as evidence in the landmark case of Brown vs. Board of education (1954) to illustrate the damage caused by segregation.

The second phase of research can be considered a transitional phase, in that it represents a merger of research on stigma and research on prejudice, which had been largely independently conducted. This merger is illustrated by the second major integrative work on stigma, Jones et al.'s (1984) book *Social Stigma: The Psychology of Marked Relationships*. Jones and his colleagues illustrate clearly the connection between prejudice and stigmatization pro-

viding further analysis of the implication of stigma for social interactions. This phase can be considered in part a result of the civil rights movement in that it was during this time that a new cultural norm emerged as to how to perceive stigmatized group members, providing new rights, higher social standing, and group pride to members of a number of stigmatized groups. During this time more affirmative theories of self-concept and group identity emerged (see *Ethnic Identity, Psychology of*; *Social Identity, Psychology of*) as well as theories about processes by which the stigmatized can protect their self-esteem. It was also during this time of upward social mobility of oppressed group members that the large body of empirical work on intergroup contact and tokenism began.

The latest development in the research on stigma can be termed 'The Target's Perspective' that has extended the research on stigma in two major ways. First, it broadens our view of the stigmatized. It highlights the importance of understanding how stigmatized individuals perceive prejudice (Swim et al. 1998) and the reasons for their responses to prejudice, which might be misinterpreted if not viewed within the larger context of their life experiences (Miller and Myers 1998). It also highlights understanding variations within stigmatized groups such as variations in extent and type of group identity (Cross 1991). Moreover, the target's perspective research argues for a more empowering view of stigmatized individuals, not as passive recipients of prejudice but as active copers (Swim et al. 1998). Second, the target's perspective research goes beyond simply merging the literatures on stigma and prejudice, instead arguing that the study of the target's experience with prejudice should be used to enlighten the larger theory concerning prejudice and its perpetrators. The target's perspective researchers have asserted that the research on prejudice primarily has studied perpetrators, failing to give a voice to the stigmatized.

2. *Current Understanding of Stigma*

Research on stigma can be conceived of as representing three primary topic areas: (a) perceptions of prejudice and discrimination; (b) effects of prejudice and discrimination on the stigmatized; and (c) coping with prejudice and discrimination. Below we highlight illustrative and consequential work in these areas.

2.1 *Perceptions of Prejudice and Discrimination*

Perceptions of prejudice include general perceptions of the prevalence of prejudice against specific groups or oneself and whether people label specific incidents that occur to themselves or others as discriminatory. An intriguing finding is that people tend to perceive that they personally are less likely to experience prejudice than are members of their group (Taylor et al. 1994). This finding spurred research examining motivational factors (e.g., a desire to not accuse others or to protect sense of personal control) and cognitive factors (e.g., difficulties in aggregating information) influencing stigmatized members to deny their personal experiences with prejudice. Consistent with a denial explanation for the personal/group discrepancy, research has revealed that members of stigmatized group are more likely than members of nonstigmatized groups to underestimate the likelihood that specific ambiguous negative incidents are a function of discrimination against them (Rugerrio and Major 1998).

Several factors influence the likelihood that people will perceive prejudice and discrimination. First, individual differences in sensitivity to prejudice and discrimination influence perceptions. For example, the more people endorse sexist beliefs, the less likely they are to label certain incidents as sexual harassment (Swim and Cohen 1997) and African-Americans who have a general cultural distrust may more readily perceive prejudice than those who are more trusting (Feldman Barrett and Swim 1998). Second, several features of particular incidents influence perceptions. Some beliefs and actions are more readily defined as prejudicial. For example, women are more likely to favorably rate a man who endorses benevolent sexist beliefs than hostile sexist beliefs perhaps in part because they do not recognize the link between these two types of sexist beliefs (Kilianski and Rudman 1998). Benevolent sexist beliefs include the endorsement of complementary gender differentiation, heterosexual intimacy, and paternalism and men who tend to endorse these beliefs tend to also endorse hostile sexist beliefs. Also, some people are more likely to be perceived to be prejudiced than others are. That is, people hold stereotypes about stereotypers such as believing that whites are more likely to discriminate against blacks than blacks are (Inman and Baron 1996). Third, there are personal costs and benefits to perceiving prejudice (Feldman Barrett and Swim 1998). Perceiving prejudice when none existed can lead to interpersonal disruption and distrust in outgroup members as well as to confirmatory biases (see *Self-fulfilling Prophecies*) and not perceiving prejudice when it does exist can endanger an individual's self-esteem and can lead to internalization of prejudicial or stereotypical beliefs.

2.2 *Effects of Prejudice and Discrimination on the Stigmatized*

As noted above, there has been much concern that prejudice psychologically impacts the stigmatized. Perhaps the best-known early set of empirical work is the previously mentioned doll studies originating in

work by Clark and Clark (1939). The conclusion that these studies illustrate self-hatred among African-Americans has been disputed (e.g., Cross 1991) and countered by findings illustrating, for example, that African-Americans have higher self-esteem than European Americans as measured on standardized measures of self-esteem (Gray-Little and Hafdahl 2000). Despite these findings, it is important to recognize that some stigmatized groups (e.g., heavy women) may be more likely to have lower self-esteem than nonstigmatized people, which can be a function of internalizing prejudice (Quinn and Crocker 1998). There also is variation within stigmatized groups with some group members, such as those that do not strongly identify with a group, being more effected by prejudice than others (Gray-Little and Hafdahl 2000). Further, experiencing discrimination can lead to other psychological effects such as increased negative daily moods (Swim et al. 2000) and long-term psychiatric symptoms such as obsessive-compulsiveness, depression, and anxiety (Klonoff et al. 2000).

Decreases in academic performance are also important consequences of being in a stigmatized group. Compared with the nonstigmatized, stigmatized individuals may more often find themselves solo members of groups which can lead to distraction due to impression management concerns that can interfere with performance (Saenz and Lord 1989). Further, situations can induce stigmatized individuals to fear that others will stereotype them and this 'stereotype threat' can impair test performance (Crocker et al. 1998). For instance, telling women that there are gender differences on a difficult exam in a stereotype relevant domain of importance to the individual is sufficient to result in decrements in exam scores. Similar findings have occured for other groups, such as African–Americans.

2.3 Coping with Prejudice and Discrimination

Coping strategies used by stigmatized individuals can be divided into psychological and behavioral responses. In many cases, coping strategies protect people from the negative effects of prejudice and discrimination and have potential costs. Disengagement or disidentification is a possible psychological response to discrimination that can allow one to not attend to potentially demeaning feedback from others (Crocker et al. 1998). However, this can result in disidentification with domains that might be useful for promoting one's academic success. One type of behavioral response is preventative. Stigmatized individuals may choose to avoid situations where they feel that they may encounter prejudice (Swim et al. 1998) or to engage in behaviors that might compensate for the negative expectations that others might have of them (Miller and Myers 1998). Although these prevention strategies may protect the individual from future encounters with prejudice, they too have their costs. Avoidance can cause people to miss opportunities, prevent disconfirmation of beliefs, and prevent the development of meaningful relationships. People can overcompensate for prejudice, which may appear out of place or fake, or they may undercompensate particularly if they are in situations where they do not feel threatened. Other behavioral responses occur after an event and these responses can be both nonassertive and assertive (Swim et al. 1998). People may choose to politely confront a person, for instance, by asking the perpetrator to explain themselves, by attempting to educate the perpetrator, or by engaging in collective action against the perpetrator. While these responses may result in change and may leave the target feeling more empowered, there are potential costs, such as retaliation on the part of the perpetrator especially with the more assertive responses.

3. Future Directions

As noted above, current research on stigma has broadened our understanding of the stigmatized and we anticipate that this process will continue to occur. For instance, there are still relatively few studies that illustrate the strengths of the stigmatized. However, we anticipate that this will change with more people focusing, for instance, on how the stigmatized support each other, confront perpetrators, and set and seek their life goals. Further, we anticipate that there will be more research on variations in experiences across stigmatized groups, such as differences in experiences of those from different Asian countries or differences in identity and economic standing within any stigmatized group. Moreover, there will be more complexity in these analyses as mixed relationships develop where children are born to parents of different ethnic heritages or adopted to parents who do not share, for instance, the same ethnic heritage as their parents.

We also anticipate that research on the stigmatized will continue to inform and be informed by other research areas. For instance, there is a strong connection between the literature on stress and stigma in that experiences with prejudice can be considered forms of stressors. Further research on stigma likely to lead to major changes in how people study prejudice and intergroup relationships. Given greater emphasis on similarities and differences between the stigmatized, there may be greater attention paid to similarities and differences between racism, sexism, heterosexism, and antifatism. There may also be greater recognition in the subjectivity in defining what is and is not prejudice in that members of different groups will likely disagree as to what constitutes prejudicial behavior. Further, there will likely be more attention paid to the contributions that the stigmatized have to intergroup relationships, such as understanding their attempts to

maintain smooth intergroup interactions as well as the origins and characteristics of their prejudices against both dominant groups and other stigmatized groups.

Stochastic Dynamic Models (Choice, Response, and Time)

The term 'stochastic dynamic model' is used in human experimental psychology to describe models of choice and reaction time (RT) in which noise-perturbed information about stimulus identity accrues in continuous time. It has gained currency since it was used by Luce (1986) to refer to a class of models first investigated in a pioneering series of articles by Pacut (e.g., 1976), in which information accrual was described by linear stochastic differential equations (SDEs). Because of the relatively rich dynamics that can be represented by equations of this kind, the term is also used in a more general sense to describe models in which informational accrual is not constant, but varies with time or state. This entry describes the mathematical methods that are used to analyze models of this kind.

Like the classical sequential-sampling models (see *Auditory Models*, *Sequential Decision Making*), the main application of stochastic dynamic models is to performance in simple decision or simple information-processing tasks, typically, those that require a speeded choice between two alternatives. Along with Signal Detection Theory and its variants (see *Signal Detection Theory: Multidimensional*), these models are members of a larger class of statistical decision models, which assume that the representation of stimuli in the central nervous system is inherently statistical, by virtue of the mass action properties of neural coding. This leads to models in which the stimulus representation, viewed as a sequence of events unfolding in time, is treated formally as a stochastic process.

Because of the assumed noisiness of stimulus representations, statistical decision models typically assume that decisions are made by an averaging or integration device, whose function is to smooth out transitory fluctuations in neural activation, thereby rendering decisions less susceptible to random perturbations in

the stimulus process than would otherwise be the case. In Signal Detection Theory, the period of integration is assumed to be fixed, or to be determined by factors external to the stimulus process, whereas in sequential-sampling models integration continues until a criterion quantity of evidence for a particular response is obtained.

From a theoretical standpoint, sequential-sampling models have greater explanatory power than signal-detection models, because they can account for choice probabilities and RT within a unified theoretical framework, whereas signal-detection models provide an account of choice probabilities only. However, sequential-sampling models are more complex to analyze mathematically because they require solution of a first passage time problem. This solution gives the distribution of times needed for the accrued evidence to attain a criterion level, which is identified in such models with the decision component of RT. In contrast, the analysis of signal detection models requires only the mean and variance of the accrued evidence as a function of time, as these suffice to determine the choice probabilities.

In the sequential-sampling literature, two main classes of model have predominated: random-walk models, in which evidence accrues as a single, signed total and counter, or accumulator models, in which evidence for competing response alternatives accrues in parallel. When formulated in continuous time, these models become diffusion process models and Poisson counter models, respectively. Although a number of researchers have contributed to the development of these models, the standard versions are those described, respectively, by Ratcliff (1978) and Townsend and Ashby (1983).

Recently, dynamic generalizations of these 'classical' models have begun to appear, in which the assumption of a constant rate of information accrual is replaced by time-dependent accrual, state-dependent accrual, or some combination of the two. These assumptions are motivated by the need to capture the complex dynamics that seem to underlie performance in some domains. State dependence can arise when the accrual process is imperfect or 'leaky' (Diederich 1995, Rudd and Brown 1997, Smith 1995), or when it is governed by resistive, or approach-avoidance, dynamics (Busemeyer and Townsend 1993).

Time dependence arises when, for any of a number of reasons, the physical mechanism that generates the stimulus process is itself time varying (Heath 1992). Examples of the latter include models in which the accrual process is driven by time-varying encoding mechanisms in the visual cortex or by a noisy, continuous-time neural network, and models in which information accrual is gated in time by selective attention. In all such cases, the theoretical principles that underlie the model lead naturally to the assumption of time-dependent or state-dependent information accrual.

1. Diffusion Process Models

Figure 1 shows a two-barrier, dynamic, diffusion process model of RT. The main elements of this model are an encoding function, a source of noise, and a decision stage. The encoding function, $\mu(t)$, is a deterministic function of time, which represents the average information available to the decision stage at time t. ('Information' is used loosely here, to refer to the output of relevant neural systems, rather than in its technical sense of entropy.) In general, the value of $\mu(t)$ is assumed to reflect the results of an ongoing matching operation between perceptual and memorial representations of a stimulus. In Fig. 1, the encoding function arises as the difference between a time-varying stimulus representation (the continuous curve) and a sensory referent or 'mental standard,' c (the dashed line), which results in a function that takes on both positive and negative values. Positive values are evidence for one response, r_A; negative values are evidence for the alternative response, r_B. In classical sequential-sampling models, the encoding function is assumed to be constant for a given experimental trial ($\mu(t) = \mu$), but in general dynamic models it may vary with time.

At each instant, t, the encoding function is additively perturbed by noise, $W(t)$. In diffusion process models, the noise is assumed to be white noise, that is, broad-spectrum (delta correlated) Gaussian noise. To make a decision, successive values of the resulting noisy comparison process are integrated, as shown in the box on the right of Fig. 1. The value of the integral as a function of time is a stochastic process, $X(t)$, which represents the accrued stimulus information at time t. The process of accrual continues until $X(t)$ exits from the region bounded by two absorbing barriers $a_A(t)$ and $a_B(t)$.

If, at the time of the first boundary crossing, $X(t) \geqslant a_A(t)$, then response r_A is made; if $X(t) \leqslant a_B(t)$, then response r_B is made. Psychologically, the time of the first boundary crossing is identified with the

Figure 1
Dynamic diffusion process model showing cognitive operations intervening between presentation of an external stimulus (s) and production of a binary identification response (r)

decision time component of RT, and the probability that the first boundary crossed is $a_A(t)$ is identified with the proportion of r_A responses. Although the figure shows $a_A(t)$ and $a_B(t)$ as constant, in general dynamic models the absorbing boundaries and the encoding function may all depend on time. Such variations may be useful when modeling the response to external time constraints, such as RT deadlines.

1.1 Stochastic Differential Equations for Information Accrual

In general, the process of information accrual in stochastic dynamic models can be described by a linear SDE of the form

$$dX(t) = [\mu(t) + b(t)X(t)]\,dt + [\sigma(t) + c(t)X(t)]\,dB(t) \quad (1)$$

This Eqn. defines $dX(t)$, the random change in the accrual process $X(t)$ in a small time interval dt. The change consists of two parts, one deterministic, the other stochastic. The deterministic change, or drift, is expressed by the quantity $\mu(t) + b(t)X(t)$. The first term $\mu(t)$, which is purely time dependent, is determined by the temporal properties of the encoding process. The second term $b(t)X(t)$ expresses a joint dependency on time and on the current (random) state. Pure state dependency arises in the special case in which $\mu(t) = 0$ and $b(t)$ is constant.

The stochastic part of the change, the so-called diffusion coefficient, is represented by the second term on the right of Eqn. 1. Stochastic perturbation is introduced via the white noise process, $dB(t)$, which is the formal derivative of the Brownian motion or Wiener diffusion process. The stochastic perturbation at any instant can also be represented as the sum of two terms, one purely time dependent, $\sigma(t)$, and another, $c(t)X(t)$, that is jointly dependent on time and state. Under appropriate regularity conditions, the process $X(t)$ that solves Eqn. 1 is a diffusion process, that is, a continuous sample path Markov process. Solutions to linear stochastic differential equations of the form of Eqn. 1 are obtained by using the Itô calculus (e.g., Karatzas and Shreve 1991).

In applications, a number of special cases of Eqn. 1 are of interest. These are instances of the case $c(t) = 0$, in which there is no state dependence in the diffusion coefficient. Under these circumstances, the solution to Eqn. 1 is a Gaussian process, $X(t)$, whose distribution at time t can be characterized uniquely by its first two moments. By means of the Itô calculus it may be shown that, for a process with initial condition $X(\tau) = y$, the value of $X(t)$ is normally distributed with mean

$$E[X(t)\,|\,X(\tau) = y] = \int_\tau^t \exp\left[\int_s^t b(u)\,\mathrm{d}u\right]\mu(s)\,\mathrm{d}s + y\exp\left[\int_\tau^t b(u)\,\mathrm{d}u\right] \quad (2)$$

and variance

$$\mathrm{var}[X(t)|X(\tau) = y] = \int_\tau^t \exp\left[2\int_s^t b(u)\,\mathrm{d}u\right]\sigma^2(s)\,\mathrm{d}s. \quad (3)$$

These eqns. provide the basis for a dynamic signal-detection model that generalizes the classical model of Signal Detection Theory. It extends in a straightforward way to multiple correlated dimensions, to give a dynamic formulation of the General Recognition Theory of Ashby and Towsend (1986).

To date, the most important subcases of the Gaussian process in Eqns. 2 and 3 are those in which $\sigma(t) = \sigma$ (constant) and $b(t) = 0$ or $b(t) = -\gamma$. These subcases represent, respectively, dynamic versions of the Wiener and Ornstein-Uhlenbeck (OU) diffusion process. From a psychological perspective, the Wiener and OU processes may be thought of as describing the dynamics of stochastic accrual processes in which information integration is perfect, or 'leaky,' respectively.

1.2 Solution of First Passage Time Problems for Time-inhomogeneous Diffusions by Numerical Integral Equations

In models of RT such as the one shown in Fig. 1, the quantities of interest are the times required for $X(t)$ to first cross one of the two absorbing boundaries, which represent decision criteria for the responses r_A and r_B. The distribution of these times are obtained by solving the first passage time problem for $X(t)$. Classical methods for solving first passage time problems treat the problem as a boundary value problem in the theory of partial differential equations (e.g., Ratcliff 1978). However, these methods are usually not tractable when the drift term in Eqn. 1 is not time-homogeneous. Instead, such problems can often be solved using numerical integral equation techniques that were developed in mathematical biology to model the properties of integrate-and-fire neurons. These methods yield integral equation representations for $g_A[a_A(t), t\,|\,x_0, t_0]$ and $g_B[a_B(t), t\,|\,x_0, t_0]$, the first passage time densities of the process $X(t)$ through the absorbing boundaries $a_A(t)$ and $a_B(t)$, given the initial condition $X(t_0) = x_0$.

To give a formal characterization of these methods, we define the transition density of $X(t)$, the unconstrained diffusion process, by

$$f(x, t\,|\,y, \tau) = \frac{\mathrm{d}}{\mathrm{d}x}P[X(t) \leqslant x\,|\,X(\tau) = y].$$

That is, the transition density is the partial derivative with respect to the spatial coordinate of the transition distribution $P[X(t) \leqslant x\,|\,X(\tau) = y]$. Classically, the transition distribution is obtained by solving the

partial differential equation that is variously known as the Kolmogorov forward equation or Fokker-Planck equation, with specified initial condition. For the special Gaussian case $c(t) = 0$ of Eqn. 1, it may be obtained directly from the solution given by the Itô calculus, namely,

$$P[X(t) \leqslant x \mid X(\tau) = y] = \Phi \left\{ \frac{x - E[X(t) \mid X(\tau) = y]}{\sqrt{\mathrm{var}[X(t) \mid X(\tau) = y]}} \right\}$$

where Φ is the normal distribution function and where the moments are given by Eqns. 2 and 3.

For an arbitrary diffusion process, which may be both temporally and spatially inhomogeneous, the first passage time densities $g_A[a_A(t), t \mid x_0, t_0]$ and $g_B[a_B(t), t \mid x_0, t_0]$ satisfy the Fortet eqns.

$$f[a_A(t), t \mid x_0, t_0] = \int_{t_0}^{t} g_A[a_A(\tau), \tau \mid x_0, t_0] f[a_A(t), t \mid a_A(\tau), \tau] \mathrm{d}\tau + \int_{t_0}^{t} g_B[a_B(\tau), \tau \mid x_0, t_0] f[a_A(t), t \mid a_B(\tau), \tau] \mathrm{d}\tau \quad (4a)$$

and

$$f[a_B(t), t \mid a_0, t_0] = \int_{t_0}^{t} g_B[a_B(\tau), \tau \mid x_0, t_0] f[a_B(t), t \mid a_B(\tau), \tau] \mathrm{d}\tau + \int_{t_0}^{t} g_A[a_A(\tau), \tau \mid x_0, t_0] f[a_B(t), t \mid a_A(\tau), \tau] \mathrm{d}\tau. \quad (4b)$$

These eqns. express the unknown first passage time densities as functions of the free transition density $f(x, t \mid y, \tau)$ of $X(t)$. They are obtained by considering the sample paths of $X(t)$ that pass through one of two small open intervals $a_A^{\varepsilon}(t) \equiv (a_A(t), a_A(t) + \varepsilon)$ and $a_B^{\varepsilon}(t) \equiv (a_B(t), a_B(t) - \varepsilon)$, on the upper and lower absorbing barriers, respectively, at time t. These intervals are both in the absorbing region for $X(t)$, so any sample path of this kind must have made at least one boundary crossing at some time $\tau, \tau \leqslant t$. It may therefore be decomposed into an initial segment representing a transition from the starting point x_0 to the point of the first boundary crossing at $a_A(\tau)$ or $a_B(\tau)$, followed by a second segment representing the subsequent transition into $a_A^{\varepsilon}(t)$ or $a_B^{\varepsilon}(t)$. Because $X(t)$ is a Markov process, the probability density for such sample paths, obtained by shrinking ε to zero, may be decomposed into a product of two density functions. One describes the first passage through an absorbing boundary at τ; the other describes the subsequent free transition (irrespective of the number of intervening boundary crossings) to $a_A(t)$ or $a_B(t)$. Equations 4a and 4b provide a mutually-exclusive and exhaustive decomposition of the probability densities of sample paths of this kind.

Formally, Eqns. 4a and 4b are Volterra integral equations of the first kind, which can be solved analytically only in special cases. While the general case can in principle be handled numerically, by approximating the integrals with sums, any simple method of approximation will be numerically unstable, because as the interval of approximation, h, becomes small, the transition density $f(x, t \mid y, t-h)$ approaches a Dirac delta function. In the terminology of integral equation theory, the kernel of the equation is said to be singular. Consequently, recent theoretical work has sought to find ways to transform the eqn. to remove the singularity.

It was shown by Buonocore et al. (1990) and subsequently, in somewhat greater generality, by Gutiérrez Jáimez et al. (1995), that for a large class of diffusion processes, Eqns. 4a and 4b can be transformed into Volterra integral equations of the second kind of the form

$$g_A[a_A(t), t \mid x_0, t_0] = -2\Psi[a_A(t), t \mid x_0, t_0] + 2\int_{t_0}^{t} g_A[a_A(\tau), \tau \mid x_0, t_0] \Psi[a_A(t), t \mid a_A(\tau), \tau] \mathrm{d}\tau + 2\int_{t_0}^{t} g_B[a_B(\tau), \tau \mid x_0, t_0] \Psi[a_A(t), t \mid a_B(\tau), \tau] \mathrm{d}\tau \quad (5a)$$

and

$$g_B[a_B(t), t \mid x_0, t_0] = 2\Psi[a_B(t), t \mid x_0, t_0] - 2\int_{t_0}^{t} g_A[a_A(\tau), \tau \mid x_0, t_0] \Psi[a_B(t), t \mid a_A(\tau), \tau] \mathrm{d}\tau - 2\int_{t_0}^{t} g_B[a_B(\tau), \tau \mid x_0, t_0] \Psi[a_B(t), t \mid a_B(\tau), \tau] \mathrm{d}\tau. \quad (5b)$$

These eqns. express the first passage time densities at time t as a function jointly of their values at all preceding times, $\tau < t$ and of a kernel function $\Psi(x, t \mid y, \tau)$. The latter may be chosen in such a way that its value goes to zero as τ approaches t, which means that, unlike Eqns. 4a and 4b, the right-hand sides of Eqns. 5a and 5b can be approximated numerically, with finite sums. A full account of this method, including details of how to obtain the kernel functions for diffusions such as the Wiener and OU processes, may be found in Smith (2000).

1.3 Finite-state Markov Chain Approximations

Another approach to modeling decision-making using diffusion processes has been used by Busemeyer and

Townsend (1992) and collaborators, in which the process is approximated numerically as the limit of a finite-state Markov chain. Computationally efficient solutions to the first passage time problem for such chains can be obtained using spectral methods when the process is time-homogeneous, as in the case of the OU process with a constant comparison function, $\mu(t) = \mu$. More recently, Diederich (1997) has extended this method to the case in which the encoding function is only piecewise time-homogeneous, that is, $\mu(t) = \mu_i = 1, 2, \ldots$, where the index i denotes one of a sequence of consecutive, nonoverlapping observation intervals. This describes a situation in which the encoding function undergoes a sequence of instantaneous shifts during the course of an experimental trial. As such, it resembles models previously considered for piecewise random walks and Wiener processes by Ratcliff (1980) and Heath (1981), respectively. Its main application has been to model shifts in attention between stimulus attributes in cognitive decision tasks, in settings in which the time scale of the decision is long relative to that of the attention shifts. In tasks in which decisions are made more rapidly, as is the case in simple information-processing tasks, it may be more relevant to represent shifts in attention as progressive rather than instantaneous events. The dynamics of such shifts can then be modeled in continuous time using the techniques of the preceding paragraphs.

2. Poisson Counter Models

Figure 2 shows an example of the second class of stochastic, dynamic models, the Poisson parallel-counter. This model consists of three main stages: an encoding stage, a point-process generation stage, and a stochastic accrual stage. The output of the encoding stage is a function $\mu(t)$ that describes the time course of the stimulus representation. This is compared simultaneously to the mental representations of the stimuli that correspond to the response alternatives r_A and r_B. The result of this comparison is a pair of independent point processes, $X_A(t)$ and $X_B(t)$, whose intensities reflect the degree of the match between the stimulus and the associated mental representations. In the classical model, these stochastic comparison processes are assumed to be homogeneous Poisson processes. More generally, however, the intensities of these processes may be arbitrary functions of time, denoted $a(t)$ and $b(t)$. Under these circumstances, $X_A(t)$ and $X_B(t)$ become time-inhomogeneous.

Figure 2
Poisson parallel-counter model with time-inhomogeneous intensities

These processes drive a pair of counting processes, $N_A(t)$ and $N_B(t)$, which count the number of point events in $X_A(t)$ and $X_B(t)$, respectively. The accrual of counts continues in this way until the total in one or another counter exceeds an associated critical count, specifically, until $N_A(t) \geqslant K_A$ or $N_B(t) \geqslant K_B$. At this point, accrual ceases and the response associated with the counter in question is given. The RT density functions for this model are determined by the integrated event rate functions $A(t)$ and $B(t)$, which are defined as

$$A(t) = \int_0^t a(s)\,\mathrm{d}s$$

$$B(t) = \int_0^t b(s)\,\mathrm{d}s.$$

The first passage time densities $g_A(t)$ and $g_B(t)$ may then be written:

$$g_A(t) = \frac{[A(t)]^{K_A-1} a(t) e^{-A(t)}}{(K_A-1)!} \left\{ \sum_{j=0}^{K_B-1} \frac{[B(t)]^j}{j!} e^{-B(t)} \right\} \tag{6a}$$

and

$$g_B(t) = \frac{[B(t)]^{K_B-1} b(t) e^{-B(t)}}{(K_B-1)!} \left\{ \sum_{j=0}^{K_A-1} \frac{[A(t)]^j}{j!} e^{-A(t)} \right\} \tag{6b}$$

respectively. Like the time-inhomogeneous diffusion process, closed-form expressions for choice probabilities and mean RT cannot in general be obtained for this model, although these quantities may always be computed from the RT density functions by numerical integration. However, for some special cases that are of interest in applications, closed-form expressions for these statistics are readily obtainable. Details may be found in Smith and Van Zandt (2000).

3. Models with Multivariate Diffusion Processes

The preceding sections described the simplest versions of the main classes of stochastic dynamic models. However, other alternatives are possible, for example, models in which several diffusion processes race one

another in parallel, as first proposed by Ratcliff (1978). Subsequent authors have considered general dynamic models in a similar vein, such as the model of simple RT described by Smith (1995), which incorporates both time inhomogeneity and state dependence. Providing the constituent processes themselves are independent, such models may be analyzed straightforwardly using the methods of Sect. 1. Usually, however, considerable complexity accompanies any attempt to relax the independence assumption in a useful way.

When the processes are not independent, their combined behavior must be modeled as a multivariate diffusion process with specified covariance properties. Distributional properties for a fairly wide variety of correlated diffusion processes may be obtained by solving the multivariate analogue of Eqn. 1 using the Itô calculus. This suffices to give the time-dependent mean and covariance function of the process, unconstrained by absorbing barriers, which provides the basis for a dynamic signal-detection model. For models of RT, however, it is usually necessary to solve the associated first passage time problem in multivariate form.

One exception to this prescription is the stochastic version of General Recognition Theory developed by Ashby (2000), which seeks to characterize how people make binary classification judgments on stimuli defined in a multivariate perceptual space. In this model, the multivariate problem can be reduced to a univariate problem because, geometrically, all the information relevant to the decision is contained in the projection of the diffusion process onto the normal to the hyperplane dividing the response categories. However, in models not possessing this structure it is necessary to solve the multivariate first passage time problem explicitly. Unfortunately, there are no general methods for solving such problems and the fragmentary results that have been obtained in special cases are usually not applicable to behavioral data. From a modeling perspective, this represents a significant limitation, because in some domains, models in which there is crosstalk between channels are of considerable theoretical interest. In these cases, because of the difficulties in obtaining relevant results in other ways, the properties of the associated models have been investigated using Monte Carlo simulation. A recent example of the use of simulation methods to investigate stochastic dynamic models is the work of Wenger and Townsend (2000).

4. Conclusions and Future Directions

This article has surveyed the mathematical methods used to obtain RT and accuracy predictions for the two main classes of continuous-time, dynamic models used to model decision-making in cognitive tasks: diffusion process models and Poisson parallel-counter models. The attraction of such models is that they allow richer and more complex ideas about the neural representation of stimuli to be embodied in mathematical models. The disadvantage of this additional freedom is that the resulting models may be more difficult to test empirically than their classical counterparts. For this reason, future developments in this area are likely to be in domains in which the dynamic characteristics of a model are strongly constrained by existing theory. Such constraints are needed to ensure models that are expressions of theoretical principles rather than simply vehicles for fitting data. Areas with a body of theory that is sufficiently well articulated to support models of this kind include early vision, mathematical studies of memory, and selective attention.

Stochastic Models

The simplest stochastic experiment is coin-toss. Each toss of a fair coin has two possible results and each of these results has probability of one half. This experiment is mathematically modeled with a random variable. A random variable is characterized by a state space and a probability distribution; in coin-toss the state space is {head, tail} and the distribution is 'probability of head = 1/2,' 'probability of tail = 1/2'.

This paper deals essentially with three issues. The first one is a description of families of independent random variables and their properties. The law of large numbers describes the behavior of averages of a large number of independent and identically distributed variables; for instance, it is 'almost sure' that in a million coin-tosses the number of heads will fall between 490 thousands and 510 thousands. The central limit theorem describes the fluctuations of the averages around their expected value. The Poisson approximation describes the behavior of a large number of random variables assuming values in {0, 1}, each one with small probability of being 1.

The second issue is phase transition and is discussed in the setup of percolation and random graph theory. For example, consider that each i belonging to a bidimensional integer lattice (that is, i has two coordinates, $i = (i_1, i_2)$, each coordinate belonging to the set of integer numbers $\{\ldots, -1, 0, 1, \ldots\}$) is painted black with probability p and white otherwise, independently of everything else. Is there an infinite black path starting at the origin of the lattice? When the answer is yes it is said that there is percolation. A small variation on the probability p may produce the transition from absence to presence of percolation.

The third question is related to dynamics. Markov chains describe the behavior of a family of random variables indexed by time in {0, 1, 2,...} for which the probabilistic law of the next variable depends only on the result of the current one. Problems for these chains include the long time behavior, law of large numbers and central limit theorems. Two examples of Markov chains are discussed. In the birth-and-death process at each unit of time a new individual is born or a present individual dies, the probabilities of such events being dependent on the current number of individuals in the population. In a branching process each new individual generates a family that grows and dies independently of the other families.

Special attention is given to interacting particle systems; the name refers to the time evolution of families of processes for which the updating of each member of the family depends on the values of the other members. Two examples are given. The simple exclusion process describes the evolution of particles jumping in a lattice subjected to an exclusion rule (at most one particle is allowed in each site of the lattice). The study of these systems at long times in large regions is called the hydrodynamic limit. In particular, when the jumps are symmetric the hydrodynamic limit relates the exclusion process with a partial differential equation called the heat equation, while when the jumps are not symmetric, the limiting equation is a one-conservation law called the Burgers equation. The voter model describes the evolution of a population of voters in which each voter updates his opinion according to the opinion of the neighboring voters. The updating rules and the dimension of the space give rise to either unanimity or coexistence of different opinions.

The stochastic models discussed in this article focus on two commonly observed phenomena: (a) a large number of random variables may have deterministic behavior and (b) local interactions may have global effects.

1. *Independent Random Variables*

The possible outcomes of the toss of a coin and its respective probabilities can be represented by a random variable. A random variable X is characterized by a set S of possible outcomes and the probability distribution or law of these outcomes: for each x in S, $\mathbb{P}(X = x)$ denotes the probability that the outcome results x. In coin-toss the set S is either {head, tail} or {0, 1} and the distribution is given by $\mathbb{P}(X = 0) = \mathbb{P}(X = 1) = 1/2$. The mean or expected value $\mathbb{E}(X)$ of a random variable X is the sum of the possible outcomes multiplied by the probability of the outcome: $\mathbb{E}(X) = \sum_x x\mathbb{P}(X = x)$. The variance $\mathbb{V}(X)$ describes the square dispersion of the variable around the mean:

$$\mathbb{V}(X) = \sum_x (x - \mathbb{E}X)^2 \mathbb{P}(X = x). \tag{1}$$

A process is a family of random variables labeled by some set. Independent random variables are characterized by the fact that the outcome of one variable does not change the law of the others. For example, the random variables describing the outcomes of different coins are independent. The random variables describing the parity and the value of the face of a dice are not independent: if one knows that the parity is even, then the face can only be 2, 4, or 6.

1.1 Law of Large Numbers and Central Limit Theorem

A sequence of independent random variables is the most unpredictable probabilistic object. However, questions involving a large number of variables get almost deterministic answers. Consider a sequence of independent and identically distributed random variables X_1, X_2,... with common mean μ and finite variance σ^2. The partial sums of the first n variables is defined by $S_n = X_1 + \cdots + X_n$ and the empiric mean of the first n outcomes by S_n/n. The expectation and the variance of S_n are given by $\mathbb{E}(S_n) = n\mu$ and $\mathbb{V}(S_n) = n\sigma^2$. The law of large numbers says that as n increases, the random variable S_n/n is very close to μ. More rigorously, for any value $\varepsilon > 0$, the probability that S_n/n differs from its expectation by more than ε can be made arbitrarily close to zero by making n sufficiently large.

The Central Limit Theorem says that the distance between S_n and $n\mu$ is of the order $\sqrt{n}$. More precisely it gives the asymptotic law of the difference when n goes to ∞:

$$\lim_{n\to\infty} \mathbb{P}\left(\frac{S_n - n\mu}{\sqrt{n}\sigma} \leqslant a \right) = \Phi(a) \tag{2}$$

where Φ is the normal cumulative distribution function defined by

$$\Phi(a) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{a} e^{-x^2/2} \mathrm{d}x \tag{3}$$

1.2 Law of Small Numbers and Poisson Processes

Consider a positive real number λ and a double labeled sequence $X(i, n)$ of variables with law $\mathbb{P}[X(i, n) = 1] = \lambda/n$, $\mathbb{P}[X(i, n) = 0] = 1 - \lambda/n$; n is a natural number, that is, in the set $\{0, 1,\ldots\}$ and i is in the 'shrinked' lattice $\{1/n, 2/n,\ldots\}$ (the nomenclature comes from the fact that as n grows the distance between points diminishes). In this way, for fixed n there are around n random variables sitting in each interval of length one but each variable $X(i, n)$ has a small probability of being 1 and a large probability of being 0 in such a way that the mean number of ones in the interval is around λ for all n. When n goes to infinity the above process converges to a Poisson process. This process is characterized by the fact that the number $N(\Lambda)$ of ones in any interval Λ is a Poisson random variable with mean $\lambda m(\Lambda)$, where $m(\Lambda)$ = length of Λ: $\mathbb{P}[N(\Lambda) = k] = e^{-\lambda m(\Lambda)}[\lambda m(\Lambda)]^k/k!$; furthermore, the numbers of ones in disjoint regions are independent. A bi-dimensional lattice consists of points with two coordinates $i = (i_1, i_2)$ with both i_1 and i_2 natural numbers and analogously the points in a d-dimensional lattice have d coordinates. When i runs in a multidimensional shrinked lattice, the limit is a multidimensional Poisson process. This is called the law of small numbers.

The one-dimensional Poisson process has the property that the distances between successive ones are independent random variables with exponential distribution (it is said that T has exponential distribution with parameter λ if $\mathbb{P}(T > t) = e^{-\lambda t}$). In this paper, one-dimensional Poisson process will be called a Poisson clock and the times of occurrence of ones will be called rings.

The classic book for coin-tossing and introductory probability models is Feller (1971). Modern approaches include Fristedt and Gray (1997), Brémaud (1999) and Durrett (1999a). Aldous (1989) describes how the Poisson process appears as the limit of many distinct phenomena.

2. Static Models

2.1 Percolation

Suppose that each site of the two-dimensional lattice is painted black with probability p and white with probability $1-p$ independent of the other sites. There is a black path between two sites if it is possible to go from one site to the other jumping one unity at each step and always jumping on black sites. The cluster of a given site x is the set of (black) sites that can be attained following black paths started at x. Of course, when p is zero the cluster of the origin is empty and when p is one, it is the whole lattice. The basic question is about the size of the cluster containing the origin. When this size is infinity, it is said that there is percolation. It has been proven that there exists a critical value p_c such that when p is smaller than or equal to p_c there is no percolation, and when p is bigger than p_c there is percolation with positive probability. This is the typical situation of phase transition: a family of models depending on a continuous parameter which show a qualitative change of behavior as a consequence of a small quantitative change of the parameter. Oriented percolation occurs when the paths can go from one point to the next following only two directions; for example South–North and West–East. The standard reference for percolation is Grimmett (1999).

2.2 Random Graphs

Consider a set of n points and a positive number c. Then, with probability c/n, connect independently each pair of points in the set. The result is a random graph with some number of connected components. Let $L_1(n)$ be the number of points in the largest connected component. It has been proven that as the number of points n increases to infinity the proportion $L_1(n)/n$ of points in the largest component converges to some value γ and that if $c > 1$ then $\gamma > 0$ and that if $c \leqslant 1$, $\gamma = 0$. This means that if the probability of connection is sufficiently large, a fraction of points is in the greatest component. In this case this is called the giant component. The number of points in any other component, when divided by n, always converges to zero; hence there is at most one giant component. The fluctuations of the giant component around γn, the behavior of smaller components, and many other problems of random graph theory can be found in Bollobás (1998).

3. Markov Chains

A Markov chain is a process defined iteratively. The ingredients are a finite or countable state space S, a sequence of independent random variables U_n uniformly distributed in the interval [0, 1], and a transition function F which to each state x and number u in the unit interval assigns a state $y = F(x, u)$. The initial state X_0 is either fixed or random and the successive states of the chain are defined iteratively by $X_n = F(X_{n-1}, U_n)$. That is, the value of the process X_n at each step n is a function of the value X_{n-1} at the preceding step and of the value of a uniform random variable U_n independent of everything. In this sense a Markov chain has no memory. The future behavior of the chain given the present position does not depend on how this position was attained. Let $Q(x, y) = \mathbb{P}(F(x, U_n) = y)$, the probability that the chain at step n be at state y given that it is at state x at time $n-1$. Since this probability does not depend on n the chain is said to be homogeneous in time. The transition matrix Q is the matrix with entries $Q(x, y)$.

When it is possible to go from any state to any other the chain is called irreducible, otherwise reducible. The state space of reducible chains can be partitioned in subspaces in such a way that the chain is irreducible in each part. Irreducible chains in finite state spaces stabilize in the sense that the probability of finding the chain at each state converges to a probability distribution π that satisfies the balance equations: $\pi(y) = \sum_x \pi(x)Q(x, y)$. The measure π is called invariant for Q because if the initial state X_0 has law π then the law of X_n will be π for all future time n. When there is a unique invariant measure π the proportion of time the chain spends in any given state x converges to $\pi(x)$ when time goes to infinity no matter how the initial state is chosen. This is a law of large numbers for Markov chains. The expected time the chain needs to come back to x when starting at x at time zero is $1/\pi(x)$. When the state space has a countable (infinite) number of points it is possible that there is no invariant measure; in this case the probability of finding the chain at any given state goes to zero; that is, the chain 'drives away' from any fixed finite region. It is possible also to define Markov chains in noncountable state spaces, but this will not be discussed here.

3.1 Coupling

Two or more Markov chains can be constructed with the same uniform random variables U_n. This is called a coupling and it is one of the major tools in stochastic processes. Applications of coupling include proofs of convergence of a Markov chain to its invariant measure, comparisons between chains to obtain properties of one of them in function of the other, and simulation of measures that are invariant for Markov chains.

Recent books on Markov chains include Chen (1992), Bianc and Durrett (1995), Fristedt and Gray (1997), Brémaud (1999), Durrett (1999a), Schinazi (1999), Thorisson (2000), Häggström (2000), and Ferrari and Galves (2000).

3.2 Examples: Birth–Death and Branching Processes

The state space of the birth–death process is the set of natural numbers $\{0, 1, \ldots\}$, the probability to jump from x to $x+1$ is p_x, a number in [0, 1] and the probability to jump from x to $x-1$ is $1-p_x$. It is assumed that $p_0 = 1$, that is, the process is reflected at the origin. The transition function is given by $F(x, u) = x + H(x, u)$, with $H(x, u) = 1$ if $u < p_x$ and $H(x, u) = -1$ if $u \geqslant p_x$. It is possible to find explicit conditions on p_x that guarantee the existence of an invariant measure. For instance, if $p_x < a$ for all x for some $a < 1/2$, then there exists an invariant measure π. The reason is that the chain has a drift towards the origin where it is reflected. On the other hand, if the drift towards the origin is not sufficiently strong, the chain may have no invariant measure.

The $(n+1)$th generation of a branching process consists of the daughters of the individuals alive in the nth generation:

$$Z_{n+1} = \sum_{i=1}^{Z_n} X_{n,i} \tag{4}$$

where Z_n is the total number of individuals in the nth generation and $X_{n,i}$ is the number of daughters of ith

individual of the nth generation. $Z_0 = 1$ and $X_{n,i}$ are assumed independent and identically distributed random variables with values in $\{0, 1, 2, \ldots\}$. When $X_{n,i} = 0$ the corresponding individual died without a progeny. The process so defined is a Markov chain in $\{0, 1, 2, \ldots\}$; the corresponding transition function F can be easily computed from the distribution of $X_{n,i}$. The mean number of daughters of the typical individual $\mu = \mathbb{E}X_{n,i}$ (a value that does not depend on n, i) is the crucial parameter to establish the behavior of the process. When $\mu > 1$ the probability that at all times there are alive individuals is positive; in this case the process is called supercritical and in case of survival the number of individuals increases geometrically with n. When $\mu \leqslant 1$ the process dies out with probability one (subcritical case). Guttorp (1991) discusses branching processes and their statistics.

4. *Interacting Particle Systems*

Processes with many interacting components are called interacting particle systems. Each component has state space S and $X_t(i)$ denotes the state of component i at time t; t may be discrete or continuous, generally i belongs to a d-dimensional lattice. The update law of each component typically depends on the state of the other components; this dependence is in general 'local,' that is, determined only by the configuration of a few other neighboring components. The references for interacting particle systems are Liggett (1985) and (1999), Durrett (1988) and (1999b), Chen (1992), Schinazi (1999), Fristedt and Gray (1997).

4.1 *The Exclusion Process*

In this process i belongs to the d-dimensional lattice and $X_t(i)$ assumes only the value 0 and 1. If $X_t(i) = 0$, site i is empty at time t and if $X_t(i) = 1$, site i is occupied by a particle at time t. The process evolves as follows. Independent Poisson clocks are attached to the sites; when the clock rings at site i (at most one clock rings at any given time), if there is a particle at i, then a site j is chosen at random and the particle tries to jump to j. If j is empty then the particle jumps; if j is already occupied the jump is suppressed. The interaction between particles is embedded in the law of the jump. The simplest case is when the distribution of the jump does not depend on the configuration. In this case the interaction is just reduced to the suppression of jumps attempted to occupied sites and the motion is called the simple exclusion process.

The measure obtained when a particle is put at each site with probability ρ independently of the other sites is called a product measure. A surprising feature of the simple exclusion process with spatially homogeneous jump laws is that if the initial configuration is chosen according to a product measure, then the configuration at any future time will also be distributed with this measure. In other words, product measures are time invariant for the process. Due to the conservative character of the dynamics, i.e., the initial density is conserved, the process accepts a family of invariant measures; there is one invariant product measure for each density ρ in $[0, 1]$.

The main questions are related to the asymptotic behavior of the process when time runs. In many cases it has been proven that the process starting with an initial configuration having an asymptotic density converges as time goes to infinity to the product measure with that density. More detailed questions are related to hydrodynamic limits obtained when large space regions are observed at long times. A particularly interesting case is the symmetric simple exclusion process, for which jumps of sizes y and $-y$ have the same probability. The large space, long time behavior of the symmetric simple exclusion process is governed by the heat equation. For example, in the one-dimensional case it has been proven that the number of particles in the region $[aN, bN]$ at time tN^2 divided by N converges to $\int_a^b u(r, t)\,\mathrm{d}r$, where $u(r, t)$ is the solution of the heat equation

$$\frac{\partial u}{\partial t} = \frac{\partial^2 u}{\partial r^2} \tag{5}$$

with initial condition $u(r, 0)$ (the initial particle distribution must be related with this condition in an appropriate sense). This is called a law of large numbers or hydrodynamic limit. The limiting partial differential equation represents the macroscopic behavior while the particle system catches the microscopic behavior of the system. The law of the configuration of the process in sites around rN at time tN^2 converges as N goes to infinity to the product measure with density given by the macroscopic density $u(r, t)$. This is the most disordered state (or measure). This is called propagation of chaos.

When the motion is not symmetric the behavior changes dramatically. The simplest case is the totally asymmetric one-dimensional nearest neighbor simple exclusion process. The particles jump in the one-dimensional integer lattice $\{\ldots, -1, 0, 1, \ldots\}$. When the Poisson clock rings at site i, if there is a particle at that site and no particle at $i+1$, then the particle jumps to $i+1$; otherwise nothing changes. To perform the hydrodynamic limit time and space are rescaled in the same way: the number of particles in the region $[aN, bN]$ divided by N at time tN converges to $\int_a^b u(r, t)\,\mathrm{d}t$, the solution of the Burgers equation

$$\frac{\partial u}{\partial t} = -\frac{\partial u(1-u)}{\partial r} \tag{6}$$

with initial condition $u(r, 0)$. Similar equations can be obtained in the d-dimensional case. Propagation of chaos is also present in this case. Contrary to what happens in the symmetric case, the Burgers equation develops noncontinuous solutions. In particular, consider $\rho < \lambda$ and the initial condition $u(r, 0)$ equal to ρ if $r < 0$ and to λ otherwise. Then the solution $u(r, t)$ is ρ if $r < (1-\rho-\lambda)t$ and λ otherwise. The well-known phenomenon of highways occur here: the space is divided in two regions sharply separated; one region of low density and high velocity and the other region of high density and low velocity. This phenomenon that was first observed for the Burgers equation (Evans (1998)) was then proven to hold for the microscopic system for the nearest neighbor case. The location of the shock is identified by a perturbation of the system: start with a configuration η coming from a product shock measure, that is, the probability of having a particle at site i is ρ if i is negative and λ if i is positive, and put a particle at the origin. Consider another configuration η' that coincides with η at all sites but at the origin. η' is a perturbation of η. Realizing two processes starting with η and η' respectively, using the same Poisson clocks, there will be only one difference between the two configurations at any given future time. The configuration as seen from the position of this perturbation is distributed approximately as η, that is, with a shock measure. The perturbation behaves as a second class particle; the sites that are occupied by particles of both η and η' are said to be 'occupied by a first class particle,' while the site where η differs from η' is said to be 'occupied by a second class particle.' Following the Poisson clocks, the second class particle jumps backwards when a first class particle jumps over its site and jumps forwards if the destination site is empty. See Liggett (1999).

Special interest has been devoted to the process when the initial condition is 'there are particles in all negative sites and no particles in the other sites.' The solution $u(r, t)$ of the Burgers equation with this initial condition is a rarefaction front: $u(r, t)$ is one up to $-t$, zero from t on and interpolates linearly between 0 and 1 in the interval $[-t, t]$. This particular case has been recently related to models coming from other areas of applied probability. In particular with increasing subsequences in random permutations, random matrices, last passage percolation, random domino tilings and systems of queues.

Hydrodynamics of particle systems is discussed by Spohn (1991), De Masi and Presutti (1991), and Kipnis and Landim (1999).

4.2 Voter Model

In the voter model each site of a d-dimensional integer lattice (this is the set of d-uples of values in the integer lattice $\{\ldots, -1, 0, 1, \ldots\}$) is occupied by a voter having two possible opinions: 0 and 1. At the rings of a Poisson clock each voter chooses a neighbor at random and assumes its opinion. The voter model has two trivial invariant measures: 'all zeros' and 'all ones.' Of course, if at time zero all voters have opinion zero, then at all future times they will be zero; the same occurs if all voters have opinion one at time zero. Are there other invariant measures? The answer is no for dimensions $d = 1$ and $d = 2$ and yes for dimension $d \geqslant 3$. The proof of this result is based on a dual process. This process arises when looking at the opinion of a voter i at some time t. It suffices to go back in time to find the voter at time zero that originates the opinion of i at time t. The space–time backwards paths for two voters may coalesce. In this case the two voters will have the same opinion at that time. The backwards paths are simple random walks. In one or two dimensions, nearest-neighbors random walks always coalesce, while in dimensions greater than or equal to three there is a positive probability that the walks do not coalesce. Hence there are invariant states in three or more dimensions for which different opinions may coexist.

A generalization of the voter model is the random average process. Each voter may have opinions corresponding to real numbers and, instead of looking at only one neighbor, at Poisson rings voters update their opinion with a randomly weighted average of the opinions of the neighbors and adopt it. As in the two-opinions voter model, flat configurations are invariant, but if the system starts with a tilted configuration (for example, voter i has opinion λi for some parameter $\lambda \neq 0$), then the opinions evolve randomly with time. It is possible to relate the variance of the opinion of a given voter to the total amount of time spent at the origin by a symmetric random walk. This shows that the variance of the opinion of a given voter at time t is of the order of t in dimension one, $\log t$ in dimension 2, and constant in dimensions greater than or equal to 3. The random average process is a particular case of the linear processes studied in Liggett (1985).

5. Future Directions

At the start of the twenty-first century, additional developments for the exclusion process include the behavior of a tagged particle, the convergence to the invariant measure for the process in finite regions, and more refined relations between the microscopic and macroscopic counterpart. The voter model described here is 'linear' in the sense that the probability of changing opinion is proportional to the number of neighbors with the opposite opinion. Other rules lead to 'nonlinear' voter models that show more complicated behavior. See Liggett (1999). The rescaling of the random average process may give rise to nontrivial limits; this is a possible line of future development.

The contact process, a continuous-time version of oriented percolation, has not been discussed here. The contact process in a graph instead of a lattice may

involve three or more phases (in the examples discussed here there were only two phases). The study of particle systems in graphs is a promising area of research.

An important issue not discussed here is related to Gibbs measures; indeed, phase transition was mathematically discussed first in the context of Gibbs measures. One can think of a Gibbs measure as a perturbation of a product measure: configurations have a weight according to a function called energy. Gibbs measures may describe the state of individuals that have a tendency to agree (or disagree) with their neighbors. Stochastic Ising models are interacting particle systems that have as invariant measures the Gibbs measure related to a ferromagnet. Mixtures of Ising models and exclusion processes give rise to reaction diffusion processes, related via hydrodynamic limit with reaction diffusion equations.

An area with recent important developments is Random tilings, which describes the behavior of the tiles used to cover an area in a random fashion. The main issue is how the shape of the boundary of the region determines the tiling. Dynamics on tilings would show how the boundary information transmits. The rescaling of some tilings results in a continuous process called the mass-less Gaussian field; loosely speaking, a multidimensional generalization of the central limit theorem.

An important area is generally called spatial processes. These processes describe the random location of particles in the d-dimensional real space instead of a lattice. The Poisson process is an example of a spatial process. Analogously to Gibbs measures, other examples can be constructed by giving different weight to configurations according to an energy function. The study of interacting birth and death processes having as invariant measure spatial process is recent and worth to develop. This is related also with the so-called perfect simulation; roughly speaking this means to give a sample of a configuration of a process as a function of the uniform random numbers given by a computer. See, for instance, Häggström (2000).

Stock Market Predictability

One of the most enduring cornerstones of modern financial theory has been that stock markets are reasonably efficient in reflecting new information and

that price movements closely fit a random walk model where future prices cannot be predicted from an examination of past prices. Toward the end of the twentieth century, however, financial economists and statisticians began to question received doctrine, and many came to believe that stock prices were at least partially predictable. Moreover, although far more controversial, many have argued that these predictable patterns enable investors to earn excess risk-adjusted rates of returns and provide evidence that the efficient market theory should be rejected. This survey reviews the findings of the empirical work concerning stock market predictability. It reviews the work done on stock prices that appears to reject the random walk hypothesis and looks at the body of studies suggesting that future returns can be predicted on the basis of such fundamental variables as dividend yields, price earnings, and price-to-book value ratios, market capitalization (size), etc. The survey also examines the relationship between predictability and market efficiency.

1. *The Efficient Market Theory and its Critics*

The basic idea behind the efficient market theory is that securities markets are extremely efficient in digesting information about individual stocks or about the stock market in general. When information arises about a stock (or the market as a whole), the news spreads very quickly and is immediately incorporated into the prices of securities. Thus, neither technical analysis (an analysis of past price patterns to determine the future) nor fundamental analysis (an analysis of a company's earnings, dividends, future prospects, etc. to determine a stock's proper value) will help investors to achieve returns greater than would be obtained by buying and holding one of the broad stock market indices. The efficient market theory is associated with the idea of a 'random walk,' which is a term loosely used in the finance literature to characterize a price series where all subsequent price changes represent random departures from previous prices. The logic of the random walk idea is that if the flow of information is unimpeded and information is immediately reflected in stock prices, then tomorrow's price change will reflect only tomorrow's news and will be independent of the price changes today. But news is by definition unpredictable and, thus, resulting price changes must be unpredictable and random. As a result, prices fully reflect all known information, and even uninformed investors buying a diversified portfolio at the tableau of prices given by the market will obtain a rate of return as good as that achieved by market professionals. Discussions of the random walk hypothesis can be found in Samuelson (1965) and Fama (1970).

Academic work published mainly during the 1980s and 1990s has tended to cast doubts on many of the tenets of the efficient market theory. This work has suggested that the random walk model is not supported and that future stock prices and returns can be predicted, at least in part, by an examination of past stock prices and certain 'fundamental' valuation methods such as the ratio of stock prices to earnings and book values. Moreover, some of this work has been interpreted as implying that markets are inefficient in the sense that arbitrage opportunities exist that enable investors to earn excess risk-adjusted returns.

2. *The Major Predictable Patterns that Have Been Discovered*

This article will now focus on the findings of empirical work about stock market predictability done during the 1980s and 1990s. The general thrust of much of the published academic work has been along the following two lines. First, it appears that there are many predictable patterns in the stock market. The stock market is *not* random. Indeed, a book published by Lo and MacKinlay (1999) has the arresting title, *A Nonrandom Walk Down Wall Street*. Second, although this is far more controversial, many have argued that these predictable patterns enable an investor to earn big risk-adjusted rates of return and are proof that the efficient market theory is wrong.

2.1 *There is Some Evidence of Short-run Momentum in the Market*

When stock returns for individual stocks and market averages are calculated over days, or weeks, or even months, there is positive serial correlation. In other words, a positive rate of return one week is more likely than not to be followed by a positive return the next week. The market is not a perfect random walk. Further evidence provided by Lo and MacKinlay uses a simple specification test based on variance estimators. Their test exploits the fact that the variance of the increments of a random walk is linear in the sampling interval. For example, if stock prices are generated by a random walk then the variance of monthly sampled log-price relatives must be four times as large as the variance of a weekly sample. Using data over a 23-year time frame from 1962 through 1985, Lo and MacKinlay reject the random walk hypothesis. The rejection cannot be explained completely by infrequent trading (where news affects smaller company stocks with a lag because they trade less frequently) or by time-varying volatilities.

This work suggests that quantitative managers who use momentum to help guide purchases have some empirical support on their side. Whether this is a true inefficiency or not, however, is open to more question. Certainly any investor who pays transactions costs is not able to outperform a buy-and-hold strategy because the kind of momentum that has been found is

small relative to the transactions costs involved, and it is far from clear how dependable any patterns that can discovered will be. The market is not statistically random, but it is nearly so.

2.2 But there is Mean Reversion

Returns may be positively correlated for short periods, such as days or weeks, but when returns are measured over longer periods, such as three or four years, there tends to be negative correlation. Just as in the Bible seven lean years followed seven fat years, so in the stock market extraordinary returns are somewhat more likely to be followed by lackluster returns. For example, Fama and French (1988) demonstrated that long holding period returns are negatively serially correlated. The serial correlation is significant and implies that 25–40 percent of the variation in long holding period returns can be predicted on the basis of past returns. Similar results were found by Poterba and Summers (1988), who conclude that there is substantial mean reversion in stock market returns at longer horizons. Some studies have attributed this forecastability to the tendency of stock market prices to 'overreact.' DeBondt and Thaler (1985), for example, argue that investors are subject to waves of optimism and pessimism that cause prices to deviate systematically from their fundamental values and later to exhibit patterns of reversal. These findings give some support to investment techniques that rest on a 'contrarian' strategy, that is buying the stocks, or groups of stocks, that have been out of favor for long periods of time, and avoiding those stocks that have had large run-ups over the last several years.

While there is considerable support for this view, it should be pointed out that such mean reversion is quite a bit weaker in some decades than it is in other periods. Indeed, the strongest empirical results come from periods including the Great Depression. Moreover, such return reversals for the market as a whole may be quite consistent with the efficient functioning of the market and could result, in part, from the volatility of interest rates. There is a tendency when interest rates go up for stocks to go down, and as interest rates go down for stocks to go up. If, in fact, interest rates fluctuate over time, one will tend to get return reversals, or mean reversion, and this is quite consistent with the efficient functioning of markets where stock returns will need to go up or down to be competitive with bonds.

Moreover, it may not be possible to profit from the tendency for individual stocks to exhibit patterns of return reversals. For example, Fluck et al. (1997) simulated over the period a strategy of buying stocks that had particularly poor returns over the past three to five years. They found very strong statistical evidence of return reversals, but it was truly reversion to the mean, *not* an opportunity to make extraordinary returns. They found that stocks with very low returns over the past three to five years had higher returns in the next period. Stocks with very high returns over the past three to five years had lower returns in the next period, but the returns in the next period were similar for both groups. While they found strong evidence of mean reversion, they could not confirm that a contrarian approach would yield higher than average returns. There was a statistically strong pattern of return reversal, but not one that implied an inefficiency in the market that would enable investors to make excess returns.

2.3 There do Seem to be Some Seasonal Patterns in the Stock Market

A number of researchers have found that January has been a very unusual month for stock market returns. Returns from an equally weighted stock index have tended to be unusually high during the first two weeks of the year. The return premium has been particularly evident for small stocks i.e., those with relatively small total capitalizations, as has been demonstrated by Keim (1983). Haugen and Lakonishok (1988) detail the high January returns in a book entitled *The Incredible January Effect*.

There also appears to be a number of seasonal effects. For example, French (1980) documents significant Monday returns. There appear to be significant differences in average daily returns in countries other than the USA, as summarized by Hawawini and Keim (1995). There also appear to be some patterns in returns around the turn of the month, as shown by Lakonishok and Smidt (1988), as well as around holidays as shown by Ariel (1990).

The general problem with these anomalies, however, is that they are *not* dependable from period to period. The January effect has not been useful to investors through much of the 1990s. Moreover, these nonrandom effects (even if they were dependable) are small relative to the transactions costs involved in trying to exploit them. They do not appear to offer investors any arbitrage opportunities that would enable them to make excess returns.

2.4 The Size Effect

Probably one of the strongest effects that investigators have found is the so-called size effect: the tendency over long periods of time for small stocks to generate larger returns than those of large stocks. Since 1926, small-company stocks in the USA have produced a rate of return about 1.5 percentage points larger than the returns from large stocks.

Fama and French (1992) looked at data from 1963 to 1990 and divided all stocks into deciles according to their size as measured by total capitalization. Decile 1

Figure 1
Average monthly returns for portfolios, formed on the basis of size, 1963–90 (source: Fama and French 1992)

Figure 2
Average monthly returns for portfolios, formed on the basis of price-to-earnings (P/E) ratios, 1962–90 (source: Hawawini and Keim 1995)

contained the smallest 10 percent of all stocks while decile 10 contained the largest stocks. The results plotted in Fig. 1 show a clear tendency for the deciles made up of portfolios of smaller stocks to generate higher average monthly returns than deciles made up of larger stocks.

If the 'Beta' measure of systematic risk from the capital asset pricing model is accepted as the correct risk measurement statistic, the size effect can be interpreted as indicating a market inefficiency. This is so because portfolios consisting of smaller stocks have excess risk-adjusted returns. But any conclusion that an inefficiency exists involves accepting the joint hypothesis that a size effect is present *and* that the capital asset pricing model (CAPM) is correct. Fama and French point out, however, that the average relationship between 'Beta' and return is flat—not upward sloping as the CAPM predicts. Moreover, within Beta deciles, ten portfolios constructed by size display the same kind of positive relationship shown in Fig. 1. On the other hand, within size deciles, the relationship between Beta and return continues to be flat. Fama and French conclude that size may well be a far better proxy for risk than Beta, and therefore that their findings should not be interpreted as indicating that markets are inefficient.

The dependability of the size phenomenon is also open to question. Certainly during the decade of the 1990s there has been little to gain from holding smaller stocks. Indeed, in most world markets it has been the large stocks that have done especially well. Finally, it is also possible that the small-firm effect is simply a result of survivorship bias in currently available computer tapes of past returns. Today's lists of companies include only small firms that have survived, not the ones that later went bankrupt. Thus, a

researcher who examined the 10-year performance of today's small companies would be measuring the performance of those companies that survived—not of the ones that failed.

2.5 *There is Evidence that Stocks with Low Price Earnings Multiples Generate Higher Returns than those with High Price Earnings Multiples*

As Fig. 2 shows, evidence first published by Nicholson (1960) and later confirmed by Ball (1978) and *Basu* (1983) shows that low price earnings (P/E) stocks provide higher rates of return than high P/E stocks. This finding is consistent with the views of behavioralists (see, for example, Kahneman and Riepe 1998) that investors tend to be overconfident of their ability to project high earnings growth and thus overpay for 'growth' stocks. The finding is also consistent with the views of Benjamin Graham and David Dodd (1934), first expounded in their classic book on security analysis and later championed by the legendary US investor, Warren Buffett. Similar results have been shown for price/cash-flow multiples, where cash flow is defined as earnings plus depreciation and amortization. See Hawawini and Keim (1995).

2.6 *Stocks with Low Price-to-book Value (P/BV) Ratios Generate Larger Returns than Stocks with High P/BV Ratios*

The ratio of stock price to book value (the value of a firm's assets minus its liabilities divided by the number of shares outstanding) has also been found to be a useful predictor of future security returns. Low price-to-book (along with low P/E) is considered to be another hallmark of so-called 'value' in equity securities, and is also consistent with the view of behavioralists that investors tend to overpay for 'growth' stocks that subsequently fail to live up to expectations. Fama and French (1992) concluded that size and P/BV together provide considerable explanatory power for future returns and once they are accounted for, little additional influence can be attributed to P/E multiples. Fama and French (1997) also conclude that the P/BV effect is important in many world stock markets other than that of the USA.

Lakonishok et al. (1994) argue that such results raise questions about the efficiency of the market. But these findings do not necessarily imply inefficiency. P/BV may be a more accurate proxy for the systematic risk priced in the stock market than traditional estimates of the CAPM Beta because of measurement errors in the traditional estimates. Indeed, this is the explanation Fama and French give for this predictable pattern. Moreover, especially with so much merger and restructuring activity, book value is increasingly hard to interpret. Thus, it is far from clear that the pattern will continue. In fact, stocks with low P/BV ratios underperformed the general market during the 1990s. Indeed, if one looks at the behavior of growth stocks and value stocks (those with low P/BV and P/E) in the USA over a 75-year period to 2000, it appears that the Fama–French period from the early 1960s through 1990 may have been a unique period in which value stocks rather consistently produced higher rates of return.

2.7 *Predicting Market Returns from Initial Dividend Yields*

Another apparently predictable relationship concerns the returns realized from stocks and the initial dividend yields at which they were purchased. The data since 1926 for the USA are presented in Fig. 3. The figure was produced by measuring the dividend yield of the broad stock market (in this case, the Standard and Poor's 500 Stock Index) each quarter between 1926 and 2000, and then calculating the market's subsequent 10-year total return. The observations were then divided into deciles depending upon the level of the initial dividend yield. In general, the figure shows that investors have earned a higher rate of return from the stock market when they purchased stocks with an initial dividend yield that was relatively high, and a below average rate of return when they purchased them at initial dividend yields that were low.

Formal statistical tests of the ability of dividend yields (dividend-price ratios) to forecast future returns have been conducted by Fama and French (1988) and Campbell and Shiller (1988). Depending on the forecast horizon involved, as much as 40 percent of the variance of future returns can be predicted on the basis of initial dividend yields.

These findings are not necessarily inconsistent with efficiency. Dividend yields of stocks tend to be high when interest rates are high, and they tend to be low when interest rates are low. Consequently, the ability of initial yields to predict returns may simply reflect the adjustment of the stock market to general economic conditions. Moreover, the dividend behavior of US corporations may have changed over time (see Fama and French 1999). Companies in the twenty-first century may be more likely to institute a share repurchase program rather than increase their dividends. Thus, dividend yield may not be as meaningful as in the past. Moreover, it is worth pointing out that dividend yields were unusually low at the start of 1995. An investor who avoided US stocks then would have missed out on one of the steepest five-year increases in stock prices in history.

Finally, it is worth noting that this phenomenon does not work consistently with individual stocks. Investors who simply purchase a portfolio of individual stocks with the highest dividend yields in the market will not earn a particularly high rate of return.

Figure 3
The future 10-year rates of return when stocks are purchased at alternative initial dividend yields (D/P) (source: The Leuthold Group)

Figure 4
The future 10-year rates of return when stocks are purchased at alternative initial price-to-earnings (P/E) multiples (source: The Leuthold Group)

One popular implementation of such a 'high dividend' strategy is the 'Dogs of the Dow Strategy,' which involves buying the ten stocks in the Dow Jones Industrial Average with the highest dividend yields. For some periods this strategy handily outpaced the overall average, and so several 'Dogs of the Dow' funds were brought to market and aggressively sold to individual investors. Such funds have generally underperformed the market averages during the 1995–9 period.

2.8 Predicting Market Returns from Initial Price Earnings Multiples

The same kind of predictability for the market as a whole has been shown for price earnings ratios. The data are shown in Fig. 4. The figure presents a decile analysis similar to that described for dividend yields above. Investors have tended to earn larger long-horizon returns when purchasing stocks at relatively low price earnings multiples. Campbell and Shiller (1988) report R^2s (a measure of goodness of fit that takes on a maximum value of one) of over 40 percent and conclude that equity returns have been predictable in the past to a considerable extent. Whether such historical relations are necessarily applicable to the future is another matter. Such an analysis conducted by Shiller in January 1996 predicted a long-horizon (nominal) return for the US stock market close to zero.

3. Concluding Comments

In summary, there are many statistically significant predictable patterns in the stock market. It is important to emphasize, however, that these patterns are not dependable in each and every period, and that some of the patterns based on fundamental valuation measures of individual stocks may simply reflect a better proxy for measuring risk. Moreover, many of these patterns could self-destruct in the future, as many of them have already done. Indeed, this is the logical reason why one should be cautious not to overemphasize these anomalies and predictable patterns.

Suppose, for example, that one of the anomalies is really true. Suppose that there is a truly dependable January effect, and that the stock market—especially stocks of small companies—will generate extraordinary returns during the first five days of January. What will investors do? They will buy late in December, on the last day of December, and sell on January 5. But then investors find that the market rallied on the last day of December and so they will begin to buy on the next-to-last day; and because there is so much 'profit taking' on January 5, investors will have to sell on January 4 to take advantage of this effect. Thus, to beat the gun, investors will have to be buying earlier and earlier in December, and selling earlier and earlier in January so that eventually the pattern will self-destruct. Any truly repetitive pattern that can be discovered in the stock market and can be arbitraged away will self-destruct. Indeed, the January effect became undependable after it received considerable publicity.

Similarly, suppose there is a general tendency for stock prices to underreact to certain new events, leading to abnormal returns to investors who exploit the lack of full immediate adjustment (see DeBondt and Thaler 1995 and Campbell et al. 1997 for a discussion of event studies and possible under reaction of market participants). 'Quantitative' investment managers will then develop strategies in an attempt to exploit the pattern. Indeed, the more potentially profitable a discoverable pattern is, the less likely it is to survive.

Moreover, many of the predictable patterns that have been discovered may simply be the result of data mining. The ease of experimenting with financial data banks of almost every conceivable dimension makes it quite likely that investigators will find some seemingly significant but wholly spurious correlation between financial variables or among financial and non-financial data sets. One amusing one that has been uncannily accurate in the past for US markets is the Super Bowl Indicator, which predicts the sign of market returns for the year by the winner of January's football Super Bowl. Given enough time and mass-aging of data series it is possible to tease almost any pattern out of every data set. Moreover, the published literature is likely to be biased in favor of reporting such results. Significant effects are likely to be published in professional journals while negative results, or boring confirmations of previous findings, are relegated to the file drawer or discarded. Data-mining problems are unique to nonexperimental sciences, such as economics, which rely on statistical analysis for their insights and cannot test hypotheses by running repeated controlled experiments.

An exchange at an academic conference (1992) between Robert Shiller (1981), an economist who is sympathetic to the argument that stock prices are partially predictable and skeptical about market efficiency, and Richard Roll, an academic financial economist who also is a businessman managing billions of dollars of investment funds, is quite revealing. After Shiller stressed the importance of inefficiencies in the pricing of stocks, Roll responded as follows:

> I have personally tried to invest money, my client's money and my own, in every single anomaly and predictive device that academics have dreamed up … I have attempted to exploit the so-called year-end anomalies and a whole variety of strategies supposedly documented by academic research. And I have yet to make a nickel on any of these supposed market inefficiencies … a true market inefficiency ought to be an exploitable opportunity. If there's nothing investors can exploit in a systematic way, time in and time out, then it's very hard to say that information is not being properly incorporated into stock prices. (*Journal of Applied Corporate Finance*, Spring, 1992)

Finally, there is a remarkably large body of evidence suggesting that professional investment managers are not able to outperform index funds that simply buy and hold the broad stock market portfolio (see, for example, Malkiel 1995). Three-quarters of professionally managed funds are regularly outperformed by a broad index fund with equivalent risk, and those that do appear to produce excess returns in one period are not likely to do so in the next. The record of

professionals does not suggest that sufficient predictability exists in the stock market to produce exploitable arbitrage opportunities.

Pricing irregularities and predictable patterns in stock returns do appear over time and even persist for periods. Undoubtedly, with the passage of time and with the increasing sophistication of our databases and empirical techniques, we will document further apparent departures from efficiency, and further patterns in the development of stock returns. But the end result will not be an abandonment of the belief of many in the profession that the stock market is remarkably efficient in its utilization of information and that whatever patterns do exist are unlikely to provide investors with a method to obtain extraordinary returns.

Stockholders' Ownership and Control

Theory and research on the relations among top managers, company directors, stockholders, and external contenders for corporate control experienced a remarkable flowering during the 1990s. Early work addressed the central puzzle raised by the widespread separation of ownership and control among large American corporations, namely, why would any sensible person—much less thousands of them—invest their savings in businesses run by unaccountable professional managers? As Berle and Means (1932) framed the problem, those who ran such corporations would pursue 'prestige, power, or the gratification of professional zeal' in lieu of maximizing profits. Shareholders weakened by their fractionation could do little to stop them. Yet generations of individuals and financial institutions continued to invest in these firms. Why?

1. Resolving the Separation of Stock Ownership from Company Control

Answering this question led to the creation of a new theory of the firm that portrayed the public corporation as a 'nexus of contracts.' In this model, the mana-

gers of the corporation were disciplined to optimize shareholder value by an array of mechanisms, from incentive compensation and vigilant directors to an unforgiving 'market for corporate control.' Taken together, these devices worked to vouchsafe shareholder interests even when ownership was widely dispersed. Research in this tradition flourished in the 1980s, as takeovers of under-performing firms in the US became common and restive institutional investors made their influence known. Studies focused on assessing the effectiveness of such contrivances as governing boards dominated by outsiders, executive pay tied to stock performance, and susceptibility to hostile acquisition (Walsh and Seward 1990).

Three developments, however, expanded research on ownership and control beyond these mechanisms and beyond American business. The first was for investigators to view the governance structure of the firm—the set of devices that evolve within the firm to monitor managerial decision making—as an *ensemble*. Rather than regarding any particular aspect of the firm's structure as essential, researchers came to study them as complements or substitutes. Remuneration highly leveraged around share price, for instance, could act as a substitute for a vigilant board, and together they could really tighten the leash.

The second development was a growth of comparative and historical research that highlighted the idiosyncrasy of the American obsession with ownership and control. American-style corporate governance, aimed at 'solving' the problems created by the separation of ownership and control, came to be seen as only one of several feasible systems. Indeed, among some advanced economies with well-developed business enterprise, the problem needed no solving at all since the separation of ownership from control remained much the exception (Roe 1994).

The third development was the articulation of a reflexive stance on the theory of ownership and control. While agency theory can be viewed as an empirical theory of the corporation, it also came to be considered a prescriptive theory, an explanation of not only what *is* but also a vision of what *could* or *should* be. Its influence on public policy debates during the 1980s and 1990s is evident in the widespread rise of the rhetoric of shareholder value in the business press and executive suite (Useem 1996).

2. *Shareholder Influence on Top Management and the Corporation*

When ownership is dispersed widely, shareholders possess few direct devices to ensure their control—or at least their influence—on the company's direction and performance. This is the essence of the 'agency problem' identified by Berle and Means (1932), and it remains potentially potent among many US firms. Three-quarters of the 100 largest US corporations in 1999 lacked even a single ownership block of 10 percent or more and, of the top 25, the biggest single holder averaged a scant four percent (Brancato 1999).

Scattered shareholders in effect relinquish their control to directors whom they elect to serve as their agents in selecting and supervising top management. Dispersed holders can influence the firm only through trading shares and voting directors. They have no real voice in the selection of executives, or even who serves on the board. By one argument, shareholder inattention is in fact the only rational course for small shareholders since the cost of learning about the governance of the firm and mobilizing change is sure to be far overshadowed by the marginal and nonselective benefits of any resulting performance improvement. This problem of collective action could result in management unaccountability in some capital markets, but investors nonetheless rest easy in the US because of a well-developed set of mechanisms that have arisen to ensure share price maximization without overt investor control (Easterbrook and Fischel 1991).

The most forceful instrument for riveting attention on share price is the 'market for corporate control.' By hypothesis, a poorly-run corporation suffers a depressed market valuation, and this opens an opportunity for outsiders with better management skills to acquire the firm at an implicit discount, oust top management, and rehabilitate the firm, thus restoring value to its long-suffering stockholders. Unwanted takeovers and their threats provide a potent mechanism to shock top managers who under-serve shareholder interests; they know that executives generally find themselves on the street after an unfriendly takeover. The market for corporate control is thus the most visible hand of Darwinian discipline, weeding out poorly run firms and protecting shareholders from bad management (Manne 1965).

Hostile takeovers are a blunt instrument for corporate control, and as a result, some US institutional investors have moved toward more fine-grained methods of influence. Large pension funds, for example, often field shareholder proxy proposals for better governance. Though little evidence yet confirms that this mode of shareholder activism has immediate impact on the share price of target firms, it does push targeted firms to improve their governance and thereby further open them further to investor influence (Karpoff 1998).

If hostile takeovers are often too blunt an instrument and shareholder activism too diffuse, stock analysts provide an intermediate form of shareholder influence on company behavior. Analysts investigate companies in order to render judgments on their prospects for future earnings and thus to estimate their appropriate valuation. Analysts are often allowed privileged access to corporate executives and are in a position to give strategic and governance advice

directly to senior managers, something rarely afforded to the firm's small shareholders. In principle, the rewards go to the most accurate analysts, giving them incentives to act as corporate watchdogs. In practice, however, some analysts are not entirely dispassionate observers: those who work for firms doing business with a corporation give systematically more favorable evaluations than do others. While analysts may serve as a more refined channel for shareholder influence, this avenue of control remains problematic as well (Useem 1996).

3. *Between Ownership and Control: Top Management*

A handful of company executives make the defining decisions, whether to launch a new product, enter a promising region, or resist a tender offer. It is they who most directly control the fate of the firm. It is they who stand between corporate owners and company results.

Firms often define their 'top' as no more than the seven or eight most senior officers. To much of the world beyond the company walls, however, top management is personified almost solely by the chief executive. Academic researchers had long been drawn to the same pinnacle of the pyramid, partly on the conceptual premise that the chief executive is the manager who really matters, and partly on the pragmatic ground that little is publicly available on anybody except the CEO. We have, thus, benefited from a long accumulation of work on their family histories, educational pedigrees, and political identities, and we know as a result that their origins are diverse, credentials splendid, and instincts conservative. More contemporarily, we have learned much about their tangled relations with directors and investors as well. To know the CEO's personal rise and board ties is to anticipate much of the firm's strategic intent and performance promise. They are also a good predictor of the CEO's own fortunes. An elite MBA degree accelerates movement to the top, a wealthy background attracts outside directorships, and a hand-picked board enhances pay and perquisites (Useem and Karabel 1986).

The conceptual and pragmatic underpinnings for shining the light solely on the CEO as the fulcrum for ownership and control, however, have eroded in recent years, as companies redefined their operations and researchers reconceived their methods. A central thrust of company restructuring during the 1980s and 1990s has been to transform the chief executive's office into the office of the executive. At many companies, CEOs have fashioned teams among their top officers that meet frequently and resolve jointly, their vertical control giving way to lateral leadership. As a result, researchers expanded their field of view from the chief executive to the entire upper echelon. They applied fresh strategies, ranging from personal interviews to direct observation and internet surveys, to acquire data on top managers other than the chief executive who now matter far more to company performance and stock analysts. A host of studies subsequently confirmed what many executives already appreciated. A better predictor of a company's performance than the chief executive's capability is the quality of the team that now runs the show (Finkelstein and Hambrick 1996).

Yet even this widening of research attention beyond the chief executive has not broadened enough. Many companies have expanded the concept of top management to include one, two, or even three hundred senior managers whose decisions have decisive bearing on firm performance. The concept of top management, then, has expanded in the minds of company managers and, to a lesser extent, academic researchers, from just the boss to the boss's team and now to the boss's court.

If shareholders are increasingly insistent that company directors require top managers to deliver steadily rising returns on their investments, their action is premised on a critical assumption that these top management teams do make the difference. While the premise may seem intuitively obvious to those inhabiting this world, it is far from self-evident to those who study it. Observers diverge from the assumption of influential executives in two opposing directions, one viewing top managers as all powerful, others seeing them as all but powerless.

Vilfredo Pareto and kindred 'elite' theorists early articulated the all-powerful view, but C. Wright Mills captured it best for the US in his classic work, *The Power Elite* (1956). Company executives, in his acid account, had joined with government officials and military commanders in an unholy alliance to exercise a commanding control over companies and the country. To the extent that top management is indeed all powerful, shareholders possess a silver bullet for righting whatever has gone wrong in a company: install new management.

For the community of management scholars, Pfeffer (1981) well articulated the opposite, all-*powerless* view with the contention that market and organizational constraints so tied top management's hands that it was much the captive, not a maker, of its own history. Production technologies and competitive frays in this view are far more determining of company results than the faceless executives who sit in their suites. It counts little who serves in top management, and, by extension, on the board. If top management is as powerless as the imagery suggests, investors seeking new management in response to poor performance are surely wasting their time.

Company executives do complain of a seeming helplessness at times, but almost anybody in working, consulting, or research contact with top managers reports just the opposite. Direct witnesses typically describe instead a commanding presence of top management, and they characterize its capabilities as

making the difference between a company's success or failure. Investors themselves think otherwise as well. When companies announce executive succession, money managers and stock analysts are quick to place a price on the head of the newly arrived, and, depending on the personality, billions can be added to or subtracted from the company's capitalization.

The importance that investors and directors attribute to top management for growing their fortunes can also be seen in the ultimate punishment for failure to do so: dismissal. Whether the US, Japan, or Germany, the likelihood of a CEO's exit in the wake of a stock free fall is increased by as much as half. And investors are often the engine behind the turnover. Study of Japanese companies stunned by a sharp reversal of fortune, for example, reveals that those whose top ten shareholders control a major fraction of the firm's stock are more often than others to dismiss the president and replace directors (Kaplan 1997, Kang and Shivdasani 1997).

Similarly, company boards are observed to reward successful executives far more generously than in the past. For each additional $1,000 added to a company's value in 1980, directors on average provided their chief executive an extra $2.51. By 1990, the difference in their payments had risen to $3.64, and by 1994 to $5.29. Put differently, in 1980 the boards of companies ranked at the 90th percentile in performance gave their CEOs $1.4 million more than did boards whose firms ranked at the 10th percentile (in 1994 dollars). But by 1990, the boards had expanded that gap to $5.3 million and by 1994 to $9.2 million (Hall and Liebman 1998).

4. *Between Stockholders and Top Management: The Governing Board*

If companies make semiconductors and concrete much the same way the world around, they organize their directors in almost as many ways as there are national economies. American boards tend to include only two or three insiders, while Japanese boards rarely include even two outsiders. German and Dutch governance is built around a two-tier governance structure, employees holding half of the upper tier seats; British and Swiss governance is designed around a single-tier, management-dominated structure. Some systems give formal voice to labor, others none: German law requires that labor representatives serve on the board, while French law places labor observers in the boardroom. American law mandates nothing, but some boards have added a labor leader on their own (Charkham 1994).

Yet such varieties in national practices may well diminish for two reasons. First, as equity markets internationalize, with companies seeking capital from all corners of the globe, investors predictably prefer relatively consistent director models that they believe will optimize shareholder value and performance transparency regardless of country. Their mental models of what's right may not always be right, but that is beside the point. Consider the preference expressed by some institutional investors in the US for a board chair who is not a sitting executive, believing that separation improves monitoring. Whatever the separatist penchant and however well it may have served some companies, research reveals that such a division creates no clear advantage for company performance (Baliga et al. 1996).

The diversity in directorship practices is likely to diminish, however, for a second, more factual reason. Certain practices do engender better performance, regardless of the setting, and as companies increasingly compete worldwide for customers and investors, they are likely to adopt what indeed does prove best. A case in point here is the number of directors on the board. Research on teams' success suggests that bigger is not better when boards exceed 15 or 20 members. When the number of directors climbs far above middle range, the engagement of each diminishes, and so too does their capacity to work in unison. Studies of American and European firms reveals that smaller boards displayed stronger incentives for their chief executive, greater likelihood of dismissing an under-performing CEO, and larger market share and superior financial performance (Conyon and Peck 1998).

It is not surprising, then, to see companies migrating worldwide toward smaller boards in search of improved performance. Directors in principle protect owner interests, direct company strategy, and select top management. In practice, they had concentrated more on strategy and selection and less on owner interests. But the rising power of investors has made for greater director focus on creating value and less coziness with top management. American and British directors, following the 'Anglo-Saxon' model, are already more focused on value than most. But directors in other economies can be expected to gravitate slowly toward the mantra of shareholder supremacy as well.

5. *Shareholders, Directors, and Executives at the Table*

With the rise of professional investors and their subjugation of national boundaries, those who occupy the executive suite and those who put them there are drawing far more research and policy attention, and justifiably so. In a by-gone era when markets were more steady and predictable, when airline and telephone executives confidently knew what to expect next year, the identity of top management mattered little. When shareholders were far smaller and decidedly quieter, when airline and telephone directors comfortably enjoyed inconsequential board meetings, the composition of the governing body mattered little

either. During the 1990s, however, all of this has changed in the US and UK, with other economies close behind. As shareholders have sought to reclaim authority over what they owned, they have brought top management and company directors back in. Company strategy and financial results can no longer be understood without understanding the capabilities and organization of those most responsible for delivering them.

The market is no longer viewed as so impersonal, the company no longer so isolated. Ownership and financial decisions are embedded in a complex network of working relations among money managers, stock analysts, company directors, senior executives, and state regulators. Given the right combination of features, that lattice can yield high investment returns and robust national growth. Given the wrong amalgam, it can lead instead to self-dealing, frozen form, and economic stagnation. The road ahead thus depends on how well researchers understand what control mechanisms and leadership styles work well both within national settings and across cultural divides, and on the extent that top managers, company directors, and stockholders learn and apply what is best.

Strategic Human Resources Management

Defining 'strategic human resource management' and placing it in context involves several related questions. In the first place, what do we mean by 'strategy'? Then, what is 'human resource management' and does it differ from '*strategic* human resource management'? What are the characteristics and issues concerning different approaches to strategic human resource management? What is the relationship between strategic human resource management and organizational performance?

1. What is Strategy?

First, a simple answer: Strategy may be defined as a set of fundamental choices about the ends and means of an organization. More recently it might be defined as policies and procedures that are aimed at securing competitive advantage. That said, there are several different approaches in exploring the question 'what is strategy?' Some focus on the *content* of strategy and its positioning in relation to factors internal or external to

the organization that might be seen as salient to its securing competitive advantage. An example of the internal, firm-focused approach would be the 'resource-based' view of strategy of the firm (e.g., Barney 1991). This perspective defines firms as unique bundles of resources and suggests that the route to developing sustained competitive advantage is to develop resources internally that meet the criteria of value, rarity, being costly to imitate, and nonsubstitutability. Examples of the latter, market-focused approach might be Porter's (1980) generic strategies (low cost, differentiation, segment, or niche) in relation to his five-forces model or Miles and Snow's (1978) categorization of firms as prospectors, analyzers, defenders, and reactors, both models emphasizing market-oriented choices. Theories that bring together internal and external perspectives are life-cycle theories of the firm or product (for example, the Boston Consultancy Group's portfolio planning growth-share matrix).

A second approach, which can subsume the content approaches, focuses on the *processes* of strategy making. A famous distinction is that between 'planned' and 'emergent' strategy (Mintzberg and Walters 1985). Building on this is a useful typology of Whittington (1993), based on two axes, relating to continua of outcomes (profit maximizing/pluralistic) and of processes (deliberate/emergent). Four perspectives on strategy are identified: the 'classical' (profit maximizing/deliberate), 'evolutionary' (profit maximizing/emergent), 'processual' (pluralistic/emergent) and the 'systemic' (pluralistic/deliberate). The processes of strategy making that are 'deliberate' comprise of rational, planned, top-down decision making ('classical' model) and decision making shaped by the social systems in which organizations are embedded ('systemic' model). 'Emergent' processes are those that reflect the very bounded, incremental, and political nature of decision making ('processual') or, in contrast, the 'population ecology' view of the competitive processes of natural selection, where the market picks the winners, rendering ineffective any deliberate strategizing ('evolutionary'). Writers typical of each of these perspectives would be Ansoff (1965) ('classical'), Hannan and Freeman (1988) ('evolutionary'), Mintzberg and Walters (1985) ('processual'), and Granovetter (1985) ('systemic').

2. *What is Strategic HRM?*

Even leaving aside the work on HRM by European writers, such as Anthony, Keenoy, Legge, Townley, and Willmott, that lies within a critical discourse tradition and which, as such, will not be considered here, there has been much debate on this question since the mid-1980s (see, e.g., Beer and Spector 1985, Fombrun et al. 1984, Guest 1987, Walton 1985). For many years, especially in the USA, human resource management was just another term for personnel management. Both terms referred to the management of the employment relationship and of the indeterminacies in the employment contract. In the early 1980s, however, a combination of factors—increased globalization of markets and perceived intensification of competition, the rise of the 'enterprise culture,' the Japanese 'Janus' and models of excellence, the decline in trade union pressure and disillusionment with 'traditional' personnel management, changes in the nature of work and in the workforce—awoke senior managers to the importance of human resources in the achievement of competitive advantage, and to a recognition that HRM/personnel management was too important to be left to personnel specialists.

Indeed, whether HRM was considered to be different from personnel management largely depended on the point of comparison. Sharp distinctions and contrasts emerged if the normative aspirations of HRM were compared to the descriptive practices of personnel management, but otherwise faded into several different emphases, all of which, though, pointed to HRM, in theory at least, being an essentially more central strategic management task than personnel management. As one commentator put it, the real difference between HRM and personnel management was 'not what it is, but who is saying it. In a nutshell HRM represents the discovery of personnel management by chief executives' (Fowler 1987, p. 3). Hence the idea of *strategic human resource management*.

However, different commentators espouse different models and approaches to strategic HRM. A major distinction may be found between the 'hard' model of the Michigan school (Fombrun et al. 1984), reflecting what has been termed a *utilitarian instrumentalism* and the 'soft,' 'mutuality' model of the Harvard school (Beer and Spector 1985, Walton 1985), more reminiscent of *developmental humanism* (Hendry and Pettigrew 1990). The 'hard' model stresses HRM's focus on the crucial importance of the close integration of human resources policies, systems, and activities with business strategy, requiring that they are not only logically consistent with and supportive of business objectives, but achieve this effect by their own coherence. From this perspective, employees are regarded as a headcount resource to be managed in exactly the same rational, impersonal way as any other resource, i.e., to be exploited for maximal economic return. Thus its focus is on human *resource management* and the implied perspective on strategy seems to have much in common with Whittington's 'classical' profit-maximizing/deliberate model of strategy.

In contrast, the 'soft,' 'developmental humanism' model, while still emphasizing the importance of integrating HR policies with business objectives, sees this as involving treating employees as valued assets, a source of competitive advantage through their commitment, adaptability, and high quality (of skills, performance, etc.). Employees are proactive and

resourceful rather than passive inputs into the productive process. Rather than exploitation and cost minimization, the watchwords in this model are investment and value added, with the focus on *human resource* management. The strategic perspective here, in Whittington's terms, is, therefore, pluralistic and echoes some of the ideas of the resource-based view of strategy.

Throughout the 1990s this model of HRM became increasingly seen, in both the USA and UK, as the exemplar of what HRM, as a distinctive philosophy of managing the employment relationship, was all about (see, e.g., Becker and Gerhart 1996, Guest 1987, Huselid 1995, MacDuffie 1995). Termed variously, the 'high commitment' (HCM), 'high performance,' or 'mutuality' model of HRM, at an operational level it was seen to comprise such policies as:

(a) Careful recruitment and selection with an emphasis on traits and competencies;

(b) Extensive use of systems of communication;

(c) Team working with flexible job design;

(d) Emphasis on training and learning;

(e) Involvement in decision making with responsibility (empowerment);

(f) Performance appraisal linked to contingent reward systems.

Increasingly, throughout the 1990s, particularly among US commentators, this model came to be equated with strategic HRM, reflecting the popularity of resource-based views of strategy in its belief in acquiring and developing employees as assets (see, e.g., Becker and Gerhart 1996, Boxall 1996). In some ways this reflects the interests of HR specialists and academics alike. Fitting HR policy and practice to business strategy always leaves HR as the 'third order' strategic decision, designed to reinforce prior 'first order' decisions about portfolio planning and 'second order' business decisions about organizational design and operating procedures, still reactive if no longer as powerless as traditional personnel management. The resource-based view of strategy accords a more proactive role to HRM as it can be valued not just for reinforcing predetermined business strategies, but for developing strategic capability, improving the long-term resilience of the firm.

However, it would be a mistake to see these two contrasting models of HRM as *necessarily* incompatible. If the stress is on integrating HRM policies with business strategy, in certain situations, choosing HCM policies may be appropriate to driving the business strategy. HCM appears the logical choice where employee discretion is crucial to the delivery of added value, and reciprocal high-trust relations are essential to organizational performance. Such a situation is often equated with organizations pursuing a strategy of producing high value-added goods and services, in a knowledge-based industry, where it adopts a policy of value-added goods and services rather than asset management. But if the organization's chosen business strategy is to compete in a labor-intensive, high-volume, low-cost industry, generating profits through increasing market share by cost leadership, such a policy of treating employees as assets may be deemed an expensive luxury. For such an organization the HR policies that may be most appropriate to driving strategic objectives are likely to involve treating employees as a variable input and cost to be minimized. Further, *human resource* management, in line with the 'soft' HCM model, is only viable if the organization is seen to be economically successful or 'hard,' if it manages effective human *resource management*.

At the heart of the distinction between 'hard' and soft' models of HRM lies a fundamental contradiction that personnel management/HRM—whatever the nomenclature—is called upon to mediate: needs it to achieve both the control and the consent of employees. Integration with business strategy may require the design and interpretation of an employment contract that veers toward control (with assumptions of labor as a commodity, embedded structural conflict, low trust, and transactional contracts) for some groups of employees; but consent (with assumptions about the employee as a valued asset, a unitary frame of reference, high trust, and relational contracts) for others.

This raises a major question about what precisely we mean by 'integrating HRM with business strategy,' the cornerstone of the 'hard' model of HRM. 'Integration' appears to have two meanings: integration or 'fit' with business strategy, and the integration or complementarity and consistency of 'mutuality' employment policies aimed at generating employee commitment, flexibility, quality, and the like. This double meaning has been referred to also as the 'external' and 'internal' fit of the HRM policies. The problem is that while 'fit' with strategy, as suggested above, would argue a *contingent* design of HRM policy, internal consistency—at least with the 'soft' human resource values associated with 'mutuality'—would argue a *universalistic* approach to the design of employment policy. Can this contradiction be reconciled without stretching to the limit the meaning of HRM as a distinct approach to managing people at work? Indeed, should we focus on HRM as a 'special variant' of personnel management, reflecting a particular ideology about how employees should be treated? Or should we regard it as a variety of very different policies and practices designed to achieve the desired employee contribution, judged solely 'against criteria of coherence and appropriateness (a less rigid term than "fit")?' (Hendry and Pettigrew 1990, pp. 8–9).

This distinction is critical as the contingent and universalistic approaches rest on very different and contradictory theoretical perspectives about organizational competitveness. The universalistic approach is consistent with institutional theory and arguments about organizational isomorphism (DiMaggio and

Powell 1983). In other words, the assumption here is that organizations that survive do so because they identify and implement the most effective, 'best' policies and practices. As a result, successful organizations get to look more and more like each other through practices like benchmarking and so on. (Here we have echoes of Whittington's 'evolutionary' perspective on strategy.) In HR terms this equates with the belief that treating employees as assets via the HCM model will always pay off, irrespective of circumstances. Contingency approaches, on the other hand, are consistent with the resource-based theories, referred to earlier, that argue that sustained competitive advantage rests not on imitating so-called 'best practice,' but on developing unique, nonimitable competencies (Barney 1991). This approach rests on a recognition of the importance of idiosyncratic contingencies that result from causal ambiguity and path dependency. From this perspective organizational performance is not enhanced merely by following 'best' HR practice (the HCM model), but from knowledge about how to combine, implement, and refine the whole potential range of HR policies and practices to suit the organization's idiosyncratic contingencies (Boxall 1996).

This brings us to what has become the key research question about strategic HRM, in both the USA and UK: what is its relationship to organizational performance?

3. *Strategic HRM and Organizational Performance*

Is strategic HRM linked to organizational performance on a universalistic (additive), configurational (patterned), or contingency (idiosyncratic) basis (Delery and Doty 1996)? At first sight the greatest support appears to be for the universalistic model: that the greater the extent to which the characteristics of the 'high commitment'/'high performance' model of HRM are adopted the better the organizational performance (see, e.g., empirical studies in both the UK and USA by Delery and Doty 1996, Guest 1997, 1999, Huselid 1995, MacDuffie 1995, Patterson et al. 1997). (For support of the contingency position, see Arthur 1992.) However, on examination, the empirical evidence for such universalism is more equivocal than it might appear at first sight.

The problems stem from methodological concerns with research design (see Legge 2000) and empirical observation (see Cully et al. 1999). Leaving aside disagreements about the specification and measurement of HCM HR practices, there are several major difficulties in drawing clear inferences from this research. Much of the work has been cross-sectional and survey-based, relying on the responses of one senior executive. The level of analysis is generally at corporate level, given the reliance on financial measures of performance, as it is at this level that much of the publicly available financial data exist. This leads to a range of difficulties. Where the research design is cross-sectional (as opposed to longitudinal), while causality may be inferred from correlation, technically it is not tested. This results in three possibilities.

A causal relationship may exist in the direction inferred, i.e., HCM HR policies and practices may give rise to positive outcomes, although even if this did exist, it might reflect no more than a temporary 'Hawthorne' effect in response to a change program (Purcell, 1999). (Of course it is possible, with the same direction of causality, that strategic HRM, particularly contingently chosen 'hard' HRM, may give rise to negative outcomes, or, positive outcomes on organizational performance measures but negative outcomes on employee measures, such as turnover and absenteeism.) Or, reverse causality may exist. Thus, as a firm becomes more profitable, it may invest in HCM HR practices, such as expenditure on training, or profit sharing, in the belief that such practices will further enhance performance, or that they will reduce the risk of performance declines, or from a belief in the justice and efficacy of wealth distribution. However, it is the profits that generate HCM practices rather than vice versa.

A further possibility is that the observed relationship between HR practices and performance may be an artefact of the implicit performance theories of survey respondents. In other words, if respondents have little detailed knowledge of the HR practices in their firm (highly likely if the firms are large, diverse and multisite and the research is being conducted at corporate level) but know that the firm is performing well in terms of productivity and profitability, they may infer that 'high performance' HR practices *must* exist, given this level of performance, based on the implicit theory that such practices are related to high performance (Wright and Gardener 2000). Similarly, the groups of employees that are likely to be most visible to such a respondent are those core employees to whom HCM is most likely to be applied, *not* the contingent workers to whom more transactional contracts are likely to be applied. The workers on the periphery of an organization may simply not be visible to the senior management single respondent to a corporate-level survey (Purcell 1999). Issues of workforce segmentation appear to be consistently neglected in such research (Boxall 1996).

Second, there is a theoretical problem with the heavy reliance on financial measures of performance (return on assets, Tobin's q) or organizational measures (productivity, quality, customer satisfaction) without equal concern to measure employee outcomes. (This is particularly marked in the US studies cited. Some recent UK studies, such as Guest 1999 and Cully et al. 1999 have attempted to measure employees' responses, such as satisfaction and employee relations climate.) The HCM model of HR practices rests on

the assumption that they will result in a positive psychological contract between employees and the organization that will give rise to employees' high commitment, quality, and flexibility, that in turn will have a positive effect on organizational performance and, ultimately, financial results. Reliance solely on financial and performance measures seems misguided as the theoretical rationales of how HR effects organizational performance rest on the assumption that it is *through* employee behaviors and outcomes. However, while the corporate level of analysis is consistent with the collection of financial data, it is not conducive to assessing employee attitudes and behaviors. Failure to open the 'black box' of employee behavior is a major limitation of many of these studies. However, to do so within the confines of quantitative positivistic designs (deemed necessary to establish generalizable causal relationships) raises immense problems about how many and what variables should be in the 'black box' and how these variables should be specified.

Then there is the issue of distinguishing between espoused and actual HR practices and employee skills and behaviors. The greater the number of intervening variables identified and the greater the level of specificity, the greater the multiplicative effect in determining the processes of a model, as the model building requires specification of the relationships between each of the specifications of the major intervening variables, giving rise to potentially unmanageable complexity (Wright and Gardner 2000).

Turning to empirical observation, we are confronted with a puzzling finding. If we are to accept at face value the research studies that suggest that there is a universalistic relationship between 'high commitment,' 'soft' model HRM and organizational performance, why do we find such relatively little implementation of this model of HRM? In the UK, for example, the latest Workplace Employee Relations Survey (WERS) in 1998 (Cully et al. 1999) found that only 14 percent of the responding workplaces have 'soft' HRM fully in place (defined as eight plus out of 15 'high commitment' management practices) as opposed to 29 percent which had three or fewer, 22 percent of which, with three or fewer HCM practices and no unions, may be defined in Guest's own memorable phrase as constituting a 'black hole.' As several commentators have observed, the implementation of any management best practice is likely to fall foul of vested interests, politicking, organizational history, and culture—precisely the factors that undermine the exercise of the 'classical' model of strategizing, but which are central to the 'processual' model. Indeed, it has been suggested that in the Anglo-American world, since about the mid-1980s, the dominant emphasis in practice has been on short-term survival rather than the development of long-term resource-based advantage, with the widespread, ad hoc adoption of the 'hard' policies of delayering, downsizing, and increasingly contingent forms of employment (Boxall 1996). Such initiatives seem consistent with Whittington's 'processual' model of strategizing, emerging as a stream of incremental, politically feasible actions in response to pressing problems.

4. *Future Directions of Research on Strategic HRM*

Whether from a practitioner or academic viewpoint, interest in the HRM/performance relationship appears to be here to stay. Most of the commentators already cited have suggestions for the improvement of research designs (e.g., more within-industry, business-level and plant-level designs; more consistent and valid measures of HR practices; more longitudinal studies; recognition of a broader range of organizational outcomes; opening up the 'black box', and so on). Guest (1997) and Purcell (1999) present two contrasting approaches, one from a universalistic and one from a contingent perspective.

Guest (1997, 1999) suggests that expectancy theory might provide a theory of process to link HRM practices and performance, as it links motivation and performance. Specifically, expectancy theory proposes that, at the individual level, high performance depends on high motivation, coupled with the necessary skills and abilities and appropriate role design and perception, equating skills and abilities with quality, motivation with commitment and role structure, and perception with flexibility. HR practices designed to foster these HR outcomes (e.g., selection and training for skills and abilities/quality, contingent pay and internal promotion for motivation/commitment, and team-working design for appropriate role design and perception/flexibility) should facilitate high individual performance, which in turn is a contributory factor in high performance outcomes (e.g., high productivity, low absence and labor turnover) that should contribute (other things being equal) to financial outcomes. In an empirical study of employees' reactions to HCM HR policies. Guest (1999) suggests that the psychological contract may be a key intervening variable in explaining the link between HR practices and employee outcomes such as job satisfaction, perceived job security, and motivation. Furthermore, although Guest's research is cross-sectional and, hence, raises the usual caveats about causality, the inferred direction of his empirical findings is supported by a similar longitudinal study (Patterson et al. 1997).

Nevertheless, Guest acknowledges the limitations of these models in terms of explaining organizational outcomes. While we may be able to measure the impact of HRM practices on HRM outcomes (quality, commitment, and flexibility), the measurable impact on organizational and financial outcomes is likely to become progressively weaker because of the range of potentially intervening variables. Guest also suggests

that we need a theory about the circumstances when human resources matter more and a theory about how much of the variance between HR practices and performance can be explained by the human factor.

Purcell (1999, pp. 36–8), building on a resource-based view of strategy has some interesting observations here. He recognizes that, on the one hand, the claim that the bundle of 'best practice' HCM HR is universally applicable 'leads us into a utopian cul-de-sac,' ignoring dual labor markets, contingent workers, and business strategies that logically do not require 'high commitment' HR practices to achieve financial success. On the other hand, the search for a contingency model of HRM is a 'chimera,' 'limited by the impossibility of modelling all the contingent variables, the difficulty of showing their interconnection, and the way in which changes in one variable have an impact on others, let alone the need to model idiosyncratic and path-dependent contingencies.' The way forward, Purcell argues, is the analysis of how and when HR factors come into play in the management of strategic change. Purcell suggests that we should explore how organizations develop successful transition management, build unique sets of competencies and distinctive organizational routines, and, in situations of 'leanness,' with greater dependency on all core workers, develop inclusiveness and the trust of such workers. The focus of research on strategic HRM (indeed, the focus of strategic HRM itself) should be on 'appropriate HR architecture and the processes that contribute to organizational performance in the short and medium term, and which positively contribute to the achievement of organizational flexibility or longevity.'

Strategic Intelligence

Intelligence is the provision of information about targets of concern, mostly foreign, for the use of decision makers, mostly governmental. The information normally prioritizes secrets and/or forecasts, and the degrees of animosity toward the targets (ranging from hostility all the way over to friendliness) are likely to shape the various efforts. The intelligence that is called 'strategic' is especially alert to the more competitive ranges of this spectrum, and is also loosely distinguished from what is called 'tactical' intelligence—the strategic seen as having wider scope, longer time horizons, and organizationally higher standing. Such strategic intelligence is several thousand years old, yet it lacked widely known, sharply focused manuals and treatises until the twentieth century (except in the narrow domain of cryptology).

The long delay was no doubt related to the traditional secretiveness of most of the intelligence activities—but also to slowness in differentiating them from broad statecraft and diplomacy and generalship, and from each other, and eventually institutionalizing various intelligence functions: distinct modes of information collection and analysis and interface with decision makers, and systematic counterintelligence shielding of one's own efforts from those of others. With these developments in the twentieth century have come incentives for elaborate doctrine and theorizing inside the intelligence organizations—and outsiders are increasingly being allowed to play a part, often driven also by their own concerns for social science applications and/or for greater democratic accountability. A significant literature is emerging.

1. *History of the Emergence of Intelligence Institutions and a Literature*

Some of the most ancient Mesopotanian tablets are cryptograms, and Western memory has highlighted espionage activities since the sieges of Troy and Jericho. Systematic literature on generalship, statecraft, and diplomacy became abundant, and commonly included passages on the need to have spies and to do assessments of information, but little, however, about exactly how to do the assessments, and even less about the subtleties of exactly how to direct one's spies, and almost nothing about how to be a spy and perform espionage. For the latter, from among published works that ever achieved wide circulation, one would have had to rely on some fiction and a few memoirs.

Sheer secretiveness does not suffice to explain the slowness of emergence of a systematic intelligence literature: such literature began to appear with the emergence of modern science—and appropriately was first about cryptology (ca. 1550), the aspect of intelligence that could most readily benefit from the application of the mathematics, etc., with 'how to' orderliness. Traditional espionage had required secretiveness too—but about methods that were thought to be sufficiently inculcated through age-old conventional wisdom and craftsmanship/apprenticeship not to require formal treatises for transmission of new specialties to novice practitioners or for continued scholarly updating, as cryptology soon did.

Many advances in science and technology were of course also contributing importantly to a general, lurching modernization of warfare and statecraft in the seventeenth and eighteenth centuries—and to a precipitation (which finally became rapid in the late nineteenth century) of new institutionalized specialties, crystalized out of the age-old fluid mixes of generalship, statecraft, and diplomacy. Again cryptology helped lead the way, from 'black chambers' of the seventeenth century to 'signals intelligence' (SIGINT), salient with the advent of telegraphy.

But until after Napoleon, the crystalization of intelligence functions in Europe was mostly discontinuous, ad hoc, and personalistic. Generals and admirals, rulers and their top advisers constructed intelligence outfits (usually rather small) as they saw fit and employed them idiosyncratically. There was a general presumption that diplomats would engage in espionage, discreetly, as part of their role as reporters to their home governments; likewise postal services dutifully would intercept accessible messages; merchant captains would be available to be debriefed, similarly traders and merchant bankers; clerics would commonly collaborate; and so forth, ad hoc.

Yet eventually the long century of relative peace after 1815 enabled the career diplomats to consolidate for themselves, as reporters, a professional status and ethic of personal abstention from conducting espionage—though their embassies and consulates might continue to harbor other functionaries in roles that did provide cover for agent running. Also, military attaches (likewise naval and later air) acquired a formally recognized 'licensed spy' status that was mutually convenient to the governments concerned. And the spread of democracy led to emphasis on differentiating one's counterintelligence security arrangements, domestic from international.

In the twentieth century, technical collection (TECHINT) methods proliferated, utilizing new technologies in SIGINT and beyond it: notably overhead reconnaissance (imagery intelligence, IMINT). Such new or reconstituted intelligence specialties, specifically identified as such, were incompatible with continuation of ad hocery; they required distinct stable career bureaucracies, at least within the armed services, and probably also outside lest political, economic, and other civilian priorities be absorbed subordinately into military juggernauts, even in peacetime. Instead, civilian intelligence services could do some of the espionage and could highlight open

sources of information, contributing to a more complete ('all-source') system of collection. To be sure, that would complicate coordination in all-source assessment/analysis of the collected information and in dissemination of it to the policy makers. So additional new institutions would be needed to reintegrate the recently proliferating institutions. And each of them, old and new, would come to need doctrines, for its own stable identity and its missions.

All of this was in fact the swiftly evolving setting for twentieth-century discourse about strategic intelligence.

2. *Components of the Twentieth Century Intelligence Literature*

Informed discourse about intelligence requires access to evidence. Yet successful conduct of intelligence requires much secretiveness and deception. The conflict between these two principles is the central dilemma retarding scholarship about the subject—in this era when the complexity and importance of the functions and institutions has finally achieved general recognition, while the prevailing standards of respectability in social science do not comport easily with the dubious quality of evidence available for open discourse about intelligence. The field is nearly unique in that evidence is not only hard to find because it is deliberately hidden but additionally is hard to trust because often it has been deliberately planted to deceive. At least some governmental relaxation of long enforced secrecy restrictions is virtually prerequisite for building an evidentiary base usable by outsiders. Yet various possible governmental motives for relaxation rouse suspicions that even the releases are being directly or indirectly rigged. Governments do hold the keys. Investigative journalists, especially those with current events preoccupations, can be stymied; defectors and adversaries can be denigrated and largely discredited; veterans can be held to oaths of silence; archives can be kept closed and/or purged. Nevertheless, whenever stonewalling erodes and instead validation gradually proceeds, any and all of these potential sources can come cumulatively to constitute the evidentiary base for informed open discourse.

That is what has in fact been slowly occurring—especially with momentum from the United States—in a widening circle of democratic and ex-communist countries during the decades since the USA's traumatic encounter with Vietnam. Exposes have led step by step to treatises. And much that in the past had indeed been factual but had been presented as intelligence fiction, so as to elude restrictions, can now be accorded less ambiguous credibility, even become part of the accepted data base. Historiography and some social science can take hold.

Among outside historians, about twentieth-century intelligence the most outstanding achievement thus far is the UK's Christopher Andrew's successive masterworks (1985, 1995, Andrew and Gordievsky 1990) on the services of each of the major intelligence powers. For coverage of earlier centuries also, the general masterwork is German: (Piekalkiewicz 1988); about cryptology it is American (Kahn 1996). Now, even for intelligence history as recent as the Cold War, multi-archival international research collaborations are sometimes successful, e.g. Russians and Americans (Fursenko and Natfali 1997, Murphy et al. 1997). For sheer massive contemporary updated data accumulation by an outsider no one anywhere rivals the USA's Jeffrey Richelson (1999).

But most important for durably connecting strategic intelligence with social science are the works that do not just add to the base of openly available evidence but use it to rethink and generalize intelligence problems. In this genre, usually the writers who have been best positioned to take early advantage of the new permissiveness come from among former intelligence practitioners (or supervisory associates) who happen to be of uncommonly reflective—even scholarly—disposition, have familiarized themselves with the open literature currently available in their respective periods, and soberly resolve to contribute their own perspectives to its cumulative advancement. Milestone works of this kind in the United States have been Kent (1966), Johnson (1989), Shulsky (1991), and in the UK, Herman (1996), all of them distinguished for comprehensiveness as well as for insider/outsider complementarity of strengths.

What kinds of contributions can they make, in the widening discourse based on increasingly available data and personal contacts? And how about authors who remain essentially outsiders yet want to study the arcane world of ongoing intelligence—not just its history? What does the existing literature already exhibit and foreshadow about the feasibility and value of various research directions?

Scholars can act like investigative journalists and 'speak the unspeakable,' in reports that are also additional evidence for generalization by others.

Scholars can act as systematic ethicists, judging different forms or instances of intelligence activity. Much of such effort has been devoted to evaluating covert action (intrigue, etc.), but not much yet about intelligence in the stricter sense, where problems like loyalties and means–ends relationships also abound, worth normative exploration.

Epistemologists and cognitive psychologists have wide room to apply their disciplinary skills studying problems of perception/misperception/deception that arise in intelligence collection and assessment, and in counterintelligence where these complexities are loosely tagged a 'wilderness of (interfacing) mirrors.' The pioneering studies here were done as academic political psychology (Jervis 1970, 1976).

There is room for management-school faculties to contribute insights from their fields of management

psychology and of operations research. Here quantitative methods are central whereas most other outsiders' work on intelligence, thus far, has been entirely qualitative or only rudimentally quantitative. However, rational-choice/game-theory modelers' increasing emphasis on their players' information levels may come to alter this imbalance, if the applicability to intelligence studies gets recognized.

Political scientists as well as psychologists can conceptualize and taxonomize in their studies of intelligence. This is a function that insiders are very familiar with on their own; they eagerly construct, debate, and reconstruct their secret lexicons, knowing full well the value of verbal precision (and deliberate imprecision). But such efforts on the inside are prone to express conflicting parochialisms.

Taxonomies by outsiders may be more objective, a moderating influence, and sometimes their conceptualization can even introduce or clarify ideas that have not already become familiar to insiders blinkered by their own secret terminology.

Similarly, outside social scientists can sometimes venture into speculative scenario writing, which implicitly can be a useful cross-check upon the range and content of comparable exercises done inside, even when the outsiders are not privy enough to the latter for the cross-checking to be made explicit.

Political scientists as well as like-minded historians can make cross-national comparisons leading to some mid-level theorizing–for example about how much the interface between intelligence analysts and top policymakers is affected by characteristics of different countries' governmental systems, be they pluralistic or relatively centralized.

All these modes of widening discourse about strategic intelligence, besides having benefits for the scholars and some practitioners, contribute to making civil society in general more knowledgeable about this important dimension of world affairs. Thus the discourse can tend to enhance broad democratic accountability, with long-term advantages that probably outweigh the occasional damage from excessive leaks and disclosures. But wide acquiescence by insiders comes only very slowly.

Strategic Planning

Strategic planning may be defined as 'a disciplined effort to produce fundamental decisions and actions that shape and guide what an organization (or other entity) is, what it does, and why it does it' (Bryson 1995, pp. 4–5). This definition implies that strategic planning is not a single thing, but is instead a set of concepts, procedures, and tools that must be carefully tailored to situations if desirable outcomes are to be achieved. Many authors have suggested generic strategic planning processes. Poister and Streib (1999) in a review of the field of strategic planning and management assert that strategic planning:

(a) Is concerned with identifying and responding to the most fundamental issues facing an organization;

(b) Addresses the subjective question of purpose and the often-competing values that influence mission and strategies;

(c) Emphasizes the importance of external trends and forces, as they are likely to affect the organization and its mission;

(d) Attempts to be politically realistic by taking into account the concerns and preferences of internal, and especially external, stakeholders;

(e) Relies heavily on the active involvement of senior level managers, and sometimes elected officials, assisted by staff support where needed;

(f) Requires the candid confrontation of critical issues by key participants in order to build commitment to plans;

(g) Is action oriented and stresses the importance of developing plans for implementing strategies; and

(h) Focuses on implementing decisions now in order to position the organization favorably for the future.

It is important to highlight what strategic planning is not. Strategic planning is not a substitute for strategic thinking and acting. It may help people do that, but used unwisely it may hinder strategic thinking and acting. Strategic planning is not a substitute for leadership. At least some key actors must be committed to the process or it is bound to fail. Strategic planning is also not a substitute for an organizational or community strategy. Strategies have numerous sources, both planned and unplanned. Strategic planning is likely to result in a statement of organizational or community intentions, but what is realized in practice will be some combination of what is intended with what emerges along the way. Finally, strategic planning is not synonymous with what is called 'comprehensive planning' for communities in the USA, or has been called 'structure planning' in Europe. There may be little difference if the agency doing the comprehensive or structure planning is tied directly to governmental decision-makers. However, in practice, there may be three significant differences.

First, the plans are often prepared to meet legal requirements and must be formulated according to a legally prescribed process with legally prescribed content. As legal instruments, these plans have an important influence. On the other hand, the plans' typical rigidity can conflict with the political process with which public officials must cope. Therefore strategic plans can provide a bridge from legally required and relatively rigid policy statements to actual decisions and operations.

Second, comprehensive or structure plans are usually limited to a shorter list of topics than a government's full agenda of roles and responsibilities. For that reason, they are of less use to key decision makers than strategic planning, which can embrace all of a government's actual and potential roles before deciding why, where, when, and how to act.

Third, as Kaufman and Jacobs (1987) argue, strategic planning on behalf of a community is more action-oriented, more broadly participatory, more emphatic about the need to understand the community's strengths and weaknesses as well as the opportunities and threats it faces, and more attentive to inter-community competitive behavior. Strategic planning is thus typically more comprehensive than comprehensive planning or structure planning, while at the same time producing a more limited action focus.

Strategic planning also is typically distinguished from strategic management. Strategic management is a far more encompassing process 'concerned with managing an organization in a strategic manner on a continuing basis' (Poister and Streib 1999, p. 310). Strategic management links strategic planning and implementation by adding ongoing attention to budgeting; performance measurement, evaluation, and management; and feedback relationships among these elements.

1. *Brief History of Development and Use of Strategic Planning*

Strategic planning for organizations has primarily developed in the private sector. This history has been amply documented by others (Eden and Ackermann 1998). However, since around 1980, public and nonprofit use of strategic planning has skyrocketed. This experience, and a growing body of literature, have indicated that strategic planning approaches either developed in the private sector, or else strongly influenced by them, can help public and nonprofit organizations, as well as communities or other entities, deal in effective ways with their dramatically changing environments.

In the USA—where strategic planning has proceeded the furthest—a substantial majority of municipal and state governments, and an overwhelming majority of federal agencies and nonprofit organizations, make use of strategic planning. Strategic planning has been principally applied to public and nonprofit organizations, but applications to communities have also increased substantially (Berman and West 1998). Other nations are also making increased use of strategic planning concepts, procedures, and tools for public and nonprofit organizations and communities (e.g., Osborne and Plastrik 1997, Salets and Faludi 2000).

2. *Benefits*

When done well, strategic planning offers a number of benefits. Advocates usually point to four main potential benefits. The first is the 'promotion of strategic thought and action.' The second is 'improved decision making,' while the third is 'enhanced organizational responsiveness and improved performance.' Finally, strategic planning can 'directly benefit the organization's people' by helping them better perform their roles, meet their responsibilities, and enhance teamwork and expertise. There is no guarantee, however, that these benefits will be achieved. For one thing, strategic planning is simply a set of concepts, procedures, and tools that must be applied wisely to specific situations. Also, even when applied wisely there is no guarantee of success.

3. Approaches to Strategic Planning

Strategic planning may be divided into 'process' and 'content' approaches. We start first with broadly encompassing process approaches, then consider more narrowly conceived process approaches, and finally discuss two content approaches.

3.1 The Harvard Policy Model

The Harvard policy model was developed as part of the business policy courses taught at the Harvard Business School since the 1920s (Bower et al. 1993). The approach provides the principal (though often implicit) inspiration behind the most widely cited recent models of public and nonprofit sector strategic planning. The main purpose of the Harvard model is to help an organization develop the best 'fit' between itself and its environment; that is, to develop the best strategy for the organization. One discerns the best strategy by analyzing the internal strengths and weaknesses of the company and the values of senior management, and by identifying the external threats and opportunities in the environment and the social obligations of the firm. Then one designs the appropriate organizational structure, processes, relationships, and behaviors necessary to implement the strategy, and focuses on providing the leadership necessary to implement the strategy.

Effective use of the model presumes that senior management can agree on the organization's situation and the appropriate strategic response, and has enough authority to enforce its decisions. A final important assumption of the model, common to all approaches to strategic planning, is that if the appropriate strategy is identified and implemented, the organization will be more effective. For the model to be useful for public and nonprofit purposes, it typically has to be supplemented with other approaches, such as the portfolio and strategic issues management approaches discussed below. A portfolio approach is needed because a principal strategic concern at the organizational level is oversight of a portfolio of agencies, departments, or programs. Strategic issues management is needed because much public and nonprofit work is typically quite political, and articulating and addressing issues is the heart of political decision making.

The systematic assessment of strengths, weaknesses, opportunities and threats—known as a SWOT analysis—is a primary strength of the Harvard model. This element of the model appears to be applicable in the public sector to organizations, functions, and communities. Another strength is its emphasis on the need to link strategy formulation and implementation in effective ways. The main weaknesses of the Harvard model are: (a) it does not draw attention to strategic issues; (b) it does not consider the full range of stakeholders; and (c) it does not offer specific advice on how to develop strategies, except to note that effective strategies will build on strengths, take advantage of opportunities, and overcome or minimize weaknesses and threats.

3.2 Strategic Planning Systems

Strategic planning is often viewed as a system whereby leaders and managers go about making, implementing, and controlling important decisions across functions and levels in the organization. When viewed this way, strategic planning is synonymous with strategic management. Strategic planning systems vary along several dimensions: the comprehensiveness of decision areas included, the formal rationality of the decision process, and the tightness of control exercised over implementation of the decisions, as well as how the strategy process itself will be tailored to the organization and managed. The strength of these systems is their attempt to coordinate the various elements of an organization's strategy across levels and functions. Their weakness is that excessive comprehensiveness, prescription, and control can drive out attention to mission, strategy, and innovation, and can exceed the ability of participants to comprehend the system and the information it produces (Mintzberg 1994, Roberts and Wargo 1994).

Strategic planning systems are applicable to public organizations (and to a lesser extent communities), for, regardless of the nature of the particular organization, it makes sense to coordinate decision making across levels and functions and to concentrate on whether the organization is implementing its strategies and accomplishing its mission (Boschken 1988, p. 1994). However, it is important to remember that a strategic planning system characterized by substantial comprehensiveness, formal rationality in decision making, and tight control will work only in an organization that has a clear mission, clear goals and objectives, relatively simple tasks to perform, centralized authority, clear performance indicators, and information about actual performance available at reasonable cost. While some public and nonprofit organizations—such as hospitals and police and fire departments—operate under such conditions, most do not. As a result, most public and nonprofit sector strategic planning systems typically focus on a few issues, rely on a decision process in which politics plays a major role, and control something other than program outcomes (e.g., budget expenditures) (Osborne and Plastrik 1997).

3.3 Stakeholder Management Approaches

Freeman (1984) states that strategy can be understood as an organization's mode of relating to or building

bridges to its stakeholders. For Freeman, a stakeholder may be defined as any individual, group, or organization that is affected by, or that can affect, the future of the organization. He argues, as do others who emphasize the importance of attending to stakeholders, that a strategy will only be effective if it satisfies the needs of multiple groups. Because it integrates economic, political, and social concerns, the stakeholder model is one of the approaches that is most applicable to the public sector. Many interest groups have stakes in public organizations, functions, and communities. If the model is to be used successfully, however, there must be the possibility that key decision-makers can achieve reasonable agreement about who the key stakeholders are and what the response to their claims should be.

The strengths of the stakeholder model are its recognition of the many claims—both complementary and competing—placed on organizations by insiders and outsiders and its awareness of the need to satisfy at least the key stakeholders if the organization is to survive. Because of its attention to stakeholders, the approach may be particularly useful in working collaboratively with other organizations, since each party to a collaboration must be viewed as a stakeholder (Huxham 1993). The weaknesses of the model are the absence of criteria with which to judge competing claims and the need for more advice on developing strategies to deal with divergent stakeholder interests. A number of other encompassing process approaches to strategic planning have been developed primarily in the UK in the field of operations research. These include Journey Making (Eden and Ackermann 1998) and Strategic Choice (Friend and Hickling 1997). They are now beginning to be used more widely around the world.

3.4 Strategic Issues Management Approaches

These approaches are process components, pieces of a larger strategic planning process. The concept of strategic issues first emerged when practitioners of corporate strategic planning realized a step was missing between the SWOT analysis of the Harvard model and the development of strategies. That step was the identification of strategic issues, or crucial challenges facing the organization. Many organizations now include a strategic issue identification step as part of full-blown strategy revision exercises, and also as part of less comprehensive annual strategic reviews between major strategy revisions. In addition, many organizations have developed strategic issue management processes actually separated from annual strategic planning processes. Many important issues emerge too quickly to be handled as part of an annual process.

Strategic issue management is clearly applicable to public organizations, since the agendas of these organizations consist of issues that should be managed strategically (Eden and Ackermann 1998). The strength of the approach is its ability to recognize and analyze key issues quickly. The approach also applies to functions or communities, as long as some group, organization, or coalition is able to engage in the process and to manage the issue. The main weakness is that in general the approach offers no specific advice on exactly how to frame the issues other than to precede their identification with a situational analysis of some sort. Nutt and Backoff (1995) have gone the furthest in remedying this defect. The final two process approaches to be discussed are 'process strategies.' They are logical incrementalism and strategic planning as a framework for innovation. Process strategies are approaches to implementing a strategy that already has been developed in very broad outline and is subject to revision based on experience with its implementation. Other important process approaches not discussed in this article, due to space limitations, include total quality management (Cohen and Brand 1993), strategic negotiations (Susskind and Cruikshank 1987), collaboration (Gray 1989), and the management of culture (Schein 1992).

3.5 Logical Incrementalism

In incremental approaches, strategy is a loosely linked group of decisions that are handled incrementally. Decisions are handled individually below the organizational level because such decentralization is politically expedient—organizational leaders should reserve their political clout for crucial decisions. Decentralization also is necessary since often only those closest to decisions have enough information to make good ones.

The incremental approach is identified principally with Quinn (1980), although the influence of Lindblom (1959) is apparent. Quinn developed the concept of 'logical incrementalism'—or incrementalism in the service of overall organizational purposes—and as a result transformed incrementalism into a strategic approach. Logical incrementalism is a process approach that, in effect, fuses strategy formulation and implementation. The strengths of the approach are its ability to handle complexity and change, its emphasis on minor as well as major decisions, its attention to informal as well as formal processes, and its political realism. A related strength is that incremental changes in degree can add up over time into changes in kind (Mintzberg 1987). The major weakness of the approach is that it does not guarantee that the various loosely linked decisions will add up to fulfillment of corporate purposes.

Logical incrementalism would appear to be very applicable to public and nonprofit organizations, as long as it is possible to establish some overarching set of strategic objectives to be served by the approach.

When applied at the community level, there is a close relationship between logical incrementalism and collaboration. Indeed, collaborative purposes and arrangements typically emerge in an incremental fashion as organizations individually and collectively explore their self-interests and possible collaborative advantages, establish collaborative relationships, and manage changes incrementally within a collaborative framework (Stone 2000).

3.6 Strategic Planning as a Framework for Innovation

As noted in Sect. 3.5, strategic planning systems can drive out attention to mission, strategy, and innovation. The systems, in other words, can become ends in themselves and drive out creativity, innovation, and new ventures without which the organization might become irrelevant or die. Many organizations, therefore, have found it necessary to emphasize innovative strategies as a counterbalance to the excessive control orientation of many strategic planning systems (Light 1998). The framework-for-innovation approach relies on many elements of the approaches discussed above, such as SWOT analyses and portfolio methods. This approach differs from earlier ones in four emphases: (a) innovation as a strategy; (b) specific management practices to support innovation; (c) development of a mission or 'vision of success' that provides the decentralized and entrepreneurial parts of the organization with a common set of super-ordinate goals toward which to work; and (d) nurture of an entrepreneurial organizational culture (Light 1998, Osborne and Plastrik 1997).

The main strength of the approach is that it allows for innovation and entrepreneurship while maintaining central control. The weaknesses of the approach are that typically—and perhaps necessarily—a great many, often costly, mistakes are made as part of the innovation process and that there is a certain loss of accountability in very decentralized systems (Mintzberg 1994). Those weaknesses reduce the applicability to the public sector, in particular, in which mistakes are less acceptable and the pressures to be accountable for details (as opposed to results) are often greater (Light 1998). Many nonprofit organizations will also have trouble pursuing this approach because a shortage of important resources will magnify the risks of failure. 'Process' approaches do not prescribe answers, though good answers are presumed to emerge from appropriate application. In contrast, 'content' approaches do yield answers. In fact, the models are antithetical to process when process concerns get in the way of developing the 'right' answers. In the next two sections, we discuss two content approaches: portfolio models and competitive analysis. Other important content approaches not covered in this article, due to space limitations, include 'reinventing government' (Osborne and Gaebler 1992), systems analysis (Senge 1990), and reengineering (Linden 1994).

3.7 Portfolio Models

The idea of strategic planning as managing a portfolio of 'businesses' is based on an analogy with investment practice in which an investor manages a portfolio of stocks to balance risk and return. Although the applications of portfolio theory to the public sector may be less obvious than those of the approaches described above, they are nonetheless just as powerful (Nutt and Backoff 1992). Many public and nonprofit organizations consist of 'multiple businesses' that are only marginally related. Often resources from various sources are committed to these unrelated businesses. That means public and nonprofit managers must make complex portfolio decisions, though usually without the help of portfolio models that frame those decisions strategically. The strength of portfolio approaches is that they provide a method of measuring entities of some sort (e.g., programs, proposals, or problems) against dimensions that are deemed to be of strategic importance (usually attractiveness of the option versus capability to implement it). Weaknesses include the difficulty of knowing what the appropriate strategic dimensions are, difficulties of classifying entities against dimensions, and the lack of clarity about how to use the tool as part of a larger strategic planning process.

Portfolio approaches can be used in conjunction with an overall strategic planning process to provide useful information on an organization, function, or community in relation to its environment. However, unlike the process models portfolio approaches provide an 'answer'; that is, once the dimensions for comparison and the entities to be compared are specified, the portfolio models prescribe how the organization or community should relate to its environment. Such models will work only if a dominant coalition is convinced that the answers they produce are correct.

3.8 Competitive Analysis

Another important content approach that assists strategy selection has been developed by Michael Porter (1998a) and his associates. Porter (1998a) hypothesizes that five key competitive forces shape an industry: relative power of customers, relative power of suppliers, threat of substitute products, threat of new entrants, and the amount of rivalry activity among the players in the industry. For many public and nonprofit organizations, there are equivalents to the forces that affect private industry. An effective organization in the public and nonprofit sector,

therefore, must understand the forces at work in its 'industry' in order to compete effectively, and must offer value to its customers that exceeds the cost of producing it. On another level, planning for a specific public function (health care, transportation, or recreation) can benefit from competitive analysis if the function can be considered an industry.

In addition, Porter (1998b) points out that for the foreseeable future self-reinforcing agglomerations of firms and networks are crucial aspects of successful international economic competition. In effect, not just firms or nations, but metropolitan regions (Shanghai, the Silicon Valley, New York, London, and Paris) are key economic actors. Regions interested in competing on the world stage should therefore try to develop the infrastructure necessary for virtuous (rather than vicious) cycles of economic growth to unfold. In other words, wise investments in education, transportation and transit systems, water and sewer systems, parks and recreation, housing, and so on, can help firms reduce their costs—particularly the costs of acquiring an educated labor force—and thus improve the firms' ability to compete internationally.

The strength of competitive analysis is that public and nonprofit organizations can use competitive analysis to discover ways to help the private firms in their regions. When applied directly to public and nonprofit organizations, however, competitive analysis has two weaknesses: it is often difficult to know what the 'industry' is and what forces affect it, and the key to organizational success in the public and nonprofit world is often collaboration instead of competition. Competitive analysis for the public organizations, therefore, must be coupled with a consideration of social and political forces and the possibilities for collaboration (Huxham 1993, Osborne and Plastrik 1997).

4. Conclusions

It should be noted that careful studies of corporate-style strategic planning in the public and nonprofit sectors are few in number. Nevertheless, it is possible to reach some tentative conclusions. First, it should be clear that strategic planning is not a single concept, procedure, or tool. In fact, it embraces a range of approaches that vary in their applicability to the public and nonprofit sectors and in the conditions that govern their successful use. Second, while any generic strategic planning process may be a useful guide to thought and action, it will have to be applied with care in a given situation, as is true of any planning process (Christensen 1999). Because every planning process should be tailored to fit specific situations, every process in practice will be a hybrid. Third, public and nonprofit strategic planning is well on its way to becoming part of the standard repertoire of public and nonprofit leaders, managers, and planners. Because of the often dramatic changes these people and their organizations confront, we can hypothesize that the most effective leaders, managers, and planners at the beginning of the twenty-first century are, and will be increasingly in the future, the ones who are best at 'strategic' planning.

Finally, research must explore a number of theoretical and empirical issues in order to advance the knowledge and practice of public-sector strategic. In particular, strategic planning processes that are responsive to different situations must be developed and tested. These processes should specify key situational factors governing their use; provide specific advice on how to formulate and implement strategies in different situations; be explicitly political; indicate how to deal with plural, ambiguous, or conflicting goals or objectives; link content and process; indicate how collaboration as well as competition is to be handled; and specify roles for those involved in the process. Other topics in need of attention include: the nature of strategic leadership; ways to promote and institutionalize strategic planning across organizational levels, functions that bridge organizational boundaries, and intra- and interorganizational networks; and the ways in which information technologies can help or hinder the process. Progress has been made on all of these fronts, but work is clearly necessary if we are to understand better when and how to use strategic planning.

Strategy: Organizational

The subject of strategy in organizations has become one of the dominant features of the contemporary world of academics and practitioners. The use of the word is pervasive. The genesis and development of the concept has been relatively swift yet has produced a rich variety of interpretations and uses. Its core meaning was taken by Chandler, to center on a logical sequence of goal-setting and resource allocation within firms. In his widely-adopted formula (Chandler 1962, p. 13): 'Strategy is the determination of the basic long-term goals of an enterprise, and the adoption of courses of action and the allocation of resources necessary for carrying out these goals.' Subsequent work has emphasized the competitive element so that the purpose of a strategy is to maintain or improve performance. Strategies are judged by their ability to neutralize threats and exploit opportunities for the organization while capitalizing on strengths and avoiding weaknesses (Barney 1997, p. 27). Strategy also refers to the direction of an organization, which matches its resources to its environment in order to meet stakeholders expectations (Johnson and Scholes 1993, p. 10). Strategic management is concerned with the process by which strategies are adopted and put into practice.

1. Origins

The practical origin of the term strategy is found in military history. In the ancient world *strategos* was applied to the generalship of an army commander, 'the art of the general.' By 330 BC it also included notions of administration and the use of armed force in order not only to defeat enemies but also establish systems of governance (Quinn et al. 1988, p. 1). The word strategy was first used in English in the seventeenth century. By 1870, military dictionaries distinguished between strategy (planning conducted away from the enemy) and tactics (the immediate engagement of an adversary) (Whipp 1996, p. 13).

The idea of organizational strategy in a business or commercial sense was a product of the second half of the twentieth century. Yet its emergence as a separate subject of teaching and research in the 1960s owed much to its military roots. The pioneering book of Ansoff (1965) on *Corporate Strategy*, for example, distinguished between corporate strategy and business strategy, paralleling the military ideas of grand strategy and battle strategy. Corporate strategy was seen as selecting what business to be in; business strategy dealt with how to operate in a given business area. A second landmark text (Andrews 1971) also relied on these military distinctions. He emphasized the aim of strategy as establishing a clear dominance in a business domain while simultaneously planning for the movements of hostile adversaries (see also Quinn et al. 1988, p. 42).

The second main influence on the development of the subject of strategy was the discipline of economics. In the early decades of the twentieth century, research on industry form, competition and innovation had pointed to the role of individual firms in economic

relations. Such writers were firmly set in the traditions of microeconomics. The approach was a rational one with a reliance on profit maximizing behavior by all economic agents, accessible information and the mobility of resources. Andrews' view of strategy was therefore clear: 'rivalry amongst peers for prizes in a defined and shared game' (Pettigrew and Whipp 1991, p. 29).

The third force to shape the emergence of strategy as a subject was the geographical and corporate context. The flourishing of large, multi-product corporations, such as General Motors and Du Pont, took place in the 1920s and 1930s in the USA. As they grew commercially and organizationally more complex, so did their need for more sophisticated means of assessing markets and competitors and matching them with the resources of the firm. The early experts on strategy worked closely with these corporations in response to their needs. Ansoff was an executive at Lockheed Aerospace while Chandler was related to the Du Pont family. As the demand for technical experts to produce strategic analysis rose, so business schools and consulting firms grew in number and importance during the 1960s and 1970s. Outside of the US, corporate forms were much slower to evolve and in Europe the large-scale growth in business schools and the study of strategy did not occur until 20 years later.

2. *Uneven Development*

Given the late advent of strategy as a subject, its development since the 1960s has often been more colorful than more mature areas of the social sciences. New approaches have arisen, offering challenges to the main orthodoxies. Insights and techniques from outside of economics have been applied to enrich and extend the subject. As the study of strategy has progressed, so its full complexity has become apparent. The growth of the area is best understood by reference to three waves of activity: the classical era of the 1960s, the challenges set by organizational analysts in the 1970s and early 80s, and the production of a more composite approach to meet the circumstances of the 1980s and early 1990s.

During the 1960s, strategy experts placed a heavy reliance on planning techniques. Financial planning tools were created to link capital investments with production and to derive profit forecasts. Forecast-based planning was constructed in the light of unstable market behavior. Business portfolio matrices and product lifecycle tools were examples of devices produced to make forecasts (Bourgeois 1996, p. 5). Early computing technology raised the expectations of strategic planners regarding the potential of this planning-led approach. The conviction that the environment of the firm was eminently capable of being captured by such techniques was strong.

In the following decades, this planning-led approach to strategy continued as the mainstream, particularly in North America. Alternative voices appeared on both sides of the Atlantic with their attention directed not to planning strategy but the process of implementation. The process perspective was built upon decision-making theory (e.g., see *Organizational Decision Making*). First Lindblom (1959), and later March and Olsen (1976), demonstrated how the decisions of senior management were often less than rational, notwithstanding their use of planning apparatus. Trade-offs, compromises, and coalition formation were shown to be routine. These writers drew attention to the haphazard and highly subjective qualities of strategic decisions and their mode of implementation. Writers, such as Mintzberg (1978), revised the profile of the strategic decision making, and implementation activities in an organization, suggesting that these constituted important change processes in their own right and should be analyzed and managed accordingly. Concepts of power and culture were applied to the problem for the first time (e.g., *Organizations: Authority and Power*). The result was a more realistic appreciation of the problems strategic management involved, including the issues of political influences, aborted ideas and unintended outcomes.

Whilst this process-based approach has continued as a separate tradition in the study of strategy (often labelled strategic change), it also had a major influence on the third wave of activity in the 1980s. The driving force behind these new developments was a dramatic shift among international competitors. Japanese firms in the manufacturing and consumer goods sectors enjoyed spectacular gains in overseas markets, notably the USA and Western Europe. Their market success was based on the ability to combine product innovations with new standards in quality, underpinned by (in the eyes of western managers) novel forms of organization. These events provoked two responses from academics.

First, was a renewed interest in competitive analysis, drawing on the microeconomic perspective (outlined in Sect. 1). Porter played the leading role by highlighting 'generic strategies' (1980)—such as cost leadership vs. differentiation—and the need for organizations to clarify their choice of strategy. He went on to offer a model of extended competition (Porter 1985) which forced firms to treat seriously new sources of competition from outside a sector (e.g., see *Competitive Strategies: Organizational*). This fresh emphasis on competitor analysis was augmented by a rejuvenation during the 1980s of the resource-based theory of the firm. Here particular attention was paid to the identification and maintenance of the unique collection of capabilities (technological, organizational, financial, for example) found in successful firms but which others would find difficult to imitate. A preoccupation grew with 'strategic intent': the

ability to create extremely long-term aspirations for an organization and link them to immediate operations (Hamel and Prahalad 1989). The insights of the strategic change analysts (e.g., see *Organizational Change*) became especially relevant to this new conception of strategy and competition (Pettigrew and Whipp 1991).

3. Current Themes

The emphasis in current strategy research, in part, arises from ideas and incomplete projects, which began in earlier eras; this is particularly true for the interest in strategic capabilities and transformation. In the empirical sphere the dominant characteristics of strategic studies has been their entry into hitherto unresearched settings. At the same time, it has been noticeable how other specialisms in the business studies area, such as human resource management have attempted to incorporate a strategic perspective (e.g., see *Strategic Human Resources Management*).

The harsh competitive conditions of the 1980s and 1990s, produced a general interest amongst business people in organizations, which could prosper in such circumstances. Companies such as Honda, Chrysler or ABB received intense scrutiny from practitioners and academics alike because of their superior strategic management. The result was that academics became exceptionally concerned with explaining their success. To this end, research has been targeted at the unusual ways in which such firms analyze their relationship with their environments, create ways of handling those relationships and do so in a consistent pattern of business behavior (Kay 1993, p. 9). The core of their success is attributed to their delivery of innovations in products or services. Research has shown that producing these innovations is explained by the existence of a set of supporting capabilities. In the case of Honda, its unique record of product innovation worldwide rests on a collection of distinctive capabilities involving: problem solving, project management and working with suppliers (Pascale 1990).

The circumstances, which prompted these exceptional feats of strategic management, have, in turn, become the subject of academic attention. The exploitation of information technology has transformed entire industries. New forms of communication have created totally novel means of acquiring information and purchasing goods or services. Information technology has also led to completely new types of products. The character of sectors, such as retail banking and insurance, has been transformed. The ability of organizations to manage the wholesale reworking of their strategic assumptions and operational methods has become a source of fascination to practitioners and academics alike. Whereas in the 1980s, the emphasis had been on the adjustment of company strategies to new rules of competition, today, the contemporary agenda is dominated by the prospect of companies facing the growth of new products, markets and sectors on a scale not seen since the twentieth century in Europe and the early twentieth century in the USA.

In parallel to these high profile projects on strategic capabilities and transformations, strategy scholars have moved away from their preoccupation with corporations. The result has been an engagement with strategic management within small businesses, voluntary and not-for-profit sectors and professional organizations. These alternative contexts have provided useful tests for established theories. Sometimes the characteristics of these under-researched sites have forced analysts and managers in the corporate sector to review their models. The ability of voluntary organizations (e.g., see *Voluntary Organizations*) to succeed with few resources and yet motivate staff is a case in point (Johnson and Scholes 1993, pp. 23–30).

4. Methods

The strategy field has witnessed the use of an extensive battery of research methods during its comparatively brief existence to-date. In the early phase, the quantitative methods associated with economics became well established. These techniques have continued to play a major role, especially in the measurement of performance and competition. From the 1970s, as the insights from psychology, politics and sociology were used to open up the strategic management process (see Sect. 2), so more qualitative approaches (including ethnography in the study of organizational culture, for example) were employed. The qualitative and quantitative currently co-exist productively (Kaplan and Norton 1996). More contentious is the common reference by strategy writers to individual company examples. Outsiders may confuse teaching cases (usually of a single organization) with full-scale research-based case studies. Nevertheless, popular accounts of corporate success stories and the personal reflections of leading executives which are light on formal research methodologies, have created an impression of superficiality which academics often have to live down.

5. Future Research

Given the youthful nature of the subject, the study of strategy in the future will continue to unravel the problems associated with understanding competitive environments, how they may be matched to the resources of an organization and how the resulting decisions can be implemented. Fresh opportunities for research will appear in the international sphere. This will include not only the continued relevance of global markets and organizations but also the further exploration of national contexts. The differences of the financial and business systems between the USA,

Europe and Japan are well known, detailed comparisons with other parts of Asia or South America await. In addition, the fragmentation of social and economic relations—around, for example, network structures or self-organized commercial ventures—will pose a challenge to a subject which was founded on the problems of large corporations. Other tests will be supplied by links between strategy writers and specialists from other subject areas. Examples include, complexity theory and knowledge management experts from organization studies (e.g., see *Learning: Organizational*). There are also signs that those who are skeptical of the precepts of strategic management will increase their attention. Their assertions that strategy is merely
a specialized form of language which enhances the power in society of management is the opening salvo in what could be a long exchange of intellectual fire power. The response by the strategy experts will demonstrate how far the subject has come of age into its mature form.

Street Children: Cultural Concerns

Since the early 1980s street children have become a focus for attention in the media, an embarrassment to many bureaucrats, and a matter of priority for international agencies and numerous non-governmental organizations. At the same time, challenging academic and practical questions have been raised regarding who 'street children' are and the best strategies for helping them.

1. Definitions and Problematic Categorizations

The term 'street children' came into widespread use following the United Nations *Year of the Child* (1979) when it was adopted by international agencies and promptly translated into many different languages (as *meninos de rua* in Portuguese, *niños de la calle* in Spanish, *enfants de la rue* in French). It arose from attempts to develop a term free of negative connotations about children popularly known as street urchins, vagrants, gaminos, rag-pickers, or glue-sniffers, and historically as street Arabs or vagrants. Utilized in 1951 by UNESCO to refer to vagrant children following World War II, it was applied in 1986 to the developing world by UNICEF, the agency primarily concerned with children's wellbeing, to designate minors who worked or slept on the streets (Williams 1993).

At a most basic level, a street child is 'a homeless or neglected child who lives chiefly in the streets' (*Oxford Dictionary*). Welfare agencies, however, have reworked their definitions many times, encountering enormous problems in devising meaningful statements about street children and making appropriate distinctions between categories of children.

Problems ensued even after the consensual definition formulated in 1983 by the Inter-NGO Programme for Street Children and Street Youth: 'Street children are those for whom the street (in the widest sense of the word that is unoccupied dwellings, wasteland, etc …) more than their family has become their real home, a situation in which there is no protection, supervision or direction from responsible adults' (see Ennew 1994, p. 15). Several terms could lead to confusion: what is meant by 'family,' 'protection,' or 'responsible' adults (Hecht 1998)? Even what is meant by 'home' is conceptualized differently across cultures: being homeless is rendered as *desamparado* (without protection or comfort of other people) in Latin America, *furosha* (floating) in Japan, and *khate* (rag-picker) in Nepal, evoking concepts of disaffiliation, transience, and marginal work rather than notions of residential access or type of abode (Desjarlais 1996).

Several attempts to categorize street children, developed to acknowledge their heterogeneous circumstances and lifestyle, have also proved problematic. In

one typology following UNICEF, 'children *of* the street' have a family accessible to them but have made the streets their home; 'children *on* the street' are child workers who return at night to their families; 'abandoned' children literally have no home to go to, while children 'at high risk' are those likely to be drawn into street-life. Distinctions have also been made between 'abandoned' and 'abandoning' street children (Felsman 1984), and among children according to their degree of family involvement and psychological characteristics. These terminologies have proved difficult to uphold in practice, given the fluidity of children's movements on and off the streets and a lack of correspondance with the ways children themselves relate their experiences. Many labels such as children 'without family contact' and 'abandoned' lacked precision and were used ad hoc rather than analytically. The focus on categories of children, which led to the popular distinction between children *of* and *on* the streets (translated as *de la calle/en la calle* in Spanish, or *de la rue/dans la rue* in French) is falling into disuse.

The term 'street children' is still widely used to highlight a set of working and living conditions rather than to refer to the personal or social characteristics of the children in question. But while street children are identified as those who occupy the public spaces of urban centres and whose activities are largely unsupervised by adults, it has proved important to move beyond definitions based solely on physical, social, and economic criteria.

2. *Statistics and the Creation of a Social Issue*

A great deal of controversy also surrounds the process of enumerating street children. Different agencies issue often widely different estimates, partly because they find street children difficult to count, partly because they are not always talking about the same children. In Brazil alone, the figure of 7 million street children is most often cited, typically with reference to the homeless, although careful surveys suggest a national estimate less than 1 percent of that figure (39,000 in Hecht 1998). The 1991 video 'About the UN Rights of the Child' stated that an estimated 200 million children around the world live on the streets, while another global figure of 100 million street children has also gained credibility. But how are the children counted and who exactly is included? Huge numbers, produced to draw attention to children's plight, rest upon largely elastic and nebulous definitions of homeless and working children; they are usually the result of guesswork and have 'no validity or basis in fact' (Ennew 1994, p. 32).

The same problems of enumeration and group definition beset studies of the homeless in the developed world. The definitions of 'homeless' may shift to include those who sleep rough, live in shelters, squat, or double up with other families, encompassing the literally homeless and the precariously housed (Glasser and Bridgman 1999). Estimates of homeless youth—whether 'runaways,' in care, or with a parent—are often inflated by welfare agencies to legitimate their role, yet minimized by bureaucratic institutions with legal or financial responsibilities; thus statistics reflect the various agendas of organizations which collect them (Hutson and Liddiard 1994). The process of identifying and counting street youths is problematic in itself and it is also a part of the construction and management of homelessness as a social issue.

Notwithstanding their imprecision, estimates can help to identify significant groups and appropriate interventions in different cultural contexts. It is important to know that the great majority of street children in developing countries are not 'homeless' but return at night to their families (they are children *on* the streets). The fact that they are predominantly boys has alerted attention on why local circumstances should differ according to gender. Care is taken to reveal the age distribution between teenage adolescents, those in late childhood, and very young children with families, who may experience different reactions from the public, as well as ethnic distribution. Estimates also help to appreciate changing trends. In the US, the fastest growing subgroup among the homeless are presently young children.

3. *Representations of Street Children*

Several different explanations have been offered to explain the phenomenon of homelessness and the dramatic rise in the numbers of street children. There are, broadly speaking, two major schools of thought: one links homelessness to personal pathology, the other to external structural factors (Glasser and Bridgman 1999). The former focuses on problems such as family dysfunction and substance abuse or mental illness, which increase an individual's risk of taking to the streets. The latter emphasizes broad economic and sociopolitical factors such as poverty and marginalization under conditions of rapid urbanization, rural-to-urban migration, or conflict, which affect the stability of households. Whether linked to biographic or structural factors, street children are often portrayed as victims of deprived environments and helpless with respect to changing circumstances, or else as social deviants (Veale et al. in Panter-Brick and Smith 2000).

The 'characteristics' of street-children—their tenuous links with families and independence from adults—do not conform to commonly held views about what constitutes a 'proper' childhood in contemporary thought. Popular images of street-children—as victims or villains—rest upon particular representations of children and twentieth century discourses about child-

hood that arose among the wealthier classes of the western industrial world (Boyden 1990). The apposition of 'street' and 'children' suggests that street location is a peculiar and significant mark of identity outside the normal frame: 'after all, children can also be found using fields, lofts, and gardens without there being any apparent need to coin terms such as 'field children,' 'loft children,' or 'garden children' (Glauser 1990). Street children upset broad expectations both about the street—a place for commerce, men, and prostitutes—and about childhood—a time for carefree and protected innocence (Hecht 1998). From the modern Western viewpoint, children who are not 'at home' and nurtured by responsible adults are 'forsaken' or 'deviant,' and street children in particular are 'out of place' in society and 'outside childhood' (Connolly and Ennew 1996).

It has been argued that such portrayals are actually unhelpful to the children themselves (Ennew 1994). Many interventions which emphasise a vulnerable and 'lost' childhood have focused on 'rescuing' children from the streets by placing them in institutions or back with a family; this tends to ignore the social networks and coping strategies developed by the children, and generally has failed to provide lasting solutions. The focus of children's activities 'on the street' has also tended to promote unidimensional accounts of their lives; for instance, it is not often realized that children who live on the street commonly attend school and retain contacts with their families (Ennew and Milne 1997). Furthermore, public condemnation of street murders in Latin America has unwittingly reduced children's status to that of hunted prey, which conveys little understanding of the ways in which violence is actually experienced: in Brazil, while harassment at the hands of police is ubiquitous and extermination or torture not uncommon, street children are far more likely to die at the hand of their peers than as victims of death squads (Hecht 1998).

4. *Child-centered Perspectives and Research Issues*

In the late 1990s fundamental assumptions about children and appropriate methods of research began to be re-evaluated, in the context of international legislation of children's 'best interests' (see *Children, Rights of: Cultural Concerns*) and the development of participatory methodology (Ennew and Milne 1997). The realization was made in social science research that children are not helpless or passive, but capable of making informed decisions about the future, and that they express views and aspirations that may well differ from those of adults. Child-centered perspectives and participatory research methods have emphasized the need to recognize the agency and social competence of street children and to enhance their participation. The key to research and project planning has changed to working 'with' children rather than 'for' them: 'they are not 'objects of concern' but people. They are vulnerable, but not incapable. They need respect, not pity' (Ennew 1994, p. 35). Remedial action in the best interests of children—as stressed by the United Nations Convention of the Rights of the Child—is not a matter of rescuing children, but of listening to them, and of fostering child participation.

A range of participatory approaches have been attempted, such as having street youths to conduct actual research, encouraging children to represent their world through drawings or plays, and staging workshops or group discussions on topics selected by the children themselves. These methods, more appropriate than the ubiquitous questionnaire survey, aim to involve the children in the research process rather than simply gather information or anecdotal testimonies. They have the potential to generate more valid data on children's lives but raise their own set of ethical questions.

Two significant research problems have been the lack of comparative information on peer groups within the same country and a failure to evaluate longitudinally the 'career' outcomes of street children (see Baker and Panter-Brick in Panter-Brick and Smith 2000). The tendency has been to focus on snap shot descriptions of street children with little time-depth or contextual information. Street children live complex and varied lifestyles—they may move home and back to the street, go to school, or work at times for an employer. Few street children remain on the street into adulthood, although the range of outcomes is enormously variable and shaped by cultural context. While prison, insanity, or death are the common expectations of Brazilian street children, stable employment, marriage, and children are achievable career paths for Nepali street children.

Comparative and longitudinal research is critical, but not easily achieved. For instance, it is easy to contend that homelessness endangers children's physical and emotional health, and indeed most studies of the homeless in the West and of street children in developing countries have emphasized the debilitating and deprived aspects of street-life. Recently, however, a number of comparative studies have questioned the expectation that homeless children should be the most vulnerable in deprived environments, arguing that poverty, not homelessness *per se*, may carry the most significant risks for health and behavior outcomes (Ziesemer et al. 1994, Bassuk et al. 1997, Veale et al. in Panter-Brick and Smith 2000). It is also recognized that the public discourse on street children has detracted from the issue of widespread poverty and violence affecting children who live at home.

The issues of violence, perpetrated by both adults and other street children, of substance abuse, of sexual exploitation, and sexually transmitted diseases, are often raised but among those most difficult to research.

The nature of appropriate interventions designed to enhance children's own coping strategies, such as social networks with street peers and resourcefulness in obtaining money, have also been discussed extensively. A compilation of studies across different continents and topics of research are found in Mermet (1997), Ennew and Milne (1997), and dedicated web sites.

5. *Conclusion*

Studies of street children and research on homelessness were first concerned with describing lifestyle situations in terms of the uses of public spaces and the links with family or institutions, hinging various categories of street life upon the constructs of home, family, and a proper childhood. Twenty years on, such research is concerned with identifying the subjective and cultural interpretations of homelessness (Desjarlais 1996), with considering explicitly the context of poverty and social exclusion (Mingione 1999), and with seeking to follow career paths and identify what transitions are possible from one situation to another. At the international level, advocacy for children is less focused on the 'street' as it is on abusive work situations, sexual exploitation, or criminality, and with promoting responses that are consistent with children's rights (Ennew 1995, Bartlett et al. 1999).

Street Children: Psychological Perspectives

The United Nations defined street children as 'any boy or girl … for whom the street (in the widest sense of the word, including unoccupied dwellings, wasteland, etc.) has become his or her habitual abode and/or source of livelihood; and who is inadequately protected, supervised, or directed by responsible adults' (quoted in Lusk 1992 p. 294). The definition of street children plays a pivotal role in research and may be a source of disagreement about the results of studies (Koller and Hutz 1996). Children and adolescents who look like drifters (wear shabby, dirty clothing, beg for food or money, sell small objects, work, or wander without a purpose on the streets) can be found in large cities all over the world. The appearance of abandonment singles them out as belonging to the same group. However, their life histories, family character-

istics, street life experiences, and prognoses are very different (Dallape 1996). Some researchers define street children based on characteristics such as sleeping location, family ties, school attendance, leisure, survival activities, occupation on the street environment, etc. Such definitions can lead to broad categorizations as: *children of the streets or children in the streets* (e.g., Barker and Knaul 1991, Campos et al. 1994, Forster et al. 1992).

Children *of* the streets would be those who actually live on the street, all day and at night, who do not attend school, and do not have stable family ties. They fulfill their needs and are socialized on the streets. In contrast, children *in* the streets would be those who live with their families, may attend school, but spend all or part of their days on the streets, trying to earn money for themselves or their families (Hutz and Koller 1999). The relationship with the family has been considered as a key feature of the definition of street children. Felsman (1985) identified three groups of street children in Colombia: (a) orphaned or abandoned children, (b) runaways, and (c) children with family ties. Leisure and occupation on the streets were added to family ties in Martins' work (1996) to identify three different groups of street children in Brazil. He found a group of children with stable family ties who worked on the streets and went home every night. These children played in their neighborhood or on the streets where they worked and many attended school. A second group had unstable family ties. Although they lived on the streets, these children knew their families and, occasionally, went home to visit or even to stay for a while. Finally, there was a group of children who were on their own on the streets and who had lost all contact with their family.

Nevertheless, it is difficult and it may even be misleading, to define a child as belonging to a specific category. Hutz and Koller (1999) claimed that in their research they rarely found children who had completely lost contact with their family. They also identified many children who lived at home and worked on the streets, but occasionally slept on the street, and children who periodically left home and lived on the streets for weeks or months, and then went back home. The variability within these groups regarding the frequency of family contact, sleeping location, occupation on the streets, the destination for the money they earn, school attendance, and several other variables (including physical and sexual abuse, sexual activity, etc.) may be so large that the distinction between the *of the street group* and the *in the street group* may be meaningless or even misleading for research or intervention purposes. These authors suggested that it would be more appropriate to categorize street children as a function of the risks to which they are exposed (e.g., contact with gangs, use of drugs, dropping out of school, lack of proper parental guidance, prostitution, etc.) and the protective factors available to them (e.g., school attendance, supportive social networks, contact with caring adults, etc.). Researchers could then determine how vulnerable children are to developmental risk and what appropriate actions could be taken in each specific case.

1. *Developmental Implications*

Children living on the streets are still children undergoing development, despite their life conditions. They experience risks and challenges that, at the same time, may jeopardize their development and promote the acquisition of strategies for dealing with life on the streets. There is some evidence that economical pressures and emotional disturbances in the family expose children to larger risks than do the conditions of the street (Hecht 1998, Hutz and Koller 1997, Matchinda 1999). Street children often face larger risks than children in general because they are exposed to negative physical, social, and emotional factors at home and still have to deal with the challenges of life on the streets. On the other hand, there is evidence that the conditions of life on the streets lead to the development of coping strategies that are adaptive and that may help to strengthen their cognitive and social skills.

2. *Social Development*

Street children are usually targets of social rejection and discrimination. They have to develop their social identity and sense of belonging to a society that views them either as victims, who deserve pitying, or as criminals who must be taken off the streets and locked in jail. On the one hand, they are seen as victims, because they do not have shelter, clothes, food, or adult protection, have to work on the streets instead of going to school, are sexually exploited, and so on. On the other hand, they are perceived also as transgressors because they often use drugs, commit robbery, make noise, and are grouped in threatening gangs. The adult environment is usually very hostile to street children. The police aggress them often, causing physical harm and humiliation. They are also harassed by street adults and gangs, which fight for space and better survival conditions.

An effective strategy to survive and develop in such a hostile environment is to belong to a group on the streets. Therefore, street children will often join gangs and develop different kinds of peer relationships that leads to the development of *emotional groups* (appropriate to spend the night and to have fun together) and *business groups* (organized to dodge street life risks and fulfill their survival needs). Another strategy consists of going to social institutions for food and shelter. However, such institutions often fail to help

them effectively, because they aim at taking the children off the streets, whereas the children seek them, because they perceive the institutions as part of street life, and not as a way out of it (Hecht 1998).

3. Emotional Development

Aptekar (1989, 1996) stated that street children are mentally healthier than their siblings who stayed at home. Koller and Hutz (1996) observed that these children have the ability to reorganize their lives on the streets, in spite of their risky conditions and their life histories. Most of them left home because their parents failed to provide a safe, nurturing, and affective environment. Many children also report sexual or physical abuse, drug use at home, and economic exploitation as reasons for leaving home (Raffaelli et al. 1995).

Some evidence presented by DeSouza and collaborators (DeSouza et al. 1995) indicated that street children were not in greater psychological distress than children of a low social economic status who lived with their families. Koller et al. (1996) investigated subjective wellbeing of street children and of children who lived in deep poverty and their findings also did not show significant differences between these groups.

4. Physical Development

Life on the streets represents a constant source of risk to children and adolescents. Their safety and survival demand energy and coping strategies to confront the daily risks. Conflicts between gangs, police harassment, and adult street dwellers physical abuse are some examples of daily violence that street children have to deal with successfully to stay safe. Cold weather, lack of food and shelter, traffic accidents, untreated injuries and illnesses, exposure to drugs and unprotected sexual activities are also important risks to their health and physical integrity (Donald and Swart-Kruger 1994, Hecht 1998).

Street children must develop adaptive strategies to survive and stay safe in spite of those risks. As previously mentioned, they form groups (emotional and business groups) that protect them from street violence and help them to survive. Also, often they find shelter and food in institutions that have rules that must be obeyed. They learn to cope with such rules, even when they do not agree with them, but their behavior becomes opportunistic and often ingenious (Donald and Swart-Kruger 1994).

5. Cognitive Development

Most street children, even those who go to school, are illiterate and have negative school experiences. Their attention span, memory, and cognitive development in general may be affected by malnutrition, drug use and intoxication, untreated illnesses, and accidental injuries. Often, they have difficulty adapting to the formal school system because it requires discipline, attention to specific tasks and schedules, planning ahead, and other routines with which they cannot deal effectively. Language, critical thinking, and intelligence also develop more slowly and may present significant deficits because street children interact mostly with their peers and have very little contact with adults. In fact, some researchers have noted that street children find it rewarding to talk to adults who will listen and speak with them in a friendly manner (Hutz and Koller 1999). Middle-class children, as a rule, are exposed daily to caring adults who talk to them, tell them stories, listen to their tales, and spend time interacting with them. Street children do not have this experience.

Spatial skills and very well developed visual and auditory discrimination, for example, are required to detect, avoid, and escape street risks. Carraher et al. (1985) noted that street children who worked at the market were very capable of dealing with money and doing sophisticated calculations to figure out the price or value of products (although they failed when presented with standard school math problems). Aptekar (1989) also referred to what he calls *street knowledge* as an important skill for social interaction.

6. Conclusion

Children living on the streets are a social problem in many countries, a problem that has to be fought by all means available. To fight this social ill requires that individuals and groups in society take the social and political responsibility to develop effective prevention and intervention projects. Children on the streets are vulnerable to risks but they manage to develop 'coping strategies' that often make them resilient (Hutz et al. 1996). They behave as children when they play or interact with peers on the streets. But, they must also act as adults when they have to provide for their subsistence and safety. In spite of their circumstances, street children are still developing persons that require appropriate health care, education, a nurturing home, safety, and human rights in order to grow with dignity and to become adjusted and productive citizens.

Stress and Cardiac Response

The origin of the concept of stress in health-related disciplines is closely linked to the idea that organisms react physiologically to the presence of danger or threat. This reactivity has a protective function since it provides the logistic and instrumental basis for adaptive behaviors such as fight or flight. However, if maintained for long periods, this protective or defensive reactivity may become a health risk, compromising the normal functioning of the organs involved. For many scientists the excessive physiological reactivity associated with stress is the main mechanism linking stress to illness.

1. *Cardiac Response*

The heart is a vital organ that reacts rapidly to physical and psychological demands. This reactivity is controlled by the central nervous system through neural and humoral pathways.

1.1 *Neural Pathways*

The neural pathway to the heart involves the two branches of the autonomic nervous system: the sympathetic and the parasympathetic. When the sympathetic nerves are activated, the heart rate accelerates and the heart contraction becomes stronger, resulting in a greater blood volume discharge and greater blood pressure in the vessels. When the parasympathetic nerves are activated, the heart rate decelerates, reducing the blood volume discharge and the blood pressure. The two branches can act reciprocally (one activated and the other inhibited), working in the same direction (increasing or decreasing the heart activity), or nonreciprocally (both activated or inhibited simultaneously), competing against each other for the final cardiac outcome.

1.2 *Humoral Pathways*

The humoral pathway involves the neural activation of the endocrine system, resulting in the secretion by

the adrenal glands of various hormones into the bloodstream. One of these hormones, adrenaline, when it reaches the heart, has the same effect as the sympathetic nerves: it increases the heart rate and the stroke volume. Other adrenal hormones, such as cortisol, facilitate the transfer of lipids and glucose into the bloodstream and also have an important indirect effect on the heart and on the arteries that supply blood to the heart muscle: the coronaries. The humoral effects on the heart are slower than the neural effects but they last longer, contributing to maintaining cardiac reactivity during prolonged periods.

1.3 Cardiac–Respiratory Interactions

The cardiovascular and the respiratory systems are both responsible for maintaining the continuous exchange of gases, oxygen and carbon dioxide, between the atmosphere and the tissues. The cardiovascular system reacts to changes in the concentration of these gases in the blood. Therefore, changes in the respiratory pattern which induce changes in gas concentration produce changes in the blood flow and cardiac activity in order to restore the appropriate gas concentration. Two examples of cardiac reactivity due to changes in respiration are the *hyperventilation* and *respiratory sinus arrhythmia* phenomena.

1.3.1 Hyperventilation. Hyperventilation is caused by rapid respiratory patterns provoking reduced carbon dioxide concentration in the blood. The cardiovascular response is a reduced blood flow to the brain and heart arteries, and an increase in cardiac activity due to parasympathetic inhibition.

1.3.2 Respiratory sinus arrhythmia. In contrast, respiratory sinus arrhythmia is caused by slow and relaxed respiratory patterns. The consequence is a rhythmic deceleration of the heart rate, due to parasympathetic activation, coinciding with each expiratory cycle.

2. Stress and Cardiac Defense

Cardiac defense can be defined as the cardiac response to perceived danger or threat. The concept of defense has a long tradition in physiology and psychology and it is in this context that the concept of stress was first introduced (see *Stress and Coping Theories*).

2.1 Historical Antecedents

At the beginning of the twentieth century, Ivan Pavlov and other Russian reflexologists used the term defense reflex to refer to protective physiological responses elicited by noxious stimulation, such as hand withdrawal from an electric shock, eyeblink to a puff of air, or vomit to bad food. A few years later, Walter Cannon used the term defense to refer to the 'fight or flight' response, a sympathetically mediated cardiovascular response to emergency situations aimed at providing energy supply to the body to facilitate adaptive behaviors such as attack (fight) or escape (flight). By the middle of the century and following Cannon's ideas, Hans Selye had introduced the concept of stress and used the term 'alarm' response to refer to the first stage of the physiological response to stressful situations.

2.2 Classical Approaches to Cardiac Defense

There have been two major approaches to the study of cardiac defense: (a) the cognitive or sensory processing approach built on Pavlov's distinction between orienting and defense reflexes, and (b) the motivational or emotional approach built on Cannon's ideas on the fight or flight response.

2.2.1 The cognitive approach. The cognitive approach assumes that cardiac changes to environmental stimuli reflect attentional and perceptual mechanisms aimed at facilitating or inhibiting the processing of the stimuli (Sokolov 1963, Graham 1979). The orienting response (a deceleration of the heart rate to moderate or novel stimulation) facilitates attention and perception of the stimuli, whereas the defense response (an acceleration of the heart rate to intense or aversive stimulation) reduces attention and perception as a form of protection against the stimuli. To study cardiac defense, this approach has developed tasks that present discrete sensory stimuli, such as noise, light, pictures, or words, manipulating their physical features—intensity, duration, and rise time—or their affective content—pleasant vs. unpleasant pictures or words. According to this approach, cardiac defense is characterized by a heart-rate accelerative response, peaking between 3 and 6 s after stimulus onset, which habituates slowly with stimulus repetition.

2.2.2 The motivational approach. The motivational approach assumes that cardiac changes in response to environmental demands reflect metabolic mechanisms aimed at providing the necessary energy to the body to support behavioral adjustments (Obrist 1981). If the appropriate behavior is to be quiet and relaxed, then the cardiac response will be a heart-rate deceleration. If the appropriate behavior is to be active, either physically or psychologically, then the cardiac response will be a heart-rate acceleration.

To study cardiac defense, this approach has developed tasks that involve emotionally or cognitively challenging situations maintained throughout several minutes, such as keeping the hand in cold water, pressing a key as fast as possible to avoid shocks, or doing complex arithmetic tasks. The term 'mental stress' was introduced in this context to refer to tasks that require 'mental effort' instead of 'physical effort.' Under such conditions cardiac defense is characterized by a heart-rate acceleration maintained during the task duration, accompanied by reduced cardiac variability linked to hyperventilation and loss of respiratory sinus arrythmia.

3. *A New Approach to Cardiac Defense*

The cognitive and motivational approaches to cardiac defense have been difficult to reconcile in the past. However, new data have been accumulated on defense responses, both in animals and humans, and on the neurophysiological brain circuits controlling such responses, which not only facilitate integration of the classic approaches but also have potential implications for the concept of stress and its relation to cardiovascular illness.

3.1 *Natural Defense*

In natural settings, such as the imminence of a predator, the defense reaction is not a unique response that could be conceptualized as cognitive vs. motivational, or vice versa. Rather, the defense reaction follows a dynamic sequential process with initial phases in which attentional factors predominate, aimed at the detection and analysis of the potential danger, and if the process continues, later phases in which behavioral factors predominate, aimed at active defense such as fight or flight. This sequential process can be divided into three stages: pre-encounter, post-encounter, and circa strike. Depending on the spatial and temporal proximity of the predator, different components of the defense reaction may take place successively.

3.2 *Protective Reflexes*

Motor startle and cardiac defense are two protective reflexes that have been extensively studied in recent years in relation to both cognitive and emotional modulatory factors. Startle is a whole-body motor flexor response, including an eyeblink that is elicited by abrupt stimulation such as a brief, intense noise or light. Startle is augmented when the organism is in an aversive emotional state and inhibited when the organism is in a positive emotional state. Similarly, startle is potentiated in the first stages of the natural defense reaction when attentional factors predominate, and inhibited during the later phases when behavioral factors predominate (Lang 1995).

Figure 1
Cardiac defense response to an intense noise of half a second duration. The horizontal axis represents 80 s after noise onset. The vertical axis represents the cardiac changes in beats per minute (bpm) from the baseline

On the other hand, studies on the cardiac components of the defense response to unexpected noises or shocks have questioned the classical models on response characteristics and their functional significance (Vila 1995, Vila et al. 1997). The cardiac response to an unexpected noise is not only a heart-rate acceleration. The response is a complex pattern of heart-rate changes, observed throughout the 80 s after stimulus onset, with two large accelerative and two smaller decelerative components in alternating order (see Fig. 1). The evocation of the response has both parasympathetic (first acceleration and deceleration) and sympathetic (second acceleration and deceleration) influences. As regards its psychological significance, contrary to the classical cognitive model, cardiac defense is accompanied by an increase in sensory processing (sensory intake). On the other hand, emotional factors are also involved, producing similar modulatory effects as in motor startle. For example, phobic subjects presented with aversive noise while viewing pictures of their phobic object show a clear augmentation of the two accelerative components of the response.

3.3 *The Brain's Defense System*

The above data support a description and interpretation of cardiac defense as a sequence of heart-rate changes with both accelerative and decelerative components, with both parasympathetic and sympathetic

influences, and with both cognitive (attentional) and emotional (energetic) significance. The structural foundation of this response is in the brain's aversive motive system. What is known about this system comes from animal research, particularly from studies on defense reactions and fear conditioning (see LeDoux 1996 and Lang et al. 1997 for a comprehensive review). Neuroscientists have traced the chain of neural activation in the brain, starting from the sensory input, proceeding through the subcortical and cortical connecting structures, and finishing in the autonomic and motor effectors. A critical structure in this circuit is the amygdala, a subcortical center located within the temporal lobes that receives inputs from the sensory thalamus and various cortical structures. Downstream from the amygdala, the defense circuit branches into different structures, controlling separate forms of defense. This hierarchical organization, together with the learned plasticity in the anatomy and functioning of the brain's structures, provides considerably variety in the pattern of defensive output. Depending on the situational context and on the weight of the local pathways within the circuit, the aversively motivated responses can be escape or avoidance, aggressive behavior, hormonal and autonomic responses, or the augmentation of motor startle.

4. *Conclusions: Implications for Stress and Cardiovascular Disease*

The classical models of defense did not emphasize the dynamic character of the defense response—obvious in natural settings—and the simultaneous involvement of different psychological processes—cognitive and motivational. The new model matches better the prevalent model of stress in health-related disciplines: the cognitive-transactional model (see *Stress and Coping Theories*). The continuous dynamic interaction between the situation and the person, leading to activation or deactivation of the stress response, is the main feature of the transactional model. In addition, the new approach to defense can help to understand the specific nature of stress, differentiating it from other related concepts such as anxiety or arousal. Based on the new defense model, stress can be defined as the sustained activation of the brain's defense motivational system. A state of maintained activation of this system implies a variety of specific defense responses being continuously elicited, including neural and humoral cardiovascular responses that correlate with poor cardiovascular health: maintained increases in heart rate, stroke volume and blood pressure, and maintained decreases in respiratory sinus arrhythmia and cardiac variability. These sustained responses are instrumental for the development of cardiovascular diseases such as essential hypertension and coronary heart disease.

Stress and Coping Theories

For the last five decades the term stress has enjoyed increasing popularity in the behavioral and health sciences. It first was used in physics in order to analyze the problem of how man-made structures must be designed to carry heavy loads and resist deformation by external focus. In this analysis, stress referred to external pressure or force applied to a structure, while strain denoted the resulting internal distortion of the object (for the term's history, cf. Hinkle 1974, Mason 1975a, 1975c). In the transition from physics to the behavioral sciences, the usage of the term stress changed. In most approaches it now designates bodily processes created by circumstances that place physical or psychological demands on an individual (Selye 1976). The external forces that impinge on the body are called stressors (McGrath 1982).

1. *Theories of Stress*

Theories that focus on the specific relationship between external demands (stressors) and bodily processes (stress) can be grouped in two different categories:

approaches to 'systemic stress' based in physiology and psychobiology (among others, Selye 1976) and approaches to 'psychological stress' developed within the field of cognitive psychology (Lazarus 1966, 1991, Lazarus and Folkman 1984, McGrath 1982).

1.1 Systemic Stress: Selye's Theory

The popularity of the stress concept in science and mass media stems largely from the work of the endocrinologist Hans Selye. In a series of animal studies he observed that a variety of stimulus events (e.g., heat, cold, toxic agents) applied intensely and long enough are capable of producing common effects, meaning not specific to either stimulus event. (Besides these nonspecific changes in the body, each stimulus produces, of course, its specific effect, heat, for example, produces vasodilatation, and cold vasoconstriction.) According to Selye, these *nonspecifically caused changes* constitute the stereotypical, i.e., *specific*, response pattern of systemic stress. Selye (1976, p. 64) defines this stress as 'a state manifested by a syndrome which consists of all the nonspecifically induced changes in a biologic system.'

This stereotypical response pattern, called the 'General Adaptation Syndrome' (GAS), proceeds in three stages. (a) The *alarm reaction* comprises an initial shock phase and a subsequent countershock phase. The shock phase exhibits autonomic excitability, an increased adrenaline discharge, and gastro-intestinal ulcerations. The countershock phase marks the initial operation of defensive processes and is characterized by increased adrenocortical activity. (b) If noxious stimulation continues, the organism enters the *stage of resistance*. In this stage, the symptoms of the alarm reaction disappear, which seemingly indicates the organism's adaptation to the stressor. However, while resistance to the noxious stimulation increases, resistance to other kinds of stressors decreases at the same time. (c) If the aversive stimulation persists, resistance gives way to the *stage of exhaustion*. The organism's capability of adapting to the stressor is exhausted, the symptoms of stage (a) reappear, but resistance is no longer possible. Irreversible tissue damages appear, and, if the stimulation persists, the organism dies.

Although Selye's work influenced a whole generation of stress researchers, marked weaknesses in his theory soon became obvious. First of all, Selye's conception of stress as a reaction to a multitude of different events had the fatal consequence that the stress concept became the melting pot for all kinds of approaches. Thus, by becoming a synonym for diverse terms such as, for example, anxiety, threat, conflict, or emotional arousal, the concept of stress was in danger of losing its scientific value (cf. Engel 1985). Besides this general reservation, specific critical issues have been raised. One criticism was directed at the theory's core assumption of a nonspecific causation of the GAS. Mason (1971, 1975b) pointed out that the stressors observed as effective by Selye carried a common emotional meaning: they were novel, strange, and unfamiliar to the animal. Thus, the animal's state could be described in terms of helplessness, uncertainty, and lack of control. Consequently, the hormonal GAS responses followed the (specific) emotional impact of such influences rather than the influences as such. In accordance with this assumption, Mason (1975b) demonstrated that in experiments where uncertainty had been eliminated no GAS was observed. This criticism lead to a second, more profound argument: unlike the physiological stress investigated by Selye, the stress experienced by humans is almost always the result of a cognitive mediation (cf. Arnold 1960, Janis 1958, Lazarus 1966, 1974). Selye, however, fails to specify those mechanisms that may explain the *cognitive transformation* of 'objective' noxious events into the subjective experience of being distressed. In addition, Selye does not take into account *coping mechanisms* as important mediators of the stress–outcome relationship. Both topics are central to psychological stress theories as, for example, elaborated by the Lazarus group.

A derivative of the systemic approach is the research on *critical life events*. An example is the influential hypothesis of Holmes and Rahe (1967), based on Selye's work, that changes in habits, rather than the threat or meaning of critical events, is involved in the genesis of disease. The authors assumed that critical life events, regardless of their specific (e.g., positive or negative) quality, stimulate change that produces challenge to the organism. Most of this research, however, has not been theoretically driven and exhibited little empirical support for this hypothesis (for a critical evaluation, see Thoits 1983).

1.2 Psychological Stress: The Lazarus Theory

Two concepts are central to any psychological stress theory: *appraisal*, i.e., individuals' evaluation of the significance of what is happening for their well-being, and *coping*, i.e., individuals' efforts in thought and action to manage specific demands (cf. Lazarus 1993).

Since its first presentation as a comprehensive theory (Lazarus 1966), the Lazarus stress theory has undergone several essential revisions (cf. Lazarus 1991, Lazarus and Folkman 1984, Lazarus and Launier 1978). In the latest version (see Lazarus 1991), stress is regarded as a *relational* concept, i.e., stress is not defined as a specific kind of external stimulation nor a specific pattern of physiological, behavioral, or subjective reactions. Instead, stress is viewed as a relationship ('transaction') between individuals and their environment. 'Psychological stress refers to a relationship with the environment that the person appraises as significant for his or her well being

and in which the demands tax or exceed available coping resources' (Lazarus and Folkman 1986, p. 63). This definition points to two processes as central mediators within the person–environment transaction: *cognitive appraisal* and *coping*.

The concept of *appraisal*, introduced into emotion research by Arnold (1960) and elaborated with respect to stress processes by Lazarus (1966, Lazarus and Launier 1978), is a key factor for understanding stress-relevant transactions. This concept is based on the idea that emotional processes (including stress) are dependent on actual expectancies that persons manifest with regard to the significance and outcome of a specific encounter. This concept is necessary to explain individual differences in quality, intensity, and duration of an elicited emotion in environments that are objectively equal for different individuals. It is generally assumed that the resulting state is generated, maintained, and eventually altered by a specific pattern of appraisals. These appraisals, in turn, are determined by a number of personal and situational factors. The most important factors on the personal side are motivational dispositions, goals, values, and generalized expectancies. Relevant situational parameters are predictability, controllability, and imminence of a potentially stressful event.

In his monograph on emotion and adaptation, Lazarus (1991) developed a comprehensive emotion theory that also includes a stress theory (cf. Lazarus 1993). This theory distinguishes two basic forms of appraisal, primary and secondary appraisal (see also Lazarus 1966). These forms rely on different sources of information. Primary appraisal concerns whether something of relevance to the individual's well being occurs, whereas secondary appraisal concerns coping options.

Within *primary appraisal*, three components are distinguished: *goal relevance* describes the extent to which an encounter refers to issues about which the person cares. *Goal congruence* defines the extent to which an episode proceeds in accordance with personal goals. *Type of ego-involvement* designates aspects of personal commitment such as self-esteem, moral values, ego-ideal, or ego-identity. Likewise, three *secondary appraisal* components are distinguished: *blame or credit* results from an individual's appraisal of who is responsible for a certain event. By *coping potential* Lazarus means a person's evaluation of the prospects for generating certain behavioral or cognitive operations that will positively influence a personally relevant encounter. *Future expectations* refer to the appraisal of the further course of an encounter with respect to goal congruence or incongruence.

Specific patterns of primary and secondary appraisal lead to different kinds of stress. Three types are distinguished: harm, threat, and challenge (Lazarus and Folkman 1984). *Harm* refers to the (psychological) damage or loss that has already happened. *Threat* is the anticipation of harm that may be imminent. *Challenge* results from demands that a person feels confident about mastering. These different kinds of psychological stress are embedded in specific types of emotional reactions, thus illustrating the close conjunction of the fields of stress and emotions.

Lazarus (1991) distinguishes 15 basic emotions. Nine of these are negative (anger, fright, anxiety, guilt, shame, sadness, envy, jealousy, and disgust), whereas four are positive (happiness, pride, relief, and love). (Two more emotions, hope and compassion, have a mixed valence.) At a molecular level of analysis, the anxiety reaction, for example, is based on the following pattern of primary and secondary appraisals: there must be some goal relevance to the encounter. Furthermore, goal incongruence is high, i.e., personal goals are thwarted. Finally, ego-involvement concentrates on the protection of personal meaning or ego-identity against existential threats. At a more molar level, specific appraisal patterns related to stress or distinct emotional reactions are described as *core relational themes*. The theme of anxiety, for example, is the confrontation with uncertainty and existential threat. The core relational theme of relief, however, is 'a distressing goal-incongruent condition that has changed for the better or gone away' (Lazarus 1991).

Coping is intimately related to the concept of cognitive appraisal and, hence, to the stress-relevant person-environment transactions. Most approaches in coping research follow Folkman and Lazarus (1980, p. 223), who define coping as 'the cognitive and behavioral efforts made to master, tolerate, or reduce external and internal demands and conflicts among them.'

This definition contains the following implications. (a) Coping actions are not classified according to their effects (e.g., as reality-distorting), but according to certain characteristics of the coping process. (b) This process encompasses behavioral as well as cognitive reactions in the individual. (c) In most cases, coping consists of different single acts and is organized sequentially, forming a coping *episode*. In this sense, coping is often characterized by the simultaneous occurrence of different action sequences and, hence, an interconnection of coping episodes. (d) Coping actions can be distinguished by their focus on different elements of a stressful encounter (cf. Lazarus and Folkman 1984). They can attempt to change the person–environment realities behind negative emotions or stress (*problem-focused coping*). They can also relate to internal elements and try to reduce a negative emotional state, or change the appraisal of the demanding situation (*emotion-focused coping*).

1.3 Resource Theories of Stress: A Bridge between Systemic and Cognitive Viewpoints

Unlike approaches discussed so far, resource theories of stress are not primarily concerned with factors that

create stress, but with resources that preserve well being in the face of stressful encounters. Several social and personal constructs have been proposed, such as *social support* (Schwarzer and Leppin 1991), *sense of coherence* (Antonovsky 1979), *hardiness* (Kobasa 1979), *self-efficacy* (Bandura 1977), or *optimism* (Scheier and Carver 1992). Whereas self-efficacy and optimism are single protective factors, hardiness and sense of coherence represent tripartite approaches. Hardiness is an amalgam of three components: internal control, commitment, and a sense of challenge as opposed to threat. Similarly, sense of coherence consists of believing that the world is meaningful, predictable, and basically benevolent. Within the social support field, several types have been investigated, such as instrumental, informational, appraisal, and emotional support.

The recently offered conservation of resources (COR) theory (Hobfoll 1989, Hobfoll et al. 1996) assumes that stress occurs in any of three contexts: when people experience loss of resources, when resources are threatened, or when people invest their resources without subsequent gain. Four categories of resources are proposed: object resources (i.e., physical objects such as home, clothing, or access to transportation), condition resources (e.g., employment, personal relationships), personal resources (e.g., skills or self-efficacy), and energy resources (means that facilitate the attainment of other resources, for example, money, credit, or knowledge).

Hobfoll and co-workers outlined a number of testable hypotheses (called principles) derived from basic assumptions of COR (cf. Hobfoll et al. 1996).

(a) Loss of resources is the primary source of stress. This principle contradicts the fundamental assumption of approaches on critical life events (cf. Holmes and Rahe 1967) that stress occurs whenever individuals are forced to readjust themselves to situational circumstances, may these circumstances be positive (e.g., marriage) or negative (e.g., loss of a beloved person). In an empirical test of this basic principle, Hobfoll and Lilly (1993) found that only loss of resources was related to distress.

(b) Resources act to preserve and protect other resources. Self-esteem is an important resource that may be beneficial for other resources. Hobfoll and Leiberman (1987), for example, observed that women who were high in self-esteem made good use of social support when confronted with stress, whereas those who lacked self-esteem interpreted social support as an indication of personal inadequacy and, consequently, misused support.

(c) Following stressful circumstances, individuals have an increasingly depleted resource pool to combat further stress. This depletion impairs individuals' capability of coping with further stress, thus resulting in a loss spiral. This process view of resource investment requires to focus on how the interplay between resources and situational demands changes over time as stressor sequences unfold. In addition, this principle shows that it is important to investigate not only the effect of resources on outcome, but also of outcome on resources.

2. Coping Theories

2.1 Classification of Approaches

The Lazarus model outlined above represents a specific type of coping theory. These theories may be classified according to two independent parameters: (a) trait-oriented versus state-oriented, and (b) microanalytic versus macroanalytic approaches (cf. Krohne 1996). Trait-oriented and state-oriented research strategies have different objectives: The *trait-oriented* (or dispositional) strategy aims at early identification of individuals whose coping resources and tendencies are inadequate for the demands of a specific stressful encounter. An early identification of these persons will offer the opportunity for establishing a selection (or placement) procedure or a successful primary prevention program. Research that is *state-oriented*, i.e., which centers around actual coping, has a more general objective. This research investigates the relationships between coping strategies employed by an individual and outcome variables such as self-reported or objectively registered coping efficiency, emotional reactions accompanying and following certain coping efforts, or variables of adaptational outcome (e.g., health status or test performance). This research strategy intends to lay the foundation for a general modificatory program to improve coping efficacy. *Microanalytic* approaches focus on a large number of specific coping strategies, whereas *macroanalytic* analysis operates at a higher level of abstraction, thus concentrating on more fundamental constructs.

S. Freud's (1926) 'classic' defense mechanisms conception is an example of a *state-oriented*, *macroanalytic* approach. Although Freud distinguished a multitude of defense mechanisms, in the end, he related these mechanisms to two basic forms: repression and intellectualization (see also A. Freud 1936). The *trait-oriented* correspondence of these basic defenses is the personality dimension repression–sensitization (Byrne 1964, Eriksen 1966). The distinction of the two basic functions of emotion-focused and problem-focused coping proposed by Lazarus and Folkman (1984) represents another macroanalytic state approach. In its actual research strategy, however, the Lazarus group extended this macroanalytic approach to a *microanalytic* strategy. In their 'Ways of Coping Questionnaire' (WOCQ; cf. Folkman and Lazarus 1988, Lazarus 1991), Lazarus and co-workers distinguish eight groups of coping strategies: confrontative coping, distancing, self-controlling, seeking social support, accepting responsibility, escape-avoidance,

planful problem-solving, and positive reappraisal. The problem with this conception and, as a consequence, the measurement of coping is that these categories are only loosely related to the two basic coping functions.

Unlike the *macroanalytic*, *trait-oriented* approach that generated a multitude of theoretical conceptions, the *microanalytic*, *trait-oriented* strategy is mostly concerned with constructing multidimensional inventories (overviews in Schwarzer and Schwarzer 1996). Almost all of these measurement approaches, however, lack a solid theoretical foundation (cf. Krohne 1996).

2.2 Macroanalytic, Trait-Oriented Coping Theories

Research on the processes by which individuals cope with stressful situations has grown substantially over the past three decades (cf. Lazarus 1991, Zeidner and Endler 1996). Many trait-oriented approaches in this field have established two constructs central to an understanding of cognitive responses to stress: *vigilance*, that is, the orientation toward stressful aspects of an encounter, and *cognitive avoidance*, that is, averting attention from stress-related information (cf. Janis 1983, Krohne 1978, 1993, Roth and Cohen 1986). Approaches corresponding to these conceptions are repression–sensitization (Byrne 1964), monitoring-blunting (Miller 1980, 1987), or attention-rejection (Mullen and Suls 1982). With regard to the relationship between these two constructs, Byrne's approach specifies a unidimensional, bipolar structure, while Miller as well as Mullen and Suls leave this question open. Krohne, however, explicitly postulates an independent functioning of the dimensions vigilance and cognitive avoidance.

2.2.1 Repression–sensitization. The repression–sensitization construct (cf. Byrne 1964, Eriksen 1966) relates different forms of dispositional coping to one bipolar dimension. When confronted with a stressful encounter, persons located at one pole of this dimension (repressers) tend to deny or minimize the existence of stress, fail to verbalize feelings of distress, and avoid thinking about possible negative consequences of this encounter. Persons at the opposite pole (sensitizers) react to stress-related cues by way of enhanced information search, rumination, and obsessive worrying. The concept of repression–sensitization is theoretically founded in research on perceptual defense (Bruner and Postman 1947), an approach that combined psychodynamic ideas with the functionalistic behavior analysis of Brunswik (1947).

2.2.2 Monitoring and blunting. The conception of monitoring and blunting (Miller 1980, 1987) originated from the same basic assumptions formulated earlier by Eriksen (1966) for the repression–sensitization construct. Miller conceived both constructs as cognitive informational styles and proposed that individuals who encounter a stressful situation react with arousal according to the amount of attention they direct to the stressor. Conversely, the arousal level can be lowered, if the person succeeds in reducing the impact of aversive cues by employing avoidant cognitive strategies such as distraction, denial, or reinterpretation. However, these coping strategies, called blunting, should only be adaptive if the aversive event is uncontrollable. Examples of uncontrollable events are impending surgery or an aversive medical examination (Miller and Mangan 1983). If control is available, strategies called monitoring, i.e., seeking information about the stressor, are the more adaptive forms of coping. Although initially these strategies are associated with increased stress reactions, they enable the individual to gain control over the stressor in the long run, thus reducing the impact of the stressful situation. An example of a more controllable stressor is preparing for an academic exam.

The general relationship between a stressor's degree of controllability and the employment of monitoring or blunting strategies can be moderated by situative and personal influences. With regard to situation, the noxious stimulation may be so intense that blunting strategies, such as attentional diversion, are ineffective with respect to reducing stress-related arousal. Concerning personality, there are relatively stable individual differences in the inclination to employ blunting or monitoring coping when encountering a stressor.

2.2.3 The model of coping modes. Similar to Miller's monitoring-blunting conception, the model of coping modes (MCM) deals with individual differences in attention orientation and emotional-behavioral regulation under stressful conditions (Krohne 1993). The MCM extends the (largely descriptive) monitoring-blunting conception (as well as the repression–sensitization approach) in that it relates the dimensions vigilance and cognitive avoidance to an explicative cognitive-motivational basis. It assumes that most stressful, especially anxiety evoking, situations are characterized by two central features: the presence of *aversive stimulation* and a high degree of *ambiguity*. The experiential counterparts of these situational features are *emotional arousal* (as being primarily related to aversive stimulation) and *uncertainty* (related to ambiguity). Arousal, in turn, should stimulate the tendency to cognitively avoid (or inhibit) the further processing of cues related to the aversive encounter, whereas uncertainty activates vigilant tendencies.

These two coping processes are conceptually linked to personality by the hypothesis that the habitual preference for avoidant or vigilant coping strategies reflects individual differences in the susceptibility to emotional arousal or uncertainty. Individuals who are

especially susceptible to states of stress-induced emotional arousal are supposed to habitually employ cognitive avoidance. The employment of avoidant strategies primarily aims at shielding the person from an increase in arousal (*arousal-motivated coping behavior*). Individuals who are especially affected by the uncertainty experienced in most stressful situations are supposed to habitually employ vigilant coping. Thus, the employment of vigilant strategies follows a plan that is aimed at minimizing the probability of unanticipated occurrence of aversive events (*uncertainty-motivated coping behavior*).

The MCM conceives the habitual coping tendencies of vigilance and cognitive avoidance as independent personality dimensions. That means, *aggregated* across a multitude of stressful encounters, the employment of vigilant strategies and of avoidant ones does not preclude each other. Thus, four *coping modes* can be defined. (a) Persons who score high on vigilance and low on cognitive avoidance are called *sensitizers*. These persons are primarily concerned with reducing uncertainty by directing their attention towards stress-relevant information. (b) Individuals with the opposite pattern are designated as *repressers*. These persons minimize the experience of arousal by avoiding aversive information. (c) *Nondefensives* have low scores on both dimensions. These persons are supposed to flexibly adapt to the demands of a stressful encounter. Instead of frequently employing vigilant or avoidant coping strategies, they prefer to act instrumentally in most situations. (d) Individuals who exhibit high scores on both dimensions are called *high anxious*. In employing vigilant as well as avoidant coping strategies, these persons try to reduce both the subjective uncertainty and the emotional arousal induced by stressful encounters. Because the two goals are incompatible in most situations, high-anxious persons are assumed to show fluctuating and therefore less-efficient coping behavior. Approaches to assess individual differences in vigilance and cognitive avoidance are described in Krohne et al. (2000). Empirical results related to predictions derived from the MCM are presented in Krohne (1993, 1996), and Krohne et al. (1992).

3. Future Perspectives

Although the fields of stress and coping research represent largely explored territory, there are still fertile perspectives to be pursued in future research. Among the promising lines of research, two perspectives will be mentioned here.

(a) Compared to the simplistic stimulus-response conception of stress inherent in early approaches on stress, the 'psychological' (i.e., cognitive transformation) approach of the Lazarus group clearly represents progress. However, in advocating a completely 'subjective' orientation in conceptualizing stress, Lazarus overstated the 'cognitive turn' in stress research. In stating that 'we might do better by describing relevant environments and their psychological meanings through the lenses of individuals' (Lazarus 1990, p. 8) he took a stand that is at variance with the multivariate, systems-theory perspective proposed in his recent publications on stress and emotions (Lazarus 1990, 1991).

First, the stress process contains variables to be assessed both subjectively and objectively, such as constraints, temporal aspects, or social support networks, as well as responses to be measured at different levels (cf. Lazarus 1990, Table 1). Second, the fact that most objective features relevant to stress-related outcomes exert their influence via a process of cognitive transformation (Mischel and Shoda 1995) does not mean that objective features can be neglected. It is of great practical and theoretical importance to know which aspects of the 'objective' environment an individual selects for transformation, and how these characteristics are subjectively represented. Third, as far as response levels are concerned, it is obvious that stressors do not only create subjective (cognitive) responses but also reactions at the somatic and the behavioral-expressive level. In fact, many individuals (especially those high in cognitive avoidance) are characterized by a *dissociation* of subjective and objective stress responses (cf. Kohlmann 1997; for an early discussion of the psychological meaning of this dissociation see Lazarus 1966). These individuals may manifest, for example, relatively low levels of subjective distress but at the same time considerable elevations in autonomic arousal. In recent years, the concept of subjective-autonomic response dissociation has become increasingly important in clarifying the origin and course of physical diseases and affective disorders.

(b) It is important to define central person-specific *goals* (or reference values) in coping, such as reducing uncertainty, inhibiting emotional arousal, or trying to change the causes of a stressful encounter. These goals are not only central to understanding the stress and coping process, they are, in fact, 'the core of personality' (Karoly 1999). Goals define the trans-situational and trans-temporal relevance of certain stressors, serve as links to other constructs such as self-concept or expectancies, influence regulatory processes such as coping, and define the efficiency of these processes (cf. Karoly 1999, Lazarus 1991, Mischel and Shoda 1995). Instead of applying global and relatively content-free trait concepts in stress and coping research such as anxiety, depression, or optimism, a more fertile perspective would be to study personality in this field by paying attention to what people are trying to do instead of only observing how they actually respond to stressful events.

Stress and Health Research

1. Introduction

1.1 The Origin of Stress Research

Stress is a term that is often related to a psychological or physical state of health (cf. Sapolsky 1994) and is used by many psychological, sociological, and medical scientists as well as laymen. A first definition of the term stress was proposed by Cannon (1935). He postulated that passing a critical stress level, triggered by physical and emotional stimuli, endangers the homeostatic control of an organism. However, the name that is most closely associated with stress is Hans Selye, who defined stress as a nonspecific response of the body to any demand characterized by the secretion of glucocorticoids. Selye developed the concept of the *general adaptation syndrome* (*GAS*), which encompasses the alarm reaction, the stage of resistance, and finally the stage of exhaustion. The bodily responses to massive or ongoing stress are summarized in the *stress triad*, including (a) the enlargement and hyperactivity of the adrenal cortex, (b) the shrinking or atrophy of the thymus, spleen, lymph nodes, and the lymphatic system, and (c) the appearance of gastrointestinal and bowel ulcers (Selye 1936, 1937). Regarding health consequences, Selye argued that stress plays a role in the development of every disease. According to Selye, there is always a particularly weak organ or system (due to heredity or external conditions) that is thus likely to break down under stress, which is why he concluded that individuals can develop different types of diseases under the influence of the same kind of stressor.

In the concept of *four basic variations of stress*, Selye (1983) emphasized that stress can be based on overstress (hyperstress) as well as understress (hypostress). He also contrasts harmful, damaging stress (distress) from good stress (eustress).

Selye's idea of an unspecific stress response to all kinds of stimuli was challenged by Mason (1968, 1975), who underlines the importance of specific emotional reactions that determine a specific endocrine stress response. Mason showed that specific situational characteristics, such as novelty, uncontrollability, unpredictability, ambiguity, anticipation of negative consequences, and high ego-involvement, lead to specific hormonal stress responses.

1.2 Definitions of Stress

To date, a large number of definitions of stress are available (see *Stress and Coping Theories*). Some researchers have even proposed to drop the term stress. Levine and Ursin (1991) have offered a comprehensive definition of stress, distinguishing between (a) input (stress stimuli), (b) (individual) processing, and (c) outcome (stress reaction). In this concept, those stimuli that require processing are defined as loads. An individual appraisal process determines whether a load becomes a stressor. Differences in processing are based for example on genetic, ontogenetic, and social factors, and early life as well as lifelong experiences. A related idea has been introduced earlier by Lazarus and Folkman (1984). According to the cognitive-transactional model by Lazarus and Folkman, stress is experienced as a process that is initially triggered by situational demands, but then mainly by the cognitive appraisal of these demands. The characteristics of a situation (primary appraisal) are evaluated simultaneously in line with the available coping capacities or resources (secondary appraisal). This results in a cognitive appraisal of challenge, threat, or harm/loss,

and, subsequently, in emotions, coping attempts, and adaptational outcomes. This process can be cyclical, and it may lead to a number of reappraisals that change the nature of the stress episode.

At the level of stress responses, physiological, behavioral, and subjective/verbal reactions could be distinguished. Physiological responses primarily include the *sympathetic–adrenal–medullary* (*SAM*) *axis*, *hypothalamic–pituitary–adrenal* (*HPA*) *axis*, and *immune system*. Behavioral responses, among others, cover attention, arousal, and vigilance; subjective/verbal reactions are interpretations, cognitions, and emotions. The stress reactions to physical and psychological stimuli are primarily determined by the individual interpretation, but also by the social context, the social status, genetic factors, gender, developmental stage, and individual lifelong experiences.

Finally, Levine and Ursin (1991) contrast an unspecific stress response (general alarm) and a specific individual stress reaction. With this idea they offer an integrational view of Selye's (1983) and Mason's (1968) approaches to a definition of stress.

2. *The Model of Allostatic Load*

2.1 *Introduction*

While homeostatic regulation reflects the stability of constants, allostatic regulation means stability through change. Homeostatic systems (e.g., body temperature, blood oxygen, blood pH, glucose levels) must be maintained within a narrow range. That means that deviations in a homeostatic system trigger a restorative response to correct the changes. In contrast, the regulation of *allostatic* (adaptive) systems can operate in a relatively broad range of regulation. Following Sterling and Eyer (1988), allostasis is the regulation of the internal milieu through dynamic change in hormonal and physical parameters. Allostasis is defined as the ability of the body to increase or decrease vital functions to a new steady state on challenge.

McEwen and Stellar (1993) concluded that the concept of homeostasis is not helpful for explaining the hidden costs of chronic stress on the organism. Therefore, they extended the concept of allostasis over the dimension of time and introduced the idea of *allostatic load*. Allostatic load is defined as the cost of chronic exposure to elevated or fluctuating endocrine or neural responses resulting from chronic or repeated challenges that the individual experiences as stressful. Stress, for instance psychological demands, physical threat/danger, or adverse life experiences, activates various adaptive (allostatic) systems, initiating adaptation and coping processes. The SAM and the HPA axes are the main endocrine stress systems of the organism involved in an allostatic response.

In the face of an internal or external challenge, these systems are activated. (a) Catecholamines are released from the sympathetic nerves and the adrenal medulla. (b) Corticotropin-releasing factor (CRF) from the nucleus paraventriculares (PVN) of the hypothalamus triggers the discharge of adrenocorticotrophic hormone (ACTH) from the anterior pituitary gland. ACTH stimulates the secretion of glucocorticoids (e.g., cortisol) from the adrenal cortex. These hormones serve as mediators of adaptational processes. Besides the sympathetic nervous system and the HPA axis, the cardiovascular, metabolic, and immune system play a crucial role in allostatic processes.

In sum, allostatic systems enable the body to respond adequately to changes in social and physical conditions and therefore protect the body in the short run. In the long run, however, the bodily responses to stress can cause damage and finally promote several diseases. The organism's 'hidden toll' of short-term adaptation to challenges is described as *allostatic load*, which constitutes a wear and tear on the body from chronic overactivity or underactivity of allostatic systems.

2.2 *Types of Allostatic Load*

Four different scenarios can cause allostatic load: (1) frequent exposure to stress, (2) inability to habituate to repeated challenges, and (3) inability to terminate a stress response. In these three types, allostatic load is promoted by an organism's increased exposure to stress hormones and other allostatic mediators. Finally, (4) an inadequate allostatic response in one allostatic system could be related to an increased activation of another allostatic system. An inadequate response of one allostatic system could trigger an inadequate (compensatory) response in another allostatic system.

The model emphasizes that allostatic load reflects not only the impact of lifelong experiences (wear and tear), but also covers early life experiences, genetic predispositions, environmental factors, as well as psychological and behavioral parameters. The cascading relationships between these factors could explain individual differences in the susceptibility to stress and, in some cases, to disease.

For example, Meaney and co-workers (1994) showed in animal studies that early life experiences can calibrate the lifelong pattern of physiological stress responses. Whereas unpredictable stress in newborn rodents led to an overactivity of HPA and SAM axis responsiveness, neonatal handling resulted in a reduced reactivity of the stress systems for the entire lifespan. Concerning the impact of genes on HPA axis functioning, Wüst et al. (2000) report on a medium-sized yet distinct genetic influence on cortisol levels after awakening. The role of genes in the regulation of stress systems is discussed in detail by Koch and Stratakis (2000). Psychological factors, such as an-

ticipating negative consequences, pessimism, anxiety, or worry also contribute to allostatic load. While the origin of allostatic load can be based on an individual psychological appraisal process, psychological factors can prolong, intensify, expand, or aggravate the amount of existing allostatic load. Finally, there seems to be a bidirectional influence of stress and lifestyle factors, for example nutrition, physical exercise, sleeping habits, alcohol, caffeine, and nicotine consumption, with significant effects on the extent of allostatic load (cf. Steptoe 2000).

3. *Stress and Health*

3.1 *Types of Allostatic Load and Health*

The four different types of allostatic load may possibly be related to increased risks of the development of different health problems. Repeated ups and downs of physiological responses or a heightened activity of physiological systems due to internal or external challenges result in allostatic load, which could predispose the organism to disease. There is evidence that acute and chronic stress are significant risk factors for cardiovascular, immunological, and psychological health problems as well as impairments in the central nervous system (CNS). However, it has to be taken into consideration that evidence for stress effects on health are mainly based on correlational analyses.

Animal and human data point to the idea that allostatic load of type 1 and type 3 may possibly be related to the risk of myocardial infarction. Repeated blood pressure elevation (allostatic load type 1), for instance, could promote atherosclerosis. The failure to recover from blood pressure increase following an acute stressor (allostatic load type 3) may lead to hypertension, which also increases the risk of atherosclerosis. Furthermore, heightened cortisol levels promote an increase in insulin secretion, resulting in an endocrine condition that may also accelerate atherosclerosis. Atherosclerosis itself appears to increase the risk of myocardial infarction.

Allostatic load type 2 covers the failure to habituate or the extent of habituation to repeated stress exposure. After repeated speaking and mentally solving arithmetic problems in front of an audience (Trier Social Stress Test), most participants showed habituation in their cortisol response, but about one-third of them still had high cortisol increases every time they were exposed to the stressor. The relationship between the inability of the HPA axis to habituate to repeated exposure to this psychosocial laboratory stress protocol and various health parameters is currently being investigated.

Chronically elevated SAM and HPA axis activity can lead to decreased bone mineral density, body weight loss, amenorrhea and/or anorexia nervosa, as observed in depressed patients or high-performance athletes (allostatic load type 3). Concerning bone mineral density, Michelson et al. (1996) showed that moderately elevated glucocorticoid levels over a prolonged period were associated with reduced levels of osteocalcin in depressed women, therefore inhibiting bone formation (allostatic load type 3).

Allostatic load type 4 is illustrated by observing that a hyporeactive HPA axis (decreased release of glucocorticoids after stress) could lead to an increased response of the immune system. In case one system does not show an adequate stress response, another system increases its activity because the underactive system does not provide the normal counter-regulatory control. For instance, lewis rats, which are known to have an HPA axis hyporeactivity, show increased susceptibility for autoimmune and inflammatory disturbances, and those rats which developed an HPA axis hyporeactivity due to a subordinate position in their social network are believed to die earlier than their counterparts (allostatic load type 4) (cf. McEwen 2000).

3.2 *Stress and the Cardiovascular System*

Animal and human studies indicate that a relationship exists between stress and cardiovascular disturbances. Stress plays a crucial role in cardiovascular diseases as a risk factor in the progressive development of hypertension and atherosclerosis and as a trigger of acute incidences, such as myocardial infarction, stroke, or even death. While stress provokes cardiovascular and endocrine changes that could be beneficial even in healthy human beings, the same stimuli can be detrimental to patients with coronary artery disease (see *Stress and Cardiac Response*).

Manuck et al. (1988) observed that socially subordinate female primates and dominant male primates in unstable social hierarchies have an increased risk of developing atherosclerosis. In humans, occupational strain, for example, jobs with high psychological demands and low control, leads to elevated blood pressure, increased progression of atherosclerosis, and increased risk of coronary heart disease (CHD) (cf. McEwen 2000). Allen and colleagues (1993) concluded that women are more likely to be cardiac reactors, whereas men are more prone to be vascular reactors, suggesting a gender-specific allostatic load within the cardiovascular system.

3.3 *Stress and the Immune System*

A large amount of literature shows the impact of stress on changes in immune system functioning (cf. Biondi 2001). Chronic psychological stress or increased allostatic load is generally shown to be associated with decreased immune responses as well as enhanced severity of infections. Consequently, a stress-related suppression of cellular immune system functioning can, for instance, lead to increased susceptibility to or

severity of the common cold (Cohen et al. 1991). While chronic stress seems to precede blunted immune response, acute stress may be potentially beneficial: experiencing acute stress can enhance the trafficking of immune cells to the site of acute challenge, resulting in an immune-enhancing effect over several days (cf. McEwen 2000). Acute stress may call immune cells 'to their battle stations,' thus enhancing short-term immunity (cf. Dhabar 2000, Dhabar and McEwen 1997).

Possible mechanisms involved in the relationship between psychological stress and immune function changes, covering the stress–disease connection, are discussed in Biondi (2001). There seems to be a complex connection between emotional stress and the development of cancer. In sum, human data on psychological factors and cancer are controversial, but apparently there is support that psychological stress may contribute to disease manifestation and progression. Concerning infectious diseases, some studies have reported negative findings. However, human data point to a possible role that stress plays in increasing the risk of tuberculosis, influenza, upper respiratory infections in children and adults, as well as recurrences of herpes labialis virus and genital herpes virus, or HIV progression. Biondi (2001) summarizes that psychological stress could act as a cofactor in the pathogenesis, course, and outcome of infectious diseases in animals and humans. The exact role of psychological factors in the pathogenesis and course of specific autoimmune diseases (e.g., rheumatoid arthritis, systemic lupus erythematosis, multiple sclerosis, ulcerative colitis, Crohn's disease, joint inflammation, psoriasis) is still poorly understood. In view of the clinical complexity of these illnesses, a simple connection between psychological stress and the status of an autoimmune disease cannot be presumed. For asthma bronchiale, there appears to be some support for the assumption that this illness could be exacerbated by psychological stress via immune–inflammatory mechanisms. Finally, the process of wound healing appears to be impaired under chronic as well as minor psychological stress, a process which may be mediated by proinflammatory cytokines (Glaser et al. 1999).

3.4 Stress and the Central Nervous System

Besides numerous peripheral effects of stress, stress-induced secretion of adrenal steroids can also affect the central nervous system (CNS). For example, elevated glucocorticoid levels can impair hippocampal and temporal lobe functioning, brain areas which are involved in declarative, episodic, and short-term memory. While acute stress can profoundly impair memory (effects reversible and relatively short-lived; Kirschbaum et al. 1996), repeated stress can end up in atrophy of the dendrites of pyramidal neurons in the CA3 region of the hippocampus, causing long-term cognitive impairments. Besides its role in memory and cognition, the hippocampus is most important for the negative feedback regulation of the HPA axis. Allostatic load during a lifetime may cause loss of resilience of HPA axis function, resulting in an attenuation of the negative feedback signal that may lead to hyperactivity of this stress system. The connection between the wear and tear on this region of the brain and the dysregulation of the HPA axis is elaborated in detail in the *glucocorticoid cascade hypothesis* (Sapolsky et al. 1986).

Animal data show that in aged rats, impairments of declarative, episodic, and spatial memory are associated with HPA axis hyperactivity. In elderly humans, Lupien et al. (1998) observed that hippocampal atrophy and cognitive impairment were related to progressive elevations of cortisol levels over a four-year interval.

In sum, animal as well as human data support the idea that elevated glucocorticoid levels could lead to a reduction in hippocampal functioning. Consequences may include the dysregulation of the HPA axis as well as cognitive impairments.

3.5 Stress and Psychological Diseases

Stress is said to be one important parameter, among others, in the manifestation or aggravation of several psychological disturbances, psychosomatic illnesses, and psychiatric disorders, including burnout, anorexia nervosa, chronic fatigue syndrome (CFS), asthma, neurodermatitis, major depression, schizophrenia, or post-traumatic stress disorder (PTSD), which are sometimes referred to as stress-related disorders. The notion that stress contributes somehow to onset or progression of these disorders does not indicate how strong the influence of stress is compared to other important contributing factors, such as genetic predisposition or organic diseases.

However, changes in the regulation of the HPA axis can be related to several stress-related disorders. For example, chronic stress, major depression, schizophrenia, or anorexia nervosa seem to be associated with a *hyper*active HPA axis, whereas a *hypo*reactive HPA axis is found more often in CFS, autoimmune processes, or PTSD. Since there are only few longitudinal data available to date on the relationship between HPA activity and stress-related disorders, the question of cause and effect remains to be answered in future research.

4. Gender Differences in Stress Responses and Health

Gender-specific prevalence rates reveal that men and women are at differential risk for a number of illnesses (see *Gender and Physical Health*). Whereas women suffer

more often from autoimmune diseases (e.g., multiple sclerosis or systemic lupus erythematosus), men are more prone to develop coronary heart diseases and appear to be more susceptible to infectious diseases. Also, the incidence of psychiatric disorders is not equally distributed between men and women. Diagnoses such as major depression, anxiety, phobia, panic disorder, and obsessive compulsive disorder are more common in women, whereas men more often develop antisocial behavior, abuse substances, or commit suicide. Life expectancy is about seven years higher for women compared to men, although women consistently appear to report more physical as well as somatoform symptoms than men.

Besides this clear *gender–disease dimorphism*, gender differences also exist in subjective and biological aspects of the human stress response (cf. Kudielka et al. 2000). Concerning subjective/verbal reactions to stress, several studies (ranging from everyday hassles to posttraumatic stress reactions) show that women experience and/or report more stress than men. As to HPA axis responses to psychological stress, men showed repeatedly higher ACTH and free, *bioavailable*, cortisol responses compared to women, but similar total cortisol increases. Only in the luteal phase of the menstrual cycle did women show similar free cortisol responses to those of men (Kirschbaum et al. 1999). There is evidence that these differences are, at least partly, explained by gender differences in the availability of gonadal steroids, especially estrogens.

The finding that men have higher blood pressure changes and higher elevations in epinephrine concentrations under psychological stress parallels the observation that some women seem to be protected from CHD (see *Gender and Cardiovascular Health*). Estrogen availability is discussed as being a preventive agent for the onset or progression of CHD, but the use of hormone replacement therapy (HRT) for prevention of heart disease is more complex than initially believed. The heart and estrogen/progestin replacement study (HERS) was a first large randomized, blind, placebo-controlled secondary prevention trial to evaluate the efficacy and safety of estrogen and progesterone replacement therapy in reducing CHD risk (cf. e.g., Hulley et al. 1998). It was conducted from January 1993 through July 1998, with a mean follow-up of 4.1 years at 20 centers. However, in sum, the results of the HERS study could not support the notion that HRT is a protective measure against CHD.

5. *Summary and Conclusion*

This article has dealt with the origin of stress research, briefly describing the basic aspects of the stress concepts of Cannon, Selye, and Mason. Then, a comprehensive definition of stress by Levine and Ursin (1991) was offered, distinguishing between stress stimuli, individual processing, and stress reactions on three different levels (physiological, behavioral, subjective/verbal).

The relationship between stress and health was elucidated using the allostatic load model introduced by McEwen and Stellar (1993): the body's cost of short-term adaptation to internal and external challenges is allostatic load, which constitutes a wear and tear on the organism. Four different types of allostatic load were presented and related to different health problems, including the cardiovascular system, the immune system, and the CNS. Finally, gender differences in stress responses and health outcome, including psychosomatic and psychiatric diseases, were briefly discussed, with the conclusion that the gender–disease dimorphism could be associated with gender-specific stress responses.

Stress at Work

1. The Changing Nature of Work and the Role of Stress

The nature of work has changed considerably over the past several decades in economically advanced societies. Industrial mass production no longer dominates the labor market. This is due, in part, to technological progress, in part to a growing number of jobs available in the service sector. Many jobs are confined to information processing, controlling, and coordination. Sedentary rather than physically strenuous work is becoming more and more dominant. New management techniques, including quality management, are introduced, and economic constraints produce work pressure, rationalization, and cut-down in personnel. These changes go along with changes in the structure of the labor market. More employees are likely to work on temporary contracts, on fixed term, or in flexible job arrangements. The workforce is getting older, and an increasing proportion of women enters the labor market, with an increase of double exposure among women with children or, more generally, in dual career families. Most importantly, overemployment in some segments of the workforce is paralleled by underemployment, job instability, or structural unemployment in other segments. This latter trend currently hits the economically most advanced societies as well as economies that lag behind. Overall, a substantial part of the economically active population is confined to insecure jobs, to premature retirement, or job loss.

Why is work so important for human well-being, and how does work contribute to the burden of stress and its adverse effects on health? In all advanced societies work and occupation in adult life are accorded primacy for the following reasons. First, having a job is a principal prerequisite for continuous income and, thus, for independence from traditional support systems (family, community welfare, etc.). Increasingly, level of income determines a wide range of life chances. Second, training for a job and achievement of occupational status are the most important goals of socialization. It is through education, job training, and status acquisition that personal growth and development are realized, that a core social identity outside the family is acquired, and that

goal-directed activity in human life is shaped. Third, occupation defines an important criterion of social stratification. Amount of esteem in interpersonal life largely depends on type of job and level of occupational achievement. Furthermore, type and quality of occupation, and especially the degree of self-direction at work, strongly influence personal attitudes and behavioral patterns in areas that are not directly related to work, such as leisure or family life (Kohn and Schooler 1983). Finally, occupational settings produce the most pervasive continuous demands during one's lifetime, and they absorb the largest amount of active time in adult life, thus providing a source of recurrent negative or positive emotions. It is for these reasons that stress research in organizations where paid work takes place is of particular relevance.

It is important to recognize that traditional occupational hazards, such as exposure to toxic substances, heat, cold, or noise, are no longer the dominant challenges of health at work. Rather, distinct psychological and emotional demands and threats are becoming highly prevalent in modern working life. There has been a recognition that the importance of work goes beyond traditional occupational diseases and, indeed, it is likely that work makes a greater contribution to diseases not thought of as 'occupational' in conventional terms. At a descriptive level, recent reports find that, for instance, almost half of the workforce are exposed to monotonous tasks or lack of task rotation; 50 percent work at a very high speed or to tight deadlines. Thus, over- and underload at work are highly prevalent. Every third employee has no influence on work rhythm, and every fifth is exposed to shiftwork (Paoli 1997). There is now growing awareness among all parties of the labor market that psychosocial stress at work produces considerable costs, most importantly a high level of absenteeism, reduced productivity, compensation claims, health insurance, and direct medical expenses. Permanent disability and loss of productive life years due to premature death add to this burden. In the European Union, the costs of stress to organizations and countries are estimated to be between 5 and 10 percent of GNP per annum (Cooper 1998). At the same time scientific evidence on associations between psychosocial stress at work and health is growing rapidly.

2. *Concepts of Work-related Stress and Selected Findings*

Research on psychosocial work-related stress differs from traditional biomedical occupational health research by the fact that stressors cannot be identified by direct physical or chemical measurements. Rather, theoretical models are needed to analyze the particular nature of the psychosocial work environment. A theoretical model is best understood as a heuristic device that selectively reduces complex reality to meaningful components. Components are meaningful to the extent that they provide the material from which the researcher can deduce explanations and, thus, produce new knowledge. Ideally, a theoretical model of psychosocial stress at work with relevance to health should encompass a wide variety of different occupations and should not be restricted to a specific time or space.

Before describing some prominent theoretical models of occupational stress, the basic terminology needs to be clarified. Much critique has been raised against the ambiguity of the term 'stress.' To avoid this, the following terms were suggested: 'stressor' is defined as an environmental demand or threat that taxes or exceeds a person's ability to meet the challenge; 'strain' is defined as the person's response to such a situation in psychological and physiological terms. Psychological responses include specific cognitions and negative emotions (e.g., anger, frustration, anxiety, helplessness), whereas physiological responses concern the activation of the autonomic nervous system and related neuro-hormonal and immune reactions. Stressors, in particular novel or dangerous ones, are appraised and evaluated by the person, and as long as there is some perception of agency on the part of the exposed person efforts are mobilized to reverse the threat or to meet the demands. Such efforts are termed 'coping,' and they occur at the behavioral (even interpersonal), cognitive, affective, and motivational level. Clearly, when judging strain, the quality and intensity of a stressor as well as the duration of exposure have to be taken into account, as well as individual differences in coping and in vulnerability to strain reactions. Recent research indicates that only part of human strain reactions are subject to conscious information processing, whereas a large amount bypasses awareness. The term 'stressful experience' is introduced to delineate that part of affective processing that reaches consciousness. Stressful experiences at work are often attributed to adverse working conditions by exposed people themselves. While they usually refer to some common sense notions of stress, it is crucial to note that these attributions differ from the explanatory constructs of stressful experience at work that have been identified by science.

2.1 *Person–Environment Fit*

The first significant contribution to modern occupational stress research dates back to studies conducted more than 30 years ago at the Institute for Social Research at the University of Michigan. They were guided by a theoretical concept termed 'person–environment fit' (Caplan et al. 1980). Stressful experience at work, in this model, is conceptualized in two ways: first, as an experience where the work

environment does not provide adequate supplies to meet the person's needs; second, as an experience where the abilities of the person fall short of demands that are prerequisite to receiving supplies. In both conditions stressful experience results from a misfit between needs or abilities of the working person and demands or opportunities of the work environment. Further job opportunities may fail to fulfill the person's needs as a consequence of unmet demands. As an example, a worker with limited skills is excluded from any promotion prospects, although, to meet his level of living, he badly needs better pay.

This approach represents a type of theorizing that is termed process theory. As such, it is applicable to a wide range of work but does not specify the particular content dimensions on which person and environment should be examined (Edwards et al. 1998). As its basic terms are rather broad, it may be difficult to reach a consensus on how to measure core constructs. Nevertheless, person–environment fit offers an elaborate set of propositions of how critical constellations of work-related environmental and personal characteristics contribute to the development of stressful experience. At the empirical level, most up-to-date studies have tested adverse effects on subjective health. Therefore, it is not quite evident to what extent these types of misfit are capable of eliciting sustained physiological strain and thus contribute to the development of bodily disease.

2.2 Demand, Support, and Control

The argument of how strain reactions affect physiological regulation has received special attention in a second influential contribution to current occupational stress research that focuses on the theoretical construct of control. Animal stress research and psycho-physiological experiments in humans confirmed the critical impact on physiological and psychological strain reactions produced by lack of control in a challenging situation (Frankenhaeuser 1979, Henry and Stephens 1977). Control is defined as the ability of a person to choose their own actions to cope with a challenge. In the workplace it ranges from task autonomy to participation in decision making, and strain evolves from challenging situations at work that leave the person with limited choice on how to react. This idea was elaborated in terms of the demand–control model of occupational stress by Karasek (Karasek and Theorell 1990, see *Occupational Health*). This model posits that strain is contingent on the combined effects of high demand and low control; though both high demands and low control may also have independent additive effects on strain and health.

Stress research based on the concept of control resulted in several important discoveries. First, it was shown that physiological strain reactions are not uniform, but may vary according to the degree of perceived control. For instance, stressful experience in terms of striving without success was found to elicit strain reactions that exert particularly harmful effects on the cardiovascular system (Kaplan et al. 1983). Second, epidemiologic studies on work-related control and health, most importantly in the framework of the demand–control model, help explaining the social distribution of some major chronic diseases, especially coronary heart disease (CHD). An inverse social gradient of CHD has been documented. Exposure to low control jobs is more frequent among lower status groups as is the prevalence of CHD. In fact, recent studies found evidence that a considerable part of the social variation in CHD is attributed to adverse psychosocial work conditions (Marmot et al. 1999). Finally, research on control at work has put special emphasis on coping resources, in particular the buffering effects produced by social support. Strain-reducing effects of social support are due to positive experience resulting from social relationships at the instrumental, emotional, and cognitive level (House 1981). This evidence has implications both for a broader conceptualization of occupational stress (e.g., the revised demand–support–control model (Karasek and Theorell 1990)) and for the design of workplace intervention measures.

2.3 Effort and Reward

In physiological terms, theories of control at work deal with the experience of power and influence which, at the psychological level, is paralleled by feelings of autonomy and self-efficacy. An alternative model of stressful experience at work, the model of effort–reward imbalance, is concerned with distributive justice, that is, with deviations from a basic 'grammar' of social exchange rooted in the notions of reciprocity and fairness (Siegrist 1996). This model assumes that effort at work is spent as part of a socially organized exchange process to which society at large contributes in terms of rewards. Rewards are distributed by three transmitter systems: money, esteem, and career opportunities including job security. The model of effort–reward imbalance claims that lack of reciprocity between costs and gains (i.e., high 'cost'/low 'gain' conditions) elicits sustained strain reactions. For instance, having a demanding, but unstable job, achieving at a high level without being offered any promotion prospects, are examples of high cost/low gain conditions at work. In terms of current developments of the labor market in a global economy, the emphasis on occupational rewards including job security reflects the growing importance of fragmented job careers, of job instability, underemployment, redundancy, and forced occupational mobility including their financial consequences.

According to this model, strain reactions are most intense and long-lasting under the following conditions: (a) lack of alternative choice in the labor market may prevent people from giving up even unfavorable jobs, as the anticipated costs of disengagement (e.g., the risk of being laid-off) outweigh the costs of accepting inadequate benefits; (b) unfair job arrangements may be accepted for a certain period of one's occupational trajectory for strategic reasons; by doing so employees tend to improve their chances for career promotion at a later stage; (c) a specific personal pattern of coping with demands and of eliciting rewards characterized by overcommitment may prevent people from accurately assessing cost–gain relations. 'Overcommitment' defines a set of attitudes, behaviors, and emotions reflecting excessive striving in combination with a strong desire for being approved and esteemed (Siegrist 1996). At the psychological level, experience of effort–reward imbalance is often paralleled by feelings of impaired self-worth or self-esteem.

2.4 Empirical Evidence

Evidence of impaired health due to exposure to stressors that are defined by the concepts described is growing rapidly. In particular, a number of well-designed prospective social-epidemiological studies found moderately elevated relative risks (two- to threefold) of incident CHD in economically active middle-aged men and women who were suffering from high demand/low control or effort–reward imbalance. Other health effects observed in prospective and cross-sectional studies concern distinct cardiovascular risk factors, gastrointestinal symptoms, mild psychiatric disorders, poor subjective health, and musculo-skeletal disorders. In addition, rates of absenteeism are elevated (Marmot et al. 1999). There is also evidence of changes in physiological patterns, release of stress hormones, and altered immune competence following stressful experience at work (see *Occupational Health*). Taken together, the burden of illness that can be attributed, at least in part, to exposure to an adverse psychosocial work environment turns out to be impressive. While further research is needed to address important issues, practical implications of this new evidence deserve special attention.

3. Practical Implications and Future Directions

Overall, worksite health promotion activities are realized with little concern about scientific advances obtained in the field of occupational stress research. Eventually, this may change in the future as all three models described in the last paragraph (as well as additional models not mentioned in detail, for summary see Cooper 1998) provide a rationale for evidence-based preventive activity. Person–environment fit theory concludes that work demands need to be tailored according to the worker's abilities. This involves both specific measures of organizational development and person development. Moreover, organizational interventions must suit the needs of affected individuals that are closely linked to the work role (e.g., motivation, learning, satisfaction; Edwards et al. 1998). In the demand–support–control model, special emphasis is put on autonomy, skill discretion, and personal growth. Measures of work reorganization include job enlargement, job enrichment, skill training, enhanced participation, and teamwork (Karasek and Theorell 1990). Practical implications of the effort–reward imbalance model concern the development of compensatory wage systems, the provision of models of gain sharing, and the strengthening of nonmonetary gratifications. Moreover, ways of improving promotional opportunities and job security need to be explored. Supplementary measures are interpersonal training and skill development, in particular leadership behavior.

Clearly, the power of economic life and the constraints of globalization limit the options and range of worksite health promotion measures. Moreover, such measures are difficult to apply to medium-sized and small enterprises where the majority of the workforce in advanced societies is employed. Finally, it must be stated that many instrumental activities that qualify as work are no longer confined to the conventional type of workplace located within an enterprise or organization, particularly with the advent of advanced communications technology (Cooper 1998).

3.1 Future Challenges for Research

There are at least three obvious future directions for occupational stress research. First, the theoretical concepts of stressful experience at work discussed need to be examined in a comparative perspective, with emphasis on their potential overlap or cumulative effects. For instance, recent studies found independent statistical prediction of the demand–control and the effort–reward imbalance model when tested simultaneously (Marmot et al. 1999). Moreover, the estimation of health risk was considerably improved when based on combined information derived from both models.

A second direction of research addresses the link or interface between work and nonwork settings, in particular work and family. In advanced societies work and family have been identified as the two most central domains, especially so in midlife. Therefore, stress-enhancing and stress-buffering experiences in these two domains significantly contribute to personal health and well-being. This interface is conceptualized in terms of spillover, compensation, or cumulation. Spillover refers to the transfer of experience and behavior from one domain to the other. For instance,

work overload or shiftwork schedules may have negative effects on family life. Alternatively, experience of competence and success at work can have beneficial effects on marital life and relationships between parents and children (Kohn and Schooler 1983). Compensation represents efforts to reduce stressful experience in one domain by improving satisfaction in another domain. For instance, leisure and family activities are enhanced to the extent that decreasing involvement in a stressful work environment is feasible. Compensation often occurs in terms of resource management in a stressful situation. In conceptual terms, there is some overlap between the buffering model of social support and compensation processes (House 1981). Cumulation refers to the fact that the critical components of stressful psychosocial experience, such as lack of control or effort–reward imbalance, generalize across core life domains. For instance, disease vulnerability may be highest among people with insecure, badly paid, effortful jobs who also live in a family arrangement that offers little emotional and material satisfaction. It is desirable to extend the theoretical models discussed, both conceptually and operationally, to life domains other than work.

A third direction of research concerns intervention studies. The implementation and evaluation of theory-based intervention is a promising area for creating new knowledge although it is admitted that established methodological principles of scientific trials cannot be fully met. Recent theory-based intervention studies have documented favorable health effects (Cooper 1998, Karasek and Theorell 1990, Siegrist 1996, see *Occupational Health*). In view of the importance of work for health, it is well justified to advance the field of occupational stress both at the science and policy level.

Stress in Organizations, Psychology of

Stress is a term widely used in the social sciences, but not well defined by them; it may refer to any noxious or unwanted stimulus, or to the effects of such stimuli. The concept of stress itself seems to have been borrowed from the fields of physics and engineering, where it is defined more precisely as any force applied to a body, and the resulting alteration or distortion is referred to as strain. This article, following those definitions, will refer to the relevant stimuli as stressors, their presence as stress, and their effects on the individual as strain.

Despite their differences in terminology and the variety of theoretical models with which they work, researchers on organizational stress agree on some or all of the following causal sequence: an objective stressor, its perception by individuals exposed to it, their appraisal of it, their immediate reactions, and its longer term effects. Models or frameworks for research along these lines have been proposed by numerous authors since the early 1960s. The major relationships specified in these models, along with some of the variables most frequently studied, are included in the

Figure 1
Theoretical framework for the study of stress in organizations (Kahn and Byosiere 1992)

'ISR model' developed by French and Kahn (1962) and elaborated by Kahn and Byosiere (1992) (for a review of stress research in organizations see Fig. 1).

1. *Early Empirical Research*

Empirical organizational studies, especially in the early years, were less comprehensive than these models suggest; most research on stress was limited to undesirable job characteristics and their effects on individual employees. Some studies, however, examined the extent to which this causal sequence is moderated by enduring characteristics of the individuals and by properties of the organization or its parts.

Still earlier, research and clinical observations of stress effects were carried out by physicians rather than psychologists. For example, medical doctors recognized angina pectoris and other diseases as the apparent result of 'stress and strain' in their patients' lives, although they did not identify working conditions as hypothetical causes. Selye (1982), who pioneered research on the physiological effects of stress, worked almost exclusively in the laboratory, with rats as experimental subjects. The stressors in his experiments, however, are suggestive of some occupational conditions. These included alarm, sustained vigilance, and physical constraint, all of which led to consequences that Selye called the *stress response* or *general adaptation syndrome* (*GAS*). The GAS included damage to the adrenal glands and the lymphatic system, development of stomach ulcers, and other indications of physiological dysfunction. Selye insisted that the GAS was evoked by any of a wide range of stressful stimuli or 'noxious agents.'

Research that was more specific to role demands in real-life settings, especially military service, was initiated by psychiatrists and psychologists during World War II (Grinker and Spiegel 1945, Janis 1951). Criterion variables in this research were mainly psychiatric symptoms. In the 1950s and 1960s, interest in occupational stress increased substantially, and experimental and field research on the subject was conducted in a number of countries. This research was stimulated by the 'human relations movement,' an unorganized but widespread concern about working conditions and their effects on employees. The emphasis on human relations, as the term implies, included psychological variables, both as causes and effects, in stress research. Centers of this early work were located at the University of Stockholm and the Karolinska Institute in Sweden, the Tavistock Institute in England, the Work Research Institute in Norway, the Institute for Social Research at the

University of Michigan, and in a number of other academic settings.

One of the early Michigan studies (Kahn et al. 1964) investigated the effects of two occupational variables, role conflict and role ambiguity. The underlying assumption was that for each person in an organization, there is a set of other people—supervisors, subordinates, and peers—whose expectations that person must meet. Role conflict for an individual occurs when the members of his or her set disagree about what that individual should do, and role ambiguity exists when the expectations themselves are unclear. In this study the effects of these two stressors, based entirely on self-report, included increased tension, internal conflict about appropriate action, and reduced satisfaction with the job, with supervisors, and with the organization as a whole.

The Swedish research, both in laboratory and organizational settings, included physiological as well as psychosocial effects of stress. Effects of stress were measured as changes in catecholamine (adrenaline and noradrenaline) excretion, creatinine clearance, and elevations in triglyceride and cholesterol levels (Levi 1972, Frankenhaeuser 1979).

2. *Recent Research Findings*

The summary of more recent research findings, with recent defined as the years since 1980, follows the sequence shown in Fig. 1, from organizational and societal characteristics that are stress-generating, to the stressors themselves, their perception and appraisal by individuals, the physical and emotional and behavioral responses they evoke, and the longer term effects on those exposed to the stressors and on others associated with them.

2.1 *Organizational Antecedents to Stress*

Job loss has been perhaps the most intensively investigated work-related stressor. Much of the research has been conducted around plant closings and the consequences for the affected workers and their families. A program to mitigate these negative effects was developed by Price and Vinokur (1995) and experimental designs to measure its effectiveness have been carried out, first in the USA and more recently in many other countries.

The psychological and physiological strains of job loss have been demonstrated beyond question at the individual level. It is plausible therefore that high levels of general unemployment would have negative effects on health. Sociologists and economists who work with variables at institutional and societal levels, however, have seldom been concerned with the measurement of stress and its effects on individuals. Brenner and his colleagues are exceptions; they have demonstrated that the health of populations is affected by changes in economic conditions at regional and national levels (Brenner and Mooney 1983). Economic growth or decline and economic instability are substantially correlated with rates of institutionalization, suicide, and all-cause mortality. These correlations, appropriately time lagged, have been replicated in nine industrialized countries. The intervening processes of stress and strain, however, are neither specified in the theory nor included in the research.

Stress-related findings are similarly sparse at the organizational level. An early correlation from a national population sample suggested that organizational size was a source of stress, presumably because it led to increased formality and rigidity. But research in The Netherlands found a curvilinear relationship between organizational size and stress, with employees in medium-sized companies reporting higher levels of both stressor presence and strain experienced. In short, research evidence indicates that organizations differ significantly in their levels of stress and strain, but does not say what structural properties explain these differences.

Somewhat more research has been done on the stress patterns associated with different positions within organizations. These studies, almost none of them replicated, suggest that span of control and location at an organizational boundary expose employees to increased stress. Data on the effects of hierarchical position are inconsistent, with some studies showing maximum stress at highest positions and other studies showing curvilinear patterns.

Occupation, which perhaps can be considered an organizational factor once removed, has been much studied for its health consequences. Most occupational studies by social scientists, however, do not deal explicitly with stress; they report outcome differences in health or other indicators of well-being and leave the intervening processes to the imagination of the reader.

2.2 *Organizational Stressors*

Job characteristics that have been identified as stressors are a miscellaneous set, some of them technological, some policy-determined, and still others interpersonal in origin. Most studied are such physical conditions as monotony and repetitiveness, shift work, the need for sustained vigilance, exposure to extremes of temperature, and ambient presence of noise and vibration. A few other job characteristics, more social psychological than physical, have also been identified as stressors; these include role conflict, in which a person is subjected to incompatible demands; role ambiguity, in which a person is not given adequate information about the requirements of the job; role overload, in which the quantitative or qualitative demands of the job exceed the person's resources or

ability; and lack of autonomy, perhaps the most frequently heard complaint of people in nonsupervisory positions.

2.3 Perception and Cognition

Some stressors, as toxicological research has demonstrated, can have effects without having been perceived by people exposed to them. Most organizational sources of stress, however, are recognized by the people they affect; their seriousness is assessed, and their physical and psychological impact is mediated by that cognitive assessment. Most research on organizational stress does not distinguish between the objective stressor and its subjective perception and evaluation by people exposed to it. Lazarus and his colleagues, however, have concentrated on this sequence of perception and cognition, which they call the appraisal process (Lazarus and Folkman 1984). There is strong experimental evidence that an individual's appraisal of a stressor and the degree of its threat to his or her well-being has effects that are independent of its objective properties. Lazarus's work has been almost exclusively experimental and not directly concerned with organizational sources of stress. Beehr and Bhagat (1985), however, have brought together those organizational studies that utilized appraisal as a predictor of strain.

2.4 Responses to Stress

Responses to organizational stress are usually classified as physiological, psychological, and behavioral. Ideally, the effects of a stressor would be measured in all three of these domains. In practice, however, the disciplinary background of researchers seems to determine the choice of criterion variables. Physicians and epidemiologists concentrate on physiological responses; psychologists are more likely to emphasize self-reports of strain and behavioral change.

2.4.1 Physiological responses. Job-related stress has been repeatedly shown to affect three kinds of physiological responses—cardiovascular, biochemical, and gastrointestinal. Cardiovascular responses to job stress include elevations in blood pressure and heart rate. Biochemical responses include elevations in cholesterol level and in catecholamines (epinephrine and norepinephrine). Gastric symptoms have been assessed primarily by self-report, sometimes with the inference of peptic ulcer. Among the stressors that evoke these symptoms are role conflict and ambiguity, unpredictability of work load and other demands, lack of control over pace and method of work, and ambient distracting noise. Repetitive motions, on jobs that require heavy lifting and on those that are limited to keyboard work, have been interpreted as causing a variety of musculoskeletal complaints, from back pain to carpal tunnel syndrome. Swedish research has been a major source of information on physiological responses to work-related stress. For summaries that include this research, see Kahn and Byosiere 1992 and Lundberg 1999.

Finally, job insecurity and actual job loss must be counted among the more serious sources of work-related stress. Studies of unemployment and job loss have been numerous for many decades, especially at times when unemployment rates were high. More recently, studies of job loss and of job insecurity have been stimulated by widespread reductions in force, usually referred to as corporate downsizing. Most such research has not included physiological measures. The early study of plant closings by Cobb and Kasl (1977) is an exception; it showed elevations in blood pressure, heart rate, cholesterol level, and catecholamine output. These symptoms occurred during anticipation of job loss and continued through the time of actual dismissal. A gradual return to prestressed levels then began and was completed as workers found new employment and adjusted to their new jobs. More recent research on the impact of job loss has included findings on the mitigating effect of an experimental program of counseling and peer support (Price and Vinokur 1995).

2.4.2 Psychological responses. Many studies of job stress include psychological responses, and they have been summarized in a number of review articles (Holt 1982, Cooper and Payne 1988, Kahn and Byosiere 1992, Lundberg 1999). As these reviews indicate, most of the psychological responses to job stress in this research are self-reported and unlinked to clinical validation or physiological measures. An exception is the work of colleagues at Stockholm University, both at the Karolinska Institute and the Department of Psychology (Stockholm University 1999).

By far the most frequently cited response to job stress is dissatisfaction with the job. More intense affective responses include anger, frustration, irritation, and hostility toward supervisors and the organization as a whole. Other negative responses correlated with job stress are more passive; among them are boredom, burnout, fatigue, feelings of helplessness and hopelessness, and depressed mood. Many of these words are virtual synonyms, a fact that reflects the tendency of researchers to design and label their own measures rather than replicate previous work. Replication in diverse organizations would be very useful, however, as would the combination of physiological and behavioral criteria with psychological responses.

2.4.3 Behavioral responses. Two behavioral correlates of job stress are well replicated: reductions in

job performance and increased absence. Several studies also reported increased turnover and increased use of tobacco. A review of these (Kahn and Byosiere 1992), along with a larger number of unreplicated findings, subsumed the behavioral responses to job stress into five broad categories:

(a) Degradation/disruption of the work role itself (job performance, accidents, errors, etc.);

(b) Aggressive behavior at work (stealing, purposeful damage, spreading rumors, etc.);

(c) Flight from the job (absenteeism, turnover, early retirement, etc.);

(d) Degradation/disruption of other life roles (marriage, friendships, citizenship);

(e) Self-damaging behaviors (drug use, alcohol use, smoking, etc.).

2.5 Mediators of Stress

The model used in this brief review shows two sets of variables that might act to mediate or buffer the effects of job stress: enduring properties of the person and properties of the work situation itself.

That people differ in their sensitivity of job stress is beyond argument, and many demographic and personality characteristics have been proposed as stress mediators. No single characteristic mediates the effects of stress in all cases, but evidence for a stress-buffering effect has been found for at least three personality traits: Type A, locus of control, and self-esteem. Type A individuals (competitive, impatient, aggressive) showed greater strain than Type B individuals working under comparable conditions. People high in internal control (belief that their own choices and decisions make a difference) show less strain than people who score high in external control (belief that their circumstances are determined by 'external' forces beyond their control). High self-esteem also seems to offer some protection from the effects of job stressors.

Few situational factors have been studied for their ability to buffer the effects of job stress. Social support is the exception; both its main effects and its buffering or interaction effects have been frequently tested. Findings are more consistent for main effects than for interactions; social support from various sources—supervisors, co-workers, family, and friends—predicts lower overall strain. Buffering effects have been frequently found as well, but the reasons for its failure in some cases are not clear. An earlier review (LaRocco et al. 1980) proposed that social support buffered (i.e., reduced) the relationship between various job stressors and indicators of mental and physical health but not between job stressors and more specific job strains (boredom, job dissatisfaction, dissatisfaction with workload).

Autonomy on the job is a second factor in the work situation that has been studied for its buffering as well as its main effects on strain. Karasek and his colleagues (1981), analyzing national survey data from the USA and Sweden, found that, among workers with heavy job demands, those who had low decision latitude (little control over pace and method) reported symptoms of physiological and psychological strain; for those who had high decision latitude, however, the relationship between job demands and strain did not hold.

3. Unresolved Issues in the Study of Stress

Research on organizational sources of stress continues and it is appropriate, therefore, to conclude by mentioning some issues that require the attention of stress researchers. They can be summarized in three categories: unresolved questions of concept and theory and of method and design.

3.1 Questions of Concept and Theory

A longstanding issue in stress theories is the distinction between stimuli that are stressful and those that are not. Stress theories must not imply that the optimum human state is absence of stimuli; to the contrary, research on sensory deprivation has demonstrated the negative effects of that state. Moreover, some stimuli are pleasant or exciting at some levels or for brief periods, but unpleasant or damaging at higher levels or longer duration. Furthermore, physical or mental demands that are experienced as stressful or challenging may have training or strengthening effects rather than effects that are weakening or damaging in other ways.

Selye (1982) attempted to distinguish between two kinds of task-related stress, eustress and distress, on the basis of the prospect for successful task completion or achievement. He did not argue that eustress avoids the long-term physiological effects of stress, but rather that to some extent these are unavoidable in life. Eustress and the psychological rewards of achievement, however, make the effort worthwhile. Levi (1972) had earlier dealt with this problem in more quantitative terms. He proposed that stress be thought of in terms of a continuum of stimulation, in which conditions of both understimulation (deprivation) and overstimulation (excess) were stressors. Somewhere between these extremes were the domains of pleasant stimulation, challenge, and training effect.

Another issue in stress research, which is as important for methodology as for concepts and theory, is the distinction between crisis events and chronic conditions. Stressful life events—job loss, bereavement, illness, and the like—have been prominent in stress research, at least since Holmes and Rahe (1967) published a scale that gave researchers a basis for rating their intensity and their combined demand as stressors. Lazarus and his colleagues (Lazarus and Folkman 1984) have emphasized the stress effects of chronic conditions, *daily hassles*, rather than the

stressful life events (*SLEs*) that characterize the work of Holmes and Rahe (1967) and of Dohrenwend and her colleagues (Dohrenwend and Dohrenwend 1984). More recent work by McEwen and his colleagues (McEwen 1998) has introduced the concept of *allostatic load*, which has something in common with the daily hassles of Lazarus. Allostatic load refers to the stress effects of sustained physical or psychological demands, even when individuals are coping with them successfully. Theories of psychological stress have yet to deal fully with these issues.

3.2 Issues of Method and Design

The main weaknesses of design in organizational research on stress are three, all of them long-standing: overreliance on self-report, on cross-sectional designs, and on single organizations. Exclusive dependence on self-reported data means that all respondents in a study describe their perceptions of some working condition and the symptoms of strain that they experience. At best, this design limitation generates data of uncertain validity as descriptors of the work situation; at worst, it is a near tautology.

The reliance on cross-sectional rather than longitudinal designs is by no means a special defect of research on job stress; it is a common weakness in social research. The criticism is similarly familiar; causal inferences from cross-sectional data are notoriously weak. The usual reliance on single-organization designs makes it impossible to bring organizational variables into the analysis of job stress.

If one could write prescriptions for research on job stress, therefore, there would be more designs that were longitudinal, that included objective measures of job characteristics, that included physiological as well as self-reported measures of strain, and that traced the effects of job stress on the performance of both work and nonwork roles. All these improvements are within reach and each of them is occasionally exemplified in current research. Progress in stress research requires that they become more general in future research.

Stress Management Programs

Rationale and contents of intervention programs developed for improving stress management skills and for cultivating a personal sense of control are described. Focus is on the cognitive-behavioral programs

which cover the most frequently used components of intervention. The range of application of stress management programs across different groups and settings, such as workplace or chronic illness, is illustrated. Results on the evaluation of the effectiveness of interventions with regard to the different outcome measures used are reported. Implications for the implementation of stress management programs are discussed.

1. Introduction

Stress is generally considered a major impediment to individual health and well-being and to social and societal functioning. Stress is associated with psychological symptoms, diminished well-being, acute and chronic health problems, and impaired performance in work and social settings. To alleviate such stress-related problems, theory-based stress management programs have been developed whose aim is to improve personal skills in dealing more effectively with stressful conditions and to cultivate a personal sense of self-efficacy and control in problem situations. In the next section of this article, the main theories and key concepts that underlie stress management interventions will be delineated. Subsequently, program designs, intervention techniques, and the range of application of stress interventions will be discussed. The fourth section presents results of the evaluation of stress management programs across different outcome measures. Moreover, methodological aspects of intervention studies will be examined. Finally, prospects for future research and program development will be considered.

2. Rationale and Theoretical Background

The majority of stress management programs are based on the following theories: (a) transactional theories of stress and coping, and (b) theories for cognitive-behavioral psychotherapy developed in clinical psychology. In addition to these psychological theories, knowledge of the physiology of stress and the physiological systems activated by stress has resulted in the view that relaxation must be a major objective in healthy stress management. Relaxation techniques have since been advocated that are aimed at reducing heightened arousal and at preventing its short- and long-term deleterious effects.

2.1 Transactional Theories of Stress and Coping

The most influential theory of stress and coping was developed by Lazarus and Folkman (1984) who defined stress as resulting from an imbalance between perceived external or internal demands and the perceived personal and social resources to deal with them. According to Lazarus and Folkman, two cognitive appraisal processes can be distinguished. The initial appraisal, defined as *primary appraisal*, involves the analysis of whether an event is personally relevant. Events perceived as personally relevant can be appraised as either positive or stressful (the latter including possible harm, threat, or challenge). If individuals perceive events as stressful, they evaluate their own resources to deal with the demands. This constitutes the process of *secondary appraisal*. Stress occurs when the demands are perceived as either exceeding or taxing the resources and coping responses become activated. Lazarus and Folkman (1984) defined *coping* as cognitive and behavioral efforts to deal with situations appraised as stressful. Generally, cognitive appraisal and coping processes are influenced by personality factors, personal and social resources, characteristics of the situation, and other variables (see *Stress and Coping Theories*).

A very similar stress model has been developed by Palmer (1997) to guide health professionals in the selection of appropriate stress interventions. It incorporates Arnold Lazarus' seven interacting response modalities comprising behavior, affect, sensory, imaginal, cognitive, interpersonal, and drugs/biology. According to this multimodal–transactional model, stress and coping proceed in five stages. In *Stage 1*, an external or internal stressor is perceived by the individual to be emerging either from an external source or from internal bodily sensations. In *Stage 2*, the individual appraises his or her capacity to deal with the stressor. The person then decides whether he or she has the resources to cope. If the individual perceives that he or she cannot cope, stress may be experienced, and stress responses are likely to become activated. Appraisal of coping capacity is influenced by social and cultural beliefs and attitudes that determine the importance of an event. An example is the belief that one must meet every deadline. If individuals perceive that they cannot cope, they progress to *Stage 3*. In this stage, stress responses occur that include behavioral, affective, sensory, imaginal, cognitive, interpersonal, and physiological changes. In *Stage 4*, the individuals appraise the effectiveness of the coping strategies they have used. If they perceive themselves to have been successful, they return to a state of equilibrium. If they believe, however, that they have failed to cope with the situation, this perceived failure exacerbates existing problems and turns into an additional strain. *Stage 5* relates to the continuing process and long-term consequences. If an individual uses strategies that alter the situation and reduce stress, he or she will return to a state of equilibrium. If the problems persist, however, eventually the person's health may be negatively affected.

In sum, transactional theories of stress and coping focus on the cognitive and affective aspects of an

individual's interactions with the environment and the coping strategies he or she uses or lacks.

2.2 Cognitive Approaches to Psychotherapy

Many of the techniques adopted in stress management programs have their origin in clinical psychology. In addition to the stress and coping theories, stress management is an explicit goal of intervention in cognitive and cognitive-behavioral approaches to psychotherapy. The basis of this form of clinical intervention is the belief that negative thoughts and cognitive distortions (e.g., 'catastrophizing' and overestimating negative outcomes) play a causal role in many clinical disorders. Cognitive interventions seek to modify biased and maladaptive beliefs by cognitive reeducation. The most influential cognitive therapies are Beck's cognitive therapy (Beck 1976) and Ellis' rational emotive behavior therapy (Ellis 1962, Ellis et al. 1997). Within the framework of his *rational emotive behavior therapy*, Ellis has developed the ABC model, which posits that an emotional, behavioral, or physiological reaction (C, for consequence) to an activating event (A) is influenced mainly by the beliefs (B) pertaining to an event and not so much by the activating event *per se*. According to Ellis, irrational beliefs such as 'awfulizing' or dogmatic and absolutist beliefs will lead to self-defeating behavioral and emotional consequences. In psychotherapy, such beliefs are challenged by asking logical, empirical, and pragmatic questions. Generally, cognitive interventions are employed in combination with behavioral techniques and the acquisition of problem solving and social skills.

3. Program Designs

3.1 Intervention Techniques

The importance of transactional theories of stress (Lazarus and Folkman 1984, Palmer 1997) and cognitive therapy approaches (Beck 1976, Ellis 1962, Meichenbaum 1985) lies in their recognition that the subjective interpretation of events plays a critical role in the experience of stress. Moreover, lack of appropriate skills in dealing with problem situations or inappropriate or rigid use of coping strategies may exacerbate stress. Thus, stress intervention now focuses on two aspects: dysfunctional cognitive appraisal such as cognitive distortions and irrational beliefs, and inefficient coping attempts and deficits in a wide range of personal and social skills. Furthermore, in accord with the physiology of stress, reducing the level of physiological arousal is acknowledged as a major objective in stress management. Based on this theoretical framework, the main intervention techniques employed in stress intervention include: (a) *relaxation techniques* that can be used to achieve short-term, *in situ* relaxation, as well as prolonged relaxation in the private setting (e.g., progressive muscle relaxation, meditation, breathing exercises, biofeedback, and autogenic training); (b) *cognitive re-education and cognitive restructuring*, mainly by challenging maladaptive cognitions and negatively biased beliefs; and (c) *skills training* in areas such as problem solving, time management, negotiation, assertive behavior, and the activation of social support (Bunce 1997, Murphy 1996, Palmer 1996, 1997).

According to reviews of stress intervention studies, combinations of individual techniques, especially the combination of relaxation and cognitive-behavioral skills training, are the most frequently used forms of intervention (Bunce 1997, Kaluza 1997, Murphy 1996). A very influential composite stress management program that represents the multicomponent approach is '*stress inoculation training*' (Meichenbaum 1985). The stress inoculation procedure typically includes three stages. The first stage, *education*, focuses on the assessment of an individual's problems, the identification of strategies usually adopted to deal with stressful situations, and reconceptualization of the individual's responses to stressors. Thus, the client learns to become aware of how he or she habitually responds to stressful situations. In the second stage, *rehearsal*, the client learns and practices various coping-skill techniques such as relaxation, problem solving, and cognitive restructuring. During the third stage, *application*, the newly acquired coping skills are practiced under simulated conditions and transferred into everyday life.

In sum, stress management programs seek to reduce physiological arousal, and to provide the individual with a positive perception of stressful situations that is more conducive to well-being. Moreover, the programs aim to teach a wide range of coping skills to be used in a flexible, situation-appropriate way. Above all, the goal of stress interventions lies in promoting a sense of control and self-efficacy in coping with problem situations (see *Self-efficacy and Health*).

3.2 Range of Application

Stress management programs have been implemented in a variety of settings. They are usually *prevention oriented* and focus on psycho-education and cognitive-behavioral skills training. Accordingly, most programs are offered to all who seek such forms of intervention for themselves (Murphy 1996). In contrast to psychotherapeutic approaches, stress management programs are primarily developed for subclinical populations. However, these programs may also address high-risk groups such as hypertension patients, persons suffering from coronary heart disease (Bennett and Carroll 1990, Dusseldorp et al. 1999), or individuals with specific psychological problems such as high levels of stress, anxiety (Murphy 1996), or anger (Novaco 1975). For these groups, there may be

no clear distinction between preventive stress management programs and psychotherapy. Moreover, stress management programs are offered to persons coping with specific stressors or chronically difficult living conditions; this may include caregiving or chronic financial problems (Kaluza 1997). Modified stress interventions are also offered to children and adolescents (Wolchik and Sandler 1997).

Stress management programs are particularly prevalent within *work settings* (Bunce 1997, Murphy 1996). The high frequency of stress interventions that target the workplace and occupational stress is a result of the recognition that stress is a major cause of problems such as absenteeism, accidents, poor work performance, and burnout (see *Stress at Work*). Coping with *chronic illness* is another important domain for which stress management programs have been developed and applied (Devins and Binik 1996, Dusseldorp et al. 1999). The most common forms of stress interventions for patients are education, behavioral training, relaxation, cognitive restructuring, and support groups. Usually, these interventions are part of composite intervention or self-management programs. Such interventions are generally designed to assist the patients to engage in active coping, to change risk behavior, and to feel less hopeless and helpless (see *Chronic Illness, Psychosocial Coping with*).

3.3 Formats

Though stress management programs can be administered individually, most programs are implemented in *small groups*. Typically, a number of weekly training sessions which may last one hour or longer are either conducted over a number of weeks or condensed into block sessions. Learning theories see advantages in both formats (Brown et al. 1998). Interest in working with *large groups* which meet for 'massed learning' format workshops may increase in the future, however, as preventive psycho-education and skills training become part of general health promotion. Brown et al. (1998) have shown that large-scale, day-long stress management workshops are just as effective as the traditional programs consisting of one weekly session. The value of large-scale stress management programs lies in their potential to make preventive training accessible to the general public and to induce more persons to avail themselves of psychological intervention measures.

4. Program Evaluation

4.1 Outcome Measures

In the studies that evaluate the effects of stress-management interventions, a wide range of health outcome measures were used to assess program effectiveness. Frequently employed measures include indices of *subjective well-being* (which, for the most part, are negatively defined as distress reduction, e.g., anxiety, anger/hostility, depression), *perceived strain* associated with different life domains, self-reported *somatic symptoms* and complaints, *control and self-efficacy beliefs*, and *physiological measures*. Moreover, some studies rely on *biochemical measures* (Kaluza 1997, Murphy 1996). According to a meta-analysis of 36 intervention studies, only five studies assessed *coping strategies* (Kaluza 1997). This is especially noteworthy in light of the fact that the acquisition of adaptive coping strategies is the primary focus of stress intervention. Obviously, the existing program evaluations have major shortcomings. In workplace intervention studies, organizational outcome measures such as job satisfaction, work performance, absenteeism, and turnover were additionally assessed (Murphy 1996). Evaluations of programs aimed at coping with chronic illness frequently assess illness-related knowledge, illness-related behavior and cognitions, and disease-related outcomes in addition to measures of subjective well-being (Devins and Binik 1996, Dusseldorp et al. 1999).

4.2 Results

There are several systematic and comprehensive reviews of studies which evaluate the success of stress management programs (Devins and Binik 1996, Murphy 1996). While there exist only a few meta-analyses of preventive stress management interventions, especially of *primary preventive* programs, they clearly attest to positive treatment effects (Kaluza 1997, Lipsey and Wilson 1993; for secondary preventive programs see Dusseldorp et al. 1999). In their review of meta-analyses of psychological treatment effects, Lipsey and Wilson (1993) reported two studies of stress management programs, with the two mean effect sizes indicating positive treatment results. Similarly, a more recent meta-analysis of 36 studies (31 of them conducted in the US) reported small to medium effect sizes found in randomized control studies. Positive effects were found for different outcome measures such as subjective well-being, anger/Type A behavior, coping strategies, physiological measures, and cognitions (Kaluza 1997). Notably, mean effect sizes were greater for follow-up measures assessed between one and six months after the intervention. Particularly remarkable is the increase in mean effect size found in five studies that assessed subjective well-being more than six months after post-test. These results suggest that the effectiveness of stress management programs may be stable or may even increase over time, at least in regard to subjective well-being.

According to a systematic review of 64 studies on *workplace* management programs (Murphy 1996), stress interventions were generally found to be effective, but the effectiveness varied with the outcome measure used. Cognitive-behavioral techniques were

more effective with respect to psychological and cognitive outcomes, mainly anxiety, whereas relaxation was more effective in regard to physiological outcomes, predominantly assessed by blood pressure measurements. Meditation was used in only six studies, but produced the most consistent results across outcome measures. Generally, composite programs which used a combination of techniques proved to be more effective than single-technique programs. Job and organizational outcome measures, mainly job satisfaction, were employed in only 40 percent of the studies. According to Murphy, the low frequency of organizational outcomes may reflect the fact that stress management programs target the individual worker, not the organization. Of the studies reviewed, two-thirds reported no increase in job satisfaction. It appears that the interventions had a greater effect on subjective well-being and physiological arousal, which are subject to personal control, than on outcomes such as job satisfaction and somatic complaints, which are more influenced by external working conditions. The conclusion may be that workplace stress management needs to be more comprehensive and should address personal coping skills as well as the work environment (Murphy 1996).

In sum, meta-analyses and systematic reviews attest to the general effectiveness of stress management programs, especially with regard to psychological and physiological well-being. The programs had less of an effect on outcomes that may be heavily influenced by external factors. Inconclusive are the results for coping skills, which were seldom assessed. However, in interpreting the results one has to bear in mind that studies examining the success of stress management programs face the problem that it is more difficult to demonstrate a significant effect in participants who enter the training with subclinical levels of complaints than it is in participants who enter with high levels of stress. For example, in the review of Murphy (1996), 79 percent of the prevention-oriented studies yielded positive effects, compared with 94 percent of the treatment-oriented studies that involved persons complaining of high stress or anxiety.

4.3 Methodological Aspects

The variety of different intervention techniques raises the question of whether some techniques are more effective than others. Results for contrasting different intervention techniques are equivocal. Murphy (1996) reported technique-specific effects, whereas other reviewers came to the conclusion that seemingly different techniques appear to have similar outcomes, which is generally known as the '*equivalence paradox*' (Bunce 1997, Palmer 1996). According to Bunce (1997), outcome equivalence may be due to two factors. First, methodological and design weaknesses may underlie outcome equivalence. Second, all the different intervention techniques or combinations of techniques may have common features which are responsible for change. The methodological shortcomings that could add to outcome equivalence include: (a) combining techniques even if only one technique is used so that it is not possible to identify which specific components are responsible for the changes that are observed; (b) small sample sizes that may be associated with insufficient statistical power to detect technique-specific effects even if they exist; (c) inappropriate or unspecific outcome measures; and (d) participant heterogeneity.

The second interpretation suggested by Bunce to explain outcome equivalence is that *nonspecific* factors common to distinct contrasting techniques produce similar effects. Such nonspecific factors may be the experience of being in a group and meeting people with similar problems, expectancy effects, or insights gained by participation in respect to the self, others, and one's environment. Indeed, studies that controlled for placebo effects, e.g., with a control group directed to sit quietly or to passively receive information, have demonstrated nonspecific effects (Bunce 1997, Murphy 1996). One may argue, however, that nonspecific effects are no less valuable. In fact, nonspecific effects may be constituent parts of psychological treatment, involving mechanisms of social interaction, expectations, and changes in beliefs and attitudes (Lipsey and Wilson 1993).

The quality of the studies that evaluate intervention effects has been a point of severe methodological critique in the past. Recent reviews, however, reveal increasing methodological rigor (Ivancevich et al. 1990, Kaluza 1997, Murphy 1996). According to a recent review of 64 intervention studies in the workplace, just over half of the studies were true experiments with random assignment to a training or control group (Murphy 1996). However, about 25 percent of the studies did not use a control or comparison group, and 25 percent did not randomly assign participants to training and control groups. Generally, the studies involving randomized groups yielded lower effects, which underscores the importance of randomized control trials. Of the 36 studies that were included in the meta-analysis of Kaluza (1997), 61 percent were true experimental studies with random assignment to training and control groups. In the remaining studies, participants were not randomized into an intervention or control condition. In addition to post-treatment assessment, 53 percent of the studies reported results for a follow-up between one and over six months after post-test.

5. Prospects for Future Program Development

Stress management programs are designed for a wide range of possible stressors and chronically difficult living conditions. Most of them are preventive in nature and open to all persons who wish to improve their skills in dealing with stressful situations and

enhance their feelings of control. Unspecific and stressor-specific stress management programs provide an invaluable service for health promotion by offering psycho-education, skills training, and adaptive perceptions of problem situations. Generally, systematic reviews and meta-analyses of intervention studies attest to the effectiveness of preventive stress management programs. Clearly, however, further research is needed, especially with nonclinical populations attending preventive stress management programs (Kaluza 1997, Palmer 1996). Future research should focus on the following four problems.

(a) Studies on stress intervention should seek to identify the factors that are responsible for change and the *mechanisms of change*. Such mediators by which changes may be engendered could be psychological variables such as personal sense of control and self-efficacy, the use of adaptive coping strategies, and insights into self, others, and work (Bunce 1997).

(b) Outcome measures should be used that reflect the specific goals of stress management intervention such as realistic and adaptive stress-related cognitions, increased skills for dealing with everyday stress, and improved social competencies (Kaluza 1997). Currently, most outcome measures pertain to subjective well-being, which may indicate improvement in coping skills, but does not clearly reflect actual changes in stress-related interactions between the individual and his or her environment. Moreover, the effectiveness of stress intervention should be evaluated by long-term follow-up assessments in order to ascertain whether the interventions guard against future stress experiences.

(c) Biographical and psychological individual differences such as age, gender, self-esteem, or locus of control may systematically influence changes effected by stress interventions (Bunce 1997). According to Bunce, future research must consider *individual differences* and should examine how these factors might act as moderators and mediators of outcome variance. Matthews and Wells (1996) assert that intervention is likely to be most successful when it is based on systematic analyses of individual styles of attention and coping. Miller has shown that interventions may be more effective when matched with the dispositional information-processing style (e.g., Miller and Mangan 1983).

(d) In the development of stress intervention programs, *cultural aspects* should be taken into consideration in addition to biographical and psychological individual differences. For instance, minority groups in work or social settings may experience stress due to racial prejudices that could become the target of special stress intervention measures (Palmer 1996). Generally, cultural differences may play an important role in successful health promotion. Matching stress interventions with cultural beliefs and models of health and illness is a challenging task for multicultural societies (Devins and Binik 1996).

There is every reason to believe that stress will continue to be a salient problem in the near future. Increasingly, individuals and organizations will seek effective interventions to improve coping skills and reduce stress-related problems. Providing methodologically sound and effective unspecific and stressor-specific stress management programs will remain a predominant task for all who are involved in health promotion.

Stress: Measurement by Self-report and Interview

The term 'stress' is used in a variety of different ways. Sometimes it is employed to refer to an experience of physical tension or distress stimulated by the environment and sometimes to the occurrence of events or experiences that are assumed to involve significant adaptive demands. In this latter case, the focus is on stressors, measured in terms of the occurrence of events and circumstances of stress-evoking potential. Even though it is useful to distinguish stressors from stress, the two terms are often used interchangeably. Despite varying characterizations of stress, Cohen et al. (1995, p. 3) have argued that all perspectives share a concern with the process in which 'environmental demands tax or exceed the adaptive capacity of an organism, resulting in psychological and biological changes that may place persons at risk for disease.'

This article is focused on stress measurement in social as opposed to laboratory contexts. For that reason, strategies for assessing the environmental activation of physiological systems are not covered. Initial consideration will be given to measures of eventful stressors, which fall into two categories—those using a checklist approach and those that rely on data obtained in detailed interviews. This will be followed by brief discussions on the measurement of chronic stress and of exposure to major, potentially traumatic events.

1. *Life Event Checklists*

By far the largest amount of available evidence linking stress exposure to physical and mental health has come from studies employing checklist measures of social stress. Stimulated by Adolf Meyer's life chart procedure, Hawkins et al. (1957) developed the Schedule of Recent Experiences (SRE). This 42-item questionnaire covered events in areas such as marital problems, relationship changes, work and residential changes, and family relationships. A decade later Holmes and Rahe (1967), elaborating on the SRE, developed the Social Readjustment Rating Scale (SRRS) by employing a panel of judges to rate the amount of adjustment each event would typically require. Although research has not supported the expectation that the weights derived from these ratings would improve estimates of stress exposure, their contribution to the face validity of event checklists was evidently substantial. Following the publication of the SRRS there was a huge outpouring of research on stressful life events and it was, for a considerable period, the best-known and most widely used instrument.

The conceptualization that initially informed the checklist approach was that an individual's level of experienced stress was embodied in the cumulative amount of change or readjustment brought about by personal events occurring in the recent past (Holmes and Rahe 1967). This idea that the amount of change is the event property responsible for the stressful impact of life events seems to have been based on Selye's (1956) contention that stress is comprised of nonspecific biological change elicited in response to environmental events and that even relatively small changes occurring in close succession can influence susceptibility and thus disease.

Over the years since the publication of the Social Readjustment Rating Scale (SRRS) there has been an active debate over its adequacy and about alternative approaches to measuring life events and to evaluating their stress-engendering properties. Indeed, at least 20 critical reviews of stressful life event methodology have been published since 1975 (Turner and Wheaton 1995). However, the checklist method has evolved in response to criticism, and a substantial array of different life event scales have been developed. Turner and Wheaton (1995) provide a nonexhaustive list of 47 different life event inventories—many targeted to specific age groups.

Despite several clearly justified criticisms and associated questions about the reliability and validity of resulting scores, the various published and unpublished life event inventories collectively represent the traditional, and still dominant, research procedure for estimating variations in stress exposure. A substantial preponderance of the now massive literature assessing the linkage between social stress and health is based on checklist measures of life stress. This literature has indicated a reliable association between life stress and the occurrence of both psychological distress and risk for physical health problems (e.g., Thoits 1983, Jemmot and Locke 1984).

A conclusion that seems to follow from the consistency with which these relationships have been observed is that, whatever the shortcomings of the method, event inventories yield meaningful estimates

of stress exposure. However, there are two major challenges to this conclusion. One is the possibility that observed associations are an artifact of operational confounding arising from the fact the many checklists, perhaps the majority historically, have included items that are arguably symptoms of physical or mental health problems, or the consequences of such problems. Although evidence on this possibility has not been entirely consistent, the majority of studies have found that the relationships at issue persist, and are little attenuated, when potentially confounding items are removed from consideration (e.g., Tausig 1982).

The second challenge involves the hypothesis of reverse causality. Concern that illness or distress also produces either real or artifactually higher numbers of reported events has been a prominent theme within the life events literature. A crucial point in this regard is that the possibility that illness also causes stress exposure does not question the causal status of life event scores with respect to illness; it simply complicates the proper estimation of this causal impact (Turner and Wheaton 1995). In this connection, longitudinal studies consistently suggest that if one controls for prior or baseline distress or mental health, life events have a net impact on change in distress or mental health over time. Thus, at least with respect to mental health, where the causal direction debate has been most intense, the literature supports two essential criteria of causality: (a) statistical association, and (b) temporal precedence.

The primary remaining issue is the possibility of spuriousness in the apparent effect of life events on health outcomes. Although this explanatory hypothesis cannot be entirely set aside, the literature is filled with examples of studies that have attempted to control for confounding factors, and almost none that have claimed to explain away the life events—illness relationship (e.g., Kessler et al. 1985, Turner and Lloyd 1999).

1.1 Change Events Versus Negative Change Events

As previously noted, the conceptualization that guided developers of earlier event checklists was that change *per se*, whether positive or negative in nature, required adaptation and can have a stressful impact. Although this perspective continues to be represented among a number of prominent investigators, the majority of life event researchers have come to focus upon undesirable change assessed with lists containing only putatively negative events. The debate about whether it is change or undesirability that is relevant to the experience of stress is difficult to resolve because there is no wholly satisfactory criterion measure—at least not one that can be applied in field settings. However, a number of researchers have argued that power to predict distress or illness represents a reasonable criterion (e.g., Turner and Wheaton 1995). From this perspective, considerable evidence on the change versus undesirability issue has accumulated. Zautra and Reich (1983) published a review of 17 studies that examined the relationships of desirable and undesirable events to measures of psychological distress. They observed a consistent pattern of clear positive relationships with negative events in contrast to weak and contradictory findings with respect to positive events. Results suggesting the dominant significance of negative compared to positive events as risk factors for distress and illness have been quite consistent across a range of study populations, dependent variables, and life event inventories (Turner and Wheaton 1995). However, the conclusion that ostensibly positive life changes play no role in either elevating or conditioning stress experiences cannot be made with confidence. The mechanisms involved may simply be more complex than research has so far been able to reveal. The data do support the recommendation that, in the context of the limited time or space that characterizes most questionnaires, event checklists be restricted to events that are presumptively undesirable in nature.

1.2 Event Timing and Duration

Most checklist studies on the health effects of social stress have employed a one-year time frame for inquiring about experienced events. This time frame appears to be favored because it is regarded as long enough to obtain a reasonable estimate of variations in exposure to recent life events, and short enough to avoid the substantial decline in the ability of respondents to recall events that appears to occur beyond one year. In contrast, studies employing two- to five-year time frames have sometimes reported higher correlations than those that have considered shorter periods. In general, the choice of an appropriate time frame must involve consideration of the nature of the outcome of interest and the estimated or assumed causal lag of event effects for that outcome. When relatively long time periods are selected, group decline in event reporting can be investigated as a function of months prior to interview and cut-points for the time frame established based on the results.

In this connection, it should be recognized that the problem of reliability of reporting or of remembering, and the contention that stressors may be time limited in their effects, cannot be applied equally to all events that may be experienced. For example, it would rarely be the case that a subject would not remember, or fail to report in response to specific questions, that his or her parent had died, or child had died, or parents had divorced that he or she had served in combat, or had been physically or sexually assaulted. Evidence that a number of major events or circumstances are relevant to mental health and that the duration of their effects is closer to a lifetime than to one year suggests the utility of considering such events within efforts to index a person's burden of stressful experience. The

measurement of major, potentially traumatic events is discussed briefly below.

It is widely recognized that both discrete life events and relatively enduring problems are relevant to distress and illness. The experience of eventful stress may alter the meanings of existing strains, generate new strains, or magnify existing strains (Pearlin 1983). Alternatively, the impact of recent events may be amplified in the presence of chronic stress (Brown and Harris 1978). To test the idea that eventful and chronic stressors act synergistically requires the capacity to distinguish stressors within the two categories. Although life event checklists aim to assess discrete events, it is clear that some occurrences of a given event are time-limited in nature, whereas other occurrences of the same event may represent the beginning of a long-term difficulty.

In a large-scale community study ($n = 1561$), Avison and Turner (1988) obtained information for each reported event on when it ended as well as when it had occurred. Analyses confirmed that event checklists routinely reflect differences in exposure to relatively enduring as well as discrete stressors. Moreover, none of the 31 negative events assembled by these investigators from established lists were found to be uniformly experienced as either discrete or chronic stressors. This research thus indicates that enduring or chronic stress is part of what is reflected in associations of checklist scores with health outcomes and that it is possible to distinguish its contribution. However, the enduring stressors that might be indexed within an event checklist are likely to be too limited and narrow to yield adequate estimates of variations in exposure to chronic stress. This issue is discussed further below.

1.3 Event Weighting

Considerable attention has been given to differential weighting of life events, presumably because the idea that there are no differences in impact potential across events is counterintuitive. There are several types of weighting, but the two most common are 'objective' ratings of change, or importance, or seriousness, of events by 'judges,' selected in random samples of defined populations, in purposive samples of individuals who have experienced the event being weighted, or by expert panels, and 'subjective' ratings assigned by individuals to their own events and considered only at the individual level. A primary difference between these two is the level of aggregation of the weight: objective weights reflect an average assigned by a group of raters; subjective weights involve self-reporting by the individual on how serious or stressful the event was for them.

Thus, 'objective' weights are attempts to capture differences in event characteristics that imply differences in impact potential that are applicable across individuals, whereas 'subjective' weights attempt to capture differences in impact potential associated with variations in the meaning of an event for individuals themselves. As noted above, despite numerous attempts to demonstrate otherwise, research has failed to yield evidence for the effectiveness of the 'objective' weighting of events. Nevertheless, some researchers have called for additional efforts, arguing that the issue is not yet settled (Turner and Wheaton 1995).

Concern about subjective weights most often revolves around the issue of confounding estimates of stress exposure with measures of outcome. Reports of illness or distress and of the seriousness or stressfulness of reported events may reflect the same domain of experience. This problem is arguably less serious when the outcome of interest is physical health status and, with longitudinal data, bias can be substantially reduced by partialling out the effects of events on later health. However, subjective weights are problematic in another respect: they tend to confound differential stress exposure with differential vulnerability to stress. The weight attached by a respondent to an event will be substantially a function of his or her capacity, real or perceived, to handle that event emotionally and/or practically. This capacity is largely determined by the individual's coping skills and the availability of social and personal resources. Thus, subjective ratings confound the effects of stress mediators/moderators with those of stress exposure and should therefore be avoided even in prospective studies and studies on physical health status.

2. Interview Measures of Life Events

Interview measures are distinguished from the checklist approaches by their use of qualitative probes. These probes are employed to more precisely specify the characteristics of life events that might be stressful. The approach avoids the violence to logic implicit in assuming that widely differing events have equivalent stress-evoking potential by specifically attempting to establish the degree of severity of each event exposure (Wethington et al. 1995). Other major strengths of intensive interview measures include achievement of greater comprehensiveness of event coverage through flexible domain-specific elicitation and self-nomination of events not evoked by direct questioning, and the ability to establish the time ordering of stress exposure and health outcomes with greater confidence. The major disadvantage of interview measures is that they are extremely time-consuming and expensive relative to checklist methods.

2.1 Life Events and Difficulties Schedule (LEDS)

The Life Events and Difficulties Schedule (LEDS) is the most widely used personal interview method and has produced perhaps the most compelling evidence available for the role of stress in psychiatric disorder (Brown and Harris 1978). This semistructured in-

strument yields a narrative story of each experienced event that is used by investigators to rate the importance of events. These investigator-based ratings attempt to estimate what the impact would be in a specific context for the average person. It is the experience of a 'severely' threatening event or of a severe chronic difficulty that is hypothesized to increase risk for the occurrence of physical or psychiatric disorder. Severity is established through ratings of 'long-term contextual threat,' aided by the use of 'dictionaries' of examples of rated events and difficulties, the use of which requires a formal training course (see Wethington et al. 1995).

The considerable strengths of this approach are offset by the very high cost noted earlier. This fact, along with the extensive amount of time required to complete the rating process, may make the method unsuitable for large-scale community studies. From certain points of view, a second disadvantage is that the method, in evaluating social context within the severity rating process, ends up aggregating stress exposure with factors that may amplify or moderate its impact. That is, what has been described as the stress process is substantially represented in the ratings of contextual threat. Although this results in powerful predictions of health outcomes, information that is crucial to interventionists is obscured when the effects of stress exposure and of differential vulnerability are confounded. As Wethington et al. (1995) have noted, Brown and his colleagues continue to refine the measure to address this criticism, at least to some extent.

2.2 *The Standardized Event Rating System*

The Standardized Event Rating System (SEPRATE) utilizes a structured interview format to develop descriptions of each event or difficulty reported (Dohrenwend et al. 1993). In addition to the narrative description, the probes allow a standardized assessment of separate aspects of events and situations thought to condition level of stress experienced. A major difference from the LEDS interview is that material that might infer differences in stress vulnerability is stripped from narratives to avoid the inclusion of vulnerability estimates within event ratings.

This interview measure is relatively new and has not been as widely tested as the LEDS. Like the LEDS it is relatively expensive to use, is lengthy to administer, and requires specialized training from the authors.

3. *Chronic Stress*

Despite growing evidence that chronic stressors affect physical and psychological health, there have been few attempts toward comprehensive measurement of such stressors. The relative lack of attention in this area may arise from concern that reports of enduring role-related or other stressors may be more a consequence or reflection, than a cause of disorder. A promising 51-item inventory has recently been offered by Wheaton (1997) who has presented evidence contrary to this concern about causal confounding. The inclusion of this measure, along with a life events checklist, has been shown to account for about 2.5 times as much variance in depressive symptomatology as typically reported in the literature (Turner et al. 1995). This measure assesses a wide range of role-related and role-unrelated chronic stressors and the observation that it is unique association with depression suggests the need in future research for including a separate sampling of items addressed to the general domain of chronic stress. There is also a variety of less comprehensive questionnaires that deal with specific domains such as work or relationship strains. These have been enumerated and critiqued by Lapore (1995) and Herbert and Cohen (1995).

4. *Lifetime Exposure to Major/Traumatic Events*

There is evidence that traumatic events or circumstances, individually or cumulatively, are relevant to mental health (Rutter 1989, Kessler and Magee 1993, Turner and Lloyd 1995). There appears to be a range of events that, presumably, can be reliably measured and that can have significant mental health consequences despite their occurrence years, or even decades, earlier. This argues strongly for the systematic inclusion of lifetime experience of such events as part of the effort to assess difference in stress exposure. Analyses should consider both the direct individual and cumulative effects of lifetime traumas and the extent to which they may condition the impact of more contemporaneous stressors. Brief inventories of major/traumatic events are presented in Kessler and Magee (1993) and Turner and Lloyd (1995). However, because the nature of traumatic experience varies across populations and age cohorts, event selection and coverage should be specific to each study population.

It is important to understand that the health significance of social stress has never been effectively tested because we have yet to adequately measure differences in stress exposure. The conceptual consequences of this inadequate measurement can be profound. This is so because unmeasured group differences in stress exposure masquerade within research findings as group differences in vulnerability. Failure to take account of differences in traumatic stress or in the stress of discrimination can inappropriately suggest group differences in coping skills or other personal attributes relevant to adaptation. It seems clear that efforts to measure stress exposure should be as comprehensive as possible and take

account of eventful stressors, more enduring strains, lifetime occurrence of traumatic events, and stress associated with discrimination and acculturation.

Stress, Neural Basis of

The term stress is semantically confusing and difficult to define. The confusion of what is meant by stress is compounded by its use both as a noun, i.e., a stressful experience or life event, and as a verb, i.e., a stress response. In addition, stress is usually seen as a negative state particularly as it is often used to describe the state of having too much to do in too little time. Despite the negative connotations, the dictionary defines stress, as something that weight is placed upon, something important. Synonyms for stress include emphasis, accent, and significance; not exactly definitions that should elect such negative responses. Another definition is raised from the field of physics, where the typical synonym is strain. That strain is typically measured through changes in the physical properties of matter. This definition has some utility when considering the neural basis of stress. That is, a given amount of stress can be useful to material, testing its strength. But when the amount of stress is increased precipitously, those physical properties can change, often irrevocably. Combining these two perspectives, then, it is tempting to assert that stress is the physical response to environmental change beyond the expected level of force. This would necessarily exclude changes in sensory processing, i.e., perception, which may or may not be stressful. However, it also excludes two of the more salient features of the stress response: subjectivity and emotionality.

With regard to subjectivity, what is stressful to one person is not necessarily stressful to another. And with respect to emotionality, few would deny the emotional

content of a stressful experience. The true definition lies somewhere between the mechanistic/physical view and a more emotional/subjective one. For the purposes of this submission, we will consider stress to be the subjective response to environmental changes beyond an expected level of force. Experience of stress and the neural processes that mediate it will be discussed here.

Possibly the most accepted definition of stress was proposed by the eminent psychologist Hans Seyle who defined it as the nonspecific response of the body to any demand placed on it. With an emphasis on non-specificity, Seyle was referring to the most well described stress response systems in the body: the hypothalamic-pituitary-adrenal axis (HPA). In response to the stressor, the paraventricular nucleus of the hypothalamus releases the corticotrophin-releasing factor (CRF), which induces the release of adrenocorticotrophic hormone (ACTH) from the anterior lobe of the pituitary. ACTH exerts its effects on the adrenal cortex promoting the synthesis and secretion of glucocorticoids, cortisol in humans, into the bloodstream. Glucocorticoids are the final effectors of the HPA axis and exert homeostatic regulatory effects including energy mobilization and inhibition of anabolic processes. The HPA axis is based on negative feedback resulting from the release of glucocorticoids into the blood that suppress the release of CRF from the hypothalamus and ACTH secretion from the pituitary, and results in termination of the stress response. Concomitantly with the release of ACTH from the pituitary, the opioid peptide beta-endorphin is also released having wide-ranging modulatory effects on neurotransmission and hormone regulation in the brain. Seemingly paradoxical, beta-endorphin plays a role in stress-induced analgesia and prevents the stress response from overwhelming the capacity of the organism to contend with the stressor.

Glucocorticoids are released in response to every type of stressor known to humans, from novelty to chronic pain, to death. They are also released in response to more positive emotions and experiences such as pleasure and learning. Because glucocorticoids are released into the bloodstream and thus have access to nearly every known organ in the body, the emphasis on non-specificity is not unfounded. Activation of the HPA is known to have widespread consequences and under supra-threshold conditions can be detrimental to neuronal functioning. However, Seyle probably did not mean to infer that the stress response in its entirety was nonspecific and certainly did not mean to infer that it was out of control. In fact, there is a recent appreciation for the role that glucocorticoids play as anti-inflammatory agents and in bringing the system back to homeostasis after a stressful experience.

The many different neural and neuroendocrine pathways activated as a result of stressful experience further exemplify the oversimplification of Seyle's emphasis on non-specifity. In addition to the secretion of glucocorticoids by the adrenal cortex, the adrenal medulla and autonomic nervous system also have prominent actions in mediating the stress response. The autonomic nervous system consists of two branches, the sympathetic and parasympathetic, which work in opposition to each other. Activation of the sympathetic division of the autonomic nervous system stimulates the chromaffin cells of the adrenal medulla to secrete the catecholamines epinephrine and norepinephrine into the bloodstream. Epinephrine and norepinephrine induce a variety of physiological changes that provide the organism with the necessary energy resources to carry out its actions under stressful experiences in preparation for the 'fight or flight' response, a term used by Walter Cannon. As a result, respiration increases to facilitate the exchange of oxygen in the lungs, while cardiac output is increased to divert blood from digestive areas to muscles. Sympathetic activation also results in an increase in the supply of glucose via the inhibition of insulin and increased glucagon production that converts stored glycogen into glucose. Although counterintuitive, the inhibition of insulin is very adaptive since it increases the availability of glucose to the brain thereby enhancing neuronal function. In contrast to the sympathetic, the parasympathetic division is promptly inhibited by stress and thereby postpones the costly non-essential anabolic processes of vegetative function such as digestion.

In addition to these peripheral responses to stress, there are numerous central responses. Among other purposes, they are important in establishing the 'what' and 'where' of the stressful experience, as well as the formation of memories about the experience. For example, CRF neurons form part of the critical HPA response to stress and are innervated by limbic areas including the amygdala, bed nucleus of the stria terminalis, and lateral septum. It is suggested that they provide emotional tone to or perception of the stressful stimulus. Brainstem afferents from catecholaminergic neurons have a stimulatory action on HPA activation, as does serotonergic input from the dorsal raphe nucleus. Inhibitory input is provided by local GABA neurons that decrease the release of CRF. CRF neurons also receive input from other hypothalamic nuclei including the superchiasmatic nucleus, which serves to synchronize circadian rhythmicity and control the daily oscillations of hormone secretion. The stress response in turn activates several brain regions and pathways. For example, exposure to stressful experience stimulates the mesolimbic/mesocortical dopamine systems, which in turn innervate the prefrontal cortex, an area involved in anticipatory phenomenon and cognitive function. Furthermore, the mesolimbic/mesocortical systems are linked to the nucleus accumbens, which are implicated in reinforcement/motivational and reward processes.

The amygdala and hippocampal components of the limbic system are also stimulated during stress. The

amygdala is important for the emotional analysis of the stressor and has direct connections with the hypothalamus, cortex, and regions of the brainstem involved in autonomic control. Thus, the amygdala may serve as an integrator linking regions responsible for detection of stressors involving cognitive processing (e.g., the cortex and hippocampus) and those that serve as effectors of the stress response (e.g., the hypothalamus and brainstem controls). The hippocampus, on the other hand, appears to be involved in inhibition of the HPA axis and thus is part of the feedback control of ACTH release. The inhibitory role of the hippocampus depends on activation of hippocampal glucocorticoid receptors, which stimulate the fimbria-fornix pathway from the lateral septum and bed nucleus of the stria terminalis inducing the release of the neuropeptide, somatostatin, to inhibit the PVN. Thus, the interaction between the stress system and neural elements function to regulate the autonomic, endocrine, and behavioral responses to stress allowing for perception of the stressor, emotional coding, and initiation of action.

The HPA axis of the stress system exerts a profound influence on the regulation of growth, reproduction, and the immune function. There is a stress related suppression of growth hormone that inhibits growth in the young organism and the repair of existing tissue in adults. In both the male and female reproductive systems, stress induced CRF and beta-endorphin secretion suppress the gonadtropin-releasing hormone (GNRH) at the level of the hypothalamus. Furthermore, glucocorticoids decrease pituitary responsiveness resulting in suppression of the leutenizing hormone (LH) and the release of the follicle-stimulating hormone (FSH). Testicular and ovarian sensitivity to LH is also decreased by glucocorticoids. Stress can thereby disrupt ovulation and implantation in females and reduce sperm production and testosterone secretion in males. Stressors also exert multiple effects on the inflammatory/immune reaction. Glucocorticoids mediate stress-induced immunosuppression via a negative feedback loop. Glucocorticoid secretion resulting from HPA axis stimulation by cytokines (i.e., interleukin-1, tumor necrosis factor-alpha) suppresses the stimulatory effects of cytokines on the HPA axis. It is obvious that the impact of stressor exposure is widespread and extends to many physiological and neural systems.

Defining stress and its neural consequences is made more difficult by the parameters of stress. For example, the duration of stressful stimulus can be either chronic or acute and the neural indices differ dramatically depending in these temporal characteristics. Stressful experience also differs in its intensity. Minor stressful experiences can induce a range of responses that are much different from more severe forms of stress. This is contradictory to Seyle's view of a common stress response regardless of the nature of the stressor. The stress system produces adaptive responses to acute stressors. However, the same stressor, when chronic or activated without sufficient physiological cause, becomes pathogenic resulting in the emergence of stress related disease. Prolonged activation of the catabolic processes of the stress response can result in cardiovascular (hypertension), metabolic (myopathy, fatigue), gastrointestinal (gastric ulcers), and reproductive (impotence and amenorrhea) consequences, as well as complications associated with immunosuppression (impaired disease resistance). Although there is consistency of responses activated during stress, responses can be specific to the particular characteristics of the stressor.

Stress physiology is not only modulated by physical stressors, but also by psychological variables. In fact, psychological factors can initiate a stress response even in the absence of physical insult and homeostatic disruption. Animals and humans have been shown to exhibit the classic stress response during circumstances such as bereavement, difficult cognitive tasks, and conditioned fear. The stress response initially evolved as a way of contending with environmental challenges but over time came to be activated by cognitive phenomenon. The magnitude of a stressful event is modulated by not only the nature of the stressor and the resulting physiological perturbations, but also individual perception and interpretation of the stressor. Lack of predictability and control are the two major elements underlying the cognitive appraisal of stress. Uncertainty about an aversive event reduces feelings of control over the situation thereby inducing higher levels of stress. Related to this is the well-documented phenomenon of learned helplessness in which prolonged exposure to uncontrollable and inescapable aversive stimuli can produce emotional disruption and some deficits in performance, while exposure to the same amount of controllable stress has no effect. Furthermore, the psychological component of stressors underscores the element of individuality of the stress response. What is stressful to one individual may not be to another. Factors such as gender, prenatal and early life psychological and physical stress have profound and long-lasting effects on the basal activity of the stress system. Just as chronic activation of the stress response can lead to a manifestation of physical pathologies, so it can lead to psychiatric syndromes including melancholic depression, anorexia nervosa, obsessive compulsive disorder, and panic anxiety.

It has been demonstrated thus far that stressors have extensive impact on various neural and peripheral systems. But, the aforementioned neuromodulatoy systems also contribute to a range of behaviors allowing for maximal ability of the organism to contend with the stressful stimulus. This reciprocal relationship between behavior and physiology is essential to overcoming a stressor and re-establishing homeostasis. Reproductive and feeding behaviors are suppressed allowing for appropriate provision of

energy to overcome the stressor. The degree of arousal and cognition is also altered. As already demonstrated, acute stress can produce adaptive behavioral responses. Such a response would include increased arousal and enhanced learning and memory resulting from blocked glucose transport to cells benefiting neuronal function by providing more glucose to neurons. As a result, the animal is able to contend with the stressful experience. On the other hand, chronic stress can be detrimental to neural function. Elevated glucocorticoids damage hippocampal neurons resulting in the inability of the hippocampus to inhibit CRF release. Consequently, there is an increased secretion of glucocorticoids leading to additional hippocampal degeneration. Such damage can produce deficits in learning and memory. An inverted U function could thus be used to represent the relationship between stress and performance. Optimal performance occurs with moderate levels of demand but is compromised at the extremes. Low levels of stress, such as boredom or drowsiness, are detrimental to performance. As stress increases, performance is facilitated up to an optimal level beyond which there is deterioration. Thus, physiological and behavioral processes are involved in the adaptive response to stress.

Although stress is difficult to define, the responses produced by stress are not. Stressors are pervasive and challenge the physiologic and behavioral well being of the organism. All stress-inducing stimuli, both physical and psychological, exert their initial effects on the central nervous system (CNS). Thus, the stress response system is predominantly under neural control. The CNS regulates the reactions of the organism through close interactions with other neuroanatomical, peripheral and functional elements to produce adaptive responses necessary for maintaining homeostasis. The stress system is designed for quick activation and disengagement. Chronic stimulation results in maladaptive responses and a multitude of physical, emotional, and behavioral pathologies. Thus, a contemporary perspective of stress has evolved from Seyle's original concept of a single stereotypical response resulting from any stress put on the body to one that reflects different patterns of biochemical, behavioral, and physiological responses of varying degrees to particular stressors.

To this point, we have focused primarily on the nonspecific or general responses to stress. However, the past few decades of research on the neural basis of stress would suggest that many responses to stressful experience are not nonspecific and are indeed specific at many levels: from their temporal characteristics, to regional location, to molecular identity. To illustrate this point, we will discuss the responses to one specific stressor, that of acute exposure to brief, low-intensity, inescapable tail shocks in the rat. Exposure to this one experience induces a number of responses that are both regionally and temporally specific. At the transmitter level, exposure to the event enhances the release of acetylcholine in the hippocampus and prefrontal cortex but not in the nucleus accumbens. At the receptor level, exposure to the stressor activates n-methyl-d-aspartate (NMDA) receptors in the basolateral amygdala, while enhancing the affinity of the AMPA type of glutamate receptor in area CA1 but not area CA3 of the hippocampus. At the biochemical level, exposure enhances the binding of phorbol esters, a marker for protein kinase C activity. This effect occurs specifically in the basolateral nucleus but does not occur in either the central nucleus of the amygdala or the hippocampus. At the physiological level, exposure to the acute stressful event reduces spontaneous unit activity in the basolateral amygdala, while enhancing theta rhythms and reducing long-term potentiation in hippocampal subregions. At the molecular level, activation of immediate early gene expression occurs in the several layers of the cortex and area CA1 of the hippocampus but not in the dentate gyrus. At the cognitive level, exposure to the stressor has been reported to impair instrumental responding while enhancing classical conditioned responses.

These responses to stress are also dependent on the sex of the animal. For example, exposure to the stressor, while enhancing classical conditioned responses in the male rat, dramatically impairs conditioning in the female rat. Finally, many of these responses to stress are immediately induced while others are persistently expressed. Moreover, a subset of these responses can be reactivated long after the stressful experience has ceased by simply placing the animal in the context where the stressful event occurred. Thus, there is a psychological component (or memory) of the experience that is sufficient to activate many indices of stress in the brain. From this one example, it is clear that the responses to stress can be both regionally and temporally specific as well as sex specific. Understanding the neural basis of stress will require an appreciation and documentation of these specifics.

Stress: Psychological Perspectives

Psychological stress, like the general term 'stress,' is a common term that defies a universally agreed-upon definition. These difficulties are not due to a lack of interest in the concept; rather, they are due to a widespread fascination with psychological phenomena related to organism–environment interactions. It is the inherent complexity of this enterprise that attracts and vexes investigators. In the place of a standard definition of psychological stress, three different perspectives have evolved with their own definitions, as well as their own conceptual and methodological traditions.

1. *Historical Considerations and Concerns*

Interest in the implications of emotions for health is age-old, dating back to the origins of holistic approaches to medicine exemplified by the writings of Hippocrates (400 BC). Interest in the influence of psychological factors on emotional functioning has consequently represented a parallel theme of interest over the centuries (see *Environmental Stress and Health*). The basic premise is that stress gives rise to distressing emotions, which in turn influence disease. Yet the connections between these words and ideas are quite rich, and more complex than current viewpoints suggest. Indeed, 'stress' is derived as a shortened form of 'distress'; disease, in turn, originally referred to 'disease,' or distress (Rees 1976). It is in this lexicographic context that varied connections between stress, distress, and disease can be appreciated, only some of which are useful for scientific purposes.

As rich in explanatory power as psychological stress might be for understanding the causes of distress and disease, the linguistic overlap of these terms also signifies problems. The intuitive appeal of the ideas and their relations may foster false theories and findings. There is a tendency to 'explain away' disorders of unknown etiology based on prevailing beliefs about the unwanted or adverse social or psychological circumstances (Monroe and McQuaid 1994). For example, before the physical causes of particular infectious diseases were discovered, the origins of these illnesses were commonly ascribed to psychological stress and distressing emotions (Sontag 1978). The intuitive appeal of explanations based on psychological stress and related ideas requires firm thinking and sound science to differentiate valid associations from plausible and convenient fictions.

2. *The Major Perspectives and Traditions*

Two traditions may be discerned which, together, have given rise to three perspectives on psychological stress. The first tradition derives from clinical observations and field studies of humans exposed to threatening circumstances. The second tradition arises from the animal laboratory, where systematic control over stimulus conditions and response alternatives of the organism has been exerted. The common denominator of the three perspectives on psychological stress emerging from these traditions is an interest in the psychological concomitants and sequelae associated with challenging or threatening environmental conditions. The differences between these perspectives, as explained next, is the relative emphasis placed on the environment, organism, or environment–organism interactions over time as a defining feature of psychological stress.

2.1 *The Stimulus or Environmental Perspective*

The stimulus or environment perspective holds that psychological stress is anchored in the environment and its characteristics. The underlying assumption is that objective external circumstances can be classified as psychologically demanding, threatening, benign, and so forth. In human field or laboratory research, the stimulus parameters were recorded in naturalistic contexts or manipulated in laboratory settings. Animal laboratory research, on the other hand, could readily control the environment, and thereby more easily operationalize and manipulate the stimulus conditions.

Other factors, too, were influential in promoting the environmental perspective. Attention to the environment for creating stress and illness became especially evident toward the mid-twentieth century; the experiences of World War II reshaped the ways in which a breakdown in human functioning was viewed. Prior to this time, it was thought that individual vulnerability (i.e., biological) largely accounted for who succumbed to stress. Normal people maintained health and survived the ravages of stress; the biologically predisposed or tainted broke down. Given that one-third of American casualties in World War II sustained no physical injury (Weiner 1992), the idea that severe stress could precipitate psychological and physical breakdown in previously normal individuals was incorporated into medical and psychiatric thinking (Dohrenwend 1998). This brought to the foreground

the importance of extreme environments for defining psychological stress.

Finally, a surge of interest and activity in psychological stress for an environmental perspective came from another avenue of inquiry: life events questionnaires. Thomas Holmes and Richard Rahe developed the idea that life events could be assessed in an objective manner. These researchers developed a list of 43 events observed to occur prior to the onset of disease, including such items as marriage, trouble with the boss, change in sleeping habits, death in the family, and vacation. The events were collated and weighted, producing the Schedule of Recent Experiences (SRE; Holmes and Rahe 1967). Literally thousands of studies were conducted with the SRE and the many derivative life event checklists it spawned (Monroe and McQuaid 1994).

2.2 The Response Perspective

The second perspective on psychological stress can be traced to the writings of Darwin and the theory of natural selection. It is in these ideas that the attention began to focus on the implications of challenges and dangers of the environment, forcing the organism's *adaptation* to ever-altering external circumstances. The response features of stress take on special importance in this framework, as it is recognized that evolution also fostered skills in *anticipation* of dangers and adversity (Weiner 1992). Being able to prepare for and prevent problems in the future drew upon mental, emotional, and behavioral capabilities that, over time, enhanced survival and reproduction. From this perspective, psychological stress is viewed as the *response* of the organism to the complex adaptive demands of the environment.

The twentieth century brought more sustained and intense interest in probing the intricacies of psychological stress, with an emphasis on the response perspective. The work on physiology by Walter Cannon posed questions about how the body maintained its regulatory functions in the face of changing environmental demands. Hans Selyé introduced the term 'stress' into more formal scientific arenas, and investigated the physiology of organisms in response to acute and extreme environmental conditions.

2.3 The Environment–Organism Interaction Perspective

The stimulus and response perspectives on psychological stress each possess certain limitations. For example, knowledge of the environment does not always predict the responses; individual differences in response to similar stimuli are a common finding. From a response perspective, there are numerous indicators to draw upon (different emotions, psychophysiologic, or hormonal indices), many of which displayed different relationships with distinct environmental challenges (Weiner 1992).

To address some of these limitations, psychological stress has been proposed to represent a particular *relationship* between organism and environment. This third perspective holds that psychological stress is the product of the individual's ongoing transactions with ambient circumstances, particularly circumstances that are perceived as taxing or exceeding adaptive resources. Several possibilities are entertained within this perspective, ranging from an emphasis on stressful *experiences* (Weiner 1992) through emphases on the ongoing process of event occurrence, appraisal, coping, reappraisal, and so on (Lazarus and Folkman 1984). The core feature of this perspective is that of denoting an *active process* between a dynamic environment and an adapting organism over time.

Broadening the definition of psychological stress to encompass the interactions between organism and environment over time also enlarged the conceptual scope of research. This shift raises additional considerations, to which we now turn.

3. Conceptual Challenges and Problems

After the 1950s, stress became a common term, cutting across sociology, psychology, medicine, physiology, and biology. A broad array of constructs were united under this common rubric. At least two issues arise from this explosive growth in research on stress: (a) individual differences, and (b) generality vs. specificity of psychological stress.

3.1 Individual Differences

Despite the promising leads of early research on psychological stress, it became apparent that there was individual variability in response to stressful circumstances. Not all people succumbed to even the most extreme of situations, while some people broke down in the face of apparently minimal demands. Theory and research needed to account for such variation, thereby introducing factors hypothesized to moderate stress effects.

Many factors have been proposed as stress moderators. Attention to this matter invoked such individual difference variables as appraisal of threat and coping (Lazarus and Folkman 1984, Monroe and Kelley 1995) and more remotely a variety of other considerations believed to moderate the effects of stress (e.g., personality factors, social support, etc.; Brown and Harris 1989, Goldberger and Breznitz 1993). The net effect was to broaden the conceptual arena of stress research considerably and to introduce multifactorial models, taking into account a host of factors that could influence stressors and responses

over time (see *Coping Across the Lifespan*; *Control Behavior: Psychological Perspectives*; *Social Support and Stress*; *Stress and Coping Theories*).

3.2 Generality vs. Specificity of Psychological Stress

A second concern was related to the omnibus nature of the stress concept. On the one hand, the stress united a variety of cognate constructs and emphasized the general nature of stress (e.g., Selyé 1976). On the other hand, the unique implications of specific environmental challenges and responses could be obscured within such a general viewpoint (e.g., Weiner 1992). Recent research from both the animal laboratory and human field studies suggests that responses to stressors can be very specific with respect to the particular demands imposed, with specificity being key for understanding many of the adaptive implications (Dohrenwend 1998, Weiner 1992) (see *Stress, Neural Basis of*).

Overall, the challenge for research on psychological stress was to remain true to its roots in extracting the 'essence' of psychological phenomena related to adversity, while at the same time not becoming so overly inclusive as to become essentially meaningless or obscure other underlying associations. Such an agenda raises important methodological issues, as discussed next.

4. Methodological Considerations

Measuring psychological stress in a reliable and valid manner has been a continuing challenge for stress researchers. For example, animal laboratory research has proven useful for more precise specification of both stimulus parameters and response characteristics associated with psychological stress. Yet the methods adopted often constrained the array of possible responses, creating unnatural stressor conditions which, in turn, yielded misleading views about how adaptation proceeds under more ecologically valid conditions (Weiner 1992) (see *Stress Management Programs*).

In terms of human field research, there has been considerable debate about measurement procedures for assessing stressful life events. Research on self-report life event checklists such as the SRE revealed serious psychometric limitations (Brown and Harris 1989, Monroe and McQuaid 1994). Naïve research designs also led to spurious findings. For example, being depressed could cause life events such as 'trouble at work,' and 'difficulties with spouse,' rather than the life events causing subsequent depression. Additionally, many of the life events on the SRE and similar checklists were direct indicators of disorder or illness (i.e., 'major change in eating habits,' 'major change in sleeping habits'). Although more refined and comprehensive measures were developed to address such concerns, fundamental problems with self-report checklists remain (Brown and Harris 1989, Monroe and McQuaid 1994).

In response to these methodological concerns, other investigators designed semistructured interviews and developed explicit guidelines, decision rules, and operational criteria for defining and rating life events (Brown and Harris 1989, Dohrenwend 1998). In general, these procedures enhance the reliability of life event assessments and provide better prediction of outcomes. Although these approaches are more time- and labor-intensive, they represent among the best available tools for measuring psychological stressors. Importantly, too, these approaches provide flexibility in measuring life stress, allowing for ratings of specific dimensions of stress and for taking into account the influences of moderators of stress impact. Thus, in theory, such approaches can help to bridge the gap between a strictly stimulus perspective, and to incorporate useful features of the response and organism–environment interaction perspectives.

5. Future Directions

The three perspectives on psychological stress are converging on a viewpoint of psychological stress as a comprehensive *process* of complex transactions over time between organism and environment. Yet each approach continues to be of value for emphasizing particular features of these complex models that do not receive adequate attention within the other perspectives.

The stimulus perspective is essential to provide valid measures of the stressor characteristics of environments. Without standardized indices reflecting the input characteristics of the circumstances animals or people face, little can be said about 'downstream' elements of the models. For example, individual differences in appraisal or coping have little meaning without considering what is being appraised or coped with. It is in relation to well-specified environmental conditions that the implications of individual differences in appraisal and coping may be most readily understood in terms of the impact on health and well-being (Monroe and Kelley 1995). Future work may benefit from further specification and standardization of the stressor characteristics associated with adverse environments and their relations to varied outcomes (Monroe and McQuaid 1994).

The response perspective suggests a number of avenues to enrich future inquiry. With respect to animal laboratory research, simple singular response indices are being replaced by more complex patterns of behavioral and biological effects. These may range from the immediate 'exquisitely specific' neuroendocrine response profiles through long-term structural changes in the central nervous system (Weiner 1992). With

respect to human field studies, retrospective recall of conditions and emotions may be enhanced through such developments as ecological momentary assessments. These procedures target multiple, immediate reports from people in their usual environments. These methods avoid many of the pitfalls of procedures based on the retrospective reconstruction of events and experiences (Stone et al. 1999).

Perhaps most promising but challenging is the interactional perspective. Formidable challenges in operationalizing key constructs exist (e.g., appraisal and coping; Monroe and Kelley 1995, Cohen et al. 1995). Yet interesting progress has been made recently, employing sophisticated longitudinal research designs with in-depth, microanalytic techniques evaluating day-to-day transactions between the person and environment (Lazarus 2000). Further work along these lines is essential for differentiating the facts from the fictions in delineating the implications of psychological stress for health and well-being.

Stressful Medical Procedures, Coping with

Many moderately invasive, potentially life saving procedures, e.g., colonoscopy to examine the colon and remove polyps, can be performed on an outpatient or 'same-day' basis. Many patients endure these procedures with minimal expressions of discomfort, while others experience and manifest moderate to high levels of pain and distress. Laboratory and clinical studies designed to assess the effects of psychological preparation in reducing distress have increased our understanding of the processes underlying these individual differences in three ways. First, the pain experience is an integration of a sensory experience and an emotional, distress response; pain is not just a sensation that is proportional to the extent of injury. Second, the type and intensity of the emotional response, e.g., fear-distress, is dependent on the patient's representation of the experience, i.e., how it is perceived and interpreted, and the perceived availability of a means of controlling it. Finally, the patient's representation of a procedure is based on information from doctors and nurses and by the ideas, beliefs, memories, and perceptions based on their own experience and observations of others.

1. Pain is Sensation and Emotion

Pain has often been conceptualized as a sensory process (see *Pain, Health Psychology of*). Thus, an injury was thought to activate receptors that sent pain messages to the brain, and pain and distress were expected to be directly proportional to the extent of injury (Leventhal and Everhart 1979). Patients who reported or showed greater discomfort than expected in response to an injury or to a treatment were assumed to have personalities that predisposed them to be excessively sensitive to pain signals or to be malingerers. Observations of wounded servicemen during World War II (Beecher 1946) contradicted the sensory model in two ways. The first was the absence of pain and distress when survival was enhanced by active coping. The second was the failure to alleviate pain and distress with analgesics such as morphine supposed to block conduction of sensory nerves. Administration of barbiturates to reduce emotional

reactions of fear and anxiety reduced pain-distress, suggesting that emotional reactions were a component of the pain response that could amplify pain reactions.

Anatomical and physiological studies as well as behavioral data show that the pain-distress experience is a product of parallel and interacting sensory and emotional systems (Melzack and Wall 1970). Situational factors that increase emotional reactions and amplify distress include the unexpectedness of the noxious sensations, the perception that more serious consequences are yet to follow, and the perception that the sensations are not controllable. Inhibition of the emotion system and minimization of pain-distress occurs when the sensations are expected, perceived as benign (imply no serious consequences), and can be controlled. Two mechanisms appear to be involved in this inhibitory process: the body's opiates, the endorphins, and direct, neural inhibition of pain centers (Strausbaugh and Levine 2000).

2. *Distress Reduction in Laboratory Settings*

A classic study by Egbert and colleagues (1964) demonstrated that postsurgical distress could be reduced by preparatory information; it triggered both laboratory and clinical studies of preparation. The laboratory studies showed how subtle differences in preparatory information had a substantial impact on the level of pain-distress. For example, subjects about to undergo a cold pressor test kept their hands submerged in the ice water for less time if they were told they were participating in a 'Vasoconstrictive Pain Study' (painful label) than if the study was described as a 'Discomfort Study' (less painful label; Hirsch and Liebert 1998). The discomfort group also gave lower ratings to their distress. In our earlier studies, subjects told to focus on the benign, sensory experience of the ice water during cold pressor immersion (pins and needles, color of the hand, etc.) experienced less distress and showed an increase in skin temperature in comparison to subjects told the experience would be painful. Distraction often proved ineffective in blocking these noxious experiences unless it was in the same modality as the pain stimulus (auditory; skin sensation).

3. *Distress in Response to Invasive Medical Procedures*

The study by Egbert and colleagues (1964) and the laboratory studies indicated that a patient's response to an invasive medical procedure can be shaped by the way their doctors and nurses frame the somatic sensations evoked by the procedure. As Janis and Leventhal pointed out years ago (Janis and Leventhal 1968), the florid symptoms often observed among surgical patients and previously attributed to underlying psychopathology were often a product of the meaning of the situation and the availability of coping reactions. For example, although the painful sensations experienced during procedures such as endoscopy or bronchoscopy are readily attributed to the procedure, their meaning is ambiguous. They could imply that the instrument has caused damage or contacted a cancer, or suggest to that patient that he will become increasingly frightened and will be unable to retain emotional control if the pain lasts much longer. Ambiguity also can extend to post-treatment symptoms, e.g., the pain experienced after coronary bypass surgery can be identified as wound pain from a healing incision or damage to the heart. The implication of the latter is far more threatening and fear arousing than the first. In the absence of information from medical practitioners, the meaning of somatic experience will reflect the patient's limited knowledge, memories of similar experiences, anecdotes from others, and their worst fears.

Providers can provide patients with information so that they will experience procedures in a nonthreatening way and minimize pain-distress. Two types of information were given to patients prior to an endoscopic examination and each had beneficial effects: sensory information regarding what they would feel during the examination (e.g., having air pumped into your stomach will make it feel that you have just eaten a large meal) and behavioral plans (e.g., techniques for mouth breathing and swallowing to reduce gagging while swallowing the endoscopic tube). Patients given both types of information were least likely to gag when swallowing the endoscope (36.4 percent) and had lower heart rates in contrast to 90 percent of those gagging who received neither type of information. Patients given only one type of information fell in between (Johnson and Leventhal 1974). Thus, providing patients with information that minimizes the threat value of an experience reduces their anxiety and helps patients to coordinate behavioral procedures with their somatic sensations. The efficacy of this combination is well illustrated in studies of preparation for childbirth. The simple act of monitoring the sensory features of labor contractions lowered postdelivery pain reports in women who had participated in LaMaze classes and were trained in the behavioral responses needed to facilitate child birth (E. Leventhal et al. 1989). Women who were offered various ways of distracting themselves did not benefit with reduced pain from their childbirth classes. Thus, monitoring increased familiarity with body sensations, '… reduced emotional behaviors and lowered the levels of pain, by facilitating the coordination of breathing and pushing with contractions' (p. 369).

Practitioners seeking to help patients cope with stressful procedures need to be aware of the influence of current levels of pain-distress on retrospective pain reports. For example, chronic pain patients underestimated the pain they had reported on electronic

diaries during the prior week if their retrospective reports were given after physical therapy when their current pain was low (Smith and Safer 1993); patients who reported their prior pain before physical therapy overestimated their diary reports. Redelmeier and Kahneman (1996) found that retrospective ratings of the overall painfulness of colonoscopy and lithotripsy was related to the peak level of pain during the procedure and the level of pain experienced at the end of the procedure. The duration of the procedure was unrelated to overall judgments of pain. Thus, memories of pain-distress during medical procedure are biased upward if patients are experiencing much pain when making their judgments, and can be biased downward if the procedure is designed to end at a low level of pain and distress. This bias may be of clinical importance as the recall of pain may affect willingness to undergo future, protective examinations.

There is evidence that interventions to reduce pain-distress are particularly helpful for patients who are most vulnerable to upset. Baron and Logan (1993) proposed that patients who have a high desire for control during a dental, i.e., root canal, procedure (perhaps because they interpret the procedure as threatening), yet perceive themselves as having little control (because they feel incapable of coping with the threat), are highly vulnerable to upset and experience the greatest anticipatory anxiety before treatment and the greatest discomfort during it. When given sensory and procedural information that reframed the procedure in a less toxic way, these patients with high desire for control but low perceived control were no more distressed by their root-canal procedure than other, nonvulnerable patients. Vulnerable patients given only 'placebo,' filler information were highly distressed.

An important caveat is whether the factors effective for the reduction of pain-distress in response to brief procedures such as colonoscopy will be effective in reducing pain and distress for prolonged stressors such as the pain and distress experienced following surgery. Informing people about somatic sensations may be ineffective in reducing pain postsurgery (Johnston and Vogele 1993) unless the information provides clear and believable nonthreatening interpretations of these somatic events. Recent work on recovery from myocardial infarction suggests that this is critical. Behavioral techniques for distress control seem to be effective in long-term stress settings if the control is effective. For example, hospitalized patients allowed to self-administer analgesics use less analgesic and report less pain.

4. *Summary*

The pain and distress experienced during invasive procedures can be modified by effective preparation. The key constituents of such preparation appear to be nonthreatening interpretations of the sensory cues evoked during the procedure and strategies for effective situational control linked to these cues. This combination appears to be effective for regulating the emotional component of the pain-distress response. Individual differences, however, can modify the effectiveness of behavioral preparation; patients lacking a sense of efficacy in controlling either the situation or their own affective reactions may benefit more when they see trusted others in control of the procedure. Preparation may also have different effects on different outcomes, some reducing pain experience, others physiological reactions, and others the time for completing the procedure. Though studies are needed to identify the mechanisms underlying the control of pain-distress during noxious medical procedures (Strausbaugh and Levine 2000), it is clear that patients can benefit from information. A humane system will provide information with regard to what patients will experience and help them to interpret these experiences as an expected part of a healing process. It will also provide behavioral procedures to facilitate the control of these noxious sensations and their associated affects.

Strikes: Sociological Aspects

The withholding of labor is known to have occurred during antiquity, the Middle Ages, and the Renaissance (Crouzel 1887). It was not, however, until the spread of wage labor under industrial capitalism that strikes became a routine expression of workers' claims. The very words by which we know the phenomenon in many European languages ('strike' in English, with its derivatives: German *streik*, Dutch *strijk*, and Swedish *strejk*, the French *grèves*, the Spanish *huelga*, the Italian *sciopero*) reveal a mid- to late nineteenth century origin. Only in English, expressions such as *strike*, *strike tools*, or *strike of work* became increasingly common starting during the mid-eighteenth century, keeping pace with the industrial revolution. 'This day the hatters *struck* and refused to work till their wages are raised' we read in the *Annual Register* on 9 May 1768. By 1793, the expression must have been common enough in England for G. Dyer to write: 'The poor … seldom strike, *as it is called*, without good reasons … The colliers had struck for more wages' (*The Oxford English Dictionary*, entry for 'strike'). In French, we have to wait until 1805 to come across the first use of the word *grève* in its meaning of withholding of labor by extension of a much earlier meaning of the word as 'unemployed' or 'without work.' But it is not until 1845–1848 that the new meaning became common (Le Grand Robert de la Langue Francaise, *grève*). The Italian *sciopero* or the Spanish *huelga* did not become part of the daily vocabulary until the later half of the nineteenth century, again by adapting a word used for centuries to refer to unemployment and lack of work (*Deli-Dizionario Etimologico della Lingua Italiana*; *Diccionario Crítico etimológico castellano e hispánico*).

1. Strike Statistics

Systematic collection and publication of strike data started in most countries between 1870 and 1900. Until then, strike data were kept secret in the hands of Ministries of the Interior. After all, strikes were viewed as crimes under Combination Acts (Perrot 1974). Only when the conception of strikes shifted from one of crime to one of 'social illness' did strikes become the concern of specialized Labor Ministries. It is these Ministries that initiated systematic recording and publishing of strike data and that standardized definitions and collecting procedures. Early statistics provided rich information on each individual strike: the immediate causes of strikes, their outcomes, their organizational bases, the occurrences of violent incidents and the number of establishments affected by any given strike. There is none of that richness in today's strike statistics. Furthermore, strike data are highly aggregated (Fisher 1973). Typically, they do not go much beyond three aggregate measures of strike activity: number of strikes (S), number of workers involved (W), and number of hours lost (H).

On the basis of these three indicators, several different measures have been constructed in the literature (Forcheimer 1948, Knowles 1952, Shorter and Tilly 1974, Hibbs 1976): *frequency* or number of strikes per thousand employed workers; *size* or average number of strikers per strike (W/S); *duration* or average number of hours lost per strikers (H/W); and *volume*, defined as frequency × size × duration = (S/thousand employed workers) × (W/S) × (H/W) = (H/thousand employed workers); the Galambos' and Evans' composite strike index based on an unweighted average of S, W, and H (Galambos and Evans 1966). Graphically, these different components of strike activity can be represented in a three-dimensional space as a parallelepiped—the 'shape' of strikes—whose sides are given by the size, duration, and frequency of strikes and whose volume corresponds to the product of the three sides (Shorter and Tilly 1974, Hibbs 1976, Franzosi 1995).

2. Data Reliability

The reliability of strike statistics varies from country to country, but it is generally low (Shalev 1978). Some countries carry out data collection through specialized offices within Departments of Labor; others rely on police departments (e.g., Italy). Some use newspapers as sources of data; others rely on self-reporting, and still others base their statistics on police records. Different countries adopt different definitions of strikes, leading to difficulties in cross-national comparisons. It is generally difficult to gauge the bias of strike statistics under any data collection arrangement. Strike size can be just as easily overestimated as underestimated. If employers report strike size, they may be inclined to play down the strike to embarrass the unions or to portray a public image of peaceful labor relations (particularly vis-à-vis clients), but they may also wish to magnify the strike in order to justify future retaliatory actions or police/government in-

tervention, or to contest the imposition of penalties by clients for late delivery. Union reported figures are more likely to be overestimated in a show of organizational strength. If police offices themselves estimate the size of the strike it may be no more than pure guesswork. Strike frequency, on the other hand, is likely to be always greatly underestimated regardless of the efficiency of collection: small, short, shop-level spontaneous work stoppages, that represent the bulk of all strike occurrences, probably escape recording, as scores of field investigations have shown (Turner et al. 1967, Korpi 1978, 1981, Batstone et al. 1978).

Bias in the data is not without consequences. When single strikes across a city or an industry are recorded separately, the number of strikes is inflated but the average strike size is reduced. To the extent that strike size is related to the workers' organizational capacities, a bias in this measure would misrepresent the organizational basis of strikes (Batstone et al. 1978, p. 22). Under-reporting of small, plant-level strikes obscures the role of informal leadership and the existence of diffused, grass-root discontent, often directed against official unions as much as against employers (Korpi 1981). The systematic lack of information on strike tactics (e.g., walk-out, sit-down, checker-board, with demonstrations through the shop, marches to city hall), and on the broader spectrum of working class actions (such as slowdowns, work to the rule, overtime ban, rallies, demonstrations), fundamentally biases the nature and extent of working-class mobilization. In any case, exclusive emphasis on what workers do and on just one type of action (strike) distorts the broader social relations in which strikes occur. 'It takes two to tango,' Franzosi argues, 'it takes at least two to fight' (Franzosi 1995, pp. 15–18). Strikes emerged in the nineteenth century out of the incessant interaction among three main actors—workers, employers, and the state; it is this interaction that ultimately defined the rules and the acceptable forms of protest (Tilly 1978, p. 161). It is not possible to understand what workers do in isolation of what employers and the state do.

Data aggregation adds problems of its own. There is no way of telling which combination of strike frequency and duration produces any given figure of number of hours lost (Batstone et al. 1978, p. 23). A yearly total of 100,000 strikers could refer to 100,000 different workers or to the same 10,000 going on strike 10 different times (Batstone et al. 1978, p. 21). 'Average' measures, such as size and duration, may mask wide differences in the distribution of actual strike sizes and durations, in particular when used for international comparisons. The same 'average' size, in fact, could be the result of a few, large and official strikes for the renewal of industry-wide, collective agreements and a large number of small, plant-level strikes (such as the Swedish or the Italian case), or of a great deal of intermediate size strikes, as in the United States, where plant-level bargaining is the rule but workforce concentration is higher (Edwards 1981, p. 231). The same 'volume' can mask marked differences in each of its constituent components. Standardized indicators, such as frequency, have been computed using different deflating procedures: total civilian labor force, non-agricultural labor force, unionized labor force, employment figures, etc., leading to an unnecessary proliferation of strike indicators that stand in the way of comparability of findings (Stern 1978).

3. *Patterns of Strikes: What we Know*

The ready availability of strike data for over a century has resulted in a rich scholarly tradition of (mostly quantitative) research on strikes, focusing on the interindustry propensity to strikes (e.g., Kerr and Siegel 1954), but notably on the temporal dynamics of strikes. From as early as the beginning of the 20th century there has been a concern with the relationship between strikes and the short- and medium-term fluctuations in the level of economic activity. Several statistical studies have shown that strike frequency follows the business cycle and the movement of unemployment in particular—the higher the level of unemployment, the lower the number of strikes (see the seminal work by Ashenfelter and Johnson 1969). As American historian David Montgomery wrote: 'Large scale strikes erupted [in the early 1900 in America] whenever the level of unemployment fell off sufficiently to give the strikers a ghost of a chance of success' (Montgomery 1980, p. 94).

Indeed, the dependence of strike frequency on the business cycle is one of the clearest findings of econometric strike research. Yet, economic theories of strikes have not gone unchallenged. For one thing, economic determinants of strikes can be statistically significant without being the main or exclusive influence (Vanderkamp 1970). Furthermore, while there is strong statistical evidence in favor of the relationship between strike frequency and the business cycle, it is not so for the other strike measures: size, duration, and volume. While strike frequency is negatively related to the level of unemployment, there is evidence supporting a positive relationship for duration (e.g., Turner et al. 1967). If economic determinants seem to play a significant role only on frequency, and each strike component measures a different aspect of strike activity, what are the determinants of strike size, duration, and volume?

No doubt, it is workers' organizational capacities that have most deeply affected the overall shape of strikes, size and duration, in particular. As early as 1911–13, French economist March showed the close statistical connection between strike size and unionization. But it is Shorter and Tilly (1974) who most systematically investigated the effect of organization on strike shape in what to date remains a landmark in strike research. For one thing, national, large-scale

strikes are only possible in the presence of national, large-scale labor organizations. But even at the local level, the organizational basis of trade unions helps to bring out on strike a larger portion of the workforce, leading to larger average strike sizes. Labor organizations have also contributed to reduce the average strike duration. The rise of labor organizations has typically shifted the timing of strikes from economically 'bad' times to 'good' times. Through organization, as Hobsbawm put it, industrial workers learned 'the common sense of demanding concessions when conditions are favorable, not when hunger suggests' (Hobsbawm1964, pp. 126, 144). By timing strikes during periods of prosperity unions also contributed to shortening the average duration of strikes. In fact, strikes are more likely to be long and drawn-out during periods of recession when employers are under no pressure to seek a quick settlement.

Changes in the timing of strikes and the consequent shortening of their average duration have also brought about changes in the likelihood of successful settlements and of the occurrence of violence during a strike. Long disputes are likely to be unsuccessful for two reasons: (a) because they tend to occur in economically unfavorable times and (b) because they have a greater likelihood of being violent (and violent strikes decrease the chances of success) (Snyder and Kelly 1976).

Yet the statistical significance of a unionization variable in econometric models of strike size hardly offers a causal explanation. After all, the reverse causal order has produced statistically significant results in union growth models, where unionization becomes the 'dependent' variable and number of strikers the 'independent' one (Ashenfelter and Pencavel 1969, Bain and Elsheikh 1976). In the end, we may have done no more than observe a strong correlation (Goetz-Girey 1965, pp. 146–7, Edwards 1981, p. 9). The exclusive reliance on highly aggregated strike and unionization figures in econometric work has obscured the causal mechanisms in the relationship between these different aspects of mobilization processes; it has also exaggerated the role of formal organization at the expense of informal shop-floor leadership (Batstone et al. 1978). Indeed, the use of temporally disaggregated firm-level data shows how rises in unionization follow (rather than precede) surges in the level of strikes, successful strikes in particular (Franzosi 1995, pp. 124–34).

The political position of labor in national power structures has also deeply affected the shape of strikes. Both strike volumes (Hibbs 1978) and strike sizes (Korpi and Shalev, 1980) have gone down in countries where labor-oriented social-democratic parties acquired stable and lasting control over governments, such as in the Scandinavian social democracies and in Austria (Korpi and Shalev, 1980 p. 320). Direct access to political power offers labor alternative and less costly means to achieve a more favorable distribution of resources: the government machinery itself, rather than the strike (Shorter and Tilly 1974, Hibbs 1976, Korpi and Shalev, 1980). When the working class has control of the government, the locus of conflict over the distribution of resources, national income in particular, shifts from the labor market and the private sector, where strike activity is the typical means of pressure, to the public sector, where political exchange prevails. Short-lived labor governments, on the other hand, or outright exclusion from the government of communist parties, are associated with higher, rather than lower, levels of strike activity (Hibbs 1976, Paldam and Pedersen 1982). Franzosi's work on postwar Italy shows that the 'historic compromise' strategy of the Italian Communist Party drastically changed the shape of strikes between 1975 and 1978 during the Governments of National Solidarity (Franzosi 1995).

4. *The Withering Away of Strikes and Cycles of Strikes*

In the 1950s arguments about the 'embourgeoisement' of the working class and the 'end of ideology' were popular. Postwar prosperity and the institutional mechanisms for conflict resolution and collective bargaining, the arguments went, have resulted in permanent industrial peace, 'the withering away of the strike, the virtual disappearance of industrial conflict in numerous countries' (Ross and Hartman 1960, p. 6, Dahrendorf 1959, pp. 257–79, Kornhauser 1954, pp. 524–5). History was to prove these arguments wrong, with the resurgence of conflict in the 1960s to unprecedented levels in those same numerous countries (Crouch and Pizzorno 1978). But once again the 'virtual disappearance' of strikes in the 1980s and 1990s rekindled the debate on the withering away of strikes, with a novel, and perhaps more powerful trump to the argument: the very working class has now virtually disappeared, with the drastic shrinking of manufacturing and the soaring of services. Since service workers are largely white collar, with a high percentage of women—both actors being traditionally little strike prone—changes in the occupational structure should result in the 'withering away of strikes' once and for all.

These arguments are compelling. No doubt the change in the location of conflict from industry to services has deeply changed the nature of labor conflicts. For one thing, it has changed the very nature of the two traditional actors involved in labor conflicts: workers and employers. The typical worker is no longer male and blue-collar, and the typical employer is public rather than private: the state has become the largest service employer in most Western countries (for comparative evidence, see Tiziano 1987). Historically, the state intervened in labor disputes in-

directly, regulating conflict via legislative means, only rarely taking a more direct role (either to repress or to arbitrate). As employer the state cannot escape being drawn directly into service disputes as a principal bargaining actor. Second, the 'essential' nature of many services (transportation, health care, etc.) and the monopoly conditions under which most services are provided has dramatically increased strikers' disruptive power (i.e., their ability to inflict severe losses to the counterpart at minimal cost to strikers). The more centralized and monopolistic a service is, and the larger the number of users affected by a service strike. Disruption is always intrinsic to service disputes, regardless of the intentions of the actors. The law-and-order potential of highly disruptive strikes further draws the state into service disputes, even when these disputes are located in the private sector.

But from here to argue in favor of the 'withering away of strikes' is to ignore fundamental characteristics of strikes. First, strikes, as we have seen, are closely linked to wage labor. The nature of employment (wage labor) does not fundamentally change with changes in the occupational structure. Technicians, teachers and college professors, nurses and doctors, pilots and air controllers have shown to be as willing to go on strike as blue-collar workers. Second, strikes are a cyclical phenomenon. Strike research has made that quite clear (Franzosi 1995, pp. 345–8). Short-term seasonal fluctuations weave in and out of medium-term fluctuations of some years duration, mostly related to the business cycle, which in turn ziz-zag around long-term fluctuations of some 40–50 years in length. Research on these long-term cycles of strikes suggests that these 'strike waves' are linked to the long-term movements of capitalist economies (the so-called Kondratieff's cycles; Mandel 1980, Cronin 1980). During wave years the characteristics of strikes are different than in surrounding years: strikes tend to be longer; they involve a higher proportion of the workforce, both at the plant and at the industry level, and a higher number of establishments (Hobsbawm 1964, p. 127; Shorter and Tilly 1974, pp. 142–6; Franzosi 1995). Strike tactics become more radical and innovative during strike waves, being mainly plant-based and in the hands of informal leaders, outside the control of the union and the institutionalized rules of the game. Demands become radicalized as well. Strike waves also often bring about legislative reforms (Shorter and Tilly 1974, p. 145; Franzosi 1995, pp. 302–6). Finally, the resurgence of conflict after long periods of peace is typically sudden and overwhelming. It takes employers, the state, and even the unions by surprise (French May of 1968 *docet* or the Italian *autunno caldo* of 1969).

If these theories are correct, the decline in strike activity in recent decades is only the result of a long-term cycle rather than a permanent downward trend leading to the withering away of strikes. If the past is anything to go by, the mobilization process will catch us by surprise with its sudden, sharp, and sweeping bouts of conflict: 1840s, 1880s, 1920s, 1960s … we may not have to wait long to be surprised.

R. Franzosi

Strong Program, in Sociology of Scientific Knowledge

The 'Strong Program' is a set of methodological claims about the proper way to conduct sociological enquiry into the nature of knowledge, including scientific knowledge. The program enjoins the investigator to adopt four requirements, which may be labeled, respectively, (a) causality, (b) impartiality, (c) symmetry, and (d) reflexivity. 'Causality' means that the aim is not merely descriptive or interpretive but also explanatory. The concern is with what brings about and sustains a body of knowledge. 'Impartiality' means that the investigator disregards his or her sense of whether the beliefs under scrutiny are true or false, or rational or irrational. Equal curiosity should attend both sides of the evaluate divide. 'Symmetry' means that this equally distributed curiosity should issue in the same general kinds of sociological explanation. All beliefs confront the same general problem of credibility and depend on the same contingencies to solve the problem. True beliefs have no more intrinsic credibility than false ones. Finally, 'reflexivity' means that sociologists of knowledge must not claim access to any transcendent standpoint, or engage in special pleading, to justify their own claims. Put simply: no sociological theory of knowledge is acceptable unless it applies to itself. These requirements all stem from the desire that the approach should itself be 'scientific' in spirit, although it is widely perceived by critics as antiscientific. To offset such misunderstandings each of the points calls for amplification.

1. *Causality*

The commitment to causality does not mean that only sociological causes are at work. It is taken for granted that belief systems are the achievements of biological entities that interact with one another and their material environment. People have their eyes open, and sensory inputs influence individual and collective belief. Unless they had effective sense organs and some innate cognitive propensities, they could neither create nor transmit a shared culture. Knowledge cannot be 'merely' or 'purely' social. Sociologists can therefore only contribute partial explanations of the overall phenomenon of cognition. They must work alongside, say, sensory psychologists—but no adequate account of human knowledge can ever proceed without due acknowledgment of the role of the social. The 'strength' of the program lies in the necessity, not the sufficiency, of the social dimension.

The idea that material reality plays little or no role in science is a form of philosophical 'idealism.' Its association with the 'Strong Program' has been solely through the imputations of critics. For example, Latour (1993) says the program is one of a family of theories based on the idea that knowledge has two ingredients ('nature' and 'society') which trade-off against one another—the more of one meaning the less of the other. Within this framework the 'Strong Program' is said to be an extreme case where one of the ingredients, nature, actually makes a nil contribution. The strength of the program is thus wrongly said to reside in the claim that knowledge (and indeed reality) is purely social.

This false view of the 'Strong Program' is widespread. The sociologist Cole (1992) who himself accepts the zero-sum picture, seeks to distance himself from the program by insisting that nature plays some role rather than no role. He suggests that it is an

empirical question to decide just how much influence is exerted by nature by comparison to that exerted by society. A variant of the error also underlies Gottfried and Wilson's (1997) article in *Nature*. They claim that the program is incompatible with science having a good record of predictive success. The allegation appears to rest on the idea that if scientists were only attending to what is going on in society, and were not attending to what is happening in nature, then their ability to make predictions would be unintelligible. That, however, is not the 'Strong Program's' claim.

The real claim of the 'Strong Program' is that scientists understand nature through and with society, not in spite of it. Society is the vehicle of understanding, not a screen or distraction. Society does not trade-off against nature, rather it enables scientific access to it. Society no more interferes with knowledge than the eye interferes with vision. They both operate as the relevant organ of cognition and as a necessary constituent of it. No one asks 'how much' of our visual experience is contributed by the eye, and 'how much' by the object seen. (We might ask 'what' is contributed, but not 'how much.') The question makes no sense, and in this framework neither does Cole's allegedly 'empirical' research program to find out how much of knowledge depends on nature and how much on society.

How do social processes enable us to have scientific access to the world? What manner of 'vehicle' or 'organ' does society provide? The answer given by Kuhn (1962) illustrates the general case. Cognition within a group is coordinated by reference to a shared exemplar or paradigm, that is, a concrete achievement on which activity is modeled. By virtue of their orientation towards that achievement, and their knowledge of its standing in the eyes of others, members of a group endow it with a normative status. Something is constituted as a paradigm in the way that money is constituted as money by being regarded as money, and a leader by being seen as and known as a leader. In this way society gets woven into the very fabric of knowledge and into the struggle to make sense of intransigent, real-world processes. Establishing a paradigm produces a qualitative change in the mode of cognition from mere individual belief to a collective relation to the world that we can recognize as scientific. Without a paradigm there may be scientists, but there is something less than science.

2. *Impartiality and Symmetry*

The reference to Kuhn puts us in a better position to understand impartiality and symmetry. He did not argue that the idea of a paradigm merely helps us make sense of old theories about natural processes, but no longer applies to current or correct theories. On the contrary, he applied the idea to all cases, that is, impartially and symmetrically, because he was searching for invariant principles. Every shared approach to nature must overcome the problem that our experience can be given more than one interpretation. The shared interpretation has to be sustained in the face of continuing difficulty, anomaly, and the threat of fragmentation into subjective opinion.

The requirements of impartiality and symmetry face a major obstacle because they run counter to some aspects of common sense. In general, our curiosity has a markedly partial and asymmetric structure. We typically confine the request for causal explanation to the breakdowns in our routine expectations. When things go smoothly we do not ask why, because nothing more needs to be said. If nothing needs to be said, perhaps nothing can be said, and we may be tempted to think that causality does not apply, or that qualitatively different kinds of causes are in operation. Thus, some philosophers have argued that while illusory perception calls for causal explanation, veridical perception does not. No professional psychologist would speak like this—just as no medical scientist would say there are causes for disease but no causes for health, and no engineer would say there are causes for why bridges collapse but none for why they stay up. If psychologists and other scientists can restructure their professional curiosity, and give it a locally symmetrical character, then this is also an appropriate posture for sociologists.

A deeper problem for symmetry comes from our capacity to follow rules. Here is the argument. Everyone accepts that the rules of a game, such as chess, are conventional and hence social. But once the rules have been agreed the question of whether or not a move conforms to the rule seems to be nonconventional. It is a matter of conceptual match or logical consistency and inconsistency. More generally, the meaning of any concept may be a matter of convention, but the question of whether an object falls under that concept seems wholly different. Meaning is conventional; truth is not. A sociologist may legitimately try to explain the choice of rules and definitions, but not, surely, matters of consistency and truth. The first is a question of causation, the latter belongs to the realm of logic and rationality. In as far as we follow rules and respond to considerations of meaning and truth our behavior must be explained rationally not sociologically. So, once again, asymmetry asserts itself.

This argument is widely accepted, but it may be challenged on the grounds that, in reality, every single act of concept application is problematic and negotiable. Not every single act is negotiated, in practice they are often routine, but as the history of science, logic and mathematics shows us, they are negotiable. Past applications of a concept do not serve to fix meanings and thereby determine in advance the norms of proper concept application or rule following. The move to the next case is always problematic. This position, known as 'meaning finitism,' follows from the determined effort to adhere to the causal and

scientific perspective. It marks an important point of contact between the 'Strong Program' and the later philosophy of Wittgenstein which centered on the analysis of rule following and the problematic character of 'sameness.'

3. Reflexivity

This requirement immediately raises the issue of relativism and self-refutation. If sociologists, own claims are socially determined and relative' why believe what they say? That the program is relativist is beyond question, but this can be seen as a strength not a weakness. Relativism (which should not be confused with idealism) is the opposite of absolutism and implies that there are no absolute justifications for any knowledge claim. All justifications end in something unjustified and merely taken for granted. But this does not mean that there is never any reason to accept what anyone says, as if it were all an ideological smokescreen. It just means that in the end reasons are local and contingent. Such an admission is not self-defeating. To draw that conclusion would be to argue in a circle from the premise that the only real reasons are absolute ones, thus begging the question on behalf of absolutism. Rather, it is the attempt to produce absolute justifications that should be viewed with suspicion.

4. Conclusion

The 'Strong Program' was formulated by an interdisciplinary group in Edinburgh in the early 1970s (see Barnes 1974, Bloor 1976). The immediate aim was to codify and clarify an emerging body of case-studies, particularly by historians of science (see Shapin 1982). The real life-blood of the sociology of scientific knowledge lies with such empirical work, for example, to name but a small sample: Mackenzie 1981) on the history of statistics and its connections with eugenics, Shapin and Schaffer (1985) on the disputes surrounding Boyle's experiments with the air-pump, Harwood (1993) on styles of research in German genetics before 1933, and Kusch (1999) on the different theories of mind generated in different psychological laboratories in the early years of the century. The program continues to serve its function, but its rich contributions to specific historical and sociological projects have been obscured to some degree by criticism of its philosophical foundations.

Structural Contingency Theory

An effective organizational structure provides the coordination necessary for people to work together so that an organization can perform at a high level. There is no 'one best way,' that is, one structural type that makes all organizations perform highly. On the contrary, the effect of an organizational structure on performance is contingent upon whether it fits certain factors called the contingency factors. An effective structure for an organization is one that fits the level of its contingency factors. Research has shown that there are three main contingency factors: size, task uncertainty, and diversification. In overview, increasing size requires a more bureaucratic structure, task uncertainty requires reducing the degree of bureaucratization, and diversification requires a divisional or a matrix structure.

1. Bureaucratic Structure and its Contingencies

The structure of an organization includes how the work of the organization is divided up and allocated among people, in terms of job specialization, sections,

and departments. It also includes the number of levels in hierarchy and how many subordinates report directly to each manager, that is, his or her span of control. Another aspect of organizational structure is the degree of formalization: how far rules, standard operating procedures, and manuals govern the way people work. A further aspect of structure is the degree of decentralization, the degree to which decision-taking authority is distributed down the hierarchy (Jones 1998).

Many of these structural variables tend to be correlated so that they compose a single structural dimension of the degree of bureaucratic structure (Donaldson 2001). An organization that is low on bureaucratization has low specialization, few departments and sections, narrow spans of control, low formalization, few hierarchical levels, and high centralization. Conversely, an organization that is high on bureaucratization has high specialization, many departments and sections, wide spans of control, high formalization, many hierarchical levels, and low centralization. Organizations are distributed widely along this continuum of bureaucratic structure.

2. *Bureaucratic Structure and the Size Contingency*

Size is the number of people who must be organized, that is the number of employees or members of the organization. For high performance, the organization needs to have the degree of bureaucratic structure that fits its size (Child 1984).

An unbureaucratic structure fits an organization of small size, while a highly bureaucratic structure fits a large size. For small size, the required, unbureaucratic, structure is a short hierarchy, with most of the decisions being taken by the top manager. The top manager controls the organization directly by giving instructions (Child 1984). There is little formalization because the top manager is making decisions on each case, rather than bothering to identify abstract rules to anticipate future cases. There is low specialization and few departments and sections, because there are few people among whom the work could be divided. The span of control is narrow, because each manager must supervise subordinates who are doing a broad range of tasks.

Conversely, large size entails a bureaucratic structure that has a tall hierarchy because an additional level of management has to be introduced each time the number of employees exceeds the feasible span of control of their supervisor. Size also brings increased complexity and this combines with the tall hierarchy to force top management to delegate decisions down the hierarchy and so decentralization increases. With so many people to be organized in the large organization, the work is finely divided up among them, producing an elaborate division of labor. There is high specialization and many departments and sections. The span of control is wide, because each manager can supervise more subordinates because the subordinates are doing a limited range of tasks. There is high formalization because, with larger size, many decisions recur about similar cases, leading to codification of best practice into rules and standard operating procedures (e.g., a hiring procedure). Such formalization relieves managers from having to attend to each decision, so that administration can be delegated to clerks who follow rules, which speeds decision-making, cuts costs, and is another reason why managerial spans increase with size. Overall, top management has relinquished much direct control and instead controls the organization indirectly and impersonally, through formalization (Child 1984). As the organization grows in size over time, so it needs to increase progressively the degree of bureaucratization of its structure in order to maintain the fit that sustains high performance.

Information technologies, whether used in operations or administration, tend to reinforce the effects of size (Donaldson 2001). Information technologies increase bureaucratization, such as by increasing formalization, because they reduces uncertainty, though their effects are weaker than size. Moreover, computerization itself is really a form of bureaucratization. Work is executed according to computer programs that are rules (e.g., 'If the checking account balance is less than $500, then apply a $10 fee to every transaction'). Knowledge workers and other employees working with computers are constrained in their actions by the programs in their computers. Thus computerization is electronic formalization that allows top management more indirect, impersonal control over lower-level employees, so that top management can further increase decentralization.

Bureaucratic structure is sometimes criticized for having too many managers and administrators relative to operating personnel (e.g., workers). However, the ratio of managers and administrators to operating personnel tends to *fall* as size increases. While larger organizations have more levels in their hierarchy, their spans of control increase so as to more than compensate (Jones 1998). Thus bureaucratic structure brings economies of scale in administration (Donaldson 1996).

3. *Bureaucratic Structure and the Task Uncertainty Contingency*

While a bureaucratic structure fits low task uncertainty, a less bureaucratic structure is required to fit high task uncertainty.

The creation of effective rules relies on all the cases of the same occurrence being similar. In routine tasks this holds, allowing rules to be formulated. However, some tasks are uncertain, so that one case varies

markedly from another, and future cases differ from past ones. Some uncertainty in organizations comes from the environment, for example, competitor pricing is hard to predict. Other task uncertainty comes from innovation inside the organization, such as designing a new product or developing a new technology to distribute a service.

Whatever the source of the uncertainty, tasks high in uncertainty cannot be handled effectively by rules. Tasks of medium uncertainty can be handled effectively by the hierarchy. However, the greater the uncertainty, the more information that has to be processed by the organization. Because of the pyramidal shape of the hierarchy, it soon becomes inadequate for dealing with more than moderate uncertainty. High task uncertainty, such as involved in radically new products or services, or making many innovations at the same time, requires reliance upon experts. The high uncertainty in their tasks prevents the organization from governing their work effectively by rules. Some decision-making authority needs to be delegated to these experts, even if they are at low hierarchical levels. Similarly, managers of innovative programs need to be able to act autonomously. Thus task uncertainty is fitted by a structure that is lower in formalization and centralization (Jones 1998).

The effect of the task uncertainty on bureaucratic structure is secondary to that of size. High task uncertainty partially offsets the high formalization that large size causes by lowering formalization. Conversely, high task uncertainty reinforces the high decentralization that large size causes by further increasing decentralization. Thus a large organization with highly uncertain tasks is less formalized and more decentralized than a large organization with highly certain tasks. The reduction in formalization decreases bureaucratic structure, while the increase in decentralization increases that aspect of bureaucratic structure.

Moreover, these effects of task uncertainty are localized to specific parts of the organization. For a firm that is developing new products, the uncertainty of its tasks is greatest in some parts, such as the research and development department that is inventing the new product. In contrast, the manufacturing department of the firm focuses mainly on the routine production of existing products, so that the uncertainty of its tasks is lower. Thus the required structure of the research and development department is low in formalization, while the manufacturing department is high. Similarly, the research and development department employs qualified scientists and technologists and devolves some decision-making to them so that they exercise autonomy and creativity. Conversely, the manufacturing department employs mainly less educated personnel who lack professional qualifications and trains them to conform to the operating procedures of the firm, so the department is run in a more formalized and centrally planned way. Nevertheless, innovation entails solving some novel problems that involve all the functional departments. For example, research needs to know whether manufacturing can make their new design on its existing machines. The integration required between the functions necessitates the adoption of cross-functional project teams. These contain representatives from each of the functional departments who are brought together for collaboration (Jones 1998). The teams provide lateral linkages that run across the hierarchy and rely upon *ad hoc* internal coordination rather than planning or formalization. Therefore they are a further way task uncertainty reduces bureaucratic structure.

4. *Divisional and Matrix Structure and the Diversification Contingency*

4.1 *Functional and Divisional Structures*

Another aspect of structure is how activities and responsibilities are grouped in the organization. In a functional structure, the managers reporting to the top manager (i.e., the CEO; chief executive officer) are specialized by function, including operational functions (e.g., manufacturing). In contrast, in the divisional structure, the senior managers are specialized by their products or services, customers, or geographical areas, and each has a broad range of operational functions within their division. A divisional structure is more specialized, formalized, and decentralized than a functional structure and so divisionalization is an extension of bureaucratization (Donaldson 2001). However, the contingency causing divisionalization is primarily diversification, with size playing a minor role (Donaldson 2001) so that the contingency determination of divisionalization differs from that of bureaucratization.

Organizations vary in their levels of diversification of their products, services, customers, or geographical areas. For brevity, product diversification will be discussed here but not service and customer diversification because similar considerations apply. Increasing diversification reduces the interdependence between the tasks involved in one product and the others. This requires less coordination between products, so each can be organized as a separate subunit acting autonomously from the other subunits and from the corporate center. Consequently, the corporate center needs to contain fewer operational functions. The greater the diversification, the greater the decentralization needs to be and thus the smaller the head office. As diversification varies from low to high, the fitting structure goes from being a pure function to a pure divisional structure. At intermediary levels of diversification, the role of the central functions decreases with each level and the role of the product heads increases. Where a firm is undiversified, such as

producing only one product, then specialization by function fosters economies of scale and avoids duplication. Each function is highly interdependent on the next, so that operational coordination is needed from the CEO, producing centralization. Also, each function is a cost center, with profitability only being assessed for the firm overall.

The next level of product diversification is where a firm offers products that are vertically integrated with each other. For example, an aluminum-refining firm might vertically integrate backward by acquiring the bauxite mine that supplies its feed material. It might also vertically integrate forward by creating a plant that fabricates its refined aluminum into window frames. Each stage along the value-added chain, that is, mining, refining, and fabricating, becomes an organizational subunit, which may be termed a division. Some decisions will be taken autonomously by each division, such as the types of production equipment to purchase, so that the structure is more decentralized than a functional structure. However, a large flow of materials must be coordinated between divisions. This necessitates some restrictions on divisional autonomy and the presence of corporate-level staff with expertise in transportation and the planing of production and inventory. Thus the corporate center contains many staff additional to the administrative functions such as accounting. Whereas the fabrication division is a profit center, the mining and the refining divisions should be cost centers because their sales are to other divisions making their profitability a contentious issue. Divisional general managers need to have their bonuses tied to corporate profitability to encourage them to cooperate.

A medium level of diversification is where a firm has two or more *related* products. The relatedness between the products lies in similarities among their materials, production technologies, skills, brands, sales force, or distribution systems. Each product is organized as a division and is run quite autonomously, except where the divisions are related and so synergies may be extracted through central coordination. For example, an electronics firm has three product divisions: avionics, computers, and domestic appliances, with each focusing on their product market. But there are commonalties in the underlying technologies so that there is a large central research and development laboratory that pursues major innovations beyond those being researched in the divisions. Therefore, the corporate center contains functions beyond the merely administrative and is quite large in size. Each division is a profit center, but the transfer pricing of shared components moderates its accountability. This is also moderated by large corporate overhead charges for the central laboratories and by corporate decisions about which division receives the profitable, new products developed in the central laboratory. Divisional general managers need to have their bonuses partly tied to that of their own division and partly to corporate profitability to encourage them to cooperate with the other divisions and the corporate staff. The divisional structure boosts innovation by having functions for each product which facilitates functional interaction. However, this is at the cost of some duplication of assets across divisions. Thus, where cost pressures are paramount, the organization instead needs to use a functional structure.

A high level of diversification is where a firm has two or more *unrelated* products, e.g., a conglomerate. There are no operating synergies to be extracted, so little central coordination of operation is required and the divisions are highly autonomous. Therefore the corporate level needs no functions beyond the merely administrative and so can be small. Each division can be straightforwardly held profit accountable. Divisional general managers need to have their bonuses tied solely to the profitability of their own division.

Area diversification has similar effects. Area diversification is how far the organization contains an area that operates separately from other areas, that is, it designs, manufactures, and sells the product all within its own area. For example, area divisions are frequently found in the food industry, where low price relative to weight makes intercontinental transportation too costly. Low area diversification fits with the functional structure, while high area diversification fits with the area divisional structure.

4.2 Matrix Structures

In a matrix structure, a subordinate reports to more than one boss. Despite the inherent complexity and resulting conflict potential of matrices, they fit some contingencies. A related product organization attains both some product innovation and some cost reduction by using a project-functional matrix structure. Each project manager heads a temporary team, which fosters close interaction between different functional specialists, to facilitate product innovation. Additionally, the heads of the functions coordinate the deployment of resources across projects to reduce costs. The relatedness of the products (e.g., at Lockheed-Gelac all the products are transport airplanes) allows the same resources to be used by the projects. This resource sharing is facilitated by the projects each being at different stages so that the same resources are not required simultaneously. The project-functional structure fits medium product diversity and low area diversity so that operations are geographically proximate and there is no area diversity that needs managing.

In contrast, an area type of matrix is appropriate for an organization that requires coordination along the area dimension in addition to coordination by either function or product. For example, a multinational corporation has offices and plants scattered around the world, each reporting up to functional or product

heads. However, the corporation also needs to have a local manager coordinating each geographical area to deal with local issues, e.g., the host government. The increase in environmental diversity, caused by cultural and political heterogeneity, that is, medium area diversification, requires that the organization mirrors and manages this diversity through having a manager for each area. Thus, area type matrices fit medium area diversification. There interdependencies exist between the areas, requiring coordination through high-level functional or product heads, at the same level as the area managers, thereby creating the matrix. Where area diversification is medium and product diversification is low, then core operations need to be structured functionally and so the fitting structure is the area-functional matrix. However, where area diversification is medium and product diversification is also medium, then core operations need to be structured divisionally and so the fitting structure is the area-product matrix (e.g., Asea Brown Boveri). Medium product diversification obtains not only for related, but also for unrelated, product diversification. This is because the medium area diversification introduces links across the separate products due to their geographical co-location (e.g., being in France and so having to deal jointly with the government there). Thus, the level of product diversification has to be determined jointly with the level of area diversification, that is, interdependence is established by examining together products and areas.

The heart of structural contingency theory is the concept of fit of organizational structure to the contingency. Many of the more promising developments in structural contingency theory delve into the concept of fit, using it to illuminate organizational performance and organizational change. A major conceptual statement about fit that has influenced subsequent research is by Van de Ven and Drazin (1985). Some researchers have extended the analysis by considering the fit of an organizational structural variable to multiple contingencies (e.g., Keller 1994). Other researchers have analyzed the fit of multiple organizational structural variables to a contingency (e.g., Drazin and Van de Ven 1985). Still other researchers have analyzed the fit of multiple organizational structural variables to multiple contingencies simultaneously (e.g., Pennings 1987). Other researchers have analyzed the differential effects of fit on different aspects of organizational performance such as financial performance vs. social costs (e.g., Kraft et al. 1995). Structural contingency theory has sometimes been criticized for being static, however, on the contrary, it contains a theory of change dynamics in that fit and misfit play crucial roles in organizational structural change (Donaldson 2001). An organization in fit tends thereby to have high performance, which leads it to increase its contingencies, such as size and diversification, so that it moves into misfit and so has lower performance. An ensuing crisis of low performance causes the organization to adopt a new structure that fits the new levels of its contingencies, thereby restoring fit and performance (Donaldson 2001). Whether the performance level of a firm in misfit becomes low enough to trigger structural change depends on other causes of performance that interact with misfit. These other causes include debt and divestment and can reinforce misfit or offset its depressive effect on performance. The set of causes of organizational performance and their effects on organizational growth and adaptation have been formalized into a new organizational theory, organizational portfolio theory (Donaldson 1999).

Fit is traditionally conceptualized as a line of iso-performance, meaning that a fit of organizational structure to a low level of the contingency (e.g., small size) produces the same performance as a fit of organizational structure to a high level of the contingency (e.g., large size). Such a model fails to provide an incentive for an organization to increase its level of the contingency (e.g., size), so that there is no explanation of why an organization changes its level of the contingency, such as by growing larger. A reconceptualization of fit has been proposed in which fit is a line of hetero-performance, in which fits to higher values of the contingency variable produce greater performance than fits to lower levels (Donaldson 2001). Therefore there is an incentive for the organization to change its level of contingency such as by growing larger over time. In this way, reconsidering the effect of fit on performance allows the explanation of changes in the contingency (e.g., size) of an organization in fit, thereby rendering structural contingency theory more comprehensive and dynamic. Thus, deeper analyses of fit, both empirically and conceptually, provide a major route for the ongoing development of structural contingency theory (for developments synthesizing structural contingency theory with other organizational theories see Donaldson 1995).

Structural Equation Modeling

In 1980, Peter Bentler (1980, p. 420) stated that structural equation modeling held 'the greatest promise for furthering psychological science.' Since then, there have been many important theoretical and practical advances in the field. So much so, in fact, that Muthén (2001) announced a 'second generation' of structural equation modeling. The purpose of this article is to provide a description of the 'first generation' of structural equation modeling and to outline briefly the most recent developments that constitute the 'second generation' of structural equation modeling. This article will not devote space to the comparison of specific software packages. For the most part, existing software packages differ in terms of the user interface. The competitive market in structural equation modeling software means that new developments available in one software package will soon be available in others.

1. *The First Generation: Definition and Brief History of Structural Equation Modeling*

Structural equation modeling can be defined as a class of methodologies that seeks to represent hypotheses about the means, variances, and covariances of observed data in terms of a smaller number of 'structural' parameters defined by a hypothesized underlying conceptual or theoretical model. Historically, structural equation modeling derived from the hybrid of two separate statistical traditions. The first tradition is factor analysis developed in the disciplines of psychology and psychometrics. The second tradition is simultaneous equation modeling developed mainly in econometrics, but having an early history in the field of genetics and introduced to the field of sociology under the name *path analysis*.

The subject of this article concerns the combination of the latent variable/factor analytic approach with simultaneous equation modeling. The combination of these methodologies into a coherent analytic framework was based on the work of Jöreskog (1973), Keesling (1972) and Wiley (1973).

2. *The General Model*

The general structural equation model as outlined by Jöreskog (1973) consists of two parts: (a) the structural part linking latent variables to each other via systems of simultaneous equations, and (b) the measurement part which links latent variables to observed variables via a restricted (confirmatory) factor model. The structural part of the model can be written as

$$\boldsymbol{\eta} = \mathbf{B}\boldsymbol{\eta} + \Gamma\boldsymbol{\xi} + \boldsymbol{\zeta} \tag{1}$$

where $\boldsymbol{\eta}$ is a vector of endogenous (criterion) latent variables, $\boldsymbol{\xi}$ is a vector of exogenous (predictor) latent variables, $\mathbf{B}$ is a matrix of regression coefficients relating the latent endogenous variables to each other, Γ is a matrix of regression coefficients relating endogenous variables to exogenous variables, and $\boldsymbol{\zeta}$ is a vector of disturbance terms.

The latent variables are linked to observable variables via measurement equations for the endogenous variables and exogenous variables. These equations are defined as

$$\mathbf{y} = \boldsymbol{\Lambda}_y\boldsymbol{\eta} + \boldsymbol{\varepsilon} \tag{2}$$

and

$$\mathbf{x} = \boldsymbol{\Lambda}_x\boldsymbol{\xi} + \boldsymbol{\delta} \tag{3}$$

where $\boldsymbol{\Lambda}_y$ and $\boldsymbol{\Lambda}_x$ are matrices of factor loadings, respectively, and $\boldsymbol{\varepsilon}$ and $\boldsymbol{\delta}$ are vectors of uniqueness, respectively. In addition, the general model specifies variances and covariances for $\boldsymbol{\xi}$, $\boldsymbol{\zeta}$, $\boldsymbol{\varepsilon}$, and $\boldsymbol{\delta}$, denoted Φ, Ψ, Θ_ε, and Θ_δ, respectively.

Structural equation modeling is a methodology designed primarily to test substantive theories. As such, a theory might be sufficiently developed to suggest that certain constructs do not affect other constructs, that certain variables do not load on certain factors, and that certain disturbances and measurement errors do not covary. This implies that some of the elements of B, Γ, Λ_y, Λ_x, Φ, Ψ, Θ_ε, and Θ_δ

are *fixed* to zero by hypothesis. The remaining parameters are *free* to be estimated. The pattern of fixed and free parameters implies a specific structure for the covariance matrix of the observed variables. In this way, structural equation modeling can be seen as a special case of a more general *covariance structure model* defined as $\boldsymbol{\Sigma} = \boldsymbol{\Sigma}(\boldsymbol{\Omega})$, where $\boldsymbol{\Sigma}$ is the population covariance matrix and $\boldsymbol{\Sigma}(\boldsymbol{\Omega})$ is a matrix valued function of the *parameter vector* $\boldsymbol{\Omega}$ containing all of the parameters of the model.

3. Identification and Estimation of Structural Equation Models

A prerequisite for the estimation of the parameters of the model is to establish whether the parameters are *identified*. We begin with a definition of *identification* by considering the problem from the covariance structure modeling perspective. The population covariance matrix $\boldsymbol{\Sigma}$ contains population variances and covariances that are assumed to follow a model characterized by a set of parameters contained in Ω. We know that the variances and covariances in $\boldsymbol{\Sigma}$ can be estimated by their sample counterparts in the sample covariance matrix $\mathbf{S}$ using straightforward equations for the calculation of sample variances and covariances. Thus, the parameters in Σ are identified. What needs to be established prior to estimation is whether the unknown parameters in Ω are identified from the elements of Σ.

We say that the elements in Ω are *identified* if they can be expressed uniquely in terms of the elements of the covariance matrix $\boldsymbol{\Sigma}$. If all elements in Ω are identified then the model is identified. A variety of necessary and sufficient conditions for establishing the identification of the model exist and are described in Kaplan (2000).

Major advances in structural equation modeling have, arguably, been made in the area of parameter estimation. The problem of parameter estimation concerns obtaining estimates of the free parameters of the model, subject to the constraints imposed by the fixed parameters of the model. In other words, the goal is to apply a model to the sample covariance matrix $\mathbf{S}$, which is an estimate of the population covariance matrix $\boldsymbol{\Sigma}$ that is assumed to follow a structural equation model. Estimates are obtained such that the discrepancy between the estimated covariance matrix $\hat{\boldsymbol{\Sigma}} = \boldsymbol{\Sigma}(\hat{\boldsymbol{\Omega}})$ and the sample covariance matrix $\mathbf{S}$, is as small as possible. Therefore, parameter estimation requires choosing among a variety of *fitting functions*. Fitting functions have the properties that (a) the value of the function is greater than or equal to zero, (b) the value of the function equals zero if, and only if, the model fits the data perfectly, and (c) the function is continuous. We first consider estimators that assume multivariate normality of the data. We will discuss estimators for non-normal data in Sect. 5.

3.1 Normal Theory-based Estimation

The most common estimation method that rests on the assumption of multivariate normality is the method of *maximum likelihood*. If the assumption of multivariate normality of the observed data holds, the estimates obtained from maximum likelihood estimation possess certain desirable properties. Specifically, maximum likelihood estimation will yield unbiased and efficient estimates as well as a large sample goodness-of-fit test.

Another fitting function that enjoys the same properties under the same assumption is the *generalized least squares* (GLS) estimator developed for the structural equation modeling context by Jöreskog and Goldberger (1972).

4. Testing

Once the parameters of the model have been estimated, the model can be tested for global fit to the data. In addition, hypotheses concerning individual parameters can also be evaluated. We consider model testing in this section.

4.1 Testing Global Model Fit

A feature of maximum likelihood estimation is that one can explicitly test the hypothesis that the model fits data. The null hypothesis states that the specified model holds in the population. The corresponding alternative hypothesis is that the population covariance matrix is any symmetric (and positive definite) matrix. Under maximum likelihood estimation, the statistic for testing the null hypothesis that the model fits in the population is referred to as the *likelihood ratio* (*LR*) *test*. The large sample distribution of the likelihood ratio test is chi-squared with degrees of freedom given by the difference in the number of nonredundant elements in the population covariance matrix and the number of free parameters in the model.

4.2 Testing Hypotheses Regarding Individual Parameters

In addition to a global test of whether the model holds exactly in the population, one can also test hypotheses regarding the individual fixed and freed parameters in the model. Specifically, we can consider three alternative ways to evaluate the fixed and freed elements of the model vis-à-vis overall fit.

The first method rests on the difference between the likelihood ratio chi-squared statistics comparing a given model against a less restrictive model. Recall that the initial hypothesis, say H_{01}, is tested against the alternative hypothesis H_a that Σ is a symmetric positive

definite matrix. Consider a second hypothesis, say H_{02} that differs from H_{01} in that a single parameter that was restricted to zero is now relaxed. Note that the alternative hypothesis is the same in both cases. Therefore, the change in the chi-squared value between the two models can be used to test the improvement in fit due to the relaxation of the restriction. The distribution of the difference between the two chi-squared tests is distributed as chi-squared with degrees of freedom equaling the difference in degrees-of-freedom between the model under H_{01} and the less restrictive model under H_{02}. In the case of a single restriction described here, the chi-squared difference test is evaluated with one degree of freedom.

There are other ways of assessing the change in the model without estimating a second nested model. The *Lagrange multiplier* (*LM*) test can be used to assess whether freeing a fixed parameter would result in a significant improvement in the overall fit of the model. The LM test is asymptotically distributed as chi-squared with degrees of freedom equaling the difference between the degrees of freedom of the more restrictive model and the less restrictive model. Again, if one restriction is being evaluated, then the LM test will be evaluated with one degree of freedom. The LM test is also referred to as the *modification index*.

Finally, we can consider evaluating whether fixing a free parameter would result in a significant decrement in the fit of the model. This is referred to as the *Wald test*.

The Wald test is asymptotically distributed as chi-squared with degrees of freedom equaling the number imposed restrictions. When interest is in evaluating one restriction the Wald test is distributed as chi-squared with one degree of freedom. The square root of the Wald statistic in this case is a z statistic. The reason why the LM and Wald tests can be used as alternative approaches for testing model parameters is that they are asymptotically equivalent to each other and to the chi-squared difference test.

4.3 Alternative Methods of Model Fit

Since the early 1980s, attention has focused on the development of alternative indices that provide relatively different perspectives on the fit of structural equation models. The development of these indices has been motivated, in part, by the known sensitivity of the likelihood ratio chi-squared statistic to large sample sizes. Other classes of indices have been motivated by a need to rethink the notion of testing exact fit in the population—an idea that is deemed by some to be unrealistic in most practical situations. Finally, another class of alternative indices has been developed that focuses on the cross-validation adequacy of the model.

In this section we will divide our discussion of alternative fit indices into three categories: (a) measures based on comparative fit to a baseline model, including those that add a penalty function for model complexity, (b) measures based on population errors of approximation, and (c) cross-validation measures.

4.3.1 Measures based on comparative fit to a baseline model. Arguably, the most active work in the area of alternative fit indices has been the development of what can be broadly referred to as measures of *comparative fit*. The basic idea behind these indices is that the fit of the model is compared to the fit of some baseline model that usually specifies complete independence among the observed variables. The fit of the baseline model will usually be fairly large and thus the issue is whether one's model of interest is an improvement relative to the baseline model. The index is typically scaled to lie between zero and one, with one representing perfect fit relative to this baseline model. The sheer number of comparative fit indices precludes a detailed discussion of each one. We will consider a subset of indices here that serve to illustrate the basic ideas.

The quintessential example of a comparative fit index is the normed-fit index (NFI) proposed by Bentler and Bonett (1980). This index can be written as

$$\mathrm{NFI} = \frac{\chi_b^2 - \chi_t^2}{\chi_b^2} \tag{4}$$

where χ_b^t is the chi-squared for the model of complete independence (the so-called baseline model) and χ_t^2 is the chi-squared for the target model of interest. This index, which ranges from zero to one, provides a measure of the extent to which the target model is an improvement over the baseline model.

The NFI assumes a true null hypothesis and therefore a central chi-squared distribution of the test statistic. However, an argument could be made that the null hypothesis is never exactly true and that the distribution of the test statistic can be better approximated by a non-central chi-squared with noncentrality parameter λ. An estimate of the noncentrality parameter can be obtained as the difference between the statistic and its associated degrees of freedom. Thus, for models that are not extremely misspecified, an index developed by McDonald and Marsh (1990) and referred to as the *relative noncentrality index* (RNI) can be defined as

$$\mathrm{RNI} = \frac{[(\chi_b^2 - df_b) - (\chi_t^2 - df_t)]}{\chi_b^2 - df_b} \tag{5}$$

The RNI can lie outside the 0–1 range. To remedy this, Bentler (1990) adjusted the RNI so that it would lie in the range of 0–1. This adjusted version is referred to as the *comparative fit index* (CFI).

Finally, there are classes of comparative fit indices that adjust existing fit indexes for the number of parameters that are estimated. These are so called *parsimony-based* comparative fit indices. The rationale behind these indices is that a model can be made to fit the data by simply estimating more and more parameters. Indeed, a model that is just identified fits the data perfectly. Therefore, an appeal to parsimony would require that these indices be adjusted for the number of parameters that are estimated.

It is important to note that use of comparative indices has not been without controversy. In particular, Sobel and Borhnstedt (1985) argued early on that these indices are designed to compare one's hypothesized model against a scientifically questionable baseline hypothesis that the observed variables are completely uncorrelated with each other. Yet, as Sobel and Borhnstedt (1985) argue, one would never seriously entertain such a hypothesis, and that perhaps these indices should be compared with a different baseline hypothesis. Unfortunately, the conventional practice of structural equation modeling as represented in scholarly journals suggests that these indices have always been compared with the baseline model of complete independence.

4.3.2 Measures based on errors of approximation. It was noted earlier that the likelihood ratio chi-squared test assesses an exact null hypothesis that the model fits perfectly in the population. In reality, it is fairly unlikely that the model will fit the data perfectly. Not only is it unreasonable to expect our models to hold perfectly, but trivial misspecifications can have detrimental effects on the likelihood ratio test when applied to large samples. Therefore, a more sensible approach is to assess whether the model fits approximately well in the population. The difficulty arises when trying to quantify what is meant by 'approximately.'

To motivate this work it is useful to differentiate among different types of discrepancies. First, there is the *discrepancy due to approximation*, which measures the lack of fit of the model to the population covariance matrix. Second, there is the *discrepancy due to estimation*, which measures the difference between the model fit to the sample covariance matrix and the model fit to the population covariance matrix. Finally, there is the discrepancy due to overall error that measures the difference between the elements of the population covariance matrix and the model fit to the sample covariance matrix.

Measures of approximate fit are concerned with the discrepancy due to approximation. Based on the work of Steiger and Lind (1980) it is possible to assess approximate fit of a model in the population. The method of Steiger and Lind (1980) utilizes the root mean square error of approximation (RMSEA) for measuring approximate fit. In utilizing the RMSEA for assessing approximate fit, a formal hypothesis testing framework is employed. Typically an RMSEA value $\leqslant 0.05$ is considered a 'close fit.' This value serves to define a formal null hypothesis of close fit. In addition, a 90% confidence interval around the RMSEA can be formed, enabling an assessment of the precision of the estimate (Steiger and Lind 1980). Practical guidelines recommended suggest that values of the RMSEA between 0.05 and 0.08 are indicative of fair fit, while values between 0.08 and 0.10 are indicative of mediocre fit.

4.3.3 Measures that assess cross-validation adequacy. Another important consideration in evaluating a structural model is whether the model is capable of cross-validating well in a future sample of the same size, from the same population, and sampled in the same fashion. In some cases, an investigator may have a sufficiently large sample to allow it to be randomly split in half with the model estimated and modified on the *calibration* sample and then cross-validated on the *validation* sample. When this is possible, then the final fitted model from the calibration sample is applied to the validation sample covariance matrix with parameter estimates fixed to the estimated values obtained from the calibration sample.

In many instances, investigators may not have samples large enough to allow separation into calibration and validation samples. However, the cross-validation adequacy of the model remains a desirable piece of information in model evaluation. Two comparable methods for assessing cross-validation adequacy are the Akaike information criterion (AIC) and the expected cross-validation index (ECVI). In both cases, it is assumed that the investigator is in a position to choose among a set of competing models. The model with the lowest AIC or ECVI value will be the model that will have the best cross-validation capability.

5. *Statistical Assumptions Underlying Structural Equation Modeling*

As with all statistical methodologies, structural equation modeling requires that certain underlying assumptions be satisfied in order to ensure accurate inferences. The major assumptions associated with structural equation modeling include: multivariate normality, no systematic missing data, sufficiently large sample size, and correct model specification.

5.1 *Sampling Assumptions*

For the purposes of proper estimation and inference, a very important question concerns the sampling mechanism. In the absence of explicit information to the

contrary, estimation methods such as maximum likelihood assume that data are generated according to simple random sampling. Perhaps more often than not, however, structural equation models are applied to data that have been obtained through something other than simple random sampling. For example, when data are obtained through multistage sampling, the usual assumption of independent observations is violated resulting in predictable biases. Structural equation modeling expanded to consider multistage sampling will be discussed in Sect. 6.

5.2 Non-normality

A basic assumption underlying the standard use of structural equation modeling is that observations are drawn from a continuous and multivariate normal population. This assumption is particularly important for maximum likelihood estimation because the maximum likelihood estimator is derived directly from the expression for the multivariate normal distribution. If the data follow a continuous and multivariate normal distribution, then maximum likelihood attains optimal asymptotic properties, viz., that the estimates are normal, unbiased, and efficient.

The effects of non-normality on estimates, standard errors, and tests of model fit are well known. The extant literature suggests that non-normality does not affect parameter estimates. In contrast, standard errors appear to be underestimated relative to the empirical standard deviation of the estimates. With regard to goodness-of-fit, research indicates that non-normality can lead to substantial overestimation of likelihood ratio chi-squared statistic, and this overestimation appears to be related to the number of degrees of freedom of the model.

5.2.1 Estimators for non-normal data. The estimation methods discussed in Sect. 3 assumed multivariate normal data. In the case where the data are not multivariate normal, two general estimators exist that differ depending on whether the observed variables are continuous or categorical.

One of the major breakthroughs in structural equation modeling has been the development of estimation methods that are not based on the assumption of continuous multivariate normal data. Browne (1984) developed an asymptotic distribution free (ADF) estimator based on weighted least-squares theory, in which the weight matrix takes on a special form. Specifically, when the data are not multivariate normal, the weight matrix can be expanded to incorporate information about the skewness and kurtosis of the data. Simulation studies have shown reasonably good performance of the ADF estimation compared with ML and GLS.

A problem with the ADF estimator is the computational difficulties encountered for models of moderate size. Specifically, with p variables there are $u = 1/2p(p+1)$ elements in the sample covariance matrix $\mathbf{S}$. The weight matrix is of order $u \times u$. It can be seen that the size of the weight matrix grows rapidly with the number of variables. So, if a model was estimated with 20 variables, the weight matrix would contain 22,155 distinct elements. Moreover, ADF estimation required that the sample size (for each group if relevant) exceed $p + 1/2p(p+1)$ to ensure that the weight matrix is non-singular. These constraints have limited the utility of the ADF estimator in applied settings.

Another difficulty with the ADF estimator is that social and behavioral science data are rarely continuous. Rather, we tend to encounter categorical data and often, we find mixtures of scale types within a specific analysis. When this is the case, the assumptions of continuity as well as multivariate normality are violated. Muthén (1984) made a major contribution to the estimation of structural equation models under these more realistic conditions by providing a unified approach for estimating models containing mixtures of measurement scales.

The basic idea of Muthén's (1984) method is that underlying each of the categorical variables is a latent continuous and normally distributed variable. The statistics for estimating the model are correlations among these latent variables. For example, the Pearson product–moment correlations between observed dichotomous variables are called *phi coefficients*. Phi coefficients can underestimate the 'true' or latent correlations between the variables. Thus, when phi coefficients are used in structural equation models, the estimates may be attenuated. In contrast, the latent correlations between dichotomous variables are referred to as *tetrachoric correlations*, and their use would result in disattenuated correlation coefficients. Other underlying correlations can also be defined.

The procedure developed by Muthén (1984) handles mixtures of scale types by calculating the appropriate correlations and the appropriate weight matrix corresponding to those correlations. These are entered into a weighted least-squares analysis yielding correct goodness-of-fit tests, estimates, and standard errors. Unfortunately, as with the ADF estimator, the method of Muthén is computationally intensive. However, research has shown how such estimation methods can be developed that are not as computationally intensive.

5.3 Missing Data

Generally, statistical procedures such as structural equation modeling assume that each unit of analysis has complete data. However, for many reasons, units may be missing values on one or more of the variables

under investigation. Numerous *ad hoc* approaches exist for handling missing data, including listwise and pairwise deletion. However, these approaches assume that the missing data are unrelated to the variables that have missing data, or any other variable in the model, i.e., missing completely at random (MCAR)—a heroic assumption at best. More sophisticated approaches for dealing with missing data derive from the seminal ideas of Little and Rubin (1987).

Utilizing the Rubin and Little framework, a major breakthrough in model-based approaches to missing data in the structural equation modeling context was made simultaneously by Allison (1987) and Muthén et al. (1987). They showed how structural equation modeling could be used when missing data are missing-at-random (MAR), an assumption that is more relaxed than missing-completely-at-random.

The approach advocated by Muthén et al. (1987) was compared with standard listwise deletion and pairwise deletion approaches (which assume MCAR) in an extensive simulation study. The general findings were that Muthén et al.'s approach was superior to listwise and pairwise deletion approaches for handling missing data even under conditions where it was not appropriate to ignore the mechanism that generated the missing data.

The major problem associated with Muthén et al.'s approach is that it is restricted to modeling under a relatively small number of distinct missing data patterns. Small numbers for distinct missing data patterns will be rare in social and behavioral science applications. However, it has proved possible to apply MAR-based approaches (Little and Rubin 1987) to modeling missing data within standard structural equation modeling software in a way that mitigates the problems with Muthén et al.'s approach. Specifically, imputation approaches have become available for maximum likelihood estimation of structural model parameters under incomplete data assuming MAR. Simulation studies have demonstrated the effectiveness of these methods in comparison to listwise deletion and pairwise deletion under MCAR and MAR.

5.4 Specification Error

Structural equation modeling assumes that the model is properly specified. Specification error is defined as the omission of relevant variables in any equation of the system of equations defined by the structural equation model. This includes the measurement model equations as well as the structural model equations. As with the problems of non-normality and missing data, the question of concern is the extent to which omitted variables affect inferences.

The mid-1980s saw a proliferation of studies on the problem of specification error in structural equation models. On the basis of work by Kaplan and others (summarized in Kaplan 2000) the general finding is that specification errors in the form of omitted variables can result in substantial parameter estimate bias. In the context of sampling variability, specification errors have been found to be relatively robust to small specification errors. However, tests of free parameters in the model are affected in such a way that specification error in one parameter can propagate to affect the power of the test in another parameter in the model. Sample size also interacts with the size and type of the specification error.

6. Modern Developments Constituting the 'Second Generation'

Structural equation modeling is, arguably, one of the most popular statistical methodologies available to quantitative social scientists. The popularity of structural equation modeling has led to the creation of a scholarly journal devoted specifically to structural equation modeling as well as the existence of SEMNET, a very popular and active electronic discussion list that focuses on structural equation modeling and related issues. In addition, there are a large number of software programs that allow for sophisticated and highly flexible modeling.

In addition to 'first-generation' applications of structural equation modeling, later developments have allowed traditionally different approaches to statistical modeling to be specified as special cases of structural equation modeling. Space constraints make it impossible to highlight all of the modern developments in structural equation modeling. However, the more important modern developments have resulted from specifying the general model in a way that allows a 'structural modeling' approach to other types of analytic strategies. The most recent example of this development is the use of structural equation modeling to estimate multilevel data as well as specifying structural equation models to estimate growth parameters from longitudinal data.

6.1 Multilevel Structural Equation Modeling

Attempts have been made to integrate multilevel modeling with structural equation modeling so as to provide a general methodology that can account for issues of measurement error and simultaneity as well as multistage sampling.

Multilevel structural equation modeling assumes that the levels of the within-group endogenous and exogenous variables vary over between-group units. Moreover, it is possible to specify a model which is assumed to hold at the between-group level and that explains between-group variation of the within-group variables. An overview and application of multilevel structural equation modeling can be found in Kaplan (2000).

6.2 Growth Curve Modeling from the Structural Equation Modeling Perspective

Growth curve modeling has been advocated for many years by numerous researchers for the study of interindividual differences in change. The specification of growth models can be viewed as falling within the class of multilevel linear models (Bryk and Raudenbush 1992), where level 1 represents intraindividual differences in initial status and growth and level 2 models individual initial status and growth parameters as a function of interindividual differences.

Research has also shown how growth curve models could also be incorporated into the structural equation modeling framework utilizing existing structural equation modeling software. The advantages of the structural equation modeling framework to growth curve modeling is its tremendous flexibility in specifying models of substantive interest. Developments in this area have allowed the merging of growth curve models and latent class models for the purpose of isolating unique populations defined by unique patterns of growth.

7. Pros and Cons of Structural Equation Modeling

Structural equation modeling is, without question, one of the most popular methodologies in the quantitative social sciences. Its popularity can be attributed to the sophistication of the underlying statistical theory, the potential for addressing important substantive questions, and the availability and simplicity of software dedicated to structural equation modeling. However, despite the popularity of the method, it can be argued that 'first-generation' use of the method is embedded in a conventional *practice* that precludes further statistical as well as substantive advances.

The primary problem with the 'first-generation' practice of structural equation modeling lies in attempting to attain a 'well-fitting' model. That is, in conventional practice, if a model does not fit from the standpoint of one statistical criterion (e.g., the likelihood ratio chi-squared test), then other conceptually contradictory measures are usually reported (e.g., the NNFI). In addition, it is not uncommon to find numerous modifications made to an ill-fitting model to bring it in line with the data, usually supplemented by *post hoc* justification for how the modification fit into the original theoretical framework.

Perhaps the problem lies in an obsession with null hypothesis testing—certainly an issue that has received considerable attention. Or perhaps the practice of 'first-generation' structural equation modeling is embedded in the view that only a well-fitting model is worthy of being interpreted. Regardless, it has been argued by Kaplan (2000) that this conventional practice precludes learning valuable information about the phenomena under study that could otherwise be attained if the focus was on the predictive ability of a model. Such a focus on the predictive ability of the model combined with a change of view toward strict hypothesis testing might lead to further substantive and statistical developments. Opportunities for substantive development and model improvement emerge when the model does not yield accurate or admissible predictions derived from theory. Opportunities for statistical developments emerge when new methods are developed for engaging in prediction studies and evaluating predictive performance.

That is not to say that there are no bright spots in the field of structural equation modeling. Indeed, developments in multilevel structural equation modeling, growth curve modeling, and latent class applications suggest a promising future with respect to statistical and substantive developments. However, these 'second-generation' methodologies will have to be combined with a 'second-generation' epistemology so as to realize the true potential of structural equation modeling in the array of quantitative social sciences.

Structuralism

For expository reasons, a specific sense of structuralism will be distinguished from a loose sense. The specific sense is the program which Claude Lévi-Strauss, borrowing from structural linguistics, tried to introduce into anthropology. It is defined by the various, not always compatible, statements by Lévi-Strauss. The loose sense is reserved for those authors who deserve to be discussed when speaking about a style of approach which has manifested itself in different ways in different times and places, but which in the history of ideas can generally be traced back to certain writings of Emile Durkheim and Marcel Mauss. Included in this groups are figures who wrote well before Lévi-Strauss, such as Dutch authors who made many of the analytic discoveries found in Lévi-Strauss's *The Elementary Structures of Kinship* (1969a), but who did not speak of structuralism, as well as contemporaries of Lévi-Strauss who though knowledgeable of Lévi-Strauss's writings did not regard themselves necessarily as structuralists in his sense, or did so only part of the time.

The specific sense of structuralism poses its own problems. Which of Lévi-Strauss's many doctrines and which of the many intellectual influences on Lévi-Strauss are to be regarded as structuralist? Is it not arbitrary to regard some as structuralist and to disregard the others? Yet taken as a whole, Lévi-Strauss's style of thought is so personal as to be impossible to imitate in its entirety. Given the elusive nature of his language and his many self-contradictions, many would not want to. Lévi-Strauss's thought and prose, for example, have been said to be influenced by the French symbolist poets and the surrealists (e.g., Leach 1970, p. 16); and according to his own testimony he has been influenced by such composers as Debussy, Stravinsky, and Wagner (Lévi-Strauss 1969b, p. 15). Elsewhere (Lévi-Strauss 1955, pp. 48–50) he describes the influence on his thought of geology, psychoanalysis, and Marxism. 'All three showed that understanding consists in the reduction of one type of reality to another; that true reality is never the most obvious of realities … .' In response Leach (1970, p. 13) has written, 'the relevance of Marxist ideology for an understanding of Lévi-Strauss is difficult to determine. Lévi-Strauss' use of dialectic, with the formal sequence of thesis–antithesis–synthesis, is Hegelian rather than Marxist and his attitude to history seems to be quite contrary to Marxist dogma.' Lévi-Strauss dedicated *The Savage Mind* (1966) to the phenomenologist Merleau-Ponty. How are we precisely to relate the influence on him of American anthropologists such as Boas, Kroeber, and Lowie to his structuralism?

Perhaps we are on surer ground when it comes to the debts which he admits to owing Marcel Granet, Georges Dumézil, and Henri Grégoire (Lévi-Strauss 1969b, p. 15, n. 5). Also there is less difficulty in seeing the similarity between his structuralism and Gestalt psychology with its emphasis or the perception of patterns (Lévi-Strauss 1963a, pp. 324–41). The relevance of Gestalt was recognized by another of his influences, namely Wiener (1948, p. 18, ff.), one of the founders of communications theory. Indeed games theory, the mathematical theory of communication and cybernetics are obvious and acknowledged sources of some of his more unquestionably structuralist ideas (Lévi-Strauss 1963a, p. 283; for a discussion see Ardener 1971, liv ff.). The most direct source of course is the linguistic methods of the structuralist linguists Troubetzkoy, Jakobson, and Halle (cf. Benveniste 1962). In an anticipatory response to a statement of Wiener (1948, p. 24) that sociology and anthropology lacked the long runs of statistics under constant conditions necessary for the applications of the mathematics of communications theory, Lévi-Strauss wrote in a paper of 1945 on *Structural Analysis in Linguistics and in Anthropology* that, 'It [linguistics] is probably the only one [social science] which can truly claim to be a science.' Lévi-Strauss's scientism (a characteristic of his thought), like that of A. R. Radcliffe-Brown, is thus programmatic rather than realized. However, it is the methods which have allegedly turned linguistics into a scientific social science that Lévi-Strauss wants to use to achieve the same transformation in social anthropology.

Referring to Troubetzkoy (1933), Lévi-Strauss reduced the structural method to four basic operations. First, structural linguistics shifts from the study of conscious linguistic phenomena to study of their unconscious infrastructure; second, it does not treat terms as independent entities, taking instead as its basis of analysis the relations between terms; third, it introduces the concept of system. 'Modern phonemics does not merely proclaim that phonemes are always part of a system; it shows concrete phonemic systems and elucidates their structure'; finally, structural linguistics aims at discovering general laws, either by induction 'or … by logical deduction, which would give them an absolute character.' Thus, for the first time, a social science is able to formulate necessary relationships (Lévi-Strauss 1963a, p. 33, 1962).

The crucial influence here was the conception of the phoneme. This idea was based on a distinction between the significant and the insignificant sounds in a given language. Only a small set of sounds in any given language are capable of determining differences of meanings. These individual phonemes are defined by contrastive features which are the distinctive features of a given languages, and these distinctive features are defined by a system of oppositions—the sort of thing that makes the difference between pat and bat.

In the early 1945 paper he drew an analogy between the phoneme and the terms of a kinship terminology: 'Like phonemes, kinship terms are elements of meaning; like phonemes, they acquire meaning only if they are integrated into systems. Kinship systems, like "phonemic systems," are built by the mind on the level of unconscious thought … in the case of kinship as well as linguistics, the observable phenomena result from the action of laws which are general but implicit' (Lévi-Strauss 1963a, p. 34).

Lévi-Strauss also took over from Ferdinand de Saussure, from whom structuralist linguistics derives, the notion of the arbitrary nature of the linguistic sign and the realization that each linguistic term derives its value from its opposition to all the other terms (de Saussure 1922, p. 126). As Ardener (1971, p. 36) comments, 'Here we have clearly stated the now fashionable anthropological view that elements in the system define themselves in opposition to all other elements in the system.'

In contrasting his views on social structure to those of Radcliffe-Brown, Lévi-Strauss held that social structure is a model made up after empirical reality. It is, therefore, a method with the following features. It is a system made of elements, none of which can change without changing other elements. As a model, it should take its place in a series of transformations resulting in a group of models of the same type. It should be possible to predict how the model will react if its elements are modified. Importantly and finally, the model should make intelligible all of the facts. The best model is the simplest model which accounts for all of the facts (Lévi-Strauss 1963a, pp. 279–81). Lévi-Strauss can be said to have brought the intellect into anthropology. As he said, 'each culture has its own theoreticians whose contributions deserve the same attention as that which the anthropologist gives to colleagues.' 'Many "primitive" cultures have built models of their marriage regulations which are much more to the point than models built by professional anthropologists' (Lévi-Strauss 1963a, p. 282). The anthropologist should take these models into consideration and after comparing them to what people actually do, form his own models which for Lévi-Strauss are the structure.

These ideas are already present in his early classic *The Elementary Structures of Kinship* (1969a) in which he treated certain positive marriage rules as transformations across a range of logically possible models, of which only some had empirical realization. They directed his study of systems of classification in his *Totemism* (1963b) and *The Savage Mind* (1966). A characteristic argument is that 'so-called totemic institutions' turn on 'an homology between two systems of differences,' that is, the differences between species is homologous to the differences between groups. These ideas are also carried into his several papers and four books on myth analysis which were intended to reveal the constraints on the human mind (Lévi Strauss 1969b, p. 10). 'Mythical thought always progresses from the awareness of oppositions toward their resolution' (Lévi-Strauss 1963a, p. 224). Lévi-Strauss (1963a, p. 228) early on proposed that every myth corresponds to a formula of the following type

$$Fx(a):Fy(b) \sim Fx(b):Fa-1(y).$$

Later he has he returned to it (Lévi-Strauss 1988, p. 57, 156, 163, 170). This formula he describes as representing 'an inversion of terms and relations, under two conditions: (1) that one term be replaced by its opposite (in the above formula, a and $a-1$); (2) that an inversion be made between the function value and the term value of two elements (above, y and a). Mosko (1991) has modified the formula and said that it works. For some, however, the formula may be incomprehensible. However, elsewhere Lévi-Strauss warns his readers against taking his mathematical formulas and symbols too seriously, as their resemblances to those of the mathematicians are only superficial (Lévi-Strauss 1969b, p. 30). Nevertheless, apart from the above formula, Lévi-Strauss never shows us how the fundamental structure of myth differs from his initial ideas of opposition, mediation and transformation. When he does set forth the structure of a given myth, the demonstration is so heavily freighted with content (the concrete elements that are in opposition) that it is hard to see the difference between the formal structure and the concrete myth.

Dumont (1975, p. 333), following Pocock (1961, p. 76), has written of a convergence between Evans-Pritchard and Lévi-Strauss in the pages of *The Nuer* (1940a), in a passing from the functionalism of

Radcliffe-Brown to meaning. Radcliffe-Brown used structure as a synonym for social structure, the true subject of social anthropology. In the closing pages of *The Nuer*, Evans-Pritchard makes several attempts to characterize his achievement and state what he means by structure, finally stating that, 'We have defined structure by what amounts to the presence of group segmentation,' that is, the segmentary principle (Evans-Pritchard 1940a, p. 265). If this is a convergence, it is a convergence before the fact; for Lévi-Strauss wrote his essay on social structure more than a decade after Evans-Pritchard wrote *The Nuer*. It is striking that in that essay Lévi-Strauss mentions *The Nuer* only in a footnote in the midst of a long list of books which have had something to say about economic formations (Lévi-Strauss 1963a, p. 319, n. 49). At the risk of reading the present into the past and taking the lead of Pocock and Dumont, we could say that in 1939 or thereabouts, Evans-Pritchard did not have the vocabulary available to talk about his achievement which would have been available a little over a decade later. Taking the better parts of Lévi-Strauss's essay, he might later have been able to write that what he had done in *The Nuer* is present a series of models, starting with the models of the Nuer themselves, that is, their meanings, and that the most salient and most abstract model he had used was the segmentary principle, which was essentially his final definition of structure.

Dumont noted too that in Evans-Pritchard's treatment of factual oppositions there were underlying conceptual oppositions and that, 'the author has well and truly discovered structuralism on his own account without direct borrowing—as was the case in other quarters—from contemporary developments in neighboring disciplines (phonology, Gestalt theory)' (Dumont 1975, p. 335). Dumont also noted that 'what is properly and strictly the structural aspect of *The Nuer* has never really taken root in England' (Dumont 1975, p. 334). For example, 'immediately afterwards, the opposite tendency to reify or solidify, in the manner of Radcliffe-Brown, was vigorously asserted by Meyer Fortes' (Dumont 1975, p. 340). Thus, Fortes stated that 'The most important feature of unilineal descent groups in Africa … is their corporate organization' (Fortes 1953, p. 25). More recently Holy stated that 'Evans-Pritchard saw the lineage system in terms of the paradigm of hierarchically structural segments, each of which was a corporation' and lists as one of his errors 'ascribing corporateness to what are empirically … only categories of people' (Holy 1996, pp. 88–9). As evidence of Evans-Pritchard's views he cites Fortes. In fact, both Fortes and Holy overlook the fact that Evans-Pritchard stated quite plainly in *The Nuer* (Evans-Pritchard 1940a, p. 89) and in his contribution to *African Political Systems* (1940b, pp. 286–7) that, 'Nuer lineages are not corporate, localized, communities' and 'clans and their lineages are not distinct corporate groups.'

In *The Nuer* structure remains close to social structure, but by 1956 in chapter IV, 'Spirit and the Social Order,' in *Nuer Religion*, Evans-Pritchard was applying similar ideas to conceptions of divinity. 'Given the segmentary political and lineage structure of the Nuer it is understandable that the same complementary tendencies towards fission and fusion and the same relativity that we find in the structure are found also in the action of Spirit in the social life' (Evans-Pritchard 1956 p. 115). This chapter understandably bears a close similarity in inspiration to Chap. 4 in his student Needham's *Structure and Sentiment* (1962) and to that mine of structuralist inspiration *Primitive Classification* (Durkheim and Mauss 1963) with its concern about the relation between the structure of society and the structure of classification (for a discussion of its influence see Needham 1963, pp. 31–2). Evans-Pritchard was one of the few Africanists who had the slightest understanding of what Asianists such as Dumont, Leach, and Needham were trying to do in bringing structuralist approaches into British anthropology, particularly, but not exclusively, in relation to the topic of marriage alliance.

A convergence between Lévi-Strauss's structuralism and early work by Dutch anthropologists was recognized and celebrated by Josselin de Jong (1952). P. E. Josselin de Jong (1977) provided a service by bringing out a selection of this early Dutch structuralism (to give it a retrospective designation) in English translation in his *Structural Anthropology in the Netherlands*, which includes Louis Onvlee's essay on the construction of the Mangili dam, a crystal clear example of pre-Lévi-Straussian structuralism that achieves more than Lévi-Strauss ever did at a similar level, but which remains entirely free of the characteristic blemishes of Lévi-Strauss's thought.

The terms structuralism and structuralist were unknown to some of the authors alluded to here, accepted retrospectively by some, and avoided by others. Leach wrote (1970, p. 9), 'I myself was once a pupil of Malinowski and I am, at heart, still a 'functionalist' even though I recognize the limitations of Malinowski's own brand of theory. Although I have occasionally used the 'structuralist' methods of Lévi-Strauss to illuminate particular features of particular cultural systems the gap between my general position and that of Lévi-Strauss is very wide.' In *Political Systems of Highland Burma* (1954), which Leach later characterized as rationalist, that is, structuralist, unlike his later book *Pul Eliya* (1961) which he characterized a empiricist, that is, functionalist (Leach 1976, p. 6), Leach writes that as opposed to social structure, culture provides the form and 'dress' of the social situation (Leach 1954, p. 16). These views did not prevent him from publishing structuralist treatments of the Bible (Leach 1962) and of Michelangelo's paintings on the ceilings of the Sistine Chapel (Leach 1977). Leach's attitude appears to be that structural-

ism is a technique to be used when it is advantageous to do so, rather than a movement within which the anthropologists must always travel. In all probability Dumont would have agreed with him. When considering north Indian kinship in relation to south Indian kinship, Dumont (1966, p. 103) found that his structuralist methods, which were so productive in the south, were unproductive, or at least not productive to the same extent, in the north. It can be said that some peoples are structuralist and others are not. Perhaps it could be said that there are structuralist topics and non-structuralist topics about a given people. The sensible course is to use whatever techniques suggest themselves and produce a result.

Structuralism, History of

The triumph of structuralism during the 1950s and 1960s was of such a remarkable nature that it became identified with the ensemble of French intellectual history since 1945. During these years, little attention was paid to anything outside of this trend which appeared as a new perspective on the world and human culture. Emphasising critical thinking and expressing the emancipatory will of nascent social sciences in search of scholarly and institutional legitimation, structuralism generated a real sense of collective enthusiasm for the whole of French intelligentsia over at least two decades.

Then suddenly, at the beginning of the 1980s, everything was overturned. Most of the French heroes of this intellectual adventure disappeared and with them their work, anxious to be buried by a new epoch, accentuating thus the impression of the end of an era. In this way, the working through of mourning, necessary in order to do justice to what had been one of the most fruitful periods of our intellectual history, had been avoided.

Taken in its most general sense, the word structure served as a password for a large part of the human sciences (*sciences humaines*), enabling a unitary pro-

gram. Where does the concept of structuralism, one that has led both to such infatuation and to such opprobrium, originate? Derived from the word structure, it starts out as an architectural term. Structure was first and foremost 'the way in which a building is constructed' (*Dictionnaire de Trévoux*, 1771 edition).

During the seventeenth and eighteenth centuries, the meaning of the term structure is modified and enlarged by the analogy with living beings. Thus, the human body is perceived as a construction in Fontenelle as is language in Vaugelas and Bernot. The term, therefore, is taken to refer to a description of how the components of a concrete object make up the whole. It can have various applications (anatomical, psychological, geological, mathematical structures, etc.). The structural approach is not really applied to the field of the human sciences until the more recent nineteenth century, with Spencer, Morgan and Marx.

It is then taken to refer to a lasting phenomenon that connects, in complex terms, the components of an aggregate according to a more abstract schema. The term structure, rarely found in Marx, with the exception of the preface to *A Contribution to the Critique of Political Economy* (1859), is consecrated by Durkheim at the end of the nineteenth century in *The Rules of Sociological Method* (1895). Structure thus gives rise to that which, in André Lalande's *Vocabulaire*, is qualified as a neologism—structuralism between 1900 and 1926. Structuralism emerges among psychologists in opposition to the functional psychology of the turn of the century. However, structuralism's real starting point, in terms of its modern meaning and standpoint of domination among all the human sciences, originates in the evolution of linguistics.

Although Saussure uses the term structure only three times in *The Course in General Linguistics*, it is the Prague School (Troubetzkoy and Jakobson) that is to make widespread the use of the terms structure and structuralism. The Danish linguist, Hjemslev, who founded the journal Acta Linguistica in 1939, asserts the reference to structure as a charter program. The first article in this journal treats the subject of 'structural linguistics.'

1. *The Structural Years*

Departing from this linguistic nucleus, the term triggers a veritable revolution throughout the human sciences at the heart of the twentieth century. To the extent that Michel Foucault observed that structuralism 'is not a new method, but the awakened and anxious conscience of modern knowledge.' Jacques Derrida defined this approach as an 'adventure in perception' and Roland Barthes saw structuralism as the passage from symbolic to paradigmatic conscience, or as the advent of the awareness of paradox. It therefore suggests a movement of thought and a new relationship to the world, much wider than a simple binary methodology confined to one or another field of specific study. This interpretation, seeing itself as unitary, privileges the sign at the expense of meaning, space at the expense of time, the object at the expense of the subject, relation at the expense of content, and culture at the expense of nature.

Primarily, structuralism functions as a paradigm for a philosophy of suspicion, or an act of exposure on behalf of intellectuals that aimed at demystifying the *doxa* and denaturalise meaning, to destabilise it while searching behind the scenes for an expression of bad faith. It is postulated that the class position of the speaker or his libidinal position enables the denouncement of the illusion under which all types of discourse are condemned to exist. This situation of exposure is inscribed in the ancestry of French epistemological tradition that proposes a position of overhang or rupture between scientific competence and common sense, the latter seen as being tied to illusion. Behind this paradigm of suspicion, a profound pessimism envelops intellectuals as well as a critique of western modernity the antithesis of which they attempt to grasp by reference to the figures of the child, the insane or the savage. Thus, beneath the liberatory discourse of Enlightenment, the discipline of the body, the confinement and imprisonment of the social body within an infernal logic of knowledge and power is exposed. Roland Barthes, then, says: 'I profoundly refuse my civilisation, to the point of nausea' and the 'Finale' of Claude Lévi-Strauss's *The Naked Man* ends with the word 'NOTHING,' written in capitals, evoking a requiem or the twilight of mankind. This structuralist paradigm proposes the prevailing of a suspension of meaning, as a means of opposing both eurocentrism and various forms of westernised teleology, in favour of a differentialist mode of thought.

The second dimension of the structuralist paradigm involves philosophy's take-over of three of the social sciences undergoing emancipation and sharing a common valorisation of the unconscious as the locus of truth. These disciplines are general linguistics when, with Saussure, they separate language (*langue*) as a legitimate object from speech (*parole*) forced back to the non-scientific domain; anthropology, with its concern with the encoding of messages rather than with messages themselves and psychoanalysis's view upon the unconscious as an effect of language. This relates to a quest for both legitimation and standing by nascent social sciences confronted with the established force of the classical humanities and by the tradition and conservatism of the old Sorbonne. Structuralism, at this stage, offers itself as a third discourse, bridging literature and the hard sciences, seeking institutionalisation through socialisation, by-passing the academic center of the Sorbonne by way of the peripheral universities. Publishing and the press through the respected institution of the *Collège De France*, serves

as a refuge for research on the cutting edge. This involves a veritable battle between the ancients and the moderns in which the themes of breaking and rupture come into play at several levels. The social sciences then attempt to free themselves by cutting the umbilical cord that tied them to philosophy by erecting the efficiency of a scientific method. On their part, some philosophers, taking into account the importance of these endeavors, capture their program and redefine the function of philosophy as a philosophy of the concept. This was to become what is known as 'effectology,' or the use of research in the human sciences for a philosophical project that simultaneously deconstructs the classifications employed from within these practices. Philosophy, therefore, retains its central position while declaring its own demise. The major role played by philosophers in this matter also relies on their ability, in the middle of the 1960s, to impose a unitary program, an endeavor in which the structuralist etiquette serves as a rallying call.

The second explanatory idea that accounts for this history is that of generation. Thus, a number of landmark events make a lasting impression upon a generation indelibly marked by the Second World War. The difficulty of thinking after Auschwitz, expressed by Adorno, meant the difficulty of thinking optimistically, as was possible at the turn of the century, of the history of a west that had turned towards atrocity, to crimes against humanity. This history was to become the very locus of doubt, questioning, and severe criticism. Hell is no longer the other, but oneself. A questioning of the self and of its illusory capacities for mastery then aroused by a society that had reduced the individual to nothing more than a number. This despair that engenders the critical distance of suspicion becomes accentuated during the 1950s and 1960s with the progressive liberation of the colonised peoples who had broken free of the colonial yoke and achieved their independence. Many intellectuals were to see this rejection of western influence as a confirmation of their critical position and held the figure of the 'other,' or the epitome of absolute alterity from the west, to be the very locus of the expression of truth and of a certain purity. This release from western history, that enabled the Bororos or the Nambikwaras to be perceived as expressing the purified cradle of humanity, is reinforced by the successive revelations about what some had taken to be the incarnation of their hopes for the real Marxism of Communist countries.1956 is to become a vital date for a generation of Marxist intellectuals that takes refuge in a structuralised Marxism, a 'vacuum-packed Marxism,' as it is dubbed by Jean-Marie Domenach, upon which the disasters of real Communism would have no bearing. Many among these intellectuals are to break with Communist culture, stealing away on tiptoes from history and taking refuge in the enclosure of text, science, and in the evacuation of the subject and the signified.

2. *Founding the Scientificity of a Third Discourse*

The hope for the scientific renovation of the social sciences found its method, a common language capable of effecting change, within structural linguistics. Linguistics then became the model for a whole range of social sciences aspiring to formalism. The discipline was progressively diffused from anthropology, to literary criticism, and to psychoanalysis and it led to the profound renewal of the mode of philosophical questioning.

The areas most affected by the linguistic contagion were those disciplines that found themselves in an institutionally precarious position. Alternatively, disciplines were in search of an identity tainted by the internal contradiction of their pretensions to scientific positivity and their relationship to the political, as in the case of sociology and those such as literary studies and philosophy, fully immersed in the dispute between tradition and modernity. This connection served to blur the boundaries between disciplines. Structuralism offered itself here as a unifying project. This temptation was most clearly expressed by Roland Barthes who advocated a general semiology capable of grouping all the human sciences around the study of the sign.

Modernization becomes articulated at this point with the interdisciplinary, as it is necessary to defy the sacrosanct boundaries in order to allow the linguistic model to infiltrate throughout the field of the human sciences. As everything is linguistic, everyone is linguistic and the world is language. This interdisciplinariness, that infringes upon the Humboltdian model of the university in which each discipline has its strictly delineated place and is related to the delegitimation of meta-narratives, creates a veritable enthusiasm for all variants of formalism, for knowledge immanent to itself. The key word of the times is 'communication' that, even beyond the journal bearing the same title is evocative of the multi-disciplinary euphoria of this period. Lévi-Strauss was the first to formulate this unifying program for the human sciences in the post-war period. To be sure, the constellation he elaborated gravitated around the social anthropology that he represented and that alone was capable of leading this totalising enterprise. The basis for anthropology's particular vocation, according to Lévi-Strauss, is its ability to bridge the natural and human sciences and, therefore, it does not reject being classed among the natural sciences at the final call of judgement. Strengthened by his fruitful encounter with Jakobson during the war in the USA, Lévi-Strauss privileges the linguistic model within his anthropological project. His search for invariants and his paradigmatic and syntactic deconstructions incorporate the teaching of Jakobson's phonology, for example binary opposites and differential variations. His contribution ensured that linguistics engendered a particularly fecund area of scholarship during the post-war period. Although Lévi-Strauss guides anthropology in a cultural di-

rection, due to the emphasis placed on language and the decoding of signs, he does not, however, neglect his ambition for unity. His quest for mental perimeters also seeks out the field of biology. The wholeness, to which Lévi-Strauss aspires, incorporating also Marcel Mauss's ambition to construct the 'total social fact,' thus aims to embrace the entire scientific domain. It also aims to finally make an anthropology of the Science of Man; a federation of auxiliary sciences strengthened by logical-mathematical models, the contribution of phonology and by a limitless field of study, able at the same time to encompass societies devoid of history or writing across the globe.

The anthropologist is therefore able to access the unconscious of social practices and can reinstate the complex combinatories of the rules in force in all human societies. Such an ambition represented a major challenge for all sciences involved in the study of human beings. It also encouraged competitive reactions to this program from within other fields of knowledge or, on the other hand, a dependency upon a process of conquest with the aim of attaining a standing for those still marginalised disciplines in search of legitimation. The excessive nature of this ambition matches the difficulty faced by anthropology at its outset to position itself within the institution. Although anthropology alone did not succeed in emancipating the human sciences, structuralism, taking up the challenge, in fact became the common paradigm if not a common school for a whole range of disciplines while converging to construct a whole and unified science.

In 1953, against a backdrop of open crisis, Lacan gives his Rome Report . He is charged with paving an attractive and specifically French way towards the unconscious. In order to win this gamble, he searches for foundations, for institutional and theoretical guarantees. Lacan heads on the quest for lifelines. Therefore he is responsible for breathing new life into psychoanalysis, for curbing its crisis by using a strategy of offence and a dynamic of alliance. While Lacan employs all the means at his disposal he nonetheless uses any available intellectual material to turn things to his advantage, here proving rather more successful.

Lacan's re-reading of Freud is inscribed in the Saussurian tradition, prioritising the synchronic dimension. With this, he shares in the structuralist paradigm and prompts a new reading of Freud that no longer privileges the importance of stage theory but submits this to a basic oedipal structure characterized by its universality, independent of the relationship to temporal or spatial contingencies and preceding all history.

Contrary to Saussure, for whom the primary object was language, Lacan privileges speech, a displacement necessary due to the therapeutic practice. But this word does not represent the utterings of a conscious subject in control of his speech, but rather the opposite. Speech is forever cut off from all access to reality. They merely convey the signifiers that rebound between them. Man, therefore, only exists according to his symbolic function that, in turn, should apprehend him. Lacan thus presents a radical reversal of the notion of the subject as a product of language and its effect, as implied by the notorious proposition that 'the unconscious is structured like a language.' There is, therefore, no point in searching for the human essence anywhere else but in language. This is what Lacan meant when he says, 'language is an organ;' 'the human being is characterized by the fact that his organs are external to himself.' This symbolic function, upon which man's identity is founded, is opposed by Lacan in his Rome lecture to the language of bees that is entirely based on the stability of its relation to the reality it signifies. Lacan finds in the Saussurian sign, cut off from the referent, the semi-ontological kernel of the human condition.

This new vision of a decentered, split subject is compatible with the notion of the subject being developed in other structuralist fields within the human sciences. This subject is in some ways fictive, not existing outside of its symbolic dimension and of the signifier. Although the signifier is prioritised over the signified, there is nonetheless no question of the latter's abandonment. These two different levels therefore interact, a process that Lacan relates to Freud's discovery of the unconscious thus making of him, in Lacan's eyes, the first structuralist. The signifier even makes the signified undergo a sort of passion. As becomes clear here, Lacan submits Saussure to a certain twisting of his concepts and in as much as the notion of the sliding of the signified under the signifier would not have made sense to Saussure, so too the notion of the unconscious escaped him. Lacan takes up the two big rhetorical figures of metaphor and metonomy used by Jakobson to highlight the deployment of discourse and assimilates the two to the functionary mechanism of the unconscious that, structured like language, situates itself in total isology from the rules of the latter.

3. *A Global Semiological Project: 1964–66*

In 1964 there were several breakthroughs in the classical schema. Structuralism now has the possibility of appearing to be a program shared by several disciplines. It is, in fact, in 1964 that the new university at Nanterre was opened, the very center of literary modernity. It is in the same year that a special edition of *Communications* appears, edited by Roland Barthes and dedicated to semiology. Barthes here defines 'structuralist activity' as the conscience of paradox and the denaturalisation of meaning. At the same time, Lacan, definitively excommunicated by the International Freudian Association, establishes the ECF (*l'École de la cause freudienne*). His seminar moves from Sainte-Anne to the *École Normale*

Supérieure at the *rue d'Ulm*, the epicenter of humanities studies that had fallen prey to the veritable fever of scientism and epistemology favoured by Louis Althusser. Lacan was not only welcomed by Althusser there but he was also welcomed to the bosom of Marxism in a text entitled 'Lacan and Freud' in which he subscribes to the new direction taken by psychoanalysis as defined by Lacan—seeing in the latter's return to Freud the mirroring of his own return to Marx. It is in the same year that Lévi-Strauss embarks upon his signature work, *Mythologiques*, a tetralogy on myths beginning with the publication of *The Raw and the Cooked* in which mythical thought is described to be structured-like language.

It is around philosophy that the formulation of a global program going beyond the positivity of any specific discipline in the social sciences can be found. At the *École Normale Supérieure d'Ulm*, the epicenter of the circumvention of the strictly classical Sorbonne, the intellectual home of structuralism and that of Lacan and Derrida, philosophy around Louis Althusser is to become the 'Theory of Theoretical Practice,' the appropriation of the contribution of the new social sciences and their internal subversion. It is due to the return to Marx, evident in the seminars beginning at the outset of the 1960s, that Althusser proposes re-*Reading Marx* by establishing his work as the advent of Science following the epistemological break discernible in it around 1845. Two versions of Marx are, therefore proposed of which Althusser refers only to the second, that of science, structural causality and over-determination. Althusser reads Marx in a way that suggests a theoretical anti-humanism and a 'process devoid of either subject or object' as many of the themes being elaborated within the structuralist project of the 1960s in which man is spoken rather than speaking.

The other attempt led by the structuralist program in the effort to globalise itself is led by Michel Foucault during structuralism's peak year—1966—the year in which *The Order of Things* was published. Foucault, thus, announces the death of philosophy and its substitution by active thought, brought about due to logic and linguistics. Foucault prioritises two (social) sciences in particular, psychoanalysis and ethnology in that he sees them as 'counter-sciences' that enable the destabilising of both history and of the subject. Foucault sees humanism as our 'middle-ages' and the figure of man as a transitory one destined to disappear. It is once again within the figure of the unconscious of the human sciences that their truth may be uncovered behind their illusory pretension to reinstate man in a command made forever impossible by the three narcissistic wounds provoked by Galileo, Darwin and Freud.

The structuralist program is, however, deconstructed from within itself in that it departs from a principled double negation that could not but cause it to fall into an aporia of the subject and of historicity. The ontologisation of structure that resulted, that which Paul Ricoeur called 'Kantianism without the transcendental subject,' could not but lead it into a dead end. I support Paul Ricoeur's warning against the untimely dissociation of the absolute complementarity of the explanatory level, represented by semiological analysis and the interpretative stage or the reappropriation by the subject of the meaning of text, allowing him to endow it not only with meaning but also with signification. The joining of the semiological and hermeneutic approach enables a reappropriation of the discourse's various components. Paul Ricoeur presents them as a 'quadrilateral of discourse:' (a) the speaker as a singular event of speech; (b) the interlocutor's bringing out of the dialogical character of the discourse; (c) meaning or the very theme of the discourse which is the unique and exclusive dimension of structuralism to the exclusion of all three other dimensions; and (d) reference or that being spoken about. This kind of reappropriation allows for the emergence, not of a transparent subject or master of meaning, but of an ontology of action based upon a triangular relation systemised by Ricoeur in *Oneself as Another*, the relationship drawn between the self (ipse), the other (alterity) and the institutional foundations (community). This perspective thus seeks to 'regroup' the metaphysics of the act, interpersonal ethics and the problem of social ties, a task made all the more pressing by the discovery in the twentieth century of the 'fallibility' of democracy. Paul Ricoeur thus enables us to develop action open to historicity, creativity and to narrativity in order to understand better the constitution of both our personal and collective narrative identities.

Structuralism, Theories of

Structuralism is an intellectual tendency that seeks to understand and explain social reality in terms of social structures. Influenced by the rising prestige of mid-nineteenth century science, theories of structuralism focused on structural form as an organizing principle underlying whole cultures and societies. Structural form is analytically distinct from cultural content such as meanings and norms, although culture and structure can be defined in terms of each other as, e.g., in cultural structuralism or in the idea of structure as a cultural pattern or model. In contrast to both culture and the reductionist view of society as an aggregate of individuals, social structure is defined as the forms of social relations (e.g., difference, inequality) among a set of constituent social elements such as positions, units, levels, regions and locations, and social formations (see *Structure: Social*).

Structuralism proceeds on two analytic levels: (a) as a method of analysis or procedure of knowing (epistemology), and (b) as an ontology or metaphysical design of social reality. It approaches its subject matter in terms of two meta-theoretical perspectives on social reality: (a) social structure as an empirical or historical reality, and (b) social structure as a model or representation of reality (see *Sociology, Epistemology of*; *Theory: Sociological*). The conceptual property space created by these analytical dimensions generates a fourfold typology that accommodates the major theories of structuralism existing today: (a1) sociological structuralism, (a2) symbolic structuralism, (b1) historical structuralism, and (b2) orthodox structuralism. Since the major symbolic and orthodox structuralist theories privilege simultaneity and synchrony over history and diachrony, b1 will only be discussed briefly in contrast to genetic structuralism in Sect. 2.

1. Sociological Structuralism

Marx and Durkheim are the two most important theorists to introduce structural concepts into the study of society. Both conceived of social structure in holistic and nonreductionist terms, i.e., not as an aggregation of individual actors, but as social facts *sui generis*, explainable only by other social facts. For Marx, the central social fact was the political economy; for Durkheim it was social ties and norms. Both were committed to the use of positivist scientific procedures in the study of society and believed in the necessity of empirical evidence and the importance of establishing objective causal connections between the phenomena to be explained and the structures explaining them. Both offered an analysis of the structural features of modern societies and were centrally concerned with the transition from premodern to modern forms of social organization. However, they developed different structural concepts and theories of historical and structural transformation.

1.1 Marx's Materialist Conception of History

Marx formulated the transition from feudal to capitalist society as a historical and structural shift in the mode of production, a high-level structural concept comprising the productive forces as the active source of continuous change and the social relations of production as the historical outcome of conscious human productive activity or self-transforming praxis. The developing contradictions between ever-changing productive forces and increasingly constraining social relations generate the possibility of the transformation of a given mode of production and the emergence of a new mode of production. Structural features such as the division of labor, the ownership and control of capital, the class structure of society, and the ideological representation of class conflict constitute a sociohistorical totality which tends to change with the progressive transformation of the mode of production. Resistance to change by social classes invested and interested in the status quo is the most proximate cause of class conflict and the possibility of social revolution. Marx's ([1859] 1904) reliance on the Hegelian causal mechanism of dialectical contradiction and on the internal dynamics of the mode of production led him to overestimate the likelihood of revolutionary change and to underestimate the relatively autonomous role of the state, legal institutions, and social movements in mediating between pressures for change and the collective accommodation to the status quo. The use of a self-transformative principle of dialectical causality intrinsic to the economic sphere to explain historical social change led to the charge that Marx's theory is one-dimensional, self-confirming, and not independently falsifiable or testable, hence worthless as a scientific theory. It can be argued, however, that the rise of the regulatory state in the twentieth century as well as specific forms of radical state intervention under state socialist or national socialist regimes interrupted global capitalist expansion, thus providing the negative evidence necessary to test and refute Marxian economic predictions. By the same token, the collapse of state socialism and the worldwide decline of regulation and intervention under neoliberal auspices have spurred the resumption of globalization. These historical processes, in turn, are likely to confirm certain Marxian expectations and to contribute to the theoretical rehabilitation of

Marxian theory (see *Marxism in Contemporary Sociology*).

1.2 *Durkheim's Sociological Realism* (*Holism*)

Durkheim ([1893] 1964) undertook to explain the transition to modern industrial society by invoking a different set of structural forces: population growth due to the agricultural revolution, the resulting rise of population density, the increase in the rate of social interaction, competition, and division of labor among differentiated and specialized social functions, and the emergence of social relations and associations among social groups and occupations. This transition from the mechanical solidarity of segmented but undifferentiated societies to the 'moral density' and organic solidarity of highly differentiated ones implied a structural theory of social change which was perfected in his work on the social causes of suicide. The resulting theory of social integration continues to be tested by empirical research. Durkheim formulated a set of methodological rules designed to put sociology on a scientific footing. His conception of social structure as a nonreducible 'social fact' was paralleled by culturalist notions of collective representations, collective conscience, as well as cognitive and normative constraints which he referred to as 'ways of acting, thinking, and feeling.' This formulation implied a theory of institutions combining structural and normative elements as 'social facts,' a theoretical framework transcending the distinction between structure and culture, just as Marx acknowledged the constant interplay of collective action, consciousness, ideology, and structure. Elements of Durkheim's and Marx's structuralism reappear in contemporary approaches, e.g. Bourdieu's (1989) constructivist structuralism and Giddens's (1984) theory of structuration.

1.3 *Modern Network Structuralism*

An important development in contemporary sociological structuralism is social network analysis (Scott 1991). Social networks, defined as the patterns of social relations among a set of actors or nodes, are generic social structures. Networks differ from organizations and institutions in that they are informal, private, self-organizing, noncontractual, unregulated, unaccountable, nontransparent, and typically of limited focus, size, and duration. Networks are the least structured social forms that can be said to possess any structure at all, yet whose structural configurations affect the behavior of their members. While networks are typically seen as real, empirical structures, they can be represented by formal models. As such, they are closely related to concepts like 'intersecting social circles' and the 'web of group affiliations' in Simmel's (1971, p. 23) formal sociology and Blau's (1998) theory of structural sociology (see *Networks: Social*).

2. *Symbolic Structuralism*

Sociological empiricism and positivism gave rise to a countervailing epistemological tendency claiming that the holistic structures identified by the new social sciences were nothing but cognitive models of reality since they necessarily had to rely on categories that represented, constituted, or constructed reality. This resurgence of neo-Kantian philosophy influenced Weber, Simmel, and Lévi-Strauss, among others, and served to justify the rejection of positivist causality and historical materialism.

Symbolic structuralism is a method of analysis that conceives of structure as a model or representation of reality. Typical is Saussure ([1915] 1966), who introduced certain methodological innovations into the study of language that would move linguistics from a descriptive historical discipline to an analytical, scientific one. The linguistic sign was seen as a holistic combination of two structural elements: a form that signifies (signifier) and a concept to which the form refers (signified). The relationship between signifier and signified is not natural or fixed, but social and arbitrary, hence infinitely variable. Linguistic symbols are meaningful only insofar as they produce identity-in-contrast, binary oppositions (difference), and formal distinctions. This method shifts the analytic focus from such metaphysical concepts as 'object,' 'reality,' or 'thing-in-itself' to the formal properties and the internal structural relations of sign systems. The content and use-value of symbols and objects are subordinated to their relational identity, their position, function, and exchange value within a given system.

A little-noted aspect of Saussure's linguistic structuralism is its origin in the categories of the capitalist economy, especially the 'radical duality' of economic history and the political economy as a system (1966, p. 79). Both economics and linguistics are 'confronted with the notion of *value*'; both are '*concerned with a system for equating things of different orders*—labor and wages in one and a signified and signifier in the other' (Saussure 1966, p.79, italics in original).

Saussure elevates the duality of system and history to central principles of linguistic analysis: the distinction between language and speech, and the priority of synchrony over diachrony. This methodological imperative entails the epistemological precedence of the code over its application, of the structure of the system over its origins and transformation, of exogenous over endogenous change. 'The linguist who wishes to understand a state must discard all knowledge of everything that produced it and ignore diachrony' (Saussure 1966, p. 81). Historical change involves merely the displacement of one form or structure by another. History becomes eventless history.

Piaget (1970) showed that these structuralist methods spread from linguistics to other disciplines,

e.g., gestalt psychology, psychoanalysis (e.g., the structure of the unconscious in Freud and Lacan), and structural anthropology (Lévi-Strauss). Piaget's (1970) own genetic structuralism replaces the historical study of social change with the notion of structure as a system of transformations. Three key elements here are the idea of wholeness, of structured wholes as determined by internal rules of transformation, and of the relative autonomy and self-regulation of structures. Piaget tacitly acknowledges the transition of structuralism from a method to an ontology by asserting that even though 'structures consist in their coming to be; that is, their being "under construction,"' they nevertheless depend on higher-level structures; i.e., 'on a prior formation of the instruments of transformation—transformation rules or laws' (1970, pp. 140–1). Distinct from genetic structuralism, historical structuralism (Marc Bloch, Lucien Febvre, Fernand Braudel and the Annales School) assumes the determinative influence of historical deep structures such as the *longue durée*.

The epistemological ambiguity of structures as models of reality or as pregiven structures appears in other sociological approaches, for example Georg Simmel's (1971) social forms and social types, Max Weber's 'ideal types' of religion and rationality, and Alfred Schutz's 'typifications,' the 'first-order constructs' (the primary, common-sense construction of social reality by participants) and 'second-order constructs' (the secondary, derivative social construction by the scientific observer) of the structures of the life-world (see Dosse 1997, p. 42 and *Phenomenology in Sociology*).

3. *Orthodox Structuralism*

The convergence of structure as a model or representation of reality and the ontological view of structure as substance constitutes orthodox structuralism. The analytic differences between structure and system are blurred. The idealist version is best represented by the work of Claude Lévi-Strauss, the materialist version by Louis Althusser.

3.1 *Lévi-Strauss and Anthropological Structuralism*

Lévi-Strauss's structural anthropology was influenced by Saussure's structuralist linguistics by way of Roman Jacobson and the phonological school of Prague as well as by Durkheim and Marcel Mauss (Dosse 1997, pp. 21–2, 29–30). In his initial attempt to formulate a method for producing a model of social reality, Lévi-Strauss develops a systemic concept of social structure implying the internal interdependence of elements or 'elementary structures' as, for example, in kinship systems. This conceptualization set the stage for the idea of a 'formal structural homology,' the reproducibility of structures on different levels such that a series of transformations can produce a group of models of the same general type, ascending from the 'order of elements' in the social structure to the 'order of orders,' and ultimately to some universal order (Lévi-Strauss 1967, pp. 302–9). For Lévi-Strauss, the advantage of structural models is that they make it possible to arrive at general laws and to specify the internal logic of social systems such that all the observed facts are immediately visible, an assumption shared with gestalt psychology and other approaches based on a coherence concept of truth rather than on a positivist correspondence concept of truth.

The search for general laws leads Lévi-Strauss to shift his attention from the study of conscious phenomena (speech, opinions, ideology) to that of the unconscious infrastructure of cognitive forms, basic codes, and myths. Here, then, the reality of social structure is but the surface manifestation of the deep structure of the mind. Ultimately, Lévi-Strauss can be said to take the structuralist model of reality from the agnostic dualism of Kant's *a priori* categories back to the pre-Socratic belief that reality can be found only in timeless, changeless 'Being.' Thus, it would be logically absurd to see history and social change as anything other than the recurrent rearrangements of internal relations and structural building blocks.

3.2 *Althusser's Marxist Structuralism*

The immediate textual source for the adaptation of Marxism to structuralism is Frederick Engels' formulation of historical materialism in terms of the complex interaction between the economic base and the political and ideological superstructure of society. In this tripartite distinction between relatively autonomous regions of a given social formation, each representing its own form of practice, 'the economic element finally asserts itself as necessary' (Engels, in Heydebrand 1981, p. 88). Althusser adapts Engels' dialectical concept of interaction among levels of social structure by developing a deterministic (rather than probabilistic) scientific model of 'contradiction and overdetermination.' This model rejects empiricism, construes dialectics as a dualism of opposites, separates 'science' from ideology, and asserts that the superstructure 'is relatively autonomous but the economy is determinant in the last instance' (Althusser 1970, p. 177). Since the structuralist concept of causality is deterministic rather than stochastic, a 'structure is always the co-presence of all its elements and their relations of dominance and subordination—it is an ever pre-given structure' (Althusser 1970, p. 255). For Althusser, theory is the work of transforming ideology into science. This 'theoretical practice' is subject only to its own determinations and is prior to, and independent of, the base–superstructure problematic. This formulation of materialist structuralism occurs at such a high level of abstraction that it becomes practically indistinguishable from idealist struc-

turalism. Althusser later recognized this problem and rejected his notion of theoretical practice as a 'theoreticist error, i.e., as an epistemological quest for categorical constants and orthodox theoretical principles that falsely impose a fixed, ontological order on the 'real object' by means of a reified 'object of knowledge.'

The controversies surrounding orthodox structuralism as an intellectual and ideological tendency have contributed to the clarification of structural concepts in the social sciences, but failed to formulate testable propositions. Sociological, symbolic, and historical structuralism, however, continue to exercise considerable theoretical influence in the social sciences and in the post-structuralism of Derrida and Foucault.

Structure: Social

The term structure (Latin *structura* from *struere*, to construct) has been first applied to construction and only later on, during the classical period, to the scientific field of biology. It began to be used, in the anatomic language, to refer to the interdependence of parts and to the corresponding mode of organization in living bodies. What is worth noticing is that the metaphor of construction on the one hand, the analogy with the organism on the other, are plainly involved in the two first main uses of the term with reference to human societies, in the mid-nineteenth century.

The metaphor is clearly used by Karl Marx, when he writes in The Preface to *A Contribution to Critique of Political Economy* (1859), the well-known sentence according to which 'the sum total of [the] relations of production constitute the economic structure (*Struktur*) of society, the real foundation, on which rises a legal and political superstructure (*Überbau*).' It was a characteristic of Herbert Spencer's thought to dwell on the analogy between organism and society, even if he used it mainly 'as a scaffolding': from the 'Prospectus of a System of Philosophy' (1858) on, he worked with a mental scheme associating structure and function, respectively, linked to anatomical phenomena and physiological processes.

These two original ideas have deeply influenced the development of the field and it should be noted that from the beginning, social structure has been conceptualized in quite different ways. Perhaps it may be added that the Marxian conception in terms of a 'real foundation' already implies the assumption of a sort of 'deep structure.'

The pronounced growth of (social) anthropology and sociology made social structure a key concept of both sciences but there never was an uncontested agreement about its definition; on the contrary, the term has been used in so many different senses that it will be quite difficult to draw up their complete list. Therefore, Merton was quite right in beginning his 'fourteen stipulations for structural analysis' by remarking 'that the … notion of ''social structure'' is polyphyletic and polymorphous' (Merton 1975).

We shall then limit our analysis to some landmarks in the history of the concept and in the more recent developments. Rather than trying at first to give a general definition, we shall emphasize the main dimensions which are, so to speak, the substratum of the most elaborated conceptions of social structure.

Our last section will be devoted on the one hand to the formulation of some theoretical principles which nowadays are (or can be) widely accepted and, on the other hand, to the major open questions scholars in the field are still faced with.

1. Some Landmarks in the History of the Concept and in Contemporary Advances

In this area of research as in many others, Emile Durkheim's work is a significant link between the

pioneers and later developments. *The Division of Labour in Society* (Durkheim 1893) can be read as based on a structural analysis. In this respect the most typical argument is to be found in Book II, in which Durkheim brings out the causes of division of labor in terms of increase of the population in the society, of its 'material density' and, mainly, of its 'dynamic or moral density.' However, it is not to be forgotten that in Book I he lays great stress on the function of a developing division of labor, which is to generate ('organic') solidarity. Thus, Durkheim gave an impulse to the morphological view on social structure, emphasizing the material and spatial distribution of population, while paying attention to the moral dimension attuned to the complexity of social relations in heterogeneous societies.

In keeping with some ideas derived from Durkheim (but not his attempt at synthesis), Radcliffe-Brown maintained the organic analogy, with the crucial distinction between structure and function and the attention given to the description of the interdependence of the component parts in human society. As he put it, 'in the study of social structure the concrete reality with which we are concerned is the set of actually existing relations … which link together … human beings' (Radcliffe-Brown 1940). What is required by 'scientific purposes is an account of the form of the structure, … abstracted from the variations of particular instances.' The British structural school of anthropology was imbued with Radcliffe-Brown's views. There is yet a book which stands out as a theoretical advance, namely Nadel's *The Theory of Social Structure* (Nadel 1957), in which he works out a conception of social structure in terms both of an elaborate idea of network and of a theory of roles.

In his attempt at building up such a theory, Nadel was bound to discuss some parts of Parsons' work, in which role is conceived as a major structural category. In Parsons' words, 'the structure of social systems … consists in institutionalized patterns of normative culture' (Parsons 1961). But norms vary according to the positions of the individual actors and also to the type of activity. On the one hand, they define roles, with the corresponding rules of behavior, on the other they constitute institutions. Social structure is thus to be studied in its essentially regulative properties and this approach strongly constrasts with the conception emphasizing the distributive dimension of social structure; we hit here upon an unmistakable dividing line.

There is another big divide which is worth noticing from an epistemological point of view, even if it conspicuously took place in the field of anthropology, bringing about dispute between different schools. It would be pointless in this article to outline an overview of such a composite movement as structuralism. However, for the social sciences it was significant in two main respects: first it meant the parting of the suitable ways for sociology and anthropology in so far as cultural anthropologists were requested to follow the lead of structural linguistics; and secondly it claimed a novel conception of structure. Levi-Strauss specificably states that 'the term "social structure" has nothing to do with empirical reality but with models which are built up after it' and consequently asserts that 'social structure can, by no means, be reduced to the ensemble of the social relations to be described in a given society' (Lévi-Strauss 1953). Therefore Levi-Strauss' followers are very keen on contrasting this '*transformational* structuralism,' emphasizing the transformability of a single relational set, with the still prevailing empirical views of social structure, grounded in the positivistic notion of 'correspondence rules.' It may perhaps be added that the rules of transformation connecting specific arrangements of the assumed underlying structure do not prevent it from being arbitrary; the argument is still needing some kind of empirical substantiation. Accordingly, Levi-Strauss is the most convincing, when he could draw upon a whole research tradition. His kinship models cannot be cut off from the large and momentous set of earlier studies in the field.

The term 'model' has often been used loosely in the social sciences; but, with regard to social structure, it generally has formal connotations. The third dividing line we want to emphasize is mainly methodological and deals with the relevant approach to social structure: must it be formal, as Peter Blau (Blau 1977) would defend it to be, or not? We have here to go back to a classical 'master of sociological thought,' namely Georg Simmel, for finding the father of the formal approach. He dwelt on 'The Number of Members as Determining the Sociological Form of the Group,' translated by Albion Small as early as 1902–3, stressed the importance of triads (vs. dyads) and analyzed the main conditions of group persistence, one of the most essential of which is organization. Peter Blau resumed this line of thought and enlarged it in a decidedly macrosociological direction. In his words, 'a social structure can be defined as a multidimensional space of different social positions among which a population is distributed.' His primary interest is 'in the two generic forms [social] differentiation assumes,' that is inequality and heterogeneity in 'the degree to which [they] intersect' and in their effect upon the integration of various segments of society; and he endeavors 'to construct a deductive theory of social structure,' by stating theorems deduced from primitive propositions. We lack space to enumerate all of them but at least two are worth noticing: the more heterogeneous social structure, the more likely intergroup relations; and the less correlated social differences, the more likely intergroup relations. These theoretical statements were later on put to an empirical test by Blau and Schwartz (Blau and Schwartz 1984).

Simmel likewise is held up as a pioneer by scholars belonging to a somewhat different and developing research subtradition—social network analysis. Its approach is positively structural, but its substantive

focus is generally microsociological; therefore in most cases it does not convey an overall view of social structure. Yet it can contribute a lot, by clarifying specific levels of structure and carrying on with other intellectual tools Merton's study of status—and role—sets and Homans' work on 'internal systems.' All the more as some synthesis has been brought about by Fararo and Skvoretz (Fararo and Skvoretz 1987) between social network analysis and the macro-structural approach, represented by Granovetter's 'strength-of-weak ties' theory and Blau's formal deductive one, respectively.

Harrison White's work has also been wholly dedicated to the investigation of structural problems. His last book, *Identity and Control* (White 1992) opens up new vistas, even if, as a commentator put it, it often requires as much attention as *Finnegans Wake*.

2. *Guiding Principles and Open Questions for Sociological Research*

First of all, to avoid any misunderstanding, we do not ingenuously intend to prescribe relevant rules for research. We have the only aim of stating theoretical propositions about which there is (or could be) general agreement. Some of them have been explicitly formulated by scholars. On other points, they have not and our statements will accordingly be more tentative. We shall succinctly comment on all of them.

To begin with, a first major principle has been tersely conveyed by Nadel: 'It seems impossible to speak of social structure in the singular.' No matter whether structure is conceived as a network of roles (Nadel) or whether it is conceptualized in terms of a multiplicity of social positions (Blau), the statement holds true. The ordering always is partial and relative both to the specific property being analyzed and to the systemic frame of reference chosen to describe it.

A second central principle has been laid down by Thomas Fararo (Fararo 1989): 'Structure is not an ultimate given but a conditional attainment.' Persistence (which is not to be mistaken for permanence) and endurance of social structures are problematic. In any case their stability has to be accounted for; the idea of equilibrium may be used as a heuristic device, provided attention is paid to moving equilibria as well as to static ones. Structures are maintained, when and if they do so, by underlying processes. These two principles are basic but some others are easily derived from them and there still are some points which are worth noticing.

Although it sounds like a cliché, it is to be remembered that structural characteristics are always constituted by the social activities of individuals, however contrary to their purposes the outcomes may be. The idea to be stressed upon here is that structures are generated by men's actions and interactions. It entails a decisive consequence for sociological research: structural analysis cannot be divorced from action theory. In other words, when we are directing our efforts to problems of social structure, we had better, as Fararo put it, 'start with … principles and models of action in social situations' (Fararo 1989).

Social structure is no more conceived as the determining factor of individuals' behavior and this view has been exploded. The Mertonian idea of a 'core process of choice between socially structured alternatives' in Stinchcombe's words (Stinchcombe 1975), is more to the point. To go further in the matter, we could say that social structure indeed is constraining but it is also enabling.

The notion of 'structural effects' is not questionable at all, although it would be better to conceptualize the corresponding phenomena in terms of emerging structural properties. But the idea of structural causality is at least dubious. There has been an impressive demise of what Raymond Boudon aptly called 'magic structuralism' (1968), even if it never was as widespread in the social sciences as in the cultural and literary studies.

It certainly is a moot point, whether and how social structure and culture are linked. But whatever importance is to be attached to cultural dimensions, social systems have to be, on an analytical level, clearly distinguished from cultural systems: Parsons has here given the lead. We can thus point out a major flaw in symbolic or transformational structuralism: it fails to specify 'the ways through which' the symbolic rules, the so-called universal rules of the human mind, 'impinge on the actual workings of societies' and 'to identify the social mechanisms through which … the principles of deeper structure are activated within institutional frameworks' (Eisenstadt in Blau and Merton 1981).

In the first part of this article, we dwelt on two contrasting epistemological positions: on one side, there are scholars linking social structure to empirical reality, on the others, scholars linking it to models. Now, this dividing line can be tackled from another point of view and perhaps understood in a less radical way. As Nadel and Blau both make it clear, the main question is whether scholars intend social structure for description or explanation. These two conceptions obviously are quite different; still you cannot describe without some selection, i.e., abstraction process: description always is the first step in explanation. In this respect, Mario Bunge's distinction between a model object, which defines a representation principle for a class of empirical phenomena, and a theoretical model, constructed with the intention of explaining these phenomena, perhaps is not irrelevant.

The stress put on the selection and abstraction process may be useful for guarding against too naturalistic a view of social structure. Structural properties are what we are interested in, not an 'entity'

called social structure. In this regard, Giddens' statement, 'structure only exists as "structural properties"' (Giddens 1979), makes good sense. But this conception, implying a principle of 'order,' a 'real' virtuality,' in Gudmund Hernes' words (in Hedström and Swedberg 1998) is still compatible with a realist epistemology.

A quite different point is worth clearing up: we began by quoting Marx but later on we did not deal with class structure and the reader may wonder why. It is indeed a significant field to study and it would deserve a paper by itself. But class structure is no more to be understood as the rock-bottom foundation of society: the continental-European 'structural marxism' is now obsolete, as the whole of our theoretical and epistemological argument, we hope, makes it clear.

Finally, we shall borrow from Merton his last and wise stipulation: 'like any other theoretical orientation in sociology, structural analysis can lay no claim to being capable of accounting exhaustively for social and cultural phenomena' (Merton 1975).

Such are the guiding lines along which scholars' work can proceed; but there are still major questions on the research agenda. Two of them especially are, in our opinion, worth noticing. The first one requires a kind of theoretical synthesis. We have previously in this paper distinguished two main dimensions of social structure: the distributive and the regulative. Yet they are strongly connected and we need an approach accounting for both of them. The durkheimian lead seems to have been forgotten and it would theoretically be a strategical move to follow it again: it is somewhat ironic that Durkheim could be read both ways (and brilliantly, by Parsons and by Blau). As regards the latter one, the scholarly investigation must fully take account of the conception of social structure as a multilevel phenomenon. Therefore due attention must be paid to the micro-macro link and to the social mechanisms and processes through which it is operating; and the on-going interaction of the micro- and macro-levels would need a more general model (from macro to macro through micro) and the identification, at each step, of the appropriate types of mechanisms.

Of course social scientists will address problems of social structure with diverse theoretical views and differing 'domain assumptions.' But today all of us know that theoretical pluralism is not a sign of the immaturity of sociology as a science.

Subaltern History

1. Gramsci in India

In the form in which it is currently known, subaltern historiography is derived from the writings of a group of historians of modern South Asia whose work first appeared in 1982 in a series entitled *Subaltern Studies* (Amin and Chakrabarty 1996, Arnold and Hardiman 1994, Bhadra et al. 1999, Chatterjee and Jeganathan 2000, Chatterjee and Pandey 1992, Guha 1982–9). The term 'subaltern' was borrowed by these historians from Antonio Gramsci, the Italian Marxist, whose writings in prison in the period 1929–35 had sketched a methodological outline for a 'history of the subaltern classes' (Gramsci 1971). In these writings, Gramsci used the word 'subaltern' (*subalterno* in the Italian) in at least two senses. In one, he used it as a code for the industrial proletariat. But against the thrust of orthodox Marxist thinking, he emphasized that in its rise to power, the bourgeoisie did not simply impose a domination through the coercive apparatus of the state but transformed the cultural and ideological institutions of civil society to construct a hegemony over society as a whole, even eliciting in the process the acquiescence of the subaltern classes. In Gramsci's analysis of capitalist society, the central place is occupied by questions such as the relation of state and civil society, the connections between the nation, the people, the bourgeoisie and other ruling classes, the role of intellectuals in creating the social hegemony of the bourgeoisie, strategies for building a counter-hegemonic alliance, etc.

In the second sense, Gramsci talked of the subaltern classes in precapitalist social formations. Here he was referring to the more general relationship of domination and subordination in class-divided societies. But specifically in the context of southern Italy, he wrote about the subordination of the peasantry. Gramsci was very critical of the negative and dismissive attitude of European Marxists towards the culture, beliefs, practices and political potential of the peasantry. Positioning himself against this attitude, he wrote of the distinct characteristics of the religious beliefs and practices, the language and cultural products, the everyday lives and struggles of peasants, and of the need for revolutionary intellectuals to study and understand them. But he also highlighted the limits of peasant consciousness which, in comparison with the comprehensiveness, originality and active historical dynamism of the ruling classes, was fragmented, passive and dependent. Even at moments of resistance, peasant consciousness remained enveloped by the dominant ideologies of the ruling classes. These discussions by Gramsci were turned to productive use by South Asian historians writing in the 1980s.

2. Against Elitist Historiography

Ranajit Guha, who edited the first six volumes of *Subaltern Studies*, wrote in the introductory statement of the project: 'The historiography of Indian nationalism has for a long time been dominated by elitism—colonialist elitism and bourgeois-nationalist elitism' (Guha 1982). The objective of subaltern historiography was to oppose the two elitisms. The field of modern South Asian history was dominated in the 1970s by a debate between a group of historians principally located in Cambridge, UK, and another based mainly in Delhi, India. The former argued that Indian nationalism was a bid for power by a handful of Indian elites who used the traditional bonds of caste and communal ties to mobilize the masses against British rule. The latter spoke of how the material conditions of colonial exploitation created the ground for an alliance of the different classes in Indian society and how a nationalist leadership inspired and organized the masses to join the struggle for national freedom. Guha argued that both these views were elitist—the former representing a colonial elitism and the latter a nationalist elitism. Both assumed that nationalism was wholly a product of elite action. Neither history had any place for the independent political actions of the subaltern classes.

In setting their agenda against the two elitisms, the historians of *Subaltern Studies* focused on two main issues. One was the difference between the political objectives and methods of colonial and nationalist elites on the one hand and those of the subaltern classes on the other. The second was the autonomy of subaltern consciousness. Pursuing the first question, the historians of *Subaltern Studies* showed that the claim of colonialist historians that the Indian masses had been, so to speak, duped into joining the anti-colonial movement by Indian elites using primordial ties of kinship and clientelism was false. They also showed that it was untrue to say, as nationalist historians did, that the political consciousness of the subaltern classes was only awakened by the ideals and inspiration provided by nationalist leaders. It was indeed a fact that the subaltern classes had often entered the arena of nationalist politics. But it was also a fact that in many instances they had refused to join,

despite the efforts of nationalist leaders, or had withdrawn after they had joined. In every case, the goals, strategies and methods of subaltern politics were different from those of the elites. In other words, even within the domain of nationalist politics, the nationalism of the elites was different from the nationalism of the subaltern classes.

The second question followed from the first. If subaltern politics was indeed different from that of elite politics, what was the source of its autonomy? What were the principles of that politics? The answer that was suggested was that subaltern politics was shaped by the distinct structure of subaltern consciousness. That consciousness had evolved out of the experiences of subordination—out of the struggle, despite the daily routine of servitude, exploitation and deprivation, to preserve the collective identity of subaltern groups. Where was one to look for the evidence of this autonomous consciousness? It could not be found in the bulk of the archival material that historians conventionally use, because that material had been prepared and preserved by and for the dominant groups. For the most part, those documents only show the subaltern as subservient. It is only at moments of rebellion that the subaltern appears as the bearer of an independent personality. When the subaltern rebels, the masters realize that the servant too has a consciousness, has interests and objectives, methods and organization. If one had to look for evidence of an autonomous subaltern consciousness in the historical archives, then it would be found in the documents of revolt and counterinsurgency.

The first phase of the work of *Subaltern Studies* was dominated by the theme of peasant revolt. Ranajit Guha's *Elementary Aspects of Peasant Insurgency in Colonial India* (1983) is the key text in this area. But most other scholars associated with the project wrote on the history of peasant revolt from different regions and periods of South Asian history. They were able to discover a few sources where the subaltern could be heard telling his or her own story. But it was always clear that there would be few such sources. What became far more productive were new strategies of reading the conventional documents on peasant revolts. The historians of subaltern politics produced several examples of ways in which reports of peasant rebellion prepared by official functionaries could be read from the opposite standpoint of the rebel peasant and thus used to shed light on the consciousness of the rebel. They also showed that when elite historians, even those with progressive views and sympathetic to the cause of the rebels, sought to ignore or rationally explain away what appeared as mythical, illusory, millenarian or utopian in rebel actions, they were actually missing the most powerful and significant elements of subaltern consciousness. The consequence, often unintended, of this historiographical practice was to somehow fit the unruly facts of subaltern politics into the rationalist grid of elite consciousness and to make them understandable in terms of the latter. The autonomous history of the subaltern classes, or to put it differently, the distinctive traces of subaltern action in history, were completely lost in this historiography.

3. *The Imbrication of Elite and Subaltern Politics*

The analysis of peasant insurgency in colonial India and of subaltern participation in nationalist politics by the historians of *Subaltern Studies* amounted to a strong critique of bourgeois–nationalist politics and of the postcolonial state. Writing about peasant revolts in British India, Ranajit Guha (1983) and Gautam Bhadra (1994) showed how this powerful strand of anticolonial politics, launched independently of bourgeois-nationalist leaders, had been denied its place in established historiography. Gyanendra Pandey (1984, 1990), David Hardiman (1984), Sumit Sarkar (1984) and Shahid Amin (1995) wrote about the two domains of elite and subaltern politics as they came together in the nationalist movement led by the Congress. Dipesh Chakrabarty (1989) wrote about a similar split between elite and subaltern politics in the world of the urban working class. Partha Chatterjee (1986, 1993) traced the development of nationalist thought in India in terms of the separation of elite and subaltern politics and the attempts by the former to appropriate the latter. The postcolonial nation-state had, it was argued, included the subaltern classes within the imagined space of the nation but had distanced them from the actual political space of the state. Although the political emphasis was not the same in each writer, there was nevertheless a strong flavor in *Subaltern Studies* of the Maoist politics that had hit many parts of India in the 1970s. Many critics thought they could detect in it a romantic nostalgia for a peasant armed struggle that never quite took place. Others alleged that by denying the unifying force of the nationalist movement and stressing the autonomous role of the subaltern classes, the historians of *Subaltern Studies* were legitimizing a divisive and possibly subversive politics.

Another connection that was often made in the early phase of *Subaltern Studies* was with the 'history from below' approach popularized by British Marxist historians. Clearly, the work of Christopher Hill, E. P. Thompson, Eric Hobsbawm or the *History Workshop* writers was eagerly mined by subalternist historians for methodological clues for doing popular history. But there was a crucial difference because of which subaltern history could never be a 'history from below.' The forgotten histories of the people, pulled out from under the edifice of modern capitalist civilization in the West, had undoubtedly made the story of Western modernity more detailed and complete. But there did not seem to be any narrative of

'history from below' that could persuasively challenge the existence, stability or indeed the historical legitimacy of capitalist modernity itself. Not surprisingly, 'history from below' was invariably written as tragedy. But in countries such as India, 'history from below' could not be confined within any such given narrative limits. The subalternist historians refused to subscribe to the historicist orthodoxy that what had happened in the West, or in other parts of the world, had to be repeated in India. They rejected the framework of modernization as the necessary emplotment of history in the formerly colonial countries. They were skeptical about the established orthodoxies of both liberal–nationalist and Marxist historiographies. As a result, they resisted in their writings the tendency to construct the story of modernity in India as the actualization of modernity as imagined by the great theorists of the Western world. This resistance, apparent even in the early phase of *Subaltern Studies*, was to be expressed later in arguments about 'other modernities.'

4. *Reorientations*

One line of argument of the early *Subaltern Studies* project that ran into serious problems concerned the existence of an autonomous subaltern consciousness. Much of the study of the insurgent peasant was a search for a characteristic structure of peasant consciousness, shaped by its experience of subordination but struggling ceaselessly to retain its autonomy. One problematic question that arose was about the historicity of this structure. If subaltern consciousness was formed within specific historical relations of domination and subordination, then could that consciousness change? If so, why could it not be said that the Indian peasantry was transformed, modernized, turned into citizens by its experience of nationalist politics? Why the resistance to a progressive narrative of history? Or was there another narrative of a changing subaltern consciousness? It was a classic structuralist impasse to which there was no easy historical answer.

A related problem was about the notion of the subaltern as an active historical agent. Research into subaltern history had shown that the subaltern was both outside and inside the domains of colonial governance and nationalist politics. To the extent that it was outside, it had retained its autonomy. But it had also entered those domains, participated in their processes and institutions and thereby transformed itself. Every bit of historical evidence was pointing to the fact that the subaltern was 'a deviation from the ideal'. Why then the search for a 'pure structure' of subaltern consciousness? Moreover, argued Gayatri Spivak (1987, 1988) in two influential articles, subaltern history had successfully shown that the 'man' or 'citizen' who was the sovereign subject of bourgeois history writing was in truth only the elite. Why was it necessary now to clothe the subaltern in the costume of the sovereign subject and put him on stage as the maker of history? Subaltern historiography had in fact challenged the very idea that there had to be a sovereign subject of history possessing an integral consciousness. Why bring back the same idea into subaltern history? It was only a myth that the subaltern could directly speak through the writings of the historian. In fact, the historian was only representing the subaltern on the pages of history. The subaltern, announced Spivak, cannot speak.

The new turn in *Subaltern Studies* began more or less from the fifth and sixth volumes published in 1987–89. It was now acknowledged with much greater seriousness than before that subaltern histories were fragmentary, disconnected, incomplete, that subaltern consciousness was split within itself, that it was constituted by elements drawn from the experiences of both dominant and subordinate classes. Alongside the evidence of autonomy displayed by subalterns at moments of rebellion, the forms of subaltern consciousness undergoing the everyday experience of subordination now became the subject of inquiry. Once these questions entered the agenda, subaltern history could no longer be restricted to the study of peasant revolts. Now the question was not 'What is the true form of the subaltern?' The question had become 'How is the subaltern represented?' 'Represent' here meant both 'present again' and 'stand in place of'. Both the subjects and the methods of research underwent a change.

One direction in which the new research proceeded was the critical analysis of texts. Once the question of the 'representation of the subaltern' came to the fore, the entire field of the spread of the modern knowledges in colonial India was opened up for subaltern history. Much studied subjects such as the expansion of colonial governance, English education, movements of religious and social reform, the rise of nationalism—all of these were opened to new lines of questioning by the historians of *Subaltern Studies*. The other direction of research concentrated on the modern state and public institutions through which modern ideas of rationality and science and the modern regime of power were disseminated in colonial and postcolonial India. In other words, institutions such as schools and universities, newspapers and publishing houses, hospitals, doctors, medical systems, censuses, registration bureaux, the industrial labor process, scientific institutions—all of these became subjects of subaltern history-writing.

5. *Other Modernities*

A major argument that has been developed in the more recent phase of writings in and around *Subaltern Studies* is that of alternative or hybrid modernities.

The focus here is on the dissemination of the ideas, practices and institutions of Western modernity under colonial conditions. The framework of modernization theory invariably produces the history of modernity in non-Western colonial countries as a narrative of lag or catching up. As Dipesh Chakrabarty has put it, these societies seem to have been consigned for ever to 'the waiting room of history'. The universality of Western modernity erases the fact that like all histories, it too is a product of its local conditions. When transported to other places and times, it cannot remain unaffected by other local conditions. What happens when the products of Western modernity are domesticated in other places? Do they take on new and different shapes—shapes that do not belong to the original? If they do, are we to treat the changes as corruptions? As deviations from an ideal? Or are they valid as examples of a different modernity?

To argue the latter is both to provincialize Europe and to assert the identity of other cultures even as they participate in the presumed universality of modernity. Chakrabarty (2000), Arnold (1993), Prakash (1999), Spivak (1999) and Chatterjee (1995), for example, have explored various aspects of this process of the 'translation' of modern knowledges, technologies and institutions. They have tried to show that the encounter between Western forms of modernity and colonized non-Western cultures was not a simple imposition of the one on the other, nor did it lead to corrupt or failed forms of modernity. Rather, it produced different forms of modernity whose marks of difference still remain subject to unresolved contestations of power. Here, the work of South Asian subalternist historians has often overlapped with and contributed to what has become known as post-colonial studies. The historical study of modern discourses and institutions of power in colonial India has fed into a growing literature on the production of hybrid cultural forms in many different regions of the formerly colonial world. More significantly, post-colonial studies has extended the argument about hybrid cultural forms to the understanding of contemporary cultures in the Western metropolitan countries themselves, instanced most immediately in the diasporic cultures of immigrants but also, less obviously, in the role of the colonial experience in the formation of Western modernity even in its purportedly 'original' form. Historical and social science disciplines have tended to merge here with the concerns and methods of the literary and cultural disciplines to break new, and still mostly uncharted, theoretical grounds.

6. *Rethinking the Political*

To return to the initial political questions raised by subaltern history writing: where have they led? The early emphasis on peasant rebellion and consciousness had widened, even in the first phase of the project, to include the resistance of other dominated and marginalized groups in colonial society. Once the idea of a paradigmatic structure of subaltern consciousness became less persuasive, the subject of resistance began to be approached from a variety of angles and without a fixed design either of the reproduction of a traditional structure or of the necessary transition to new structures. Recent subaltern historiography has vigorously participated in three sets of South Asian debates—over religious minorities, caste and gender. These debates have opened up the way to rethinking the political formation of the nation as well as the political process of democracy.

In India, the broader political debate over religious minorities has been carried out between two opposed groups—the Hindu chauvinists on the one hand and the secularists on the other. What the researches of subalternist historians have shown is that the debate between secularism and communalism is in no way a struggle between modernity and backwardness. Both the rival political positions are firmly planted in the soil of modern government and politics. Second, the two groups are pursuing two different strategies of consolidating the regime of the modern nation-state. Both strategies are elitist, but they involve two different modes of representation and appropriation of the subaltern. Third, faced with these rival elitist strategies, subaltern groups in India are devising, in their own ways, independent strategies of coping with communal as well as secularist politics. The recent experience of ethnic violence and authoritarian politics in Sri Lanka and Pakistan have raised even more fundamental questions about the adequacy of the nation-form as a field where subaltern politics might be negotiated (Chatterjee and Jeganathan 2000).

The second question on which there has been significant recent discussion is caste. There has been a transformation in the politics of caste in India following the agitations in 1990–1 over the Mandal Commission report. By looking at the politics of caste in its discursive aspect, it has become clear that the supposedly religious basis of caste divisions has now completely disappeared from public debate. The conflicts now are almost exclusively centered on the relative positions of different caste groups in relation to the state. Second, the debate over whether or not to recognize caste as a criterion for affirmative action by the state once again reflects two different elitist strategies of representing and appropriating the subaltern. And subaltern groups too, in their efforts to establish social justice and self-respect, are devising various strategies of both resisting the state as well as of using the opportunities offered by its electoral and developmental functions. Strategies of alliance between castes at the middle and bottom rungs of the ritual hierarchy with other oppressed groups such as tribals and religious minorities have produced significant electoral successes. But with the creation of new

political elites out of subaltern groups, the questions of 'who represents?' and 'to what end?' are being asked with a new urgency.

The third debate concerns the social position of women. In one sense, all women living in patriarchal societies are subalterns. Yet, it is not true that women are not identified by class, race, caste, and community. Hence, just as it is valid to analyse the subordination of women in a society ruled by men, so also is it necessary to identify how the social construction of gender is made more complex by the intervention of class, caste, and communal identities. Recent discussions on this question have focused on the Indian social reform movements of the nineteenth century, especially the various legal reforms to protect the rights of women, in the context of the colonial state and nationalist politics. Subaltern feminist writings have raised questions about the adequacy of a modernizing agenda of legal reform from the top without facing up to the challenge of reforming the actual structures of patriarchal power within the local communities which continue to flourish outside the reach of the law.

The recent debates raise new questions about conceptualizing old modernist ideas such as nation, citizenship and democracy. By virtue of these implications, the recent subaltern history writings from South Asia have been productively used in writings on the history of modernity in other parts of the formerly colonized world, such as, for instance, on nationalism and gender in the Middle East or on the politics of peasant and indigenous groups in Latin America. Having traveled from Italy to India, the idea of subaltern history has now produced a generally available methodological and stylistic approach to modern historiography that could be used anywhere.

Subaltern Studies: Cultural Concerns

Subaltern Studies is an Indian school of historiography whose inspiration lay in the Maoist movement of the 1970s, and whose *raison d'être* has been the critique of the perceived elitist bias of Indian nationalist discourse in history writing. Since 1983, when the first

volume appeared, Subaltern Studies has produced 10 volumes of collected research articles, which comprise the main corpus. After the appearance of the sixth volume, a collective has managed editorial work. Individual members of the collective have also written texts that exemplify the 'subaltern' viewpoint.

1. The Origins

The school was founded by Ranajit Guha, a Marxist intellectual from Bengal. Once a member of the Communist Party of India, Guha was influenced by the radicalism of the Chinese Cultural Revolution in the late 1960s to align himself with Indian Maoism, which characterized independent India as a semifeudal and semicolonial state. Arguably, the project's impetus derived from an effort to establish the truth of this proposition: 'the price of blindness about the structure of the colonial regime as a dominance without hegemony has been, for us, a total want of insight into the character of the successor regime too as a dominance without hegemony' (Guha 1989, p. 307). However, Subaltern Studies has changed a great deal since then. Ranajit Guha is acknowledged by the collective to be its intellectual driving force and edited the first six volumes. He is also the author of *Elementary Aspects of Peasant Insurgency in Colonial India* (Guha 1983), recognized as a seminal work in the genre of radical Indian historiography.

Subaltern Studies began with an attempt to apply the approach known as 'history from below' in the Indian context. The term *subaltern* was inspired by the Italian Marxist Antonio Gramsci, and is used to indicate powerlessness in a society wherein class differentiation, urbanization, and industrialization had proceeded very slowly. Gramsci is the source of the subalternist respect for 'culture' and the 'fragment' in history writing. Subaltern Studies was also influenced by the critical Marxism of the English historian E. P. Thompson, who attempted to move beyond economistic definitions of class interest, as well as by Foucauldian critiques of power/knowledge systems. Its (earlier) Maoist orientation and polemical concern with the nationalism of Indian colonial elites made for a slant toward the investigation of peasant rebellion under colonial rule as well as peasant recalcitrance vis-à-vis Gandhian nationalism and the Indian National Congress.

2. The Significance of 'Culture'

Initially overtly political in its stance, Subaltern Studies was popular among young Indian historians and scholars of modern India abroad as a radical alternative to an uncritical academic celebration of Independence. The Indian national movement was seen as a failed hegemonic project (Sen 1987, pp. 203–35, Guha 1983, 1989, pp. 210–309). Following Guha's investigation of elementary forms of insurgent peasant consciousness, the school attracted the hostility of the Indian Marxist establishment for being 'idealist' (see Chakrabarty 1986, p. 364)—a sign that it had departed from economic reductionism. In a society where cultural symbols play an important role in everyday life as well as in political mobilization, this was a fruitful departure, necessary for comprehending phenomena such as charismatic leadership and communal conflict (see, e.g., Amin 1984, pp. 1–55, 1995, Pandey 1982, pp. 143–97, 1983, pp. 60–129, 1984, pp. 231–70, 1990, Hardiman 1982, pp. 198–231, 1984, pp.196–230, 1987). It has since expanded 'beyond the discipline of history' to engage 'with more contemporary problems and theoretical formations' (*Subaltern Studies* 1998, Vol. 9, Preface). These include the politics of identity and literary deconstruction. The shift in the 1990s was marked by the interest shown in the project by literature scholars and critics such as Edward Said and Gayatri Chakravorty Spivak. The analysis of discourse has since become a major preoccupation for subalternist research.

It would be wrong to adduce a uniformity of vision in the output of *Subaltern Studies* over the years. The explicit, if unorthodox Marxian bent of its 'history from below' phase has been superseded by a recent preoccupation with community, rural innocence, and cultural authenticity. The epistemological approval of the Leninist 'outsider' as the bearer of 'higher' revolutionary consciousness (Chaudhury 1987, pp. 236–51) sits in unresolved tension with the oft-expressed critique of elitism and statism in historiography (Pandey 1994, pp. 188–221), and the belief in the immanence of culturally mediated forms of universal community (Chatterjee 1989, pp. 169–209). A thematic that persists, however, is the opposition of two 'domains'—that of the elite, meaning the colonial state and its allies, and their forms of politics, knowledge, and power, vs. the subaltern. The latter has been variously interpreted as the peasantry, community, locality, and traditional domesticity and distinguished by its resistance to colonization. The difficulty caused by the problem of mass complicity has been dealt with by valorizing the recalcitrance of 'fragments.'

The subalternist stance of giving voice to the repressed elements of South Asian history has engendered valuable research. A prominent example is Shahid Amin's meticulous and thought-provoking investigation of the prolonged aftermath of the (in)famous Chauri Chaura riot of 1922, which resulted in the death of 22 policemen, the suspension of the first noncooperation movement, and the subsequent punishment by hanging of 19 accused rioters (Amin 1987, pp. 166–202, 1995). This unravelling of 'an event which all Indians, when commemorating the nation, are obliged to remember—only in order to forget,' (Amin 1995, p. 1) relentlessly juxtaposes event to

nationalist metaphor and existential reality to ideological representation. It will remain an outstanding text in the subalternist corpus.

Pandey's intricate account of cow-protection movements in eastern India in the late nineteenth century exposes the interplay of symbolism, class interest, and public space. This path-breaking essay in the prehistory of communal politics (Pandey 1983, pp. 60–129), along with his writings on the 'construction' of communalism in colonial India (Pandey 1989, pp. 132–68, 1990) has contributed significantly to a raging historical debate. Guha's (1987, pp. 135–65) 'Chandra's Death' skilfully uses a legal narrative from mid-nineteenth century Bengal to analyze the workings of patriarchal culture and indigenous justice with great sensitivity to the existential predicament of 'low-caste' women. In a brilliant passage, Guha qualifies a description of conventional systems of asylum thus:

> this other dominance did not rely on the ideology of Brahmanical Hinduism or the caste system for its articulation. It knew how to bend the relatively liberal ideas of Vaishnavism and its loose institutional structure for its own ends, demonstrating thereby that for each element in a religion which responds to the sigh of the oppressed there is another to act as an opiate. (Guha 1987, p. 159)

3. *Theoretical Tensions*

Subaltern Studies' concern with issues of ideological hegemony elicits a questioning of the school's own theoretical tensions. The juxtaposition of statist versus subalternist history; or the tyrannical march of Western-inspired universals versus the resistance/occlusion of heroic subalterns expresses a view of a society divided into discrete social zones—with a concomitant oversight regarding the osmosis between these 'domains.' The idea that contemporary history encompasses a grand struggle between the narratives of Capital and Community, that the latter is the truly subversive element in modern society ('community, which ideally should have been banished from the kingdom of capital, continues to lead a subterranean, potentially subversive life within it because it refuses to go away'—P. Chatterjee 1997, p. 236), raises the question of why 'class' has been demoted from the estate of subalternity, even though it too refuses to go away. In an era wherein the assertion of community is rapidly transiting from the realm of peasant insurgency to that of mass-produced identity, might not 'community' actually function as the necessary metaphysic of Capital rather than its unassimilable Other?

The tensions extend beyond theory to that of discursive choice and indeed, silence. The political success of the movement for Pakistan, for example, the transformation in this case, of 'communalism' into 'nationalism,' has not been investigated despite Guha's pointers 1989, pp. 210–309, Guha 1992, pp. 69–120), and despite the urgent need for reflection on the Indian communists' transitory but significant support in the 1940s for the two-nation theory and Partition. Nor has the subsequent history of Pakistan and the emergence of Bangladesh been addressed—a rich field for those interested in the ever-shifting paradigms of nationhood and identity in South Asia. Has subalternist thinking confined itself ideologically within the fragmentary remainder of 1947? Similarly, the category of labor and the history of the working class is absent from the main corpus of research after Chakrabarty's (1983, pp. 259–310, 1984, pp. 116–52, 1989) publications on the jute-mill workers of Calcutta.

Nor would it appear from this fleeting passage of workers through the subalternist corpus, that the national movement and nationalism had any impact on them. Despite insightful commentaries by P. Chatterjee (1984, pp. 153–95, 1986) on Gandhian ideology and Amin's work on Chauri Chaura, the widespread popular appeal of Gandhi and his *ahimsa* remains an underexamined theme. The scholar who tires of negativity and is looking for answers on the role of charisma might find emotional sustenance as well as food for thought in an essay by Dennis Dalton (1970). Dalton is neither a historian nor a subalternist.

This lacuna coexists with a reluctance to tackle the history of the communist movement, within India or internationally. Given its founder's abiding interest in the failure of radical historiography to produce a 'principled and comprehensive (as against eclectic and fragmentary) critique of the indigenous bourgeoisie's universalist pretensions' (Guha 1989, p 307), it would have been intellectually appropriate for him to address the history and historiographical practice of the movement to which he owed theoretical inspiration. The subalternist antipathy towards what is perceived as the representational pretension of the Gandhian Congress, its habit of translating a constricted, bourgeois aspiration into a nationalist universal (see Guha 1992, pp. 69–120), elicits a query about the political practice of the 'true representatives' of the workers and peasants.

Guha can hardly be faulted for polemical shyness—and this makes Subaltern Studies' sustained avoidance of 'principled and comprehensive' research on the fractious and tragic meanderings of Indian communism quite remarkable. The observations on Guha's own political trajectory (Amin and Bhadra 1994, pp. 222–5) which refer to his disillusionment with the Soviet invasion of Hungary in 1956, and to his association with Maoist students in Delhi University in 1970–1, throw no light on the nature and content of his theoretical transformation. These are not mere matters of biographical detail. They are linked to vital historical questions on Bolshevism and its impact on anticolonial struggles in the twentieth century, and not just in India. The fact that *Subaltern Studies* has

carried the occasional essay on non-Indian societies, implies that the project of exposing elitist bias and ideological camouflage has been (notionally at least) thrown open to cross-national debate. Yet its sole addressal of Leninism in 17 years takes the form of a theoretical apology (Chaudhury 1987, pp. 236–51) without raising the matter of political hegemonism and subalternity in the USSR, initiatives 'from below' in the Russian Revolution, or the impact of Stalinism on the international communist movement.

4. A Radical Historiography?

As a discursive field Subaltern Studies has produced provocative research on the history of colonial India and, of late, into more recent developments. It has been a forum for fresh scholarship on a variety of themes, ranging from 'low' caste and 'tribal' peasant insurgency, middle-class ideologies of nationalism, prison life, and disciplinary structures under colonialism, to the politics of liquor, the significance of myth, and interpretations of 'bondage.' It has also contributed important theoretical reflections on questions of nationalism, colonial science, caste, gender, and identity. This includes an evaluation of the historiographical antecedents of *Hinduttva* or majoritarian nationalism (Chatterjee 1994, pp. 1–49), a critique of colonial penology (Arnold 1994, pp. 148–87), a commentary on recent developments in Indian feminism (Tharu and Niranjana 1996, pp. 232–60), research on concubinage and female domestic slavery (Chatterjee 1999, pp. 49–97) and an epistemological analysis of colonial ethnography (Ghosh 1999, pp. 8–48).

The inquisitive scholar will also find it worthwhile to read a critique of the school written by an erstwhile member of the collective. Sarkar's (1998) essay on 'The Decline of the Subaltern in Subaltern Studies' challenges what he considers to be its valorization of the indigenous, its 'enshrinement of sentimentality', and the shift in its polemical target from capitalist and colonial exploitation to Enlightenment rationality. A caveat might also be entered on the status of any scholarly claim to 'represent' the voice, interest or agency of a preferred subject—the historian's discipline may indeed never be free of bias, but surely it must be as committed to the ideal of truth-as-the-whole, and balance, as to polemic. Be that as it may, Subaltern Studies has raised the level of debate in Indian historiography—the corpus may be critiqued, but certainly not ignored. It has had an impact on the orientation of many scholars, within and outside the discipline of history, and beyond the frontiers of India. Whether it will retain its original radical impetus by engaging boldly with questions posed by its own practice and the rapidly changing social and political environment in the post-Soviet global order remains to be seen.

Subculture, Sociology of

More than the notion of culture, that of subculture poses more problems for sociologic analysis than it is able to solve. Just as specialists have enumerated several dozens of definitions of the word culture (Kroeber and Kluckhohn 1952, Shils 1961), it would be easy to do likewise for the notion of subculture.

1. *The Concept of Subculture*

When the concept of culture is taken in a normative manner, as being the set of works of the mind, art, philosophy, religion, and science, thus entailing a high level of work and development, the notion of subculture would seem to subtend the degraded or 'vulgar' forms of that culture. Within the hierarchical framework of culture, the subcultures may be understood as the popular cultures, often marginal, and especially the mass culture engendered by the cultural industries. On the one hand, a whole conservative tradition (Bloom 1987) and on the other, a critical one, the Frankfurt School (Adorno 1980), has analyzed this mass subculture as being a mixture of propaganda, commerce and alienation, and as being a degradation of both the aristocratic and rationalist ideal of a great culture, as widespread as civilization itself. In short, this view holds subculture to be an inferior culture.

While much thinking on mass culture has considered subculture as being centered on leisure activities, entertainment and cultural consumption, the limitations of such a view were soon revealed. First (Morin 1962), it was demonstrated that mass culture could play an integrating and communicative role at the same time as the traditional social cultures and affiliations were declining, such as those involving classes and religions. Moreover, this form of culture does not remain superficial when it induces strong cultural transformations, and when it is partially associated with social movements such as youth culture and the production and consumption of music. For many years thought of as a soft form of propaganda, the mass subculture conveyed by the media plays a more ambiguous and probably more democratic role than one might believe (Lazarfeld et al. 1968). Finally, the notion of mass cultures comprises a set of specific forms of cultural consumption, ranging from art to leisure activities, including more private activities which have become the object of public cultural policies playing a leading role in the definition of ways of life and social identities. This mass culture might even be a degradation of 'real' culture; indeed, while some of its productions are authentic cultural works, the question arises as to whether cinema, sport and television are an integral part of culture, or whether they are only subcultures. In fact, the issue is hardly of scientific interest and has perhaps come about only through the ethnocentricity of culturally dominant and legitimate groups. At best, the notion of subculture in this view is only a polemic device, the danger being that we may become blind to the diversity of mass culture and to the value of studying its modes of production and forms of consumption.

2. *The Hierarchy of Cultures*

When culture is considered from an anthropologic viewpoint as a set of values, representations, and ways of being and acting, the problem of the hierarchy of cultures is resolved, since each group is logically defined by a culture (Lévi-Strauss 1952). In this case, however, it is only the nature of the difficulty which changes, because the major issue is that concerning the

demarcation between cultures held to be coherent and relatively closed entities and consequently defining where the frontier with subcultures lies. In fact, there is a risk of associating a subculture to just about every identifiable activity/practice, and therefore of diluting the concept into an ongoing continuum.

It is clear that any group, social category or set of activities/practices may be more or less clearly defined by a subculture. It is valid to talk of youth subcultures, peasant subcultures, class subcultures, the subculture of chic or delinquent city quarters, and even professional subcultures. Numerous authors have investigated these themes and there is now a whole anthropology of modernity. However, the notion of subculture took on a particular meaning with studies on the culture of poverty. R. Hoggart (1957) highlighted two essential dimensions to working-class culture: first, the way a community culture can be based on social distance and how the working class is locked into its own values; second, the manner in which a culture serves to ratify the social domination that the working class undergoes, with the result that one's class destiny is widely accepted. In this view, the subculture is seen as a way of maintaining social order. In describing the culture of poverty, O. Lewis (1963) treads similar ground, but with more clarity. For him, poverty engenders a specific culture which, more than just a form of adaptation to economic constraints, is rather a normative interiorization of poverty, thus explaining the way it is reproduced and why its actors are unable to escape from their situation in life. Thus, poverty may be explained by its own subculture. This idea has been heavily criticized owing to its conservative undertones, suggesting that the poor are victims, more of their culture, than of the social conditions that are imposed on them.

Beyond this criticism, the notion of subculture is problematic, since it is difficult to know where the frontiers between cultures lie in a porous society where there is interpenetration, imitation and opposition between groups and cultures (Bourdieu 1979). Moreover, this view tends to reify cultures and subcultures, to give them more homogeneity than they really have, and to explain the conduct of actors only by their cultural identification.

3. *The Links Between Culture and Action*

To these first two difficulties is to be added a third, i.e., the links between culture and action. While it is clear that social action is normatively and culturally orientated and that it proceeds in 'patterns' of action, it is problematic to explain action as the simple application of a cultural program, as postulated by the most radical thinkers on culturalism (Benedict 1935, Kardiner 1939, Linton 1968). More precisely, by explaining social conduct in terms of cultures and subcultures, there is a great risk of getting into a tautologic loop. For example, deviant behavior could be explained by the existence of a deviant subculture, authoritarian behavior by the existence of authoritarian subcultures, and people might play soccer because it likewise has its own subculture. Even if such an explanation were to be admitted, the main scientific issue remaining would be the ability to explain the development and logic of subcultures. Regarding deviance, for example, there are several competing theories of the subculture, because they explain the development of the subcultures differently.

It is clear that delinquent behavior supposes specific norms, a particular form of socialization, a conception of social life and its values, if only to neutralize the interiorization of conformist norms (Matza 1964). Three schools of thought may be distinguished here. The first (Thrasher 1927, Jankowski 1991) considers the subculture of gangs of youngsters as being a response to a phenomenon of social disorganization and anomie. Enhancement of the bonds of solidarity in the gang, the logic of confronting other gangs and the police, and the obsession with honor may all be seen as ways of constructing a subculture, guaranteeing limited social integration for individuals who cannot play a full role in social life. The second school of thought regarding delinquent subculture derives from the Mertonian model of anomie (Merton 1965). Here, subcultures are seen as a way to reduce the structural tension brought about by the juxtaposition of profound social inequality with the democratic culture of achievement and its concomitant realization of the individual in economic success. The various deviant cultures may therefore be considered to enhance either delinquency as a response to frustrated conformism (Cohen 1955), or social retreat, withdrawal from the game and holing up in a primary group (Cloward and Olhin 1960). Finally, other more marginal theories hold deviant subculture to be the product of confrontation between the working class and the conformism of the middle classes. Consequently, the actors of social control are seen as engendering deviance and the labeling of individuals by way of their own professional subcultures. Hence, social conflicts may be considered to be conflicts between subcultures.

To be clear and not fall foul of tautology, subculture may be explained as the product of social relations and of the strategies that the actors implement. In general, subcultures result from the meeting of wider cultures and particular social situations (Dubet 1987). Therefore, subcultures could be considered as the way in which actors interpret whole cultural settings in the light of the situations and contexts in which they find themselves. In these terms, subcultures are 'constructed' by actors and are not imposed on them as principal determinants of their action. Moreover, it is difficult to free the notion of subculture from the value judgments that define it. Indeed, it is very often used in a naive ideological way by researchers oscillating

between populist enchantment and aristocratic loftiness.

Subjective Probability Judgments

1. Introduction

Life is rife with uncertainty. Do our enemies have biological weapons? Will it rain next Sunday? How much oil can be found by drilling in this spot? Important decisions in areas as diverse as medicine, business, law, public policy, and one's private life, must be made under uncertainty, hence hinge on odds and probabilities. 'Probability,' in the famous words of Bishop Butler (1736), indeed 'is the very guide to life.' Yet the theories of mathematical probability or of statistical inference cannot deliver the probabilities sought. So we have to make do with subjective probabilities—the probabilities that people generate in their own minds to express their uncertainty about the possibility of the occurrence of various events or outcomes. How do people generate these subjective probabilities? Since the 1970s, this question has attracted much research attention from cognitive psychologists. The present article will review this research.

Although statistics and probability theory can seldom replace intuitive judgments, a favored paradigm in the study of subjective probabilities has been to use the norms and dictates these theories provide as yardsticks against which people's intuitions can be compared, thereby illuminating the cognitive heuristics people use, and the biases to which they are subject. Appropriately, the dominant school in this line of research is called *the heuristics and biases approach* (Tversky and Kahneman 1974, Kahneman et al. 1982). At its core are two heuristics for judging probabilities—the representativeness heuristic, and the availability heuristic.

2. Representativeness

This is a heuristic for judging the probability that a certain target case, presented by some individuating information, belongs to a certain category (or comes from a certain source, or possesses a certain feature). This is a common type of probability judgment: a doctor judges the probability that a particular patient has pneumonia, a juror judges the probability that a particular defendant committed murder, or an employer judges the probability that a particular job candidate would be a good employee. Its essence is to base the probability judgment on the extent to which the target case's relevant particulars (e.g., the patient's symptoms, the defendant's motives, or the job candidate's background) match, resemble, or represent the attributes which the judge considers typical of, or central to, the category (Kahneman and Tversky 1972).

Similarity judgments, however, obey different rules than probability. For example, a person could well be more *like* a typical New Yorker than *like* a typical American—but a person can never be more *likely* to be a New Yorker than an American. This difference between resemblance and probability can bias judgments of the latter when they are based on the former. Consider, for instance, the following example.

Example 1: After graduating from college, Sarah took a trip around the world, writing frequent letters home. One contained the following description: 'It is so clean here, you could eat off the streets. Snow-capped mountains frame picturesque log cabins, with geraniums in every window.' Where do you think this letter was written?

Respondents given this question sensibly thought it was more likely that the letter was written from Switzerland than from Brazil. But they also thought it was more likely that the letter was written from Switzerland than from ... Europe! When asked to select the most likely of several possibilities (which included Switzerland, Brazil, and Europe, among others), they ranked Switzerland—not Europe—first (Bar-Hillel and Neter 1993).

Probability theory does not provide an answer to the question: 'What is the probability that this letter was written from Switzerland?' But once this probability is assessed, it sets constraints on certain other probabilities. Thus, whatever the probability that the letter was written from Switzerland, it cannot possibly be higher than the probability that it was written from Europe. This is the *extension principle*, and people realize its validity. Those that rely on it when performing the experimental task do not rank Switzerland before Europe. Most, however, just compare the description in the letter with their idea of the places under consideration. The match between the description and Switzerland is the best—better even than the match between it and Europe. So, in accordance with the representativeness heuristic, Switzerland is ranked most likely.

Results such as this point out both what people often do (namely, base probability judgments on judgments of representativeness), and what they often fail to do (namely, rely on formal rules of probability). One factor, which plays an important role in formal probability calculations but is relatively neglected in subjective probability reasoning, is size—either category size, or sample size. This is shown in the following example.

Example 2: A certain town is served by two cab companies, the Blue Cab and the Green Cab, named after the color of cab they operate. The Blue Cab Company has many more cabs than the Green Cab Company. One dark and foggy night, a pedestrian was knocked down by a hit-and-run cab. She later testified that it was green. Her accuracy rate in distinguishing green from blue cabs under the conditions that existed that night was found to about 85 percent. What is the probability that the errant cab was a Green Cab?

This problem, and many variants thereof, has been studied in scores of studies (e.g., Tversky and Kahneman 1982a, Bar-Hillel 1980, 1983). Formatted like a high school math problem, it invites explicit numerical calculation. The modal response is to assign the witness' testimony a probability that matches her accuracy, 85 percent. The same happens when the witness is said to have identified the cab as belonging to the larger company, Blue Cab. Indeed, the relevance of the relative size of the cab companies to the question eludes most people. After all, they argue, the pedestrian was run over by a single cab, not by the entire fleet. Nonetheless, when the witness is unable to identify the color at all, most people properly realize that the errant cab is probably from the larger company, simply because *it is* the larger company. Normatively, the witness' testimony should be integrated with this base-rate consideration, rather than replacing it.

The inclination to neglect category size is known as *the base-rate fallacy*. Since Example 2. does not involve judgment by representativeness, it shows that base-rate neglect is not merely a side effect of this heuristic, as it was in Example 1. Example 3. shows that size considerations are neglected not only when considering the source population, but also when considering the sample.

Example 3.: A game of squash can be played either to 9 or to 15 points. If you think you are a better player than your opponent, which game gives you a higher chance of winning, the short game, or the longer game? Suppose, instead, that you are the weaker player, which game gives you a higher chance now?

If you are inclined to favor the same length in either case, consider this theorem from probability theory: The larger the sample of rounds (i.e., 15 rather than 9), the likelier it is to yield the expected outcome, namely victory to the stronger player. So if you believe you are the stronger player, you should prefer the longer game, but if you believe you are weaker, your chances are better with a shorter game. Intuitively, though, winning a game seems equally representative of player strength whether it is a shorter or longer game (Kahneman and Tversky 1982b).

This is not to deny that people can—spontaneously or by mild prompting—appreciate that larger samples are better for estimating population parameters than smaller samples. But they erroneously think that the advantage lies in being *relatively* larger (in terms of the ratio of sample size to population size) rather than *absolutely* larger. Many, for example, indicate equal confidence in the accuracy of a survey of 1 in every 1,000 people in predicting election outcomes in a city of a million voters as in a survey of 1 in every 1,000 people in a town of 50,000—even though the former survey samples 20 times as many people (Bar-Hillel 1979).

Example 4., which follows, demonstrates another judgmental bias, which is related to size neglect and is known as *failure to regress*.

Example 4.: When Julie was 4, she was rather tall for her age—in the 80th percentile (i.e., taller than about 80 percent of her peers). She is now 10 years old. What would you guess is her present height percentile?

If you think that Julie may have moved up, or she may have moved down, but she probably is still taller than most of her peers, you are quite right. However, if you also think that Julie is as likely to be in a higher percentile as in a lower percentile, and that by and large she is probably still most likely to be approximately in the 80th percentile, then you are sharing a common, but erroneous, disregard for the phenomenon known as regression to the mean. This is the fact that the mean of a second sample from a population

Figure 1
Which matrix is more 'randomly' mixed?

can always be expected to be closer to the population mean than was the first sample's (unless the first sample's mean happens to have coincided with the population mean to begin with). In the present example, this follows from the fact that a larger proportion of the population of children were shorter than Julie (80 percent) than were taller than her (20 percent).

Failure to recognize regression to the mean can result in inventing causal explanations for what may be mere statistical artifacts (Kahneman and Tversky 1973), such as for the observation that very bright women tend to have somewhat less bright husbands.

The following example demonstrates some difficulties that people have with the concept of randomness.

Example 5: Consider the two 12×12 matrices in Fig. 1. Each consists of 50 percent black cells and 50 percent white cells. In one, the colors are mixed in a manner typical of truly random mixing. In the other, the cells are not mixed randomly at all. Which do you think is the 'random' matrix?

Most people perceive B as more 'random' (Falk 1975). A seems to them too 'clumpy.' But in fact, about half the pairs of adjacent cells in B are of the same color—exactly as much clumpiness as expected in a randomly mixed matrix. On the other hand, in A, almost two-thirds of neighboring cells are of different colors, which is more alternation than could be expected statistically. But people's intuitions of randomness (see, e.g., Bar-Hillel and Wagenaar 1991) are characterized by 'local representativeness'—the erroneous expectation that the short run should exhibit the properties which *the law of large numbers* promises only in the long run. Thus, local representativeness is like a *law of small numbers* (Tversky and Kahneman 1971).

3. *Availability*

If the representativeness heuristic tends to overlook category size, the availability heuristic is used primarily for judging category size—or rather, relative size. Category size relates to probability inasmuch as probability is sometimes taken to be the proportion, in the population as a whole, of instances that belong to some specific category, or possess some specific feature. A statistician who wants to estimate relative frequencies draws a random sample. The cognitive counterpart of the statistician's procedure is to 'sample in the mind'—namely, to bring to mind, either by active search or spontaneously, examples of the target population. Sampling in the mind, however, is hardly random. It is subject to many effects that determine the ease with which examples come to mind (Tversky and Kahneman 1973). Examples of such effects are salience, recency, imaginability, and—fortunately—even actual frequency.

Effects that determine the ease of calling to mind are known as *availability effects*. The availability heuristic is the judgmental procedure of reliance on mental sampling, and is demonstrated in the following example.

Example 6: Subjects were read a list of 39 names of celebrities. In List 1, the 19 women were rather more famous than the 20 men, and in List 2 it was the 19 men who were more famous than the 20 women. Each person heard a single list. They were then asked whether they had heard more female names or more male names. As predicted, when the men [women] were more famous, male [female] names were more frequently recalled. They were also judged, by independent respondents, to be more frequent.

It turns out to be unnecessary actually to bring examples to mind, as it is enough just to estimate how many could be brought to mind. People seem to have a pretty good notion of availability (Tversky and Kahneman 1973), and use it to estimate probabilities.

In Example 7., the availability heuristic leads to a violation of the aforementioned extension principle, mentioned before.

Example 7.: Imagine the following scenarios, and estimate their probability. (a) A massive flood somewhere in America, in which more than 1,000 people die. (b) An earthquake in California, causing massive flooding in which more than 1,000 people die.

Respondents estimated the first event to be less likely than the second (Tversky and Kahneman 1983). As discussed earlier, the extension principle logically precludes this possibility: a flood with unspecified causes in a relatively unspecified location is necessarily more likely than one with a more specific cause and location. An earthquake in California, however, is a readily imaginable event which greatly increases the availability—hence the subjective probability—of the flood scenario.

A particularly prominent result from the availability heuristic is *the unpacking effect*, shown in Example 8.

Example 8.: A well-known 22-year-old Hollywood actress was admitted to a hospital emergency room with pains in the lower right abdomen, which had

lasted over 12 hours. What could she be suffering from?

A group of general practitioners from the Stanford area were given this question. Half were asked to assign a probability to the following possibilities: (a) Indigestion (b) Extra-uterine pregnancy (c) Other. The list given to the other half was: (a) Indigestion (b) Extra-uterine pregnancy (c) Acute appendicitis. (d) Inflamed kidney. (e) Cervical inflammation (f) Other. The first group assigned a probability of 50 percent to the 'Other' category. The second group assigned a probability of 69 percent to categories (c) to (f), although of course these are but a more detailed breakdown ('unpacking') of 'Other' (Redelmeier et al. 1995). A similar effect is found even when it is hard to argue that the unpacking itself provides additional information. When the category of 'homicide' is broken down into 'homicide by a stranger' and 'homicide by an acquaintance,' the latter two are given a higher total probability as causes of death than the unbroken category (Tversky and Koehler 1994). Here, apparently, the different descriptions of the categories merely call attention to different aspects of the categories. Either by affecting memory or by affecting salience, enhancing the availability of subcategories through more detailed descriptions enhances their perceived probability.

4. *Subjective Uncertainty*

When judging probability, people can locate the source of the uncertainty either in the external world or in their own imperfect knowledge (Kahneman and Tversky 1982). The latter is what Bayesian theory means by the term *subjective* probability (whereas in this article, recall, the adjective refers to the mode of assessment, rather than to the locus of the uncertainty). When assessing their own uncertainty, people tend to underestimate it. The two major manifestations of this tendency are called *overconfidence*, and *hindsight bias*.

Overconfidence concerns the fact that people overestimate how much they actually know: when they are p percent sure that they have answered a question correctly or predicted correctly, they are in fact right on average less than p percent of the time (e.g., Lichtenstein et al. 1982, Keren 1991). Hindsight bias concerns the fact that people overestimate how much they would have known had they not possessed the correct answer or prediction: events which are given an average probability of p percent before they are known to have occurred, are given, in hindsight, probabilities higher than p percent (Fischhoff 1975)—a phenomenon sometimes known as 'I knew it all along.'

Both these biases can result from biased availability. After all, what we know is almost by definition more available to us than what we do not know. Regarding hindsight, it is enough to note that once something (such as the final outcome) has been brought to mind, it is nearly impossible to ignore (try to 'not think of a white elephant').

Regarding overconfidence, it has been shown that it can be dampened by instructing people to 'think of reasons you might be wrong' prior to asking them to assess their own confidence (Koriat et al. 1980)—a direct manipulation to increase the availiability of the complementary event, the one competing for a share of the total 100 percent probability. In addition, overconfidence turns to underconfidence in very hard questions (e.g., May 1986). Perhaps in answering easy questions, one's best guess is mentally prefaced by: 'I'm not sure I know, but I think that …' which focuses on the available. In answering hard questions, on the other hand, one's best guess might be mentally prefaced by: 'I don't think I know, but I guess that …' which focuses on the unavailable.

5. *Conclusion*

The survey of heuristics and biases involved in people's judgments under uncertainty shows that subjective probabilities (in the sense of judged probabilities) are not just imperfect or inaccurate versions of objective probabilities, but rather are governed by cognitive principles of their own. These may often lead to good judgments—but in many circumstances entail violations of normative dictates, and hence systematic departures from more rational judgments. This view stands in contrast to earlier views, which saw 'Man as an intuitive statistician,' (Peterson and Beach 1967). It also contrasts with recent views (e.g., Cosmides and Tooby 1996, Gigerenzer 1998), which challenge the very appropriateness of a research program that asks people to make probability judgments. This school of thought insists that we evolved to judge frequencies, not probabilities, so we are not to be faulted for the biases in our subjective probabilities. But as long as people are called upon, as in modern life they so often are, to make probability judgments, awareness of the phenomena this article described would benefit them greatly.

Sub-Saharan Africa, Archaeology of

1. *The African Stone Age: A Hard Act to Follow*

People evolved in sub-Saharan Africa from a common ancestor with the other African apes about 5 or 7 million years ago. The earliest recognizable artefacts, which are stone tools associated with animal bones, come from a number of sites in east Africa about 2.5 million years ago. The earliest members of our own genus, *Homo*, date from a little after that time. The earliest claimed evidence for the controlled use of fire and the earliest persuasive bone artefacts come from sites in eastern and southern Africa dated to just before or just after 2 million years ago. Some time before 1 million years ago, a first 'out of Africa' expansion took archaic humans across the land bridge into Eurasia. The earliest handaxes, beautiful as well as functional, spread from Africa some time after 1 million years ago. Current opinion is that between a half and a quarter of a million years ago African early *Homo* populations evolved into our own species, *Homo sapiens*, whilst relatives in southeastern Asia and in Europe took other directions. Eventually, perhaps 100,000 years ago, a second 'out of Africa' movement, or perhaps a series of waves, arguably caused the replacement of archaic humans by modern ones, as *Homo sapiens* completed the process of global colonization. These early modern people in southern and eastern Africa left behind the earliest evidence for systematic marine food use and substantial early evidence for the manufacture of pigment, presumably for ritual use. If this sounds somewhat 'earlier than thou,' it nevertheless underlines the massive contribution of sub-Saharan Africa to the story of human evolution and the emergence of modern behavior.

John Goodwin effectively began the systematization of sub-Saharan stone age prehistory when, in 1929, along with van Riet Lowe, he published *The Stone Age Cultures of South Africa*, in which he established the terminological framework still used throughout the continent. He recognized similarities between the stone artefact assemblages in South Africa and Europe,

particularly in the earlier phases, but elected to coin a new set of terms, the Earlier, Middle, and Later Stone Ages. His vision was that these major units, broadly equivalent to the Lower, Middle, and Upper Palaeolithic of Europe, could be subdivided into geographically bounded assemblage sets that he called cultures or variants. Whereas the Earlier and Middle Stone Age assemblages closely resembled their European counterparts, the Later Stone Age (LSA) was quite different from the Upper Palaeolithic of Europe. At least one of his cultural constructs, the Wilton culture, became popular as a designation of microlithic Later Stone Age assemblages from the Cape of Good Hope to Cape Horn. After the foundation of the Pan African Congress meetings in the 1940s, which created a structure for French and English speaking archaeologists working in sub-Saharan Africa to better coordinate their efforts, the notion of 'intermediates' between Earlier and Middle and between Middle and Later Stone Ages was briefly entertained. These were to contain assemblages that illustrated the technological and typological transitions, but for reasons explained later were unsuccessful.

The most serious attempt to standardize what had become a terminological nightmare was the brave but ineffective set of recommendations of the Burg Wartenstein conference, held in Austria in 1964. This template envisaged a set of hierarchically organized terms (occurrences, phases, industries, and industrial complexes), replacing the older tripartite system of Goodwin's. It never found much favor and archaeologists seem simply to have moved on from terminological angst, choosing to use older or newer terms informally and to investigate behavior rather than debate the structure of the archaeological record. Significantly, this early obsession with stones as determining materials has been diffused by attention to other materials and other issues.

2. *Human Origins*

A question of considerable interest is that of whether the archaeological record is an accurate reflection of the distributions of early people. Fossil fragments of the genus *Australopithecus* (and *Ardipithecus*) were known only from the sedimentary lake basins of East Africa and the dolomite caverns of South Africa until the discovery of australopithecines from the deserts of Chad. The classic sites of eastern and southern Africa are depositional environments, which might suggest that australopithecines were more widespread but not preserved in more erosional landscapes without such catchments. Chad is certainly a hint of wider distributions. Stone tools, however, are less affected by poor preservational contexts and establish the significance of the lake basins of the African Rift Valley as the focal places in early human technological history.

Mary Leakey's pioneering archaeology of living floors at Olduvai Gorge in East Africa established that the hand axe containing Acheulean assemblages of the African Earlier Stone Age, which Goodwin had wanted to call the the Stellenbosch culture in the Cape, were preceded by earlier assemblages without such bifaces. With the first potassium argon dates of about 1.8 million years from the base of Bed 1 at Olduvai came the realization of the huge antiquity of stone tool making in Africa. The earliest assemblages, naturally referred to as Oldowan, had a variety of cores, flakes, and rather crudely retouched pieces. Pre-hand axe assemblages are now known to date from as early as 2.5 million years ago, at a number of sites in the stratified lake basin deposits of the East African Rift Valley. The assemblages vary, at least in part, with the variable nature of the stone raw materials available. Very little has yet emerged as to the likely precedents of these Oldowan assemblages, but presumably a long period of more informal tool use and modification precedes the localized concentrations now claimed as the earliest sites. By comparison with recently recorded chimp tool uses, we might expect that the changes in behavior which led to the localization of tool making debris in specific places is what is actually reflected in the archaeological record. Initial experiments with stone tool making must substantially predate 2.5 million years, but may never be recognized.

The earliest assemblages with recognizable bifaces, characteristically both roughly teardrop shaped hand axes and blade ended cleavers, date to about 1.6 million years or so, soon after the earliest appearance of the fossil remains of what used to be African *Homo erectus*, more recently termed *Homo rudolfensis*. These are now universally referred to as Acheulean assemblages, named after the much later, though discovered earlier, French sites, in contradiction to Goodwin's wishes. Three remarkable aspects of these occurrences have continued to puzzle archaeologists. First is the observation that hand axes are extremely widespread, from the river gravels of the Somme and Thames in England, through the beach terraces of the Mediterranean to the lakeside camps of the East African Rift and on to the caves and coastal dunes of the Cape. A spatial distribution of several million square kilometers and a time span of more than a million years implies a broad functionality and a lasting usefulness, a veritable Palaeolithic Swiss army knife. Suggestions as to the uses of hand axes have included digging up underground plant foods, butchering animal carcasses, implementation as missiles, and suspension as parts of animal snares. This issue is not independent of the other two enduring characteristics of these often beautifully made tools.

Many archaeologists have noted that in many, but not all, cases hand axes appear to have been flaked beyond the apparent functional requirements. Indeed the pursuit of symmetry and regularity of outline is

undeniable in many examples, raising the question of whether the objects are functional or works of art, or both. Associated with this observation is the remarkable number of such hand axes at many, but again not all, sites. At Olorgesailie and other East African sites, and particularly at the hand axe localities along the Orange River in South Africa, there are thousands, and in some cases millions of bifacially worked hand axes. Even allowing for the fact that such sites are obvious palimpsests, there seems to be a case for questioning the production strategy of artefacts that often appear to the casual observer to be still relatively usable. Why did people put so much energy into the finishing of such pieces, and why did they make so many? A recent suggestion has been that both of these characteristics imply that the making of the tool has to be seen as just as important as its use. Like the tail of the peacock, the ability to lavish attention onto the making of a hand axe, and then discard it after little use, must imply a set of evolutionary capacities to impress the opposite sex. We cannot say who was making and who was impressed, but the assumption of many archaeologists is that men made and women gasped.

There is little doubt that all developments in human genetic evolution and technological history prior to about 1.8 million years ago happened in Africa. The earliest non-African sites at Dmanisi in Georgia and Ubeidiya in Israel are not Acheulean assemblages. Although not strictly a matter of African prehistory, the absence of the hand axe and cleaver, and hence the designation Acheulean, from southeast Asian stone tool assemblages, has caused much comment. If it is confirmed that the first 'out of Africa' movement preceded the invention of these bifacial forms, and if it is further confirmed that genetic exchange between southeast Asia and Africa has been minimal after this movement, then a long independent trajectory for both hominid evolution and artefactual tradition in southeast Asia becomes plausible. By contrast, the artefactual records of Europe, southwestern Asia, and Africa remain rather tightly linked throughout most of the Pleistocene.

In an intriguing cycle of argument and counter argument, it now appears that Raymond Dart's belief that australopithecines or early members of the *Homo* lineage were both firemakers and bone tool makers may have some support. Dart's original ideas were based on his work at Makapansgat, South Africa, which he initially believed to be a place where australopithecines lived. The hearths, however, turned out to be manganese staining. C. K. (Bob) Brain, in an inspiring programme of taphonomic, experimental, and ethno-archaeological research, showed that the complex stratigraphies of the (then) Transvaal dolomite caves were places where early hominids died and were deposited by predators. Patterns in associated faunal remains were produced by the actions of predators and other forces on bones of variable density, not by tool makers' choices. It is ironic, then, that working at the stratigraphically better understood site of Swartkrans, Brain later began to record the existence there of evidence for both fire and bone tools. It should be recognized that the Swartkrans evidence is much later than that claimed by Dart from Makapansgat, and that the argument is much more robust, if still somewhat vulnerable. The current claims from Swartkrans are that over a hundred small pointed bones were used for excavating underground plant foods and that charred bones among the faunal remains reflect the controlled use of fire, both claims for behaviors predating 1 million years.

3. *Regionality and the Appearance of Modern Humans*

The transition from Earlier to Middle Stone Age assemblages is poorly understood, in part because it happened much before radiocarbon dating became useful and after the time period best suited to potassium argon dating. Many Middle Stone Age (MSA) sites are open sites difficult, in any case, to date. Most archaeologists presume that the assemblages without hand axes, characterized by some facetted platform flakes and radial and Levallois cores, first appear about 250,000 years ago, but there is much room for debate. The decision no longer to make hand axes or cleavers from about this time may signal the invention and dissemination of methods of mounting and hafting stone points onto wooden shafts. Assuming this required smaller stone components, we might interpret the many kinds of points, unretouched, unifacial, bifacial, leaf-shaped, hollow-based, tanged and serrated, as versions of the spear point. As Desmond Clark pointed out some time ago, regionalization of point 'style' characterizes the MSA and distinguishes it from the preceding Earlier Stone Age (ESA), where change was slow and dissemination of form more encompassing. For some archaeologists this regionality within the MSA, along with the more rapid replacement of one form by another, is a mark of symbolic storage, because it reflects decisions by presumably identity-conscious groups, choices that reflect not function but style, a first indication of 'them' and 'us.'

The most dramatic development in thinking about the African Middle Stone Age has been its remarkable rise, in Desmond Clark's words, 'from peripheral to paramount.' In the late 1960s, bolstered by a rather naive belief in the accuracy of some of the earliest radiocarbon results obtained, MSA assemblages were thought to be contemporary with Upper Palaeolithic assemblages in Europe. Because of the obvious similarities between MSA and Middle, rather than Upper, Palaeolithic stone tool technologies and types, this was taken as a reflection of Africa's backwardness in

progressing along the (presumed standard) tool-making trajectory. It was also wrongly believed at that time that the Kabwe (formerly Broken Hill) cranium and the Saldanha calvarium were 'African neanderthalers.' After Vogel and Beaumont began to doubt the radiocarbon 'dates' for MSA assemblages, new, more experimental dating techniques, such as luminescence and ESR dating, became available (see *Chronology*, *Stratigraphy*, *and Dating Methods in Archaeology*). These have shown that almost all of the MSA is beyond the range of radiocarbon dating and confirmed the rough contemporaneity of Middle Palaeolithic and Middle Stone Age. We should also not underestimate the impact of the genetic work on mitochondrial DNA of the mid 1980s on archaeologists' thinking about the age of the MSA and the significance of the morphology of associated hominid remains. The 'out of Africa' genetic model, a re-evaluation of the modernity of MSA hominids and new dating assessments for African MSA sites have transformed our understanding of the origins of anatomically and behaviorally modern people. In this process, Africa has emerged as paramount, the likely source area of modernity in both senses.

Central to this change of thinking has been the set of assemblages known to John Goodwin and referred to by him as Howiesons Poort. These formed part of the short-lived notion of a 'second intermediate' between the Middle and Later Stone Ages, but have been shown repeatedly to lie stratigraphically within the suite of MSA assemblages, most effectively at Klasies River (South Africa) main site. Howiesons Poort assemblages are MSA in that they contain radial cores and sub-triangular flakes with facetted platforms, but they have an interesting set of novel characters that make them, in some estimations, precocious manifestations of later stone tool making patterns. Unlike assemblages above and below them, for example, there is a tendency for tool makers to prefer finer grained rocks and to manufacture substantial numbers of blades, some of them punch-struck, from them. There are also many backed pieces, including segments, some of them microlithic, trapezes and truncated blades, and in some assemblages, burins. These assemblages are increasingly well dated to beyond 60,000 years, which has interesting implications for these 'Upper Palaeolithic-like' characteristics, which seem to appear in Europe, along with unquestionably modern people, some 20,000 or more years later.

The African Middle Stone Age, but not specifically the Howiesons Poort, is increasingly viewed as the product of anatomically modern people. From Dar es Soltan in the north to Klasies River main site in the south, MSA hominids are anatomically modern, as indeed, or nearly so, are their contemporaries at Middle Palaeolithic sites in southwest Asia. Klasies River main site is, in fact, the most persuasive example of a set of associations that constitute anatomical and behavioral modernity. A deep depositional pile that is unquestionably a shell midden, associations of food-waste and stone tools with hearths, well dated by radiometric dates and faunal observations to Marine Isotope Stages 5 and 4, and with excellent stratigraphic associations of MSA artefacts, including a Howiesons Poort component, with enough hominid fragments to be sure of a modern morphology, sets the standard for claims about modernity. Elsewhere in southern Africa, MSA assemblages are associated with abundant, clearly utilized ochre, bone tools, and decorated pieces of ostrich eggshell. So far it is not clear whether the relative paucity of these kinds of associations elsewhere in Africa is due to incomplete survey, poor preservation or the geography of ancient innovations. Claims for MSA manufacture of bone harpoons at Katanda would, if confirmed, support the innovative character of African MSA people.

Why, we may wonder, has Africa become so clearly paramount, so definitively not peripheral in the evolutionary history of modern people. One possibility is the accumulating evidence for the necessary consumption of marine and freshwater foods as the nutritional substrate for intellectual advances. Rather than being a consequence of increased intelligence, something that modern people did, the regular gathering of shellfish and other marine and freshwater organisms, appears to be essential if people were to acquire the structural lipids necessary to build a bigger brain. Coastal, stream, and lakeside site locations have been the pattern in Africa since the time of early hominids: it may be as much the available foods as the accessibility of water that had significance. Because the earliest shell middens are located along the shores of the Mediterranean-type terrestrial ecosystems at the northern and southern extremities of Africa, it is from here that the surge to modernity may have been fueled.

4. *The Survival of Hunting and Gathering*

Our understanding of the transition from Middle to Later Stone Age (LSA) is complicated by poor dating resolution, highly episodic site occupations, and by the fact that it apparently happened when much of the central parts of northern and southern Africa were even more arid than they are today. Additionally, at this time, approximately 20,000 to 50,000 years ago, the mean sea level was lower and some of the most attractive parts of the subcontinent were the exposed continental shelves, now lost to study by the rise in sea level. One interesting consequence of a lengthy expansion during Marine Isotope Stages 2, 3, and 4 of the Kalahari and Sahara arid zones, is the probable reduction in genetic exchanges between subtropical African populations and their contemporaries in the two Mediterranean-type ecosystems to the north and south. It was perhaps during this time, after the emergence and expansion out of Africa of modern

people, that the current geographic patterns in African human phenotypes became established. Apparently supporting this projection is the increasingly regionally differentiated and localized nature of the African LSA.

Goodwin was correct in recognizing little similarity between the African LSA as a whole and the European Upper Palaeolithic. The transition from the MSA to the LSA technologically involved the abandonment of radial and Levallois core techniques and the focusing on small bipolar and unipolar cores that had already appeared in the MSA (see *Lithics and Archaeology*). It may have happened at different times in different parts of the sub-continent, something that now appears likely in the European transition from Middle to Upper Palaeolithic as well. Microlithic assemblages appear much earlier in Kenya than in southern Africa, but robust regional chronological patterns are yet to emerge.

Certainly by 20,000 years ago the sub-continent is widely but patchily occupied by hunter gatherers making a variety of (mostly) microlithic tools on fine grained raw materials and, where preservation is good, leaving behind tools of ostrich eggshell, bone and other organic raw materials that loosely resemble those of the recent ethnographic past. There are, however, many important technological, social, and demographic changes within the last 20,000 years, especially as pastoralism and farming began to spread slowly and irregularly through the ecosystems of sub-Saharan Africa.

An important component of the heritage of LSA hunter–gatherers is the large corpus of paintings and engravings, commonly referred to as rock art (see *Prehistoric Art*). Throughout southern and eastern Africa there are images made by farming people, usually in white paint, often presenting geometric forms or images of colonial times and almost always made with the finger. Easily distinguished from these is a tradition that extends south from Zambia, Zimbabwe, northern Botswana, and Namibia to the Cape, characterized by relatively naturalistic fine line images of people and animals, in places overlain by handprints. These paintings and engravings may have begun to appear as early as 25,000 years ago, were certainly widespread by 10,000 years ago and were still being made in the century before last. From the research of Partricia Vinnicombe and David Lewis-Williams, we can now relate the images to the world view of surviving San hunter–gatherers and their ancestors. A particularly important set of reference material has been the texts recorded by Wilhelm Bleek and his sister in law Lucy Lloyd in the 1870s and related to them by a group of Xam San informants from the South African interior. Recent Kalahari hunter–gatherers do not themselves paint or engrave, but clearly subscribed to the same cosmology as the now extinct Xam. A point of some interest is the corpus of Tanzanian fine line images that resemble those from much further south. There is here an artistic parallel to the enigma of 'click' languages in more or less the same part of eastern Africa, also isolated from a host of such languages in the south. No doubt there is still much to learn about the history of the interface between Khoesan people and their traditions with other Africans to the north.

There is a significant irony in the discovery of Africa's paramount role in the story of human evolution. Because European science gave rise to the intellectual discipline of archaeology, European scientists have always been searching for origins in Europe. Gradually and serially these have failed, to be replaced by a growing realization of the African contribution. But it is tragic that with few exceptions this legacy of African prehistory has been revealed by people of European ancestry, albeit ones with a strong sense of belonging to Africa. But then, in the longer view, we are all Africans.

Substance Abuse in Adolescents, Prevention of

Substance abuse is a problem that countries throughout the world have struggled with for many decades. In the USA where substance abuse is the highest in the industrialized world, the annual prevalence of illicit drug use among adolescents peaked in 1979, declined for more than a decade, and then rose sharply throughout most of the 1990s (Johnston et al. 1995/96; see Fig. 1). Concern for substance abuse as a problem derives from the fact that it can lead to a host of adverse consequences including long-term disability and premature death. Broadly conceived, substance abuse involves the inappropriate use or misuse of one or more psychoactive substances including tobacco,

Figure 1
Trends in annual prevalence of an illicit drug use index for 12th graders (Johnston et al. 1995/96)

alcohol, and illicit drugs such as marijuana, cocaine, and heroin.

For most individuals, substance abuse has its roots in childhood and adolescence (Hartel and Glantz 1999). It begins with a brief period of 'experimental' use of one or more substance followed by escalation in both the frequency and amount of the substance(s) used. As use increases, so too does tolerance for the pharmacological effects of most substances, leading to further increases in the amount used per occasion and the frequency of use as well, as the eventual development of psychological and/or physical dependence. Thus, the developmental course of substance abuse progresses from onset and occasional use to frequent and/or heavy addictive use. It also typically progresses from the use of widely available legal substances (alcohol and tobacco) to the use of illicit substances.

Efforts to combat the problem of substance abuse have included actions by law enforcement agencies to interdict the flow of drugs, legislative initiatives, treatment interventions, mass media campaigns, and prevention programs. In view of the obvious difficulty of solving the problem of substance abuse through enforcement or treatment approaches, many experts have long argued that prevention offered the greatest potential. Since the early 1980s, there has been considerable progress in understanding both the causes of substance abuse and how to prevent it. This article summarizes what is currently known about both effective and ineffective prevention approaches.

1. *Informational and Affective Approaches*

Efforts to prevent substance abuse have largely emphasized the dissemination of factual information about psychoactive substances, their pharmacological effects, and the adverse consequences of use (Botvin et al. 1995b). These approaches assume that individuals begin using both licit and illicit substances after logically considering the potential risks and expected benefits. It is further assumed that individuals who elect to use drugs do so because they are unaware of the adverse consequences of using drugs. Given this, prevention approaches were initially designed to provide information about the risks associated with substance use so that people would be more likely to choose not to use drugs. Closely related to information dissemination were fear arousal approaches to prevention that attempted to deter use by dramatizing the dangers of substance abuse. Despite the intuitive appeal of these approaches, evaluation studies have consistently found that they do not decrease substance use (Schaps et al. 1981). Some studies suggest that these approaches may even increase substance use by stimulating curiosity.

Another approach to substance abuse prevention that was widely used during the 1960s and 1970s attempted to prevent substance abuse by promoting affective development. These 'affective education' approaches, as they were called, were designed to increase self-understanding and acceptance through activities such as values clarification and responsible decision making, improving interpersonal relations by promoting effective communication and assertiveness, and providing students with the opportunity to fulfill their basic needs through existing social institutions. Once again, evaluation studies have found little evidence to support the effectiveness of these approaches (Schaps et al. 1981).

2. *Social Influence Approaches*

In contrast to the cognitive and affective approaches, prevention approaches targeting the social factors that promote and sustain adolescent substance abuse have shown considerably more promise. These approaches were based on studies showing the important role that social factors play in the initiation and development of substance abuse. They are also based on social psychological theories of human behavior, particularly social learning theory, persuasive communications theory, and problem behavior theory.

2.1 *Psychological Inoculation*

Derived from persuasive communications theory, psychological inoculation involves first exposing adolescents to weak social influences promoting substance use, followed later by progressively stronger social influences. Through this process, it was hypothesized that the exposed adolescents would build up resistance to more powerful prodrug messages, similar to what they would be likely to encounter as they entered junior high school. Despite the prominence of psychological inoculation in the initial formulation of the social influence prevention approach, it has not been supported by the empirical evidence and consequently has received considerably less emphasis in

more recent variations of the social influence model. Other components of the social influence model have assumed greater emphasis, particularly normative education and resistance skills training.

2.2 Normative Education

The prevalence of smoking, drinking, and illicit drug use is usually overestimated by adolescents (Fishbein 1977). This overestimate leads to the formation of inaccurate normative expectations—the forming of a set of normative beliefs that support substance use. In order to reduce pressure to use drugs, social influence approaches to substance abuse prevention generally include a component designed to correct the misperception that many adults and most adolescents use drugs. Two different strategies have been used to modify or correct normative expectations. The first is straightforward and simply involves providing adolescents with information from national or local survey data concerning the prevalence of substance use among adolescence and/or adults. A second method involves having adolescents conduct their own local surveys of substance use within their school or community. This information provides adolescents with a more realistic view of the prevalence of substance use and, because substance use in most communities is far lower than adolescents believe, it corrects the misperception that most people use drugs and helps establish antisubstance use norms.

2.3 Drug Resistance Skills

Drug resistance skills are the hallmark of most contemporary approaches to substance abuse prevention (Ellickson and Bell 1990). The primary focus of these prevention approaches is on teaching adolescents a set of skills or tactics for resisting influences to smoke, drink, or use illicit drugs—particularly influences coming from the media and peers. Adolescents are taught how to identify and respond to prodrug messages in advertisements, movies, rock videos, etc. They are also taught to identify the persuasive appeals used by advertisers to promote the sale of tobacco products and alcoholic beverages, to analyze advertisements and their messages, and to formulate counterarguments to common advertising appeals (Flay et al. 1989). Teaching these skills is designed to provide adolescents with the tools for actively resisting advertisements promoting cigarette smoking and alcoholic beverages, particularly given the growing recognition that advertisers have developed rather sophisticated ad campaigns explicitly designed to target the youth market.

Perhaps the best known aspect of resistance skills training involves teaching adolescents a set of skills that they can use to resist offers from their peers to smoke, drink, or use illicit drugs. Prevention programs that include resistance skills training emphasize verbal and nonverbal skills for resisting these offers. These programs teach adolescents what to say when they are offered or pressured to engage in some form of substance use as well as teaching them how to say it in the most effective way possible. Adolescents are taught to identify 'high-risk' situations where they are likely to experience peer pressure to use drugs, are taught to avoid those situations whenever possible, and are taught to develop 'action plans' so that they are prepared to handle situations involving peer pressure to use drugs.

In order to be optimally effective, resistance skills training must provide adolescents with a general repertoire of verbal and nonverbal skills that they can use when confronted by peer pressure to use drugs. Adolescents must not only develop these skills, but also the confidence that they can apply them when necessary. To accomplish this, prevention programs teach students these resistance skills and also provide opportunities to practice the use of these skills.

3. Personal and Social Skills Training

Since the early 1980s, prevention approaches have also been developed and tested that are broader in their focus than social influence approaches. These approaches are designed to teach information and skills that are specifically related to the problem of substance abuse within the context of enhancing the development of general personal competence, hence they are also referred to as 'competence enhancement' approaches. Although these approaches include elements of the social influence model, a distinguishing feature is an emphasis on teaching a variety of personal self-management skills and general social skills. An underlying assumption of this approach is that merely teaching drug refusal skills is not likely to be effective with adolescents who are motivated to use drugs. Put differently, teaching adolescents how to say no to drugs will not succeed among those adolescents who want to say yes. Moreover, advocates of this approach argue that prevention approaches that target a more comprehensive set of risk and protective factors are more likely to be effective than those intended to target a limited number of these factors.

Competence enhancement approaches teach generic skills such as general problem-solving and decision-making skills, cognitive skills for resisting interpersonal and media influences, skills for increasing self-control and self-esteem, skills for coping effectively with anxiety or stress, general social skills, and assertive skills. One prominent approach, called *life skills training* (LST), teaches several types of self-management skills such as self-appraisal, goal setting and self-directed behavior change, decision making and independent thinking, and anxiety management skills (Botvin et al. 1990). Adolescents are also taught

a set of general social skills including communications skills, conversational skills, skills for asking someone out for a date, complimenting skills, and both verbal and nonverbal assertive skills. All of these skills are taught using a combination of instruction and demonstration, behavioral rehearsal (practice), feedback, social reinforcement (praise), and extended practice through behavioral homework assignments.

4. Evidence of Effectiveness

A growing literature shows that several approaches to substance abuse prevention can substantially reduce adolescent substance use. However, it is now clear that not all prevention approaches are effective. In fact, the only prevention approaches that have consistently reduced substance use are those that teach resistance skills and normative education, either alone or in combination with components designed to enhance general personal and social competence. Studies testing these approaches provide strong evidence for the short-term effectiveness of prevention, but somewhat weaker evidence of long-term effectiveness.

4.1 Short-term Effects

Studies testing the effectiveness of social influence approaches to cigarette smoking have generally shown that they are able to reduce the rate of smoking by 30 to 50 percent after the initial period of intervention (e.g., Luepker et al. 1983, Ellickson and Bell 1990, Sussman et al. 1993). One study has also demonstrated that the social influence approach can reduce the use of smokeless tobacco (Sussman et al. 1993). Studies testing interventions that contain social influence components in combination with personal and social skills training components show that they can cut cigarette smoking by 40 to 75 percent (Botvin et al. 1995a, Schinke 1984).

Social influences approaches have also been shown to reduce alcohol and marijuana use by roughly the same magnitude as for tobacco use (Ellickson and Bell 1990). Similarly, studies show that the personal and social skills training approaches can also reduce the use of alcoholic beverages and marijuana (Botvin et al. 1990). When comparing the relative impact of these prevention approaches on tobacco, alcohol, and marijuana use, the strongest effects are for cigarette smoking and marijuana use, while there are somewhat weaker and less consistent effects on the use of alcoholic beverages.

It is important to recognize that the social influence approaches and the competence enhancement approaches discussed here both include program components designed to increase drug resistance skills and promote antidrug norms. The results from one study (Caplan et al. 1992) suggests that generic competence enhancement approaches to substance abuse prevention may not be effective unless they also teach normative education and/or resistance skills training. Although approaches that combine the key elements of the social influences approach and the broader competence enhancement approach appear to be the most effective based on current evidence, additional research is necessary to better understand how and why effective prevention programs work.

4.2 Long-term Effects

The results of longer-term follow-up studies present a somewhat mixed picture. Evidence from several studies indicates that current prevention approaches have a reasonable degree of durability. Studies show prevention effects lasting anywhere from one to four years (Luepker et al. 1983, Flay et al. 1989).

Several factors appear to play a role in determining how durable these prevention approaches are. These include (a) the length of the initial intervention, (b) the inclusion of ongoing (multiyear) intervention or booster sessions, (c) the quality and completeness of implementation, and/or (d) the number of risk and protective factors targeted. Prevention approaches that produced longer-lasting effects generally have a stronger initial dosage (eight class sessions or more), include booster sessions, are implemented with high fidelity, and utilize a more comprehensive prevention approach.

Results from a large-scale, randomized field trial involving nearly 6,000 seventh graders from 56 public schools in the USA found long-term reductions in smoking, alcohol, and marijuana use at the end of the twelfth grade (Botvin et al. 1995a). In this study schools were randomly assigned to prevention and control conditions. Participating students in the prevention condition received the LST program during the seventh grade (15 sessions) with booster sessions in the eighth grade (10 sessions) and ninth grade (five sessions). No intervention was provided during grades 10 through 12. According to the results, the prevalence of cigarette smoking, alcohol use, and marijuana use for the students in the prevention condition was as much as 44 percent lower than for controls. Significant reductions were also found with respect to the percentage of students who were using multiple substances one or more times per week. These results suggest that to be effective, prevention programs need to be more comprehensive and have a stronger initial dosage than most studies using the social influence approach. Another implication is that prevention programs also need to include at least two additional years of interventions (booster sessions) and must be implemented in a manner that is consistent with the underlying prevention model.

4.3 Effectiveness with Ethnic Minority Youth

Several studies have examined the impact of prevention approaches on minority youth. Two strategies

have been followed. One strategy, common to many local prevention efforts, assumes that the etiology of substance abuse is different for different populations. Thus, many prevention providers have developed interventions designed to be population-specific (e.g., projects for African-American youth with an Afrocentric cultural focus). A second strategy assumes that the etiology of substance abuse is more similar than different across populations. This approach involves the development of preventive interventions designed to be generalizable to a broad range of individuals from different populations. As information concerning the etiology of substance use among minority youth has accumulated, it has become clear that there is substantial overlap in the factors promoting and maintaining substance use among different populations. The results of these studies suggest that prevention approaches may have application to a broad range of individuals from different populations. Indeed, studies show that both the social influence approach and the combined social influence/competence enhancement approach are effective with minority youth (Botvin et al. 1995b). Research also shows, however, that in environments with homogeneous populations, prevention effects can be further enhanced by tailoring the intervention to the target populations.

5. *Concluding Comments*

Substantial progress has been made since the early 1980s in the area of substance abuse prevention. Much has been learned concerning the etiology of substance abuse and how to prevent it. Despite the advances in prevention, additional research is needed to determine the long-term effectiveness of current approaches; further refine existing approaches, and identify new ones that may be more powerful; identify and test the mechanisms through which effective programs work; develop and test more comprehensive prevention strategies that combine the best features of existing prevention modalities; and extend the findings from substance abuse prevention to other related health and social problems such as HIV/AIDS, teen pregnancy, violence, and delinquency. Finally, it is vitally important that a concerted effort be made to translate research into practice in order to capitalize on the progress that has been made in prevention research.

Suicide

1. *Definition*

The term suicide was mentioned for the first time in medieval times in 1177 (van Hooff 1990) according to the Latin *sui cidium* (self-killing) and *sui caedere* (to kill himself/herself). Now, this term is used in the international scientific literature. It avoids judgment, as do terms like 'self murder' and 'voluntary death.'

In the realm of the term suicide, there are other terms that have to be defined. Suicide ideas include: thinking about death either of one's own or someone else's or death in general; the wish to die; suicide ideas in a more narrow sense. It is not easy to define the term suicide attempt. The definition most commonly ac-

cepted is the following: 'An act with nonfatal outcome, in which an individual deliberately indicates a non-habitual behavior that, without the intervention of others, will cause self-harm, or deliberately ingests a substance in excess of the prescribed or generally recognized therapeutic dosage, and which is aimed at realizing changes which the subject desired via the actual or expected physical consequences' (WHO 1989, Platt et al. 1992). This definition includes an active intention for self-harm but not necessarily self-killing. Suicide and suicide attempt are also considered as suicidal behavior.

2. *Importance of Suicide*

Suicide belongs to the 10 most frequent causes of death among adults in industrialized European and North American countries. In these countries, suicide is considered the second most frequent cause of death among adolescents and young adults (15–35 years). Suicide in young male adults has increased constantly during the last 20 years. Table 1 shows the frequencies of causes of death worldwide (WHO 1990) disregarding the most frequent causes of death such as cardiovascular diseases, stroke, cancer, infectious diseases, and malnutrition. These figures have to be taken *cum grano salis* because of a dearth of or inaccurate statistics on death in developing countries. As shown in Table 1, only fatal car accidents had a similar frequency of death as compared with suicide rates. War activities, crime, or even AIDS at the beginning of the 1990s had a considerably lower death rate.

3. *Epidemiology*

The most recent available suicide rates from all over the world are depicted in Fig. 1. This shows that a high variability of suicide rates exists across cultures and countries. Looking at the rank order of the frequency of suicide rates, a relatively stable pattern can be described—at least for European countries. There exist a North–South down gradient and a East–West down gradient of suicide rates: eastern and northern countries have higher suicide rates than western and southern countries. Hereby, sociological factors seem to play an important role in terms of secularization and industrialization with the collapse of the family group as a consequence as well as climate factors, which cannot be disentangled sufficiently.

Table 1
WHO statistics: causes of death worldwide (1999)

856,000	Death because of car accidents
818,000	Death because of suicide
322,000	Death because of war
292,000	Death because of crime
291,000	Death because of Aids

There exist distinct sex differences with a preponderance of males in suicide and preponderance of females in suicide attempt. This distribution is stable across all countries and cultures. Only China reports a prevalance of suicide among women in selected areas.

The highest rate of suicide is found in people of older age and that of suicide attempt in younger people. Suicidal behavior has been found very rarely in children but, without doubt, there is clinical evidence that children from 4 years of age have suicide ideas and make a suicide attempt or kill themselves. However, suicide occurring in children before prepuberty is very rare. Furthermore, it has to be taken into consideration, that until prepuberty (8–10 years) children normally do not experience death as something irreversible (Pfeffer 1986). Cultural differences exist in terms of using different suicide methods. So-called weak suicide methods (ingestion of drugs, wrist cutting) and hard suicide methods (shooting, hanging, jumping, drowning, etc.) will be distinguished. Weak suicide methods prevail in suicide attempts, hard methods in successful suicide. In general, females more often prefer weak methods than males. The most frequent method for suicide in females and males in North America is shooting, in Europe hanging.

Suicide rates in several European countries such as Germany, England and Wales, France, Hungary, and the Nordic countries show an astonishing stability over decades and even a century. The same holds true for counties such as Saxonia, Brandenburg, and Thuringia, where suicide rates have been stable over a century. Figure 2 depicts suicide rates over one century in Germany (Deutsches Reich and Federal Republic of Germany) (Wedler 1992). Such stability can be traced also (in other countries) back to the nineteenth century such as in Prussia, France, and the Nordic countries. On the other hand, there have been dramatic changes in suicide rates as during the nineteenth century, where secularization, industrialization, and individualization have taken place in western and northern European societies. During World War I and II further dramatic changes occurred not only affecting both males and females but also countries which have not been involved in these wars, such as Switzerland. Finally, the last changes have occurred after the fall of the Iron Curtain in Eastern Europe between 1985 and 1995 with a dramatic decrease in suicide rates by up to 40 percent (Diekstra 1996). (See *Mental Illness, Epidemiology of*.)

4. *Differing and Common Aspects between Suicide and Suicide Attempts*

There are considerable differences between suicide attempters and suicide victims (Stengel 1964). The group of suicide victims is rather small in comparison

Figure 1
WHO statistics: suicide rates of males and females (1994–96)

with the group of suicide attempters. The sociodemographic characteristics are quite different: suicide victims are older and predominantly male, suicide attempters are younger age and predominantly female. The tendency of a transition from the group of suicide attempters to the group of suicide victims is rather small with a 10 percent chance. Whereas the life of the victim is terminated by suicide, a nonfatal suicide

Figure 2
Suicide rates per 100,000 inhabitants in the German Reich from 1900 to 1940 and in West Germany from 1945 to 1990 (Wedler 1992)

attempt becomes a very important event in the life of this person, often with a change in the further life trajectory.

Nevertheless, there are also some common aspects between these two groups: the probability of suicide is higher, the more often suicide attempts happen. Despite the fact that more males are committing suicide and more females make a suicide attempt, there is a considerable overlap between both groups. The same holds true for age distribution: a considerable proportion of young males and females commit suicide, while older males and females make suicide attempts. Most of the risk factors are equally valid for both suicide victims and suicide attempters (see below).

5. *Risk Factors for Suicide and Suicide Attempts*

Risk factors for suicide and suicide attempts are as follows: increased age; marital status like being separated, divorced, widowed; single; unemployment; gender and economical status (suicide occurs more often in males, suicide attempts occur more often in females and the lowest social class). The most important risk factors for suicide and suicide attempts, however, are a previous suicide attempt and a psychiatric disorder (Kreitman 1977).

Psychiatric hospitals bear a great risk of losing a patient to suicide. It has been estimated that 15 percent of depressed patients, 15 percent of patients with a drug or alcohol addiction, and 10 percent of patients with schizophrenia, who have been treated in a psychiatric hospital, finally die by committing suicide. Patients with anxiety disorders or personality disorders also have a considerable risk of committing suicide. From an epidemiological point of view, subjects with a depression or an addiction have a 15-fold to 60-fold higher risk of committing suicide as compared with the general population (Bronisch 1999).

There are differences between urban and rural areas with respect to suicide rates. The highest suicide rates are seen in urban areas, whereas the lower rates are seen in rural areas. An exception are the states of the former USSR, where a preponderance of suicide rates in rural areas is found.

Climate seems also to play an important role in the distribution of suicide rates. The highest suicide rates are found during late spring and summer time. This distribution can be found across the northern as well as the southern hemispheres. Countries in southern parts of Europe show a lower suicide rate than countries in the northern parts of Europe.

Religious affiliation also plays in important role in the frequency of suicides. Especially in those countries with a predominance of Catholics, suicide rates are lower, whereas in countries with a predominance of Protestants, suicide rates are higher. However, if the degree of urbanization and the distribution of social classes are taken into consideration, the differences between catholic and protestant countries are fading (Kreitman 1977).

6. Origins of Suicidal Behavior

6.1 Suicide as a Basic Human Existential Problem

Ever since the written history of mankind, suicide has been considered a basic human existential phenomenon that has been reflected in many philosophical and religious contributions as well as in all kinds of arts. The attitude towards suicide did not only depend on the *Zeitgeist* of the respective historical period, but also on the individual stance of different philosophical schools such as of Stoa and Epikur in antiquity and different religions such as Christianity and Buddhism. The sociological theories are a consequence of the enlightment of the seventeenth and eighteenth centuries. During the second half of the nineteenth century, psychological theories developed upon the influence of psychological thinking and emerging psychoanalysis. During the second half of the twentieth century, biological theories were finally stimulated by the natural sciences focusing on the brain.

Suicide requires self-reflecting properties of an individual, i.e., an individual who can differentiate between an observing and experiencing ego. Suicide does not exist in animals. Even nonhuman primates do not show suicidal behavior, neither in natural settings nor in preservations. However, suicide has been found in Neolithic societies.

6.2 Sociological Aspects

6.2.1 Durkheim's theory. Sociological theories are influenced by the theory of Durkheim (1897) based upon the evaluation of suicide statistics of western European countries (France and Prussia) during the second half of the nineteenth century. Durkheim proposed four different types of suicide depending on the degree of successful adaptation of the individual to different types of societies. A prerequisite to adaptation of the individual to society is that individualization is neither too weak nor too strong. If the individualization is too strong, the individual will be isolated from society and the danger of an egoistic suicide increases. If the individualization is too weak, the danger of an altruistic suicide increases.

On the other hand, a prerequisite to the equilibrium between the individual and society is that social norms are neither too strong nor too unspecific. Norms that are too strong facilitate fatalistic suicide such as an expiatory death. Norms that are too unspecific favor anomic suicide. With the help of the existing suicide statistics, Durkheim tried to verify three of the four types (he did not discuss the fatalistic suicide). He tried to prove that Protestant countries have a higher suicide rate than Catholic countries, since Protestantism allows the individual a higher degree of freedom than does Catholicism: it is called egoistic suicide. He explained the increase in suicide rates during political crises (Dreyfuss affair in France) in terms of an egoistic suicide. During times of flourishing economic growth, implying a derestriction of social norms, suicide rates should lead to an anomic suicide, whereas during times of war, stronger norms lead to a stronger coherence of society resulting in a decrease in suicide rates.

6.2.2 General sociological trends. During the nineteenth century, only parts of Durkheim's theories could be confirmed such as the differences between Catholic and Protestant countries in western Europe and the decrease of suicide rates during both world wars. Generally speaking, Durkheim's data and statistical data from the twentieth centuries could demonstrate an increase in suicide in Europe during the nineteenth and twentieth centuries depending on the development of industrialization, secularization, and individualization of the respective countries, i.e., the more pronounced these developments were the more frequent suicide and suicide attempts occurred (Retterstol 1992). However, through the fall of the Iron Curtain in Eastern Europe between 1985 and 1995, the theory of anomic suicide has been opposed. Also, a remarkably stable sex difference with male preponderance in suicide and female preponderance in suicide attempts has been shown in nearly all cultures and societies. Another quite remarkable trend of the last decades has been the increase in suicide rate of 15–35-year-old adolescents and young adults. In most western societies, this development has been correlated with an increasing rate of depression and addiction potential. An increasing urbanization, loss of social structures and familial bonds, as well as changes in sex roles may play an important role in this development (Klerman 1987).

6.3 Psychological Aspects

Psychological models include psychodynamic, attachment, and cognitive-behavioral theories that are only partially substantiated by empirical research. The main theories are concerning aggression directed inward instead of outward, the loss of a symbiotic relationship, and a severe personal insult resulting in severe loss of self-esteem. Finally, classical conditioning, operant conditioning, and model learning are, in terms of the behavioral point of view, also of great importance.

6.3.1 Aggression directed against the ego. Freud (1917) conceptualized one of the first psychological theories about the development of suicidal behavior in 'mourning and melancholia.' To him, the psychodynamics of suicidal behavior and depression were

indistinguishable, i.e., suicidal behavior and depression were seen as a turn of aggression against the ego and an ambivalent attitude towards other people. Aggression directed against other people will be followed by loss of a desperately needed person. Turn of the aggression against the ego is expressed by feelings of guilt, self-devaluation, and finally self-killing.

6.3.2 Distorted cognitive schemes. Beck (1967) also emphasized a strong connection between suicidal behavior and depression. The depressive sees himself, the world, and the future (so called cognitive triade) negatively because of their distorted cognitive schemes. Catastrophization, minimizing, maximizing, and overgeneralization belong to typically distorted cognitive schemes. As a consequence of such a cognitive triade, helpnessless, hopelessness, and powerlessness result. In this case, the only solution for an individual may be to end their miserable life by committing suicide.

6.3.3 Narcissistic crisis. Henseler (1974/1984) formulated the first narcissistic theory of suicidal behavior. Individuals with narcissistic personality traits are people who can be hurt easily by significant others through criticism or lack of special attention. They are lacking a stable self-esteem and their self-perception is distorted: they oscillate between overestimation and underestimation of their own abilities. This is not restricted to one's own character but also extends onto a corresponding distorted view of other people. Insults through criticism or lack of special attention lead to aggressive outbursts that can be directed either towards others or their own character in terms of a suicide or suicide attempt.

6.3.4 Appeal to human bonding. Attachment of the newborn to the mother is a characteristic common to all mammals. In all mammals, the newborn is very dependent and the reproductivity rate at least in the nonhuman and human primates is rather small. Therefore, the strong attachment is a life-preserving measure of the evolution to protect the dependent newborn until it is grown up. The emotional bonding in primates is very intense, a separation of the mother will be experienced as very painful (Bowlby 1977a, 1977b).

As has been known from many empirical studies, most suicides and suicide attempts are consequences of imminent separation, separation, or divorce of males and females. The intention to die is ambivalent in most suicide attempts, i.e., besides a true tendency to end life in nearly all suicide attempts there are tendencies to survive. That can be seen easily in the choice of suicide methods, which often are not so dangerous, i.e., ingestion of small amounts of pills, or in the arrangement of suicide attempt that leaves a rescue open, i.e., by attempting suicide in the presence of a significant other.

The painfully expected or experienced separation from a significant other and the appeal of the significant others not to be left behind both seem to play an important role in the meaning of a suicide attempt (Bronisch 1995).

6.3.5 Classical and operant conditioning. Basic principles of behavioral theory and therapy can be described using the Stimulus Organism Reaction Kontingency Consequence Scheme (SORKC scheme) of Kanfer (Schmidtke 1988) (see Fig. 3). The SORKC scheme tries to describe each behavior in a broader context of conditions, which can be placed linearly in a chain or circle. The constituents of the SORKC scheme for suicidal behavior are the following:

(a) life events and social situations as Stimuli variables (S), which may trigger suicidal behavior;

(b) behavioral repertoire based upon organic conditions of the individual such as psychiatric disorders and the personality (e.g., cognitive styles and stances) as Organism variable (O), which may predispose to suicidal behavior;

(c) suicidal behavior as a reaction (R) to the S and O variables;

(d) Kontingency (K), i.e., the reinforcement conditions, which support or suppress suicidal behavior; and behavior according to a regular or irregular order of the consequences;

(e) Consequences (C) in the sense of negative reinforcement (e.g., death) or positive reinforcement (attention of the environment) of suicidal behavior.

The process hereby is rather circular, i.e., consequences can again influence further suicidal behavior. This might be possible by changing the individual (O variable) and the surroundings (S variable).

6.3.6 Model learning. Imitation of suicidal behavior is a new area in suicide research. The observation that suicidal behavior is running in certain families, cultures, and countries could be explained by genetic transmission, psychological conflicts, or by model learning. In regard to model learning, three hypotheses have been proposed: the imitation hypothesis, the contagion hypothesis, and the suggestion hypothesis. All three hypotheses have in common that suicidal behavior of a model will be imitated, whereby predisposition of the individual (so-called 'presuicidal personality'), lack of social support in coping with life crises and enduring social burden are the contributing factors. Furthermore, a high degree

Figure 3
The cognitive-behavioral scheme for the development of suicidal behavior

of social suggestibility of predisposed individuals plays an important role.

During the 1980s and 1990s the influence of different media, such as books, newspapers, journals, television, and movies, on increasing suicide rates can be demonstrated (Phillips and Lesyna 1995). Suicide victims have resembled the person portrayed by the respective media: there have been similarities between this person and the suicide victim in terms of age, gender, motives for the suicide, and the methods used for suicide. The increase of suicide rate was in temporal relationship to the reported suicide cases and was not compensated by a decrease in later time, i.e., these suicides were committed earlier than planned. Also very impressive are studies that demonstrate a decrease in suicide rates not only by changing the information towards being more informative and being less sensational, but also by reducing information about suicide (Phillips and Lesyna 1995). One example is a study of railway suicides reported in newspapers, which could be reduced by cooperation with local newspapers in reducing and confining to nonsensational reports on this matter (Sonneck et al. 1994).

In a broader sense, traditions in different cultures and countries concerning either permissive or restrictive attitudes towards suicide can also be regarded as a form of model learning. These attitudes may be transferred over generations such as in Hungary where an extremely high suicide rate can be observed throughout an entire century.

6.4 *Biological Aspects*

During the nineteenth century, Esquirol (1838) was the first to observe that suicidal behavior ran in families and, therefore, postulated that suicidal behavior was a kind of mental illness. Family, twin, and adoption studies gave hints about suicidal behavior having a genetic component.

There is a familial burden due to suicide and suicide attempts (of suicide victims or suicide attempters as compared with subjects without suicide or suicide attempts). Separation of nature (heritage) and nurture (rearing) is not possible within family studies, but is within twin and adoption studies. In twin studies, identical (identical genes) and fraternal twins (half of the genes are nonidentical as in sisters and brothers) are compared with regards to suicide or suicide attempts. The respective studies demonstrate a significantly higher frequency of suicide and suicide attempts in identical as compared with fraternal twins (Roy et al. 1991). In adoption studies, identical twins have been compared with each other, whereby one twin has

been raised with his biological parents, while the other twin has been adopted right away after birth. Significantly fewer twins raised by their biological parents developed suicidal behavior or committed suicide than twins who had been adopted following birth. Furthermore, within biological families, a significantly higher rate of suicides or suicide attempts was shown than within adoptive families of the respective identical twin. All these studies also demonstrate that suicidal behavior has to be seen apart from a specific psychiatric diagnosis, especially apart from a depressive illness. On the other hand, the distinctive feature that might be inherited may not be suicidal behavior as such but rather personality traits such as lack of impulse control or aggressiveness (Wender et al. 1986). Postmortem studies of suicide victims and in vivo studies (investigation of cerebrospinal fluid and the platelets in the blood of suicidal persons concerning molecular genetic, biochemical and physiological parameters) support the so-called serotonin hypotheses of suicidal behavior: impulsiveness, aggression directed inwards or outwards, and violent suicidal behavior are correlated with a dysfunction of the serotonergic transmitter system in the human brain (Mann 1998).

7. *Prevention*

Prevention can be divided into primary, secondary, and tertiary prevention. With regard to primary prevention the main focus implies a reduction of tendencies within the society that support suicidal tendencies. A verdict of suicidal behavior by means of social ostracizing or punishment has not been successful in reducing suicide rates in medieval and modern times (Minois 1995). However, primary prevention also concerns the prevention of suicidal behavior by ameliorating life conditions in general and socioeconomical conditions in particular as well as effective treatment of psychiatric disorders. It also refers to a support of tolerance for individual life styles. Furthermore, the restricted approach to frequently used methods, such as guns for shooting, can be helpful. Primary prevention implies also an amelioration of power of resistance against suicidal tendencies in the individual. Education of lay people and professionals in detecting and treating suicidal persons could be the most effective strategies. Secondary and tertiary prevention provided by fellow citizens (e.g., Samaritans) or medical or psychological professional personnel mean prevention of relapses in suicidal behavior or rehabilitation of patients with suicidal behavior. Empirical studies proving the effect of the above mentioned preventive strategies are still lacking. There is now an emerging trend to develop national suicide prevention programs in several western and northern European countries (Silverman and Maris 1995).

8. *Therapy*

Therapy has to be divided into crisis intervention, with actual psychiatric-psychotherapeutic intervention, into pharmacotherapy and psychotherapy. Crisis intervention primarily means prevention of an imminent danger of suicide. Crisis intervention should provide care and protection to the individual, i.e., protection of life, since suicide attempts often require medical care such as admission to an internal intensive care unit for detoxification or a surgical intervention. Crisis intervention also includes immediate evaluation of still existing suicidal tendencies of the patient in order to make decisions for further preventive measures: admission to a closed psychiatric ward for relapse prevention or crisis intervention on an inpatient or outpatient basis. Crisis intervention also includes acute psychotherapy and pharmacotherapy of the patient. The most important determinant of the psychotherapy is hereby the development of a supportive relationship between the suicidal person and the therapist. The greater the time lapse between the suicide attempt and help offered, the more often suicidal people are inclined to disregard this help. A supportive relationship means that the therapist is accepting the patient's 'cry for help' and is making a commitment trying to understand the patient, however, is not willing to accept the patient's decision to end their life as a form of reasonable problem solving. They clarify the triggering situation that has led to the suicide attempt. Together with the patient, the therapist tries to develop other strategies to resolve seemingly insoluble conflicts in the patient's life. Also, an important determinant of a successful intervention is the involvement of significant others of the patient as well as the social environment in general. The acute pharmacological intervention means primarily sedation of the patient in order to keep him or her from further suicidal behavior.

Psychotherapy means treatment of psychopathological states such as depression, dysfunctional behaviors like impulsiveness, or pathological personality traits such as low self-esteem (Bronisch 1999). It includes the classical types of psychotherapy, i.e., psychodynamic approaches and cognitive-behavioral approaches. So far, empirical studies could only demonstrate efficacy for some groups of patients, such as patients with Borderline Personality Disorders by cognitive-behavioral therapies (Linehan 1997).

Pharmacotherapy of suicidal behavior primarily is focused on the underlying psychiatric illness of the patient such as schizophrenia (antipsychotics), depressive disorders (antidepressants), anxiety disorders (anxiolytics), and addiction (drugs against withdrawal symptoms). However, during the 1990s drugs specifically targeting the typical characteristics of suicide attempters such as impulsiveness and aggressiveness seem to have been successful in reducing suicide and suicide attempts: lithium (Ahrens 1997) and selective

serotonin reuptake inhibitors (Montgomery 1997). (See *Antidepressant Drugs*.)

9. Concluding Remarks

Suicide and suicide attempt are a behavior confined to human beings. They are rooted fundamentally in the human existence and have as a prerequisite self-reflecting properties of the individual, i.e., conscious acting with the consequence or the attempt to extinguish the own existence.

The attempts to describe suicide and suicide attempt based on a single cause in only one dimension has been tried by Esquirol (1838) in biology, Durkheim (1897) in sociology, or Freud (1917) in psychology and seems to be inappropriate. Suicide and suicide attempt are multidetermined acts (Roy 2000). However, the weighting of different aspects of suicide and suicide attempt seems to be rather difficult to explain, so that in the following, only a synopsis of the empirical findings will be given.

Suicide is lacking in animals and even in nonhuman primates. However, it has already been found in Neolithic societies as well as later on in the old Greek and Latin societies. Precise empirical data about suicide in different countries and cultures has been lacking up to the nineteenth century so that a description of the development of suicide from the antiquity via the medieval to modern times is impossible. However, there is a considerable increase of suicides in societies with a high degree of secularization, industrialization, and individualization starting in the middle of the nineteenth century. For individual countries, there is often a stability of suicide rates on a high or low level depending at least in Europe on the degree of industrialization, religious affiliation and climate: northern countries with a high degree of industrialization, Protestant religious affiliation and rather few sunny days have considerably higher suicide rates than southern countries with a low degree of industrialization, Catholic religious affiliation, and many sunny days have lower suicide rates. The differences could best be explained by human bonding as a protective factor, whereas climate could influence biological rhythms, hence, triggering suicidal behavior.

In regard to sex differences and suicidal behavior, very stable differences exist between males and females with a male preponderance in suicide and female preponderance in suicide attempts. The reasons for these sex differences, which seem to be stable across countries, cultures, and times, have not been well investigated and need further empirical research. There is no doubt that psychological motives play not only an important role as triggers for suicidal behavior but also are important determinants for the development of suicidal behavior. The most important motive for suicidal behavior is certainly the impending loss of a human relationship, even if the wish to die outweighs the wish to survive in the suicidal act, i.e., in the seriousness of the suicide attempt. Besides that, the turning of aggressive tendencies towards the own character and narcissistic vulnerability are personality traits predisposing to suicidal behavior. From the cognitive-behavioral point of view, classical conditioning, operant conditioning, and model learning are basic learning principles, which also can be transferred to behaviors such as suicide and suicide attempt. This way, model learning is not only important for perpetuating suicidal behavior in families and peer groups but also in societies with traditional high (Hungary) suicide rates (so called imitation hypothesis).

In certain families, a genetic burden of suicidal behavior could be confirmed by twin and adoption studies. This genetic burden is often connected to psychiatric illnesses such as depressive disorder, addiction, anxiety disorder, schizophrenia, and personality disorder. Biological studies (postmortem brain and peripheral biochemical studies) could demonstrate a dysfunction of the serotonergic system in suicide victims and suicide attempters, which in psychopathological terms is correlated to a loss of impulse control, aggressiveness, affective instability, and violent suicide attempt.

As empirical studies could confirm, suicidal behavior is not a 'normal' behavior, but is rooted in psychological and biological abnormalities of the respondent with the corollary of prevention and therapy. However, empirical data about successful prevention of suicidal behavior is still lacking and successful therapeutic interventions only exist for subgroups of suicide attempters such as depressives with a successful treatment with lithium and serotonin reuptake inhibitors as well as cognitive-behavioral therapy for patients with a borderline personality disorder. Life as a precious good, desperation, and suffering of the respondents as well as suffering of the relatives should bring the focus on suicide more into the scientific scope of view as other life threatening illnesses already have been for a long time.

Suicide: Ethical Aspects

In 1917, perhaps still troubled by the suicides of two of his brothers and of a close friend, Ludwig Wittgenstein wrote:

> If suicide is allowed then everything is allowed.
> If anything is not allowed, then suicide is not allowed.
> This throws a light on the nature of ethics, for suicide is, so to speak, the elementary sin…

In contrast, in 1961 the Nobel physicist Percy Bridgman, then almost 80 years old and suffering from terminal cancer, shot himself, leaving a final note:

> It isn't decent for society to make a man do this thing himself.
> Probably this is the last day I will be able to do it myself.

These views frame the scope of the contemporary debates over the ethics of suicide. At one extreme, some hold the view that suicide is, as Wittgenstein put it (though he questioned even this view), 'the elementary sin,' the act most clearly 'not allowed.' At the opposite extreme, others hold that control over one's own life is a matter of right, and ending that life something for which, at least in circumstances like painful terminal illness, a person ought to receive assistance and social support.

These debates are both ancient and new. In the West, prior to the beginning of the twentieth century, suicide had often been viewed as a moral question; at the beginning of the twentieth century, however, 'scientific' views of suicide as the product of social forces or of individual psychopathology worked to remove suicide from ethical scrutiny. Suicidality came to be seen largely as a clinical matter for prevention and treatment. Not until the emergence of the right-to-die movement in the latter part of the twentieth century did ethical issues about physician-assisted suicide and hence about suicide itself begin to re-emerge as a matter for philosophical reflection and for public debate.

1. Conceptual Issues

In popular discourse, the term 'suicide' carries extremely negative connotations. However, there is little

agreement on a formal definition. Some authors count all cases of voluntary, intentional self-killing as suicide. Others include only cases in which the individual's primary intention is to end his or her life. Still others recognize that much of what is usually termed 'suicide' is neither wholly voluntary nor involves a genuine intention to die, including many of the cases usually labeled 'suicide'—especially those associated with depression or other mental illness. Many writers exclude cases of self-inflicted death which, while voluntary and intentional, appear aimed to benefit others or to serve some purpose or principle: for instance, Socrates' drinking the hemlock, Captain Oates' walking out into the Antarctic blizzard to allow his fellow explorers to continue without him, or the self-immolation of war protesters. These cases are usually not called 'suicide' but 'self-sacrifice,' 'martyrdom,' 'heroism,' or other terms with strongly positive connotations. However, attempts to differentiate these positive cases often seem to reflect moral judgments, not genuine conceptual differences.

Nonwestern traditional cultures offer many additional conceptual puzzles. Is the label 'suicide' appropriate for wives and royal retainers who allow themselves to be buried alive at the death of the king? For widows who, responding to strong social expectation, commit *sati* by throwing themselves on their husband's funeral pyre? For *jihad* or religiously motivated holy-war acts certain to cause one's own death? For kamikaze missions undertaken by volunteers who know they will not return but who are seen as making a supremely heroic sacrifice for the good of the nation? In all cultures, cases of death from self-caused accident, self-neglect, chronic self-destructive behavior, victim-precipitated homicide, high-risk adventure, and self-administered euthanasia—which all share many features with suicide but are not usually termed such—cause still further conceptual difficulty. Consequently, some authors claim that it is not possible to reach a rigorous formal definition of suicide, and that only a criterial or operational approach to characterizing uses of the term can be successful. Nevertheless, conceptual issues surrounding the definition of suicide are of considerable practical importance in policy formation, as for instance in coroners' practices in identifying causes of death, psychiatric protocols, insurance disclaimers, religious prohibitions, and laws either prohibiting or permitting aiding suicide in situations such as terminal illness.

2. *Traditional and Contemporary Ethical Arguments Concerning Suicide*

Because recent scientific views of suicide have tended to presuppose that suicide is not a voluntary act, much of the most significant argumentation concerning the moral status of suicide is to be found in the historical tradition. Traditional discussions of suicide employ a wide range of types of arguments, including principle-based, consequentialist, and virtue-based arguments. In each of these categories, some arguments are directed toward the conclusion that suicide is immoral and/or should be prohibited; others lead to the conclusion that suicide is morally permissible and/or should be permitted; a few lead to the conclusion that suicide is morally obligatory in certain sorts of circumstances.

2.1 *Principle-based Arguments*

Many thinkers in Western philosophical and religious traditions which employ principle-based, duty-based, or other deontological forms of moral reasoning have argued that suicide is intrinsically wrong, and, hence, that it is prohibited. Conversely, others argue that because suicide is prohibited (by God), it is known to be intrinsically wrong. For example, traditional Judaism cites the Biblical passage at *Genesis* 9:5, 'For your lifeblood I will surely require a reckoning,' as the basis of the principle that suicide is wrong; the only exceptions involve self-killing to avoid spiritual defilement, a practice known as *Kiddush Hashem* (as in the mass suicide at Masada), and temporary insanity. In classical Greece, Socrates, as portrayed in Plato's *Phaedo*, cites the secret, 'whispered' Orphic principle that man is a 'prisoner' or 'possession' of the gods and ought not run away; thus suicide would violate the wishes of the gods. Early Christian thinkers implied or asserted that suicide is wrong *per se*, since, as Augustine argued, it is to reject God's gift of life and runs counter to the will of God. In exceptional cases like those of Samson pulling down the temple on the Philistines—and himself—, and Saul falling on his sword, Augustine insists, suicide must have been commanded by God, but such cases are very, very rare and do not excuse ordinary persons.

In the high Middle Ages, Thomas Aquinas definitively established Christianity's opposition to suicide with a set of five arguments. Central among these is the principled claim that suicide is unnatural: 'everything naturally seeks to keep itself in being.' From this principle, Thomas drew the conclusion that '… suicide is, therefore, always a mortal sin in so far as it stultifies the law of nature …' Still later, philosopher Immanuel Kant argued that suicide can be shown to be intrinsically wrong by application of the Categorical Imperative: one cannot will without contradiction that it be universal law. Many other moralists have held that, as a matter of basic ethical principle, suicide is intrinsically wrong.

At the same time, however, other thinkers employing deontological or principle-based reasoning have argued that suicide can be morally permissible or even

praiseworthy. Typically, these thinkers assert that the principle of autonomy is fundamental, claiming that unless the person is not acting voluntarily or does not have adequate information, or unless serious harm to others will follow, a person's choice of suicide is to be respected. Defenses of suicide by Seneca, by Rousseau's character St. Preux in the novel *Heloise*, by Schopenhauer, and by Mme. de Stael (though she later argued against suicide) are of this form: they assert that as a matter of principle, suicide is not intrinsically wrong and that suicide can be a morally acceptable, sometimes praiseworthy thing to do.

Although the language of moral rights is not available to the earlier thinkers, some have elevated the principle of autonomy into the basis of a fundamental right to suicide. For example, Schopenhauer and Nietzsche see suicide as a matter of the basic right of the individual to choose whether to continue to exist in the world. As Nietzsche put it, 'suicide is man's right and privilege.'

2.2 *Consequentialist Arguments*

Other thinkers have argued that suicide is morally permissible in certain situations, though not in others. Typically, these arguments are consequentialist or utilitarian in character—outcome-oriented, so to speak—assessing the permissibility of suicide in terms of its impact on the suicidal person, on family members, on friends and associates, and on the larger society. Aristotle, for example, says that suicide is wrong because it 'treats the state unjustly'; he is concerned about its impact on society. Christian and Islamic thinkers often argue not only that suicide is wrong in itself but that it will mean damnation for the victim. Blackstone argued that the suicide is an 'offense against the king,' who has an interest in the preservation of all his subjects. Samuel Pepys, recounting in his diary his efforts to intervene on behalf of the widow of a man who has just drowned himself, points to the disastrous impact suicide could have on family members, inasmuch as the English legal system made a suicide's property forfeit to the Crown.

Using similarly consequentialist arguments, many contemporary authors also point to the consequences suicide can have for family members (especially children) and other close associates. They particularly emphasize the sense of guilt and shame that may be aggravated in survivors. Suicide, on these consequentialist arguments, damages its victim, damages family members, and can damage the society of which they are part.

However, not all consequentialist arguments speak against the morality of suicide. Greek and Roman Stoics, defending suicide in principle, also point to the beneficial consequences suicides like that of Cato might have in protecting the freedoms of society. Both traditional and contemporary authors acknowledge that the suicide of an aggressive or abusive person may have positive consequences for others by removing a threat, that the suicide of a person suffering an extended, expensive illness may relieve burdens on an overwrought family, and that suicides of self-sacrifice and principle can have substantial benefits for society. Because these arguments appear to favor or even encourage suicide in many sorts of circumstances, they are currently viewed as extremely controversial. They are rarely openly discussed, though they play an influential role in the background of concerns about 'slippery slope' pressures on vulnerable persons.

2.3 *Virtue-based Arguments*

Still other thinkers treat suicide as an index of character. For example, Aristotle asserts that suicide is 'cowardly'—that is, that it is evidence of a defect of character, a failure to act virtuously by exhibiting insufficient courage in facing a difficult situation. Many later thinkers, including Augustine and Thomas Aquinas, have adopted the view that suicide is 'cowardly.' These and other Christian writers also celebrate the willing acceptance of suffering, particularly in emulating the sacrifice made by Christ. As Mme. de Stael put it in her second essay on suicide opposing the libertarian stance of her first, 'Suffering is a blessing…it is a privilege to be able to suffer.'

In contrast, Greek and Roman Stoics favoring suicide, as well as many later authors, also employ virtue criteria, but argue to the opposite conclusion. The Stoics held that real cowardice held in fearing death, and that committing suicide itself requires courage. Examples cited in this tradition include the heroic suicides of Cato, Lucretia, and Seneca, respectively involving commitment to an ideal of political liberty, sexual virtue, and personal courage in the face of an untrustworthy emperor. For some virtue theorists, suicide can involve other virtues as well: fortitude, loyalty, civic responsibility, and many others. Thus, on a virtue-based analysis, too, arguments may be made both against and for the ethical permissibility of suicide.

3. *Social Correlates, Biochemical Findings, and Markers of Suicide Risk*

The question of whether suicide is wrong—whether in principle, or because of its consequences, or as a fault of character—seems to presuppose that the act is at least to some degree under the agent's voluntary control. Traditional accounts of the morality of suicide, both those which allow it in some or all circumstances—including Plato, the Stoics, Hume, Nietzsche, and others—and those which oppose it in all or virtually all circumstances—Aristotle, Augustine, Thomas Aquinas, Kant, and others—agree in

assuming that the act is sufficiently voluntary that the person whose death it will be can appropriately be blamed (or praised) for so acting—after all, he or she could have refrained from suicide and kept on living.

Scientific views of suicide, introduced by Durkheim and Freud at the beginning of the twentieth century, have challenged this assumption. Durkheim's anomie theory held that suicide is a function of the degree of integration of the social body: suicide can be altruistic, where suicide practices are highly institutionalized; it can be egoistic, where individuals do not respond to social expectations and regulations; or it can be anomic, where society does not provide adequate regulation of its members, as, Durkheim believed, in modern industrial society. In contast, Freud insisted that suicide was the product of mental illness. For much of the twentieth century, whether suicide was understood as the product of social forces or as the consequence of underlying depression or other mental disorder, in either case it has been seen as largely beyond the voluntary control of its victim.

Suicide prevention, pioneered by Edwin Shneidman in the mid-twentieth century and continued by many later suicidologists, works in part to identify risk factors associated with elevated rates of suicide: risk is greater for males (especially older white males), for alcohol abusers, for those with low religiosity, for those with poor or rigid coping skills, for those less willing to seek professional help and more likely to ignore the warning signs of suicide, for those with poorer support systems, for those with access to more lethal technology such as guns, and for those for whom failure is more obvious in the primary adult role (defined for males as economic success; for women, as success in relationships). Also at heightened risk are teens who listen to heavy-metal music and white males who listen to country music, though these factors are not causes but proxies for other variables, like alcohol or drug use or divorce. Copycat effects following celebrity suicides, holiday dips and post-holiday peaks, and seasonal variations in suicide have all been explored in the search for explanations, as has the concept of suicidal 'careers' as a form of coping mechanism.

At the same time, new findings in psychiatry, biochemistry, epidemiology, and genetics are beginning to erode assumptions about voluntariness as they reveal biological correlates of suicidal behavior. Depression, it has long been known, is strongly associated with suicide (some studies suggest that it is present in as many as 80–90 percent of cases, though in other studies the rate is lower). Levels of 5-HT, or serotonin, a neurotransmitter, and its metabolite 5-HIAA are decreased, as measured in CNS spinal fluid. Fenfluramine used as a challenge agent evokes an impaired response in people who have made serious suicide attempts. Prolactin release is stimulated by serotonin; it too is decreased in suicidal persons. There is some evidence of heritable genetic patterns in families with multiple suicides: adoption studies show that adoptees with suicide in their biological families are at greater risk for suicide than other adoptees, and there is some evidence of significant association between genetic variation in the gene for tryptophan hydroxylase (TPH) and violent suicide attempts. It may even be the case that depression and suicidality are associated with second-trimester exposure during pregnancy to winter flu.

Such findings suggest that suicide, as well as suicidal ideation and suicidal and parasuicidal behavior, along with aggressive behavior generally, may be to some degree biologically determined, either directly or in conjunction with social and environmental factors. If so, suicidality would thus be less a focus for moral blame or praise than for clinical treatment and concern. It may even be possible to develop a biological test—for example, a blood test, a saliva assay, or a urine analysis—that would screen for CNS neurotransmitter abnormalities associated with suicidal behavior. While work to date establishes correlations rather than causes, it nevertheless points to psychological and situational factors that may play a causal role in suicide.

Some theorists have assumed that such research will eclipse ethical issues in suicide altogether. However, this research faces two challenges: first, the definitional issue of who counts as a 'suicide' (as distinct from martyr, hero, self-sacrificer, or terminally ill patient seeking an easier death), and second, the prudential issue of whether suicide can ever serve the interests of the person who commits it. Definitional challenges to research programs are numerous: should research on completed 'suicides' include among its cases, for example, self-sacrificing parents who put themselves in harm's way to protect their children, or social protesters who immolate themselves for political causes, or the sea captain who elects, as tradition has required him, to go down with the ship? The prudential challenge asks whether there can be 'good reason' for suicide in some cases, such as painful terminal illness or extreme old age, and hence whether research is misguided if it focuses primarily on negatively valued cases; that is, those called 'suicides' in ordinary parlance.

Some theorists suggest that there are two basic groups of suicides: on the one hand, people with neurotransmitter abnormalities or other biological defects who suffer from mental illness, depression, or extreme emotional stress, people who cannot consider their best alternatives, and on the other hand biologically normal people who can make such considerations but who find themselves caught in situations in which suicide appears to be the most reasonable choice, a way out of their difficulties. These groups are sometimes distinguished as 'irrational' or mentally ill, and 'rational' suicides. A clear differentiation is not adequately supported by current findings, primarily because research on 'suicide' typically includes just

those attempts and completed cases conventionally labeled suicide, overlooking cases not usually identified as suicides where the motivation is viewed as understandable or heroic, as in, for example, cases of political protest or of hastened dying in terminal illness. By some estimates, 95 percent of suicide cases are 'irrational' and five percent 'rational,' though this estimate is itself challenged by conceptual concerns about what counts as 'suicide' in the first place.

Nevertheless, this distinction influences much of contemporary discussion about ethical issues in suicide. 'Irrational' suicides are assumed not to pose moral issues concerning the agent, since they are assumed not to be voluntary in a robust sense, though of course second parties like family members and physicians may face moral questions about whether and how to intervene. 'Rational' suicides, on the other hand, are assumed to be appropriately considered in ethical terms: these are people who make a choice to end their own lives, and the moral issue is whether it can ever be right to choose as they do.

4. *The Contemporary Debate over Physician-assisted Suicide*

Beginning in the latter part of the twentieth century, the so-called 'right-to-die' movement began to challenge life-prolongation practices in the treatment of the terminally ill. Patients, it argued, should have the right to control the care given them as they are dying, whether by refusing treatment like respirators or antibiotics or by discontinuing treatment already in progress—even if this means they will die. By giving a central role to patients' autonomous decisions about medical care at the end of life, the right-to-die movement also raised the issue of whether the terminally ill patient may deliberately and directly end his or her own life—and receive help from his or her physician in doing so. As of the year 2001, physician-assisted suicide had become legal only in the Netherlands and the US state of Oregon, and had briefly been so in the Northwest Territory of Australia, but the issue was being widely debated in many countries, especially in the USA, Canada, the UK, Belgium, Australia, Colombia, and several Scandinavian countries.

Four principal ethical arguments, all to be found in earlier, historical discussions of the ethics of suicide, contribute to this broadly international public debate over whether physician-assisted suicide (and, in some countries, voluntary active euthanasia) should be regarded as morally acceptable and legally permitted. The two principal arguments on the pro side are (a) the argument from autonomy, that the autonomous choice of a competent person is to be respected, and (b) the argument from mercy, an argument for freedom from suffering, that the dying patient has the right to try to avoid pain and suffering as much as possible, including by means of a deliberately undertaken earlier death if that is the only effective way to avoid them. At least on some views, both conditions are necessary and neither sufficient in itself: a person must both choose autonomously and have no realistic alternative in seeking freedom from suffering in the process of dying to underwrite an adequate case for physician-assisted suicide. Neither voluntary choice alone in the absence of terminal suffering nor terminal suffering without genuine choice would be sufficient to make such a case.

On the opposing side, two principal arguments against moral recognition or legal acceptance of physician-assisted suicide also inform the current debates, (a) the argument from the intrinsic wrongness of killing—that killing, and hence self-killing, is in itself wrong, and (b), that permitting assisted suicide would risk the 'slippery slope': it would invite pressures on patients by overwrought or greedy families, unscrupulous physicians, or cost-conscious institutions, all of which might force a vulnerable patient to 'choose' suicide when they did not really wish to die.

Each of these arguments is open to rebuttal. For instance, the claim that killing is not morally permissible can be countered by the objection that killing in self-defense, in war, and in capital punishment are regarded as permissible. The claim that death may be the only way to avoid pain and suffering is countered with the possibility of deep sedation. Such counter-arguments are themselves open to rebuttal: for example, that it is only the killing of innocents that is prohibited, or that deep, irreversible sedation is tantamount to causing death, in that it permanently ends the possibility of human experience. These counter-counter-arguments are in turn open to still further reply. In practice, the disputes over physician-assisted suicide are hugely extended and extremely complex, simmering in many disciplinary areas—philosophy, law, medicine, psychology, sociology, political theory, theology, social anthropology, economics, and public policy—in many countries around the world.

These disputes have had a focusing effect, redirecting the larger normative debate about suicide, quiescent since Durkheim, Freud, and the beginning of the twentieth century, toward a specific type of case, terminal illness. Contemporary disputes about the ethical issues in suicide no longer address the larger range of cases in which suicide had been considered permissible or impermissible by various cultures at various times: in shame or dishonor, in chronic illness, in old age, in extreme poverty, for blindness or other disability, on being widowed, for social protest or the defense of principle or religious belief, to avoid degrading labor or coercion in unacceptable activities, and many other reasons. The debate over right-to-die issues and physician-assisted dying that has emerged in the latter part of the twentieth century is indeed a debate about the ethics of suicide, but it is a highly

specific, highly focused debate, raised virtually exclusively with regard to physical suffering in the context of terminal illness; it does not yet address whether and when suicide is morally impermissible, permissible, or obligatory in any of a much wider range of situations.

While the right-to-die debates over the ethics of physician-assisted suicide in terminal illness continue to ferment, primarily in the developed nations, work is re-intensifying in suicide prevention, focused especially on teens and on some groups of persons at higher identified risk, and on improvement in the care of dying patients, particularly on more effective pain control. Some believe that these measures will be able to reduce both the incidence of suicide and the call for physician-assisted suicide in the future.

5. *The Future*

In 1975, Henry Van Dusen, former president of Union Theological Seminary, and his wife Elizabeth—both leaders in American theological life—committed suicide together by taking overdoses. Mr. Van Dusen was 77 and had had a disabling stroke five years earlier; Mrs. Van Dusen was 80, blind, and suffering from serious arthritis. They left a letter saying that 'We still feel this is the best way and the right way to go,' predicting that it would become more frequent and more publicly accepted. It is not yet possible to say whether they were right; some observers argue that the ethical issues in suicide will recede again out of public view as modern medicine becomes more and more capable of alleviating pain and suffering now feared by the dying, while others think the ethical issues will become more and more broadly explored, as patients seek greater and greater autonomy in the matter of their own dying. And some think that these ethical issues will be central in the moral life of many societies for the foreseeable future, as life expectancies increase and the likelihood of dying from late-life degenerative disease grows. If so, ethical scrutiny in the matter of suicide will turn to two sorts of issues: the morality of approaching terminal illness and unavoidable death by 'designing' one's own dying, and the risks of social encouragement and pressures that could develop as it becomes a normal, socially tolerated, expected thing to do. Whether such trends will in fact develop is impossible to predict, but it is possible to predict what ethical issues such trends would raise.

Suicide, Sociology of

Although the word itself has been used only since the seventeenth century, the reality that is suicide has been part of human history for a long time. Many suicides occurred in Greece in the fifth century BC and in Rome during the first century AD. The first writings about suicide present it as a religious, moral, or pathological phenomenon, frequently attributed to supernatural causes or to mental illness. Empirical studies appear only at the beginning of the nineteenth century, with still moral overtones. Statistics are analyzed according to an individual or social patho-

logical perspective and the suicide rates are correlated with such variables as the regional economic situation and the homicide or mental illness rates.

1. *Durkheim*

The first truly sociological writing on the subject is *Le Suicide. Étude de Sociologie* by Durkheim (1967) (see *Durkheim, Emile (1858–1917)*). Making use of official statistics, he points out the variations in suicide rates throughout time and space. For him, the rate of suicide constitutes a social fact. Each society has a specific tendency toward suicide. The structure of a society decides, so to speak, its own contingent of voluntary deaths.

Durkheim refutes the theories that explain suicides by extrasocial individual factors. He not only dismisses psychopathic or normal psychological factors, but also cosmic factors and the imitation factor which includes contagion. He constantly distinguishes between the cause of suicide, which is always social, and the motives, which are merely pretexts. Applying the concepts of integration and regulation to religious, domestic, and political societies, Durkheim constructs a typology of suicides. Egotistic suicide results from insufficient social integration and differs from altruistic suicide that is seen in societies too strongly integrated. Anomic suicide occurs in societies where rapid changes are not, or insufficiently, regulated; on the contrary, fatalistic suicide, scarcely touched upon by Durkheim, follows from an excess of social regulation.

Several criticisms have been directed against Durkheim's work. In particular, Baechler (1975) compares his lack of interest in the victim of suicide with his great concern for the social rate of suicide. Baechler observes that, for Durkheim, it is not individuals who take their own life, but society itself that commits suicide through some of its members. Durkheim's analysis of the low suicide rate among women is also severely criticized, along with his lack of development of fatalistic suicide and the confusion he perpetuates between anomy and egotism.

2. *In Durkheim's Wake*

Controversy was not the only reaction to *Le Suicide*. The book awakened a keen interest in the study of suicide, although that interest showed itself only in the 1950s, especially in the USA. Durkheim's research generated a number of studies seeking to replicate, extend, clarify, and even to rectify not only his conceptual analysis but also his empirical results. Still widely taught today in many countries, Durkheim continues to exert a powerful influence on the sociology of suicide.

Using the notions of social status and social roles, Gibbs and Martin (1964) developed a theory around the Durkheimian concept of social integration. When a society engenders a status incompatibility and therefore role conflicts, it has a greater risk of suicide. For Gibbs and Martin, a relationship exists between the suicide rate and the integration of status and roles. It gives rise to their theorem: the suicide rate of a given society varies inversely with the degree of integration of the status and the roles which make up that society.

Lester (1989, 1997) is one of the sociologists who have contributed the most—and he continues to do so—to the operationalization of Durkheim's concepts, especially social integration, and to the widest possible verifying of his empirical conclusions. Although he remains open to psychological and individual perspectives, Lester is part of the Durkheimian movement, as witnessed by his numerous statistical and comparative studies of national and regional suicide rates throughout the world and his insistence on deepening the direct relationship between suicide and the modernization of society. In this regard, Lester recommends greater precision in the criteria for modernization, beyond the vague notions of industrialization, urbanization and secularization. Declining birth and death rates and the increases in the divorce rate and in the gross national product are specific indices that should be taken into account.

3. *Psychosocial Approach*

Notwithstanding the studies that throw light on the social factors of suicide, they do not satisfy several researchers who are interested in studying how such factors influence the persons who commit suicide and what moves them, as individuals, to take their life. The study of suicide thus moves more and more inward, refusing to see the causes of suicide as only social and external. Without neglecting social factors, the study of suicide now considers psychological and individual factors, in both their affective and cognitive dimensions.

3.1 *Affective Dimension*

Halbwachs (1930) gives a different interpretation to the Durkheimian notion of anomic suicide. For him, the increase in the number of suicides should be more correctly attributed to the loneliness felt by those individuals who are faced with an increasingly complex society that makes it difficult for them to establish satisfactory social contacts. The key concept is to be found in the lifestyle of people, since it determines the opportunities for a relationship with others. One therefore finds fewer suicides in rural areas because of a more harmonious lifestyle. Loneliness with its accompanying social isolation, brought on by a complex and conflicting urban society, thus becomes the cause of suicide, which is consequently explained by psychosocial factors.

Henry and Short (1954) suggest another psychosocial explanation of suicide by incorporating the

Freudian concepts of frustration and aggression. An integrated society, in which external constraints increase, has a lower rate of suicide. This is because external constraints have more effect on persons of low status; the subsequent frustration causes their aggressiveness to be turned outwards, with the potential for homicide. Conversely, persons of high status, who impose their demands on others, have no one but themselves to blame if they feel frustrated; their aggressiveness is directed inwards upon themselves, with the potential for suicide. Far from being unanimously accepted, Henry and Short's theory still captured the attention of some researchers. Maris (1981) endorses the idea of social constraints. However, while they are fewer for the person socially isolated, they nevertheless increase the likelihood of suicide.

Giddens (1966) also puts forward a psychosocial approach to suicide. He presents a typology of suicide, using the Durkheimian notions of egotism and anomy with which he associates the Freudian theory of depression. Different kinds of societies spawn various depressed and suicidal personalities. On the one hand, an egotistic society produces introverts who are incapable of relating to others; their suicidal behavior seeks expiation or social reintegration. On the other hand, an anomic society creates personalities dissatisfied with their performance; their suicide aims at surpassing themselves. In any event, for Giddens, all cases of suicide presuppose social isolation, marked by the absence of significant relationships.

3.2 Cognitive Dimension

Sociology also progressively integrates the cognitive dimension that is linked to a concrete suicide. The possible meanings of suicidal behavior gradually come to revolve around the idea that suicide is the solution to one's problems.

Douglas (1967) has left his mark on this approach to the study of suicide by his work on meanings. Influenced by Weber, Douglas states that suicide is a social act that includes subjective meanings constructed from interactions between the victim and his cultural context. He thus advances a social constructionist theory of meanings. Suicide is seen as 'a means of transforming the soul from this world to the other world,' 'a transformation of the substantial self in this world or in the other world,' 'a means of achieving fellow-feeling,' or 'of getting revenge' (Douglas 1967, pp. 284, 300, 304, 310).

Also inspired by Weber, Baechler (1975) attempts to understand what makes human beings put an end to their lives. He defines suicide as any behavior that seeks and finds the solution to an existential problem in the act of putting an end to one's life. His strategic theory includes several types of suicidal behavior: the escapists, who see a way out, the aggressives, who wish to attack someone, the oblates, who sacrifice themselves, and the gamblers, who take a chance with death.

Taylor (1978) also studies the significance of the suicide act for the actor himself. Even as they commit suicide, individuals are rarely seeking death. Aligning himself with Baechler, Taylor suggests two meanings to this behavior. The first is the 'ordeal' character of suicidal action that represents the risk, the game, the betting with death. The second is the aspect of 'rebirth' that the suicide act may take. In risking his life, the individual hopes to escape his problems and reinvest in a new life that will make more sense to him. He is seeking a renewal of life.

4. Psychological and Biological Approaches

Since the 1980s, the increasing influence of the psychological approach on the sociology of suicide has become evident. For Shneidman (1985), suicide is a multidimensional distress of which the main component is always psychological. Suicidal people always suffer from an unbearable psychological pain and from a cognitive constriction, a 'tunnel vision.' Suicide becomes the only solution to their problems. Following Shneidman, Kral (1994) also insists on the psychache felt by the suicidal person. However, for Kral, the direct cause of the fatal act is the idea itself of suicide. Suggested by the victim's culture, it acquires more and more credibility in his eyes and is gradually transformed into an acceptable alternative for getting rid of his psychache. The cultural schema of suicide is progressively internalized into a personal schema.

Some sociologists underline the influence of biology on suicidal behavior. De Catanzaro (1981) adopts a sociobiological standpoint. In his literature review on suicide, Maris (1981) takes note of a biopsychosocial model of suicide. For certain individuals, their life has been so strewn with multiple problems that their capacity for adaptation is severely impaired, possibly owing to their biological condition, e.g., a failure of serotonin or an imbalance of neurotransmitters triggered by social and psychological factors.

5. Differentiation of Suicidal Behaviors

The sociology of suicide progressively differentiates. First interested in *completed suicides*, it examines their many particular forms; multiple studies grouped around gender, ethnic origin, and age group proliferate rapidly. Then, sociologists gradually widen their field to include studies of *noncompleted suicides*.

5.1 Various Forms of Completed Suicides

Instead of a general analysis of the completed suicides, several sociologists isolate particular groups of the

fatal acts. Some of them concentrate on suicides by imitation or contagion, studying the fluctuation of suicides following publicity about certain voluntary deaths. When there is widespread coverage by the press, there follows an increase in the number of suicides. This is known as the 'Werther effect,' referring to suicides committed in 1774 after the publication of a novel by Goethe. Tinged with controversy and a lack of unanimity in the results, a good number of studies have been carried out around that point since the early 1980s (Stack 1987).

Other particular forms of completed suicides are examined according to sex, ethnic origin and age group. Analyses of the sex of persons who committed suicide become more detailed and more discriminating. Invoking his concepts of integration and regulation, Durkheim himself had accounted for a higher suicide rate among men than among women. In most societies, researchers still observe far more male suicides than female, with the particular socialization of each gender often offered as an explanation. Researchers are also looking more and more at links between suicide and homosexual orientation, because of the stigmatization and social exclusion that result from the latter.

Sociologists continue to be deeply interested in the ethic origin of persons who died by their own hand. The suicide rate of immigrants to the USA is analyzed and found similar to the rate in their country of origin. Even the methods for suicide used by Asian Americans differ from those chosen by the majority of Americans. The immigrants' culture of origin is thus a determining factor in their suicide. Intrigued by the low suicide rate of African American men and women in spite of the several risk factors associated with them, some sociologists point out the protective influence of their cultural patterns, particularly of their religious family roles. Black women are protected by their network of social support. As for Chinese women, almost the only ones who take their life more often than their male counterpart, it is because of their traditional culture making them responsible for family problems.

Suicide rates according to age group are carefully and more painstakingly examined. The peaking of suicide in old age is confirmed by Lester (1997) on an international scale. On the other hand, several researchers observe an increasing rate of suicide among the youth in contemporary Western societies. Suicides by imitation and suicide pacts are studied among teenagers who, it is well known, are vulnerable to this phenomenon.

5.2 Other Suicidal Behaviors

It is only in the 1960s that sociologists began to explore the subject of noncompleted suicides. For some researchers, attempted suicide and completed suicide do not show the same characteristics and therefore constitute two distinct social facts. The attempted suicide is presented either as a typical behavior of egotistic societies or as a form of blackmail or a call for help. Often individuals who attempt suicide are hoping more for an intervention that will reconcile them with their social environment than they are seeking death.

Other sociologists consider noncompleted suicides as part of a process of which the final step is a completed suicide. Maris (1981) underlines the importance of attempted suicides in the suicidal process. Identifying 15 predictors of completed suicides during the lifetime of a suicidal person, he puts forward a model of suicide careers. One of the predictors is the greater number of nonfatal suicide attempts, especially among young women. In fact, a higher frequency of attempted suicides and of 'suicidal ideations'— a concept only timidly discussed in sociology—is generally found among girls.

In their review of the literature published between 1963 and 1993, Arensman and Kerkhof (1996) make a distinction between those whose suicide attempts have been rather weak, those whose attempts have been serious, and those who have ended up killing themselves. For these authors, the link between mild attempts and completed suicides is not shown; they refer to those attempts as parasuicides and reserve the expression 'attempted suicide' for severe attempts.

6. Methods Used

In the wake of Durkheim's work, the analysis of the social factors of suicide was mostly done by means of quantitative and statistical studies of the macrosociological type. Along with its focusing on the suicidal persons themselves, sociology gradually opened itself to qualitative studies of a more microsociological type that favored sociological individualism (see *Macrosociology–Microsociology*).

6.1 Quantitative Studies

Durkheim's use of statistics has been severely criticized, particularly by Douglas (1967), who reproaches Durkheim for choosing statistics that confirmed his theory, while giving scant attention to those that did not. However, the school of Columbia University, especially via Selvin, praised the work of Durkheim and greatly contributed to reviving the interest for his study of suicide in the USA and in France. In particular, Selvin (1958) pointed out the cleverness and the innovative character of Durkheim's statistical analysis, not merely contented with simple correlations but using multivariate analysis to validate the complex links between suicide and many social factors.

Macrosociological studies of suicide involving official statistics continue to abound, indeed are in the majority. The relative inaccuracy of such statistics has been argued by some authors, but the hesitation about using them is less and less relevant in contemporary advanced societies where they enjoy greater credibility (Lester 1997). More and more sophisticated statistical tests allow for rigorous longitudinal analyses, as well as precise verification of the correlations between suicide and numbers of variables: gender, marital status, hereditary and biological characteristics, family history, profession, religious affiliation, ethnic origin, immigration, use of drugs or alcohol, emotional problems, previous suicide attempts, economic, geographical and seasonal context of suicides, and means used to commit suicide.

6.2 *Qualitative Studies*

Correlational studies identify the associations between suicide and different social and psychological factors (see *Positivism: Sociological*), without delving too deeply into the concrete influence such variables actually exert on individuals. With time, sociology, turning more to the person who took his own life, wished to go to the heart of this human and social drama and capture the dynamics and the diversity of its significance. Thus, qualitative studies of suicide were undertaken.

In this type of research, the sociology of suicide often prefers the biographical approach in either of its two forms. It is a life story, if it is reconstructed from accounts and documents furnished by the persons themselves who had suicidal ideas or had attempted suicide. The expression life history refers to accounts given by others as well as to various documents allowing the reconstruction of the person's history in situations of completed suicides.

Baechler (1975) retraces, through accounts written by others, short life histories of individuals who have attempted or completed suicide. Adopting the Weberian idealtype, he ends up with several types of meanings in suicidal behavior, which have been mentioned above. Gratton (1996) writes on her own thorough life stories of some Quebec youngsters who committed suicide, using their personal material left behind as well as 29 in-depth interviews with their kin. On that basis, she constructs four Weberian idealtypes involving, for young people, a lack of connectedness between their values and resources. Two of those idealtypes are centered around the values of the youth, either excessive or inadequate, and two around their resources, either turned powerless or so weak that they depend on others.

Published biographies are used to analyze the suicide of 30 famous people in order to check which theories best clarify the meaning of their suicide. Each biography is analyzed according to situations corresponding to each of the theories. Some theories, such as those of Maris and Shneidman, explain better than others those suicides. The least applicable was Freud's theory.

Suicide notes, in particular, offer a privileged instrument with which to capture the significance that the actors themselves attribute to their suicide. Researchers are more and more sensitive to the analysis of such notes. For example, the collective suicide of Jim Jones and his sect members, in 1978, was investigated through that medium. Seven hundred audiotapes were found at the scene of the drama. The words exchanged between Jones and his followers are deciphered in the light of the Durkheimian concepts of altruistic and fatalistic suicides. The leaders who influenced the collective suicide appear to have committed an altruistic suicide. On the other hand, the climate of despair, hostility, and degradation which reigned in that community seems to have provoked a fatalistic suicide for the majority of Jones' disciples.

Life histories of suicide committers also provide the means to map out their psychological autopsies. At first, these autopsies were meant to retrace the social and psychological events that preceded the suicide, in order to understand their subjective significance. However, even if this instrument is still mentioned by Maris (1981) to establish the life trajectory of suicide victims, it is often used by psychologists and psychiatrists merely in the form of standardized questionnaires, aimed at determining the presence or absence of mental illness in those people. Other researchers, interested in intergenerational suicide behavior, will use the 'génogramme' in the reconstruction of life histories; it is a graphic representation of the main events that marked the history of a family for at least three generations.

In summary, when sociology looks at suicide as a social phenomenon of a group or of a society, it tends to favor quantitative and generalizing approaches coming from the natural sciences. However, as soon as sociology becomes concerned with the social actors themselves who adopt suicidal behavior and with the diversity of their experiences, it turns to cultural sciences and uses qualitative approaches focused on the individuals.

7. *Conclusion*

It seems that, ever since Durkheim, the sociology of suicide has been developing by accretion, advancing in three major stages. First of all, Durkheim's *Le Suicide* was a pioneer text, identifying suicide as a social phenomenon whose causes had to be sought in the society itself. The sociology of suicide thus made its appearance on the scene of theoretical and empirical knowledge. However, in the following 50 years, it

made almost no progress. Durkheim's study reigned practically alone. It did not, during that period, awaken a strong current of research on suicide.

Then, in the 1950s, the sociology of suicide began to flourish, especially in the USA. Sociologists were busy verifying, extending, refining, and revising Durkheim's research. Interest in suicide and its social factors broadened progressively, to include the study of the victims of suicide themselves and of their different suicidal behaviors, and to admit psychosociological and psychological approaches. In this regard, social and clinical psychology, Freud's psychoanalysis and Weber's comprehensive sociology have been determining influences in the development of the sociology of suicide.

In the third stage, the prevailing one at the start of the twenty-first century, the sociology of suicide is diversifying greatly, as much in its research subjects as in its methodological tools. It has become a field of study, called suicidology, that is increasingly complex and autonomous, with stretchable boundaries and where multidisciplinarity takes on more and more importance (Kral 1994). In that regard, it is emphasized that the various disciplines need not be in competition with each other, since their common ground is suicide. What they ought to do is to confront their different bodies of knowledge and articulate them in a common reflection. The recent publication of Maris et al. (1999) bears witness to this necessary sharing of knowledge about suicide.

Simultaneously, interest in the sociology of suicide is rapidly becoming universal, embracing researchers in almost all corners of the world. Studies on the subject abound. A search of *Sociological Abstracts* alone, from 1986 to 1999, reveals more than 150 articles from authors in the UK, France, Germany, Spain, Italy, Switzerland, The Netherlands, Norway, Finland, Iceland, Brazil, New Zealand, Japan, Canada, and notably the USA. Periodicals devoted exclusively to suicide have been published: *Suicide and Life-threatening Behavior, Archives of Suicide Research, Giornale Italiano di Suicidologia*.

Finally, given the gravity of the suicidal phenomenon in several societies or groups, particularly among the youth, suicidologists from all scientific disciplines are no longer content merely to study suicide. More and more they demonstrate the desire and the need to act socially. With the goal of intervening to prevent suicide, they join national and international associations and take part in seminars and colloquia around the world. The sociology of suicide has contributed, as have other disciplines, to the fact that scientific research is nowadays trying to apply itself to improving society.

Sun Exposure and Skin Cancer Prevention

Sun exposure can be defined as the exposure of human beings to natural and artificial ultraviolet radiation (UVR). UVR is a component of natural sunlight and is produced artificially (e.g., by sunbeds) for cosmetic (e.g., to get tanned skin) or medical reasons (e.g., therapy of psoriasis). Sun exposure is the most

important environmental risk factor for all forms of skin cancer (Marks 1995). Sun protection behavior, on the other hand, is the most effective form of skin cancer prevention. This article provides an overview of the incidence and causation of skin cancer, of the psychological conditions for sun exposure and sun protection behavior, and of skin cancer prevention programs.

1. *Skin Cancer: Incidence and Causation*

The two major classes of skin cancer are malignant melanoma (MM) and nonmelanoma skin cancers (NSC; subtypes: basal cell carcinoma, squamous cell carcinoma). In many countries, skin cancer is the cancer with the most rapidly increasing incidence rate. In the United States, the incidence rates of skin cancer are 12.0 per 100,000 Caucasians for MM (mortality rates: men 3.3 per 100,000 people/year, women 1.7) and 236.6 per 100,000 Caucasians for NSC (mortality rates: men 0.7, women 0.3) (Marks 1995). Incidence rates for people with darker skin are much lower (see *Cancer Screening*).

The development of skin cancer depends on constitutional and environmental factors (for an overview, see Marks 1995). The major constitutional factors are skin color, skin reaction to strong sunlight, and, additionally for MM, large numbers of moles, freckles, and family history of MM. The major environmental risk factor for skin cancer is sun exposure. Cumulative sun exposure is related to the development of NSC. For MM, the role of sun exposure is less clear. Increased risk of MM seems to be related to severe sunburns, in particular in childhood, and intermittent recreational sun exposure.

2. *Predictors of Sun Exposure*

Sun exposure not only accompanies many working and recreational outdoor activities, it is also seeked intentionally (for an overview of studies on psychosocial factors of sun exposure, see Arthey and Clarke 1995, Eid and Schwenkmezger 1997). The major motivational predictor for unprotected sun exposure is the desire for a suntan. Level of suntan is related to the perception of other people as being healthy and attractive in a curvilinear manner, with a medium tan considered the healthiest and most attractive skin color. Therefore, getting a suntan helps people to make a good impression on others. The belief that a suntan improves one's physical appearance is the strongest predictor of suntanning. Voluntary sun exposure is related to thinking more about one's physical appearance, to a higher fear of negative evaluations by others, and to a higher body self-consciousness and body self-esteem. In addition to these variables of personal appearance, suntanning is related to a positive attitude toward risk taking in general and to having friends who sunbathe and use sunbeds (see *Health Behavior: Psychosocial Theories*).

3. *Predictors of Sun Protection Behavior*

The harmful effects of UVR on the skin can be prevented by sun protection behavior. The four most important protection behaviors are: (a) Avoiding direct sunlight, particularly during the peak hours of daylight (10 am to 4 pm), (b) seeking shade, (c) wearing a hat, (d) wearing skin-covering clothing, and (e) using sunscreen with a sun protection factor of at least 15. Even in high-risk countries such as Australia, the prevalence rates of these protective behaviors are rather low indicating that about half of the population are inadequately protected on sunny days (e.g., Lower et al. 1998). Voluntary sun exposure and the use of sun protection are two largely independent and only weakly correlated behaviors. Moreover, the predictors for sun protection behavior differ from the predictors for sun exposure. In contrast to sun exposure, appearance-oriented variables are less important for predicting sun protection behavior. The major predictors for sun protection behavior are perceived threat of skin cancer, the benefits and barriers of different sun protection behaviors, social factors, and knowledge about skin cancer (Eid and Schwenkmezger 1997, Hill et al. 1984).

Perceived threat of skin cancer depends on the perceived severity of and the vulnerability to skin cancer. People who rate skin cancer as a severe disease and who think that they are more vulnerable to skin cancer are more likely to use sun protection. Furthermore, individuals with a sensitive and fair skin, both which are more prone to skin cancer, use sun protection more often. This risk perception is strongly related to gender. Women have stronger vulnerability and severity beliefs. Moreover, women use sunscreen more often and apply sunscreen with a higher sun protection factor than men (see *Gender and Cancer* and *Gender and Health Care*).

The actual display of specific sun protection behaviors depends on (a) the belief that these behaviors are effective in preventing skin damage, sunburns, and skin cancer, and (b) the specific barriers of each behavior (Hill et al. 1984). Specific barriers to the application of sunscreen is the belief that sunscreen is greasy and sticky and the fact that sunscreen has to be applied repeatedly. An additional barrier for men is the belief that sunscreen makes men appear seemingly sissy and looks unattractive. Barriers against wearing hats are the beliefs that hats are inconvenient to wear as well as causes problems with hairstyle. Additionally, for men, wearing a hat is associated negatively with the beliefs that wearing a hat causes baldness and a sweaty head, is inconvenient on windy days, and gets in the way when playing sports. The major barriers against

wearing shirts are the discomfort from heat and the feeling of being overdressed. Therefore, a goal of skin cancer prevention programs must be the removal of these specific barriers against sun protection behavior. Because these barriers partly depend on temporary fashion influences, the present-day barriers of specific sun protection behaviors have to be examined before a prevention campaign is planned.

Social factors also have an important influence on sun protection. Use of sun protection is correlated with peers' sun protection behavior, parental influence, and parental sun protection behavior. Furthermore, people who know a person suffering from skin cancer use sun protection more often. Finally, knowledge about the risks of sun exposure has been proven a significant predictor for sun protection in many studies. In particular, people with more knowledge about skin cancer use sunscreen with a higher sun protection factor.

4. *Skin Cancer Prevention*

With respect to the target groups considered, sun exposure and sun protection modification programs can be grouped into three classes: (a) programs using mass media, (b) community intervention programs, and (c) educational programs (for an overview of these programs, see Eid and Schwenkmezger 1997, Loescher et al. 1995, Morris and Elwood 1996, Rossi et al. 1995).

4.1 *Mass Media Programs*

Typical mass media programs use informational pamphlets, comic books, newspaper reports, TV and radio advertisements, or videotapes to carry their messages. These mass media campaigns are either often not evaluated, or the evaluations are published in reports that are not accessible to the public, or the evaluations suffer from methodological problems (e.g., missing control group). However, there are some studies evaluating single videotapes or informational pamphlets by an experimental or control-group design (for an overview see Eid and Schwenkmezger 1997, Morris and Elwood 1996). According to these studies, videotapes and informational pamphlets can increase knowledge about, perceived severity of, and vulnerability to skin cancer, as well as increase individual sun protection intentions. Studies focusing on long-term effects on behavior, however, are missing. Furthermore, these studies show that an emotional prevention video imparting knowledge by employing a person with skin cancer might be more appropriate than a more unemotional presentation of facts. Moreover, educational texts focusing on the negative effects of sun exposure for physical appearance (wrinkles, skin aging) might be more appropriate than texts on the negative health-related consequences. This, however, might only be true for people with a low appearance orientation, whereas appearance-based messages can result in boomerang effects for high appearance-oriented people. Finally, the manner in which a health message is framed is important. Detweiler et al. (1999) demonstrated that messages on sun protection behavior are more effective when they highlight potential positive effects of the displayed sun protection behavior (gain-framed messages) than when they focus on the negative effects of the omitted behavior (loss-framed messages).

4.2 *Community Intervention Programs*

Mass media are often a component of community intervention programs, but community intervention programs can implement several other methods as well (see *Gender and Cancer*). Community-based programs can make use of local peculiarities (e.g., the daily UVR rate in a community) and can focus on local places of risk behavior, for example, swimming pools and beaches. Based on principles of learning theory, Lombard et al. (1991) designed an intervention program with pool lifeguards as models for sun protection behaviors and daily feedback posters of the sun protection behavior displayed the day before. This program was effective with respect to two sun protection behaviors (staying in the shade, wearing shirts) but not other ones. Rossi et al. (1995) describe several new techniques such as special mirrors (sun scanner) and photographs (sun damage instant photography) that have been used in intervention programs on beaches to show the effects of sun damage and photoaging in a more dramatic fashion.

4.3 *Educational Programs*

Because of the cumulative risk of sun exposure and the risks of sunburn in childhood, intervention programs are particularly important for children and adolescents. Educational programs have been developed for students of different ages from preschool to high school (see *Health Promotion in Schools*). In general, these programs are effective in enhancing knowledge about skin cancer and the awareness of the risks of unprotected sun exposure. Changing attitudes toward sun protection, however, have only been found after participation in programs consisting of more than one session. With respect to changes in behavioral intentions the results are inconsistent. Significant changes in intentions have been found in only a few studies and not consistently across the intentions to different behaviors. Changes in observed behavior, however, have not been analyzed. The failure of educational programs in changing behavioral intentions might be

due to the fact that these programs have focused more on motivational than on behavioral factors. Multimethod educational programs including components on the implementation of behavioral routines that are very important for developing health behavior in childhood are desiderata for future research.

5. Future Directions

Sun exposure and skin cancer prevention are relatively new fields of research. Future research will profit from the use of multimethod assessment strategies of behavior that does not only assess self-reported behavioral intentions but also uses observational and physical measures of behavior (e.g., spectrophotometers for measuring the melanin skin content). Furthermore, research on new components of intervention programs is needed. For example, future programs could consist of behavior change methods in addition to attitude change methods as well as strategies for weakening the association between suntan and attractivity.

Supply Chain Management

1. Introduction

Supply chain management is one of the most essential aspects of conducting business. Many people outside of the direct community (in research and industry) do not realize this because an ordinary consumer often experiences only its effects. Recall the times when the item that you wanted was not available in your favorite garments or grocery store, recall how many times you got a great 'deal' at the end of the season, recall the sudden increases in gas prices due to shortages, recall the times when your e-commerce site promised availability but later could not send the required product or sent you the wrong product, or recall the times when your customized product (like a personal computer or kitchen cabinet) was delayed to a great extent. All the above and several other experiences that consumers have on a routine basis are direct consequences of supply chain practices followed by firms. As opposed to business-to-consumer transactions, supply chain practices have immediate impact on business-to-business transactions. A few years back Toyota had to shut down its manufacturing facility in Japan due to supply shortages for its brake pedals, Boeing took a charge for several million dollars in the late 1990s due to insufficient capacity and part shortage resulting from an inability of the supply base to ramp up production, while firms such as Dell Computers, Wal-Mart, and 7-Eleven Japan have consistently outperformed competition due to their great strengths in supply chain management.

2. Definition

Supply chain management is such a vast topic that as a result people often give it a different definition based on their own personal experience. To some, supply chain management is all about managing the supplier base, determining what to outsource and to whom, and managing relationships with the various suppliers. To some others it is efficient ways of transferring goods from one place to another taking into account the distribution and transportation costs. To another set of people it is all about how the different firms in the distribution channel or value chain are integrated in terms of information systems and inventory management practices. To yet another group it is effective management of fixed and variable assets required for running the business. In a sense all these definitions are like the blind men defining the elephant based on its different organs. A comprehensive definition of supply chain management can be given as follows.

A supply chain is the set of entities that are involved in the design of new products and services, procuring

Figure 1
Supply chain process

raw materials, transforming them into semifinished and finished products and delivering them to the end customer. Supply chain management is efficient management of the end-to-end process starting from the design of the product or service to the time when it has been sold, consumed, and finally disposed of by the consumer. This complete process includes product design, procurement, planning and forecasting, production, distribution, fulfillment, and after-sales support (see Fig. 1).

Supply chain management issues can be classified into two broad categories—configuration and coordination. Configuration-level issues relate to the basic infrastructure on which the supply chain executes and coordination-level issues relate to the actual execution of the supply chain.

2.1 Configuration-level Issues

2.1.1 Supply base decisions. How many and what kinds of suppliers to have? Which parts to outsource and which to keep in house? How to standardize and streamline procurement practices? Should one use vertical marketplaces for auctions or should one invest in developing highly integrated supply partnerships? How long or short contracts with suppliers should be?

2.1.2 Plant location decisions. Where and how many manufacturing, distribution, or retail outlets to have in a global production distribution network? How much capacity should be installed at each of these sites? What kind of distribution channel should a firm utilize—traditional brick and mortar, direct to consumer via Internet or phone, or a combination?

2.1.3 Product portfolio decisions. What kinds of products and services are going to be supported through the supply chain? How much variety to provide to customers? What degree of commonality to have across the product portfolio?

2.1.4 Information support decisions. Should enterprise resource planning software be standardized across functional units of a firm? Should the supply chain work on standard protocols such as XML (extended markup language) or on proprietary standards?

2.2 Coordination-level Issues

2.2.1 Material flow decisions. How much inventory of different types of products should be stored? Should inventory be carried in finished form or semifinished form? How often should inventory be replenished? Should a firm make all of its inventory decisions or is it better to have the vendor manage the inventory? Should suppliers be required to deliver goods just in time?

2.2.2 Information flow decisions. In what form is information shared between different entities in the supply chain—paper, voice via telephone, EDI (electronic data interchange), XML? To what degree does collaborative forecasting take place in the supply chain? What kind of visibility is provided to other entities in the supply chain during execution? How much collaboration takes place during new product or service development among the supply chain partners?

2.2.3 Cash flow decisions. When do suppliers get paid for their deliveries? What kinds of cost reduction

efforts are taken across the supply chain (or expected of suppliers)? In a global firm, in which currency will a supplier be paid?

2.2.4 Capacity decisions. How to optimally utilize the existing capacity in terms of manpower and machines? How to schedule on a manufacturing line to complete jobs on time? How much buffer capacity to have for abnormal situations with excess demand?

As is evident, configuration and coordination issues are interdependent. Configuration issues can be viewed as strategic long-term decisions whereas coordination issues are medium-to-short term decisions. Generally, firms develop a strategy for the configuration-level decisions and then constrain the coordination decisions based on those.

3. Complexities Associated with Supply Chains

As evident from discussions in the earlier section, supply chain management spans several functional and geographical areas. This introduces complexities both in terms of design and execution of supply chains. Some of the pertinent factors that complicate supply chain management decisions are as follows.

3.1 Multiple Agents

Supply chain issues need to be decided by different entities sometimes having different interests. For example, a retailer may want that the distributor provide very high availability for the products but at the same time not charge anything additional from the retailer. The distributor may sometimes agree to that but in turn may want information about actual customer sales which the retailer may not want to share. Even when decisions have to be made within the same firm there could be incentive issues. For example, the marketing or sales department, typically a revenue center, presents the future demand forecast to the manufacturing department that is a cost center. Clearly, there is incentive for the former to over-forecast and the latter to under-produce (as compared to the forecast). This creates several difficulties while deciding on the amount of inventory to be stocked. Another related issue is encountered where the marketing department may push for huge amount of variety in the product/service offerings; the manufacturing department may not want to embrace that because additional complexities are created during execution.

3.2 Uncertainty

Accurately matching supply and demand is the ultimate goal of effective supply chain management but that is complicated by uncertainty at various levels of the process. There is uncertainty in product and technology development, in predicting customer demand, in day-to-day operations and manufacturing, and supply. Typically, uncertainty creates more inefficiency in the system. For example, if the final demand for a sweater at a store cannot be predicted accurately then the firm either stocks too little (in which case it suffers from stock-outs) or produces too much (in which case it has to salvage the inventory through a huge sale at the end of the season). Similarly, the uncertainty in supply may necessitate additional buffer inventory.

3.3 Information Asymmetry

Since supply chain processes extend across multiple functional units within a firm and often across different firms there is a high degree of asymmetry in terms of information. This is caused primarily by two main reasons—one relates to lack of adoption of information technology and the other relates to reluctance to share information with other supply chain partners. The lack of information causes several problems during actual fulfillment. For example, when a consumer goes to an e-commerce site and buys an item off the electronic catalog, the consumer expects to receive the product on time. The consumer is not aware that the inventory status on the product may be updated only once a week and that the information on the site may be outdated. As a result, the consumer is disappointed when the product does not arrive on time.

3.4 Lead Time

Each and every task in the supply chain process needs time to be completed and the resources (labor, machines, or computers) have limited processing capacity. As a result, not all tasks can be completed after the actual demand is known and some of the tasks need to be done up front (which may or may not get utilized based on the actual demand realized). Further, the limited capacity associated with the resources creates variability in the actual realized lead-time, which in turn necessitates greater resource requirements at the next stage in the supply chain. The above complexities lead to several types of inefficiencies in the supply chain that are often perceived as the 'bad effects' of inefficient supply chain management. Some of the major inefficiencies can be classified into the following categories.

4. Inefficiencies of Supply Chain Management

4.1 Poor Utilization of Inventory Assets

One common effect of poor supply chain management is having excess inventory at various stages in the

supply chain, at the same time having shortages at other parts of the supply chain. Since inventory forms a substantial part of working assets of a firm, poor management could lead to huge inefficiencies. Lee and Billington (1992) provide an excellent overview of pitfalls and opportunities associated with inventory management in supply chains.

4.2 Distortion of Information

Another effect relates to lack of visibility of demand and supply information across the supply chain which causes the bullwhip effect. This effect describes how a small blip in customer demands may get amplified down the supply chain because the different entities in the supply chain generate and revise their individual forecasts and do not collaborate and share actual demand information. Lee et al. (1997) describe the causes and controls for this effect.

4.3 Stock-outs

Poor supply chain management also results in late deliveries and large stock-outs. Fundamentally, these effects are caused due to an inability of the firm to predict the requirement for raw material and equipment capacity together with the uncertainty associated with obtaining deliveries of products on time from its suppliers. Fisher et al. (1994) describe how accurate forecasts in the apparel industry could potentially reduce this inefficiency.

4.4 Customization Challenges

As the degree of customization has increased in the marketplace, one of the immediate effects of poor supply chain management relates to late deliveries of customized products. Firms are developing several strategies in order to provide variety while keeping costs under control. These include delaying differentiation of the product and introducing more commonality and modularity in product lines (see Swaminathan and Tayur 1998).

5. Supply Chain Models: Past, Present, and Future

The science related to supply chain management traces its history back to the early 1950s when several researchers were interested in understanding the optimal policies related to inventory management. One of the first pieces of work in this stream relates to the models developed by Clark and Scarf (1958) for managing inventories at multiple echelons. Several hundreds of researchers have studied related inventory problems under stochastic and deterministic environments since the 1950s.

This research is captured concisely in the research handbook edited by Graves et al. (1993). There is a large amount of literature in the area of transportation and distribution as well as plant location models in the context of supply chain management. Traditional researchers focussed on developing optimal policies and rules for specific supply chain issues assuming a centralized control of the supply chain. In the 1990s researchers have started to study problems which take a decentralized multi-agent approach to analyzing supply chain problems, integrate information availability across the supply chain with logistics decisions, develop new models for supply contracts, and demand forecasting and integrate product design with supply chain management. A collection of prominent pieces of research in this area is contained in Tayur et al. (1999). In addition to academic research, several firms in the 1990s have developed successfully and employed large analytical and simulation models for supply chain optimization and execution. Arntzen et al. (1995) describe one such system developed for Digital Equipment and recently, IBM was awarded the Franz Edelman Award by INFORMS (The Institute for Operations Research and Management Sciences) for a supply chain optimization project which led to $750 million in inventory savings.

In the twenty-first century, firms face severe challenges in terms of global competition and customer requirement for greater variety, shorter and reliable delivery times, and lower prices. The advent of e-commerce has created immense opportunities but at the same time has made firms more vulnerable to logistics pitfalls. Today customers do not just buy products but they buy delivered products. As a result fulfillment is as important as making the sale. As opposed to traditional channels where inventory could be stored to hide other inefficiencies in terms of lead time and poor forecasts, in the fast-paced electronic business environment such arrangements are not as useful. As a result, firms are beginning to pay more attention towards supply chain management. Both business-to-consumer and business-to-business e-commerce environments have introduced several issues related to supply chain management which are likely to be studied by researchers in the near future.

The prevalence of the Internet has led to the development of vertical market places that promise to reduce the inefficiencies in the buying process in several industries. On one hand, these market places are likely to reduce the cost of goods for the manufacturer due to more competition leading to better prices. This line of thought indicates that in future supply chains may be more agile and supplier relationships may be short-term oriented. On the other hand, several firms realize that greater benefits can be attained if some of these market places can in fact be used for process integration and collaboration across the supply chain.

In such an environment, firms need to develop greater trust so that they would be willing to share information with their supply chain partners. Researchers today are trying to identify under what conditions one or the other scenario may play out and what kinds of new models and analysis need to be developed. A related effect of the Internet is the expansion of global supply chains. Today it is much easier for any supplier located in a remote part of the world to bid on contracts from large firms in developed nations with whom they may not have done business in the past. Issues related to coordination of global supply chain management are likely to be an integral part of supply chain management research in the future. Another important research topic is the reverse logistics issues related to supply chain management. Traditionally, researchers have only concerned themselves with efficient movement of goods from supplier to the customer. Now a greater number of researchers are studying problems related to disposal of used products, refurbishing old products, making packaging more environmentally friendly, and basing supplier selection on environmental criteria in addition to traditional criteria related to cost, quality, and reliability. Another new stream of research is the study of supply chains in the service industry. As opposed to traditional manufacturing-oriented supply chains, service supply chains are more complicated due to the inability to store inventory. Uncertainty is handled in those cases using additional buffer capacity. Finally, researchers are beginning to focus more on the integration of product design and supply chains and developing models to understand the concepts related to design for supply chain management.

Support and Self-help Groups and Health

1. Nature and Use of Self-help and Support Groups

As psychosocial interventions, support groups and mutual aid, self-help (MASH) groups have a great deal in common. Their members share a similar health concern, life event, role transition, or chronic stressor, and they exchange a variety of types of support through face-to-face interaction, bringing to bear their experiential knowledge to gain an understanding of their personal and collective predicament and of ways of coping with it. The differences between these two small group structures are that support groups are organized, governed, and led by professionals who provide supplementary expert knowledge or skill training, whereas MASH groups are self-governing, and led by individuals who are peers by virtue of sharing the group's problem or concern. In addition, support groups tend to have a closed membership whereas MASH groups are open, and support groups tend to have a fixed duration whereas MASH groups are indefinite in duration. Finally, some MASH organizations engage in advocacy efforts on behalf of marginalized or vulnerable segments of the population (Reissman and Carroll 1995), whereas support groups tend to look inward rather than outward. Both support and MASH groups differ quite dramatically from therapy groups; the leader does not engage in any clinical activities, such as psychological assessment, and the members are not assigned to a group on the basis of their symptomatology, diagnostic label, or prognosis.

A recent national US survey revealed that approximately 7 percent of adults had participated in a MASH group in the prior 12 months, and 18 percent had done so at some point in their lifetime (Kessler et al. 1997). A similar study in Canada, also based on a national probability sample, revealed a much lower prevalence of 2 percent of adults who had participated in a MASH group in the prior 12 months (Gottlieb and Peters 1991). Perhaps the self-help ethos is stronger in the US than in Canada, where a national healthcare system may also serve as a disincentive to MASH participation. Humphreys and Klaw (1998) report

that, in the US, there are MASH organizations for almost every major chronic condition and leading cause of mortality. Examples of the former include groups for arthritis sufferers, people diagnosed with ischemic heart disease, cancer patients, diabetics, and people with hearing and visual impairments. MASH organizations are heavily utilized by people with substance abuse and emotional problems, Alcoholics Anonymous (AA) being the most widely used of all MASH organizations and probably the most widely accepted by professional referral agents such as family physicians and addictions counselors. AA also has been subjected to more evaluation research than other MASH groups, one recent study finding that, over three years, participants decreased their daily alcohol intake by 75 percent while also effecting substantial cost savings relative to those receiving professional outpatient treatment (Humphreys and Moos 1996).

Although no corresponding census has been taken of public participation in support groups, prior reviews of the literature have spotlighted the abundance of groups for cancer patients (Fawzy et al. 1995, Helgeson and Cohen 1996), family caregivers of older adults, particularly those suffering from dementia (Bourgeois et al. 1996, Lavoie 1995, Toseland and Rossiter 1989), and people coping with loss through death or divorce (Hughes 1988). The fact that support groups have been subjected to far more research than MASH groups testifies to the greater ease of access they provide, due in part to their professional sponsorship and more casual attitude toward maintaining anonymity.

Both support and MASH groups function as specialized personal communities that supplement or compensate for deficiencies in the participants' natural networks (Helgeson and Gottlieb 2000). These deficiencies may stem from the natural network's inability to comprehend or tolerate the thoughts, feelings, and behaviors that arise from relatively novel stressors, the network's impatience with or exhaustion from lengthy periods of rendering support and aid, or from other interpersonal dynamics that compromise the network's prosocial behaviors, such as conflicts about appropriate ways of coping (Gottlieb and Wagner 1991) and emotional overinvolvement (Coyne et al. 1988). In some circumstances, coparticipants substitute for a natural network that has proved destructive, such as when the fellowship offered by AA supercedes former drinking buddies (Humphreys and Noke 1997). In some contexts coparticipants serve functions complementary to the natural network's, such as when a weight loss group helps to maintain the gains effected by dietary changes at home.

2. *Group Design and Dynamics*

From the perspective of an observer, meetings of MASH groups and support groups would be virtually indistinguishable except for two differences. First, the support group would devote a portion of its time to education or training provided by an expert, whereas the MASH group would devote the entire meeting to the swapping of experiences and the exchange of support. Second, many, but not all MASH groups would operate on a 12-step model or a variation thereof, which consists of quite elaborate ideological formulations about the cause and source of difficulty and about the ways members need to think about their situations in order to come to terms or resolve them (Antze 1976). Underlying the 12-step belief system are the ideas of spiritual surrender and personal struggle, along with the need for moral cleansing and mutual aid. In contrast, support groups rarely import an ideology but develop their own norms, with whatever cognitive restructuring occurring as a result of the resources introduced by the professional leader and the influences arising from the members' interactions.

Aside from these two differences, the same set of structural elements need to be considered in designing both MASH and support groups. These include: (a) the setting and scheduling of the group sessions, including their number, length, duration, and intervals; (b) the leadership, which may be consistent or rotating, and involve one or two (co-led) facilitators; (c) the group composition, taking into account demographic (e.g., age, gender, socioeconomic status), stressor-related (e.g., stage, severity), and coping-related (e.g., extent of distress and resource mobilization) criteria; and (d) the format, including the extent of meeting structure, extra-group contacts among members, and behavioral training. To date, there has been relatively little research comparing the effects on both the process and outcomes, as well as attrition, resulting from systematic manipulation of these structural elements. For example, little is known about ways of composing the groups to optimize the social comparisons that members make, and whether aspects of the social mix or of the problem they share more strongly affect members' attraction, participation, social learning and supportive exchanges in the group (Gottlieb 1998).

The beneficial psychosocial dynamics that underlie the mutual aid occurring in both support and MASH groups include the emotional venting along with the validation and normalization of emotions that are gained from contact with similarly afflicted peers, the opportunity to enhance one's sense of worth and control by providing support to others, a process that has been called helper-therapy (Riessman 1965), and the opportunities for self-enhancement and self-improvement that derive from the social comparisons that members make. These latter comparisons may take an upward, downward, or lateral direction, ideally respectively serving self-improvement, self-enhancement, and normalizing functions. For example, in a widely cited study, Taylor (1983) found that the vast majority of women with breast cancer

found a real or imagined dimension on which they compared more favorably to other women with the same diagnosis.

These psychosocial dynamics have yet to be integrated within a comprehensive model of the process through which support and MASH groups exert an impact on health outcomes, whether psychiatric or medical. That is, to understand the mechanisms of action through which these psychosocial dynamics influence health and morale, competing theoretical models should be specified and tested. Cohen (1988), Stroebe et al. (1996), and Wills and Filer (1999) have described several potential direct and indirect pathways through which social support may affect health, including physiological mechanisms, appraisal and reactivity mechanisms, and behavioral mechanisms of action. For example, it is presently unknown whether the increased survival time documented by Spiegel et al. (1989) and Fawzy et al. (1993) for women with metastatic breast cancer and malignant melanoma respectively resulted from mediating improvements in their immune and endocrine function, the enhancement of positive health behaviors such as diet, exercise, and compliance with their therapy regime, or a purely psychological process involving hope and a sense of being needed by interdependent group members. Naturally, there may also be a complex interaction among these mechanisms. The important point is that support and MASH groups that are informed by these models should be designed to impact the hypothesized mediating processes, and measures that are sensitive to change in these processes must also be included.

3. *Group Impacts*

Evaluation of the effects of MASH groups has consisted largely of feedback regarding consumer satisfaction, not randomized controlled trials that administer standardized outcome measures at several intervals following the intervention. Indeed, since most MASH groups are open-ended in nature, allowing members to flexibly come and go as their needs dictate, it is virtually impossible to assess anything that resembles a uniform intervention. Moreover, many MASH groups are not oriented to personal change, recovery, or improved adjustment; instead, they offer acceptance, support, and fellowship to people who feel marginalized (e.g., people with developmental disabilities) or who have been stigmatized (e.g., people with mental illnesses), or people who live with and care for someone who has one of those statuses. In short, many MASH groups view support as an end in itself rather than as a means to other ends, rendering conventional outcome evaluation irrelevant.

Those MASH groups that have been rigorously evaluated consist of both *ad hoc* groups designed along self-help principles and groups that are part of a MASH organization, such as AA. Examples of *ad hoc* groups are parents of premature infants (Minde et al. 1980), bereaved wives (Marmar et al. 1988), and older adult men who have diabetes (Gilden et al. 1992). All three of these studies report significant desirable health effects that lasted for several months after the group ended, compared to less effective or equally effective but more costly comparison interventions such as psychotherapy. Though limited in number, evaluations of groups that are part of a larger MASH organization show similar beneficial effects, including Humphreys and Moos' (1996) study of participants in AA, and Lieberman and Videka-Sherman's (1986) study of bereaved participants in THEOS (They Help Each Other Spiritually). One provocative finding of the latter study is that participants who developed friendships through their group experience achieved significantly better adjustment than those who did not, suggesting that MASH group effects are magnified for those who have the social skills, personality, or motivation to convert a tie based on shared organizational membership and stressful circumstances into a strong personal tie.

As previously noted, there exist far more evaluations of the health impact of support groups than of MASH groups, including review papers on groups for cancer patients, the family caregivers of elderly persons with dementia, and the bereaved. Both within and across these three stressor contexts there is much variability in the characteristics of the participants, the structure, content, and format of the meetings, and the measures used to tap the intended effects. The only constant is the 'dosage,' with the vast majority of groups meeting between 6 and 10 times for 1–2 h on each occasion. As for the impacts, there seems to be far more consensus about the limited impact of support groups for family caregivers than for the other two stressor contexts.

Specifically, the evidence shows that the mental health of family caregivers does not improve much from such a brief intervention, but that longer-term groups and groups that involve skill training that is tailored to situational demands and needs effect larger gains, whether measured in terms of general (e.g., depressive affect and anxiety) or domain specific (e.g., role performance and hostility toward the recipient of care) indicators (Gottlieb 1998, Lavoie 1995, Toseland and Rossiter 1989, Ostwald et al. 1999). It appears that a short-term intervention is not matched appropriately to the chronic character of the caregiving experience, and it is also hard to see how such a limited group experience can mitigate the distress that is a natural biproduct of helplessly witnessing the deterioration of a family member.

Fawzy et al. (1995) also concluded their review of the effects of support groups for cancer patients with the recommendation that short-term groups were best suited to the needs of newly diagnosed patients who are early in their treatment, whereas long-term groups were better suited to those with advanced metastatic disease. An example of the latter is a year-long support

group intervention that involved weekly 90-min meetings plus abundant extra-group contact among the members, women who had metastatic breast cancer (see *Gender and Cancer*). Co-led by a professional and a counselor whose breast cancer was in remission, the group achieved better adjustment (e.g., mood disturbance, tension-anxiety, vigor, confusion) than a control group by the 12-month measurement interval, but not by the two preceding 4-month and 8-month intervals. Moreover, by the time of the 10-year follow-up, the support group participants had increased their survival time by 18 months relative to the control group. Although this study gives reason for optimism about the health benefits of longer-term support groups, the findings must be replicated before any definitive conclusions can be drawn. Moreover, future research should devote more attention to identifying the mechanisms underlying the group's ameliorative effects and determining which subgroups of participants and which disease diagnoses benefit most from this type of psychosocial intervention. Clearly, people who are more extraverted, inclined to cope by seeking information and venting their feelings, and have the skills and motivation to form attachments with co-participants, are more likely to be attracted to this medium in the first place and perhaps more prone to benefit from the provisions it supplies. Conceivably, the group offers a sense of belonging and being needed by others, and these perceptions may stimulate more active immune system functioning, which may account for the superior outcomes that have been observed.

Helgeson and Cohen (1996) limited their review of psychosocial interventions for cancer patients to a comparison of peer support vs. education vs. combined support and education groups. The former concentrate on the provision of emotional support, whereas the latter mainly deliver informational support. Although their conclusions are hedged due to the numerous methodological weaknesses of the studies and differences in the samples and disease sites and stages, they offer important insights into the mechanisms that may be implicated in psychological and physical adjustment to cancer (see *Cancer: Psychosocial Aspects*). These mechanisms include enhanced self-esteem, gains in perceived control, optimism regarding the future, improved processing of emotions, and opportunities to derive meaning from their adversity. These and other pathways, including biobehavioral processes, deserve greater scrutiny in future intervention trials.

Support groups for people who have experienced losses through death or divorce have proved to speed the adjustment process, compared to people who have not used any professional or mutual aid resource (Bloom et al. 1985, Hughes 1988, Vachon et al. 1980, Silverman 1986). Groups for children whose parents have divorced have also been found to foster improved behavioral, academic, psychological and social adjustment (see Grych and Fincham, 1992, for a review). Support groups have also been offered to adolescents with eating disorders and to children of varying ages who have a parent with a mood disorder (Beardslee et al. 1993) or with an alcohol or substance abuse problem (Emshoff 1990).

Evaluation of support groups is complicated by the fact that these interventions usually consist of multiple active ingredients, not just the support that is exchanged among the members. In fact, in a rare comparison of support groups with and without a skill-training component, Stolberg and Mahler (1994) found that the group that lacked skills training was no more effective than the control group for children whose parents had divorced. More studies that adopt such a dismantling design (West et al. 1993) need to be conducted in order to demonstrate that changes in social support are responsible at least in part for improved outcomes. This means that measures of support need to be taken and then related to the distal outcomes of the intervention as a strategy of confirming the mediating role of support.

Finally, recognizing that many people who might be attracted to a support group live in geographically remote communities, have disabilities that limit their mobility, or prefer not to divulge their identity, a number of investigators have implemented computer-mediated groups, using the technology that has recently become available at relatively low cost. For example, Dunham et al. (1998) trained 50 poor, young, single mothers to use a bulletin board system to post both private and network-wide messages to one another and to hold text-based teleconferences with up to eight mothers at a time. With the mothers' permission, Dunham et al. (1998) analyzed the extent and nature of the participants' communications, and found a significant pre- to post-test decrease in parenting stress for those mothers who participated consistently over the 6-month study period. Telephone support groups have also been implemented for family caregivers of persons with dementia (Goodman and Pynoos 1990), a vulnerable population that is largely home-bound. A distinct psychological advantage of support groups that use computer and telephone media is that they moderate the emotional intensity of the group experience, which in turn may decrease its threat. On the other hand, without direct exposure to the other group members, the social comparison process (see *Social Comparison, Psychology of*) may be more limited and the possibility of friendship formation, which has proved to be so vital in the bereavement and cancer studies reviewed earlier, is diminished.

4. *Conclusion*

MASH and support groups are relatively low-cost and highly accessible helping resources that promote health and well being through many psychological

processes. In the health field, these groups have been employed both as an alternative and a complement to professional services. Moreover, as the actual and potential health benefits of these groups become more widely recognized, mutual aid strategies are more likely to become integrated within health care and health promotion programs (Humphreys and Klaw 1998). More systematic investigation of different ways of structuring the groups and tailoring them to the needs and coping styles of prospective members, promises to augment their attractiveness and health impacts.

B. H. Gottlieb

Suprachiasmatic Nucleus

The suprachiasmatic nucleus (SCN) of the hypothalamus is the principal circadian pacemaker in the mammalian brain and, as such, it generates circadian rhythms in rest and activity, core body temperature, neuroendocrine function, autonomic function, memory and psychomotor performance, and a host of other behavioral and physiological processes. The SCN is the central player in an important neural system, the circadian timing system (CTS).

1. Circadian Rhythms are Adaptations to the Solar Cycle

The physical environment of living organisms presents extraordinarily diverse circumstances requiring complex adaptations. The most prominent, regularly recurring stimulus in the physical environment is the solar cycle of light and dark and, not surprisingly, nearly all species, plant and animal, have evolved daily rhythms in organismal functions and behavior in response to the solar cycle which enhance adaptation and survival. Such rhythms, when they have special properties, to be outlined below, are designated circadian rhythms. Circadian rhythms are found in nearly all living organisms, from prokaryotes through eukaryotes, from simple to higher plants, and simple invertebrates to the human. The nature of these rhythms is diverse but in mammals, the major subject of this article, the most evident expression of circadian function is the sleep–wake cycle. This rhythm, and associated rhythms in physiological and endocrine functions, are expressions of the activity of a specialized neural system, the CTS.

Mammals present two patterns of behavioral adaptation to the solar cycle. In those species in which olfaction and audition dominate the animals' perception of their environment, the rest-activity (sleep–wake) rhythm is 'nocturnal'; the animals are awake at night and sleep during the day. In animals in which vision is the major sensory modality, the rest-activity rhythm is diurnal with activity during the day and rest at night. The nocturnal pattern is typical of rodents and carnivores, for example, whereas the diurnal pattern is exemplified by birds and primates.

2. Circadian Rhythms Have Two Principal Properties

Under normal conditions of the light-dark cycle, circadian rhythms have a period of exactly 24 hours. If photic cues are removed, however, by placing animals in constant darkness or constant light, the rhythms are maintained but with a period that differs from 24 hours. In the first circumstance, in which the period of the rhythm is the same as that of the solar cycle, the rhythm is said to be 'entrained.' When the period differs from 24 hours in constant conditions, the rhythm is termed 'free-running' (Fig. 1). These two properties, entrainment and endogenous maintenance of free-running rhythmicity, provide us with insight into the necessary organization of the CTS. That is, the phenomenon of a free-run in the absence of environmental cues indicates that circadian rhythmicity is generated by a clock-pacemaker within the animal. Entrainment implies that photoreceptors and a visual pathway to the clock-pacemaker are necessary components of the system and the diverse functions under circadian control imply the presence of pathways from the clock-pacemaker to sites expressing effector rhythms (Fig. 1). The effect of circadian regulation is not to alter a function but to provide a temporal organization for its expression.

3. The SCN is the Center of the CTS

3.1 The SCN is an Endogenous Circadian Pacemaker

The SCN is a small, paired hypothalamic nucleus that lies immediately about the optic chiasm and just lateral to the third ventricle in all mammals. Typically it is composed of small neurons that are compactly organized. There are four lines of evidence supporting the conclusion that the SCN is a circadian pacemaker.

Figure 1
The left panel shows an entrained and free-running rhythm in diagram. Each line represents a day and the length of the line would be the duration of the walking period in a wake–sleep cycle. LD refers to a light–dark cycle and DD to constant darkness. The first six days are entrained in LD and the last six free-running in DD. The right panel is a representation of the circadian timing system with light acting upon retinal photoreceptors to be transduced to neural information to be carried through an entrainment pathway to the pacemaker. The pacemaker generates a circadian signal which is transmitted to effector systems which express circadian regulation of function

3.1.1 The SCN is the site of termination of the retinohypothalamic tract—an essential entrainment pathway. For an explanation of this, see below.

3.1.2 Ablation of the SCN abolishes circadian rhythms. The initial studies of SCN ablation were performed in the early 1970s. Following these lesions, there is a complete loss of temporal organization of functions under circadian regulation. For example, SCN-lesioned animals show an arrhythmic pattern of sleep-wake behavior yet the amount of time spent awake is normal as is the amount of time spent in REM and non-REM sleep. Similarly, the rhythm in adrenal steroid secretion is lost but the total amount of steroid secreted is normal and responses to stress are maintained. Thus, in these and many other functions, the effect of SCN lesions is only to alter the temporal organization of functions, not the functions themselves.

3.1.3 Circadian rhythmicity is maintained in the SCN in isolation in vivo and in vitro. In elegant experiments, Inouye and Kawamura were able to isolate the SCN from the rest of the brain in intact animals and record from SCN neurons in these animals. Although the animals were arrhythmic in behavior, and other brain areas lost rhythms in neuronal firing, SCN neurons maintained a stable rhythm of firing with high levels during the day and low levels at night, and the firing rate rhythm free-runs in constant conditions. Subsequent studies by a number of investigators confirmed these observations in SCNs maintained *in vitro* in the absence of the rest of the brain. This has not been found for other brain areas. Thus, the SCN is a unique brain area in that it main-

tains rhythmicity in isolation both from environmental cues and input from other brain areas.

3.1.4 Circadian rhythmicity is restored in SCN-lesioned animals that receive transplants of fetal SCNs. In arrhythmic animals with SCN lesions, placement of small transplants of fetal hypothalamus containing the SCN into the third ventricle restores the circadian sleep–wake rhythm. The transplants must contain SCN tissue and be placed in the relative vicinity of the lesioned area to be effective. It was unclear until recently how the transplants functioned but work by Silver and Lehman and co-workers, who were early leaders in the transplant studies, showed conclusively that the transplants can communicate with the rest of the brain through a humoral signal released into the cerebrospinal fluid to diffuse into the adjacent brain, hypothalamus and thalamus. These data on transplantation of SCN provide the final, conclusive evidence that the SCN is the principal circadian pacemaker.

3.1.5 SCN Neurons are circadian oscillators. There are two potential mechanisms by which the SCN might generate circadian rhythms. The first is that individual SCN neurons are born as circadian oscillators that are then coupled to make a pacemaker. The second is that circadian function arises as an emergent property of coupled SCN neurons which are not themselves oscillators. The SCN is formed embryologically from precursor cells located in the diencephalic germinal epithelium. As these precursor cells divide, the newly formed neurons migrate from the germinal epithelium to form the SCN. In the rat, the most extensively studied species, SCN neurons are formed in late prenatal life with the process completed by three days before birth. At 2 days before birth, the SCN is very primitive and contains no synapses, indicating that its neurons do not participate in a neural network. Nonetheless, a circadian rhythm in glucose utilization appears in the SCN on that day, and this is not generated by maternal influences, or other fetal influences, indicating that SCN neurons have become rhythmic and, hence, at least a subset must be individual circadian oscillators. Subsequently, the neurons are coupled through neural connections to make a pacemaker. The validity of this interpretation of SCN organization is shown by other studies in which individual SCN neurons, isolated in tissue culture, exhibit circadian rhythms in firing rate. This type of pacemaker organization is also consonant with observations on invertebrate pacemakers.

3.1.6 Circadian function in the SCN is genetically determined and generated through protein interactions. Data presented over many years have established that circadian rhythmicity is a genetically-determined function. Among the studies contributing to this understanding are experiments in Neurospora and Drosophila that have indicated the existence of clock genes. Beginning in the mid-1980s, clock genes were cloned and analyzed, largely by Dunlap and his co-workers for Neurospora and by Hall, Rosbash, and Young for Drosophila. This work shows that circadian rhythmicity, at the molecular-cellular level, is the expression of clock genes producing proteins that, in turn, regulate expression of the clock genes, that is, the clock mechanism can be viewed as a simple feedback loop. This field is evolving very rapidly at present and recent findings indicate that there is a substantial conservation of function from invertebrates to mammals. Homologues of the Drosophila clock genes are present in the mammalian SCN and cycle in a pattern similar to that in Drosophila. This work will continue to expand rapidly and we should expect a reasonably complete understanding of the molecular-cellular events underlying circadian rhythmicity in the mammalian SCN to be elucidated in the near future.

3.2 The SCN is Coupled to Effector Systems by Neural Pathways

The major output of the SCN is to hypothalamus and thalamus with very limited projections to basal forebrain. Within this context, the densest projections are to anterior hypothalamus for the control of body temperature and autonomic function and to the paraventricular and arcuate nuclei for neuroendocrine regulation and to the posterior hypothalamus and thalamus for behavioral state regulation. Thus, these projections form the basis circadian control of effector systems. A scheme for this is shown diagrammatically in Fig. 2.

4. The SCN in Nonmammalian Vertebrates

There appears to be an SCN, or an SCN homologue, in the brains of all vertebrates. The function of the SCN, however, differs in nonmammalian vertebrates in comparison to mammals. As described above, the SCN is the circadian pacemaker responsible for the temporal organization of behavior into 24-hour sleep-wake cycles in virtually all mammals. Relatively little work has been done on fish, amphibia, and reptiles but birds have been studied extensively. In avian species there are three patterns of organization of the circadian timing system. The first, represented by the domestic chicken, is somewhat similar to mammals. The SCN is the pacemaker responsible for the temporal organization of behavior but the pineal is

Figure 2
Diagrammatic representation of the functional organization of SCN control of effector system

capable of independent circadian activity. The second, represented by passerine species, differs in that the pineal is the principal pacemaker but the pineal acts through effects on the SCN, that is, if the pineal is removed from animals in constant conditions, the animals become arrhythmic and transplantation of the pineal to the anterior chamber of the eye restores rhythmicity. If the SCN is ablated in animals with intact pineals, behavioral rhythmicity is lost even though the pineal continues to put out a rhythmic signal. The third variation, seen in some quail species, is characterized by three structures, the pineal, SCN, and retina being capable of generating rhythmicity. Thus, in avian species, the SCN, the pineal or the retina are potential circadian pacemakers. This is of interest in that recent data indicate that the mammalian retina is capable of generating intrinsic circadian rhythms and there is some evidence that mammals can exhibit a very limited amount of circadian function in the absence of the SCN. This is only evident in specialized environmental situations and, under usual circumstances, SCN-lesioned animals do not recover circadian function and remain arrhythmic throughout their lives.

5. *Conclusions*

The adaptation of animals to their environment is characterized by a temporal organization of behavior into cycles of rest (sleep) and activity. In mammals, this temporal organization of behavior, facilitated by a precise temporal organization of physiological, neural, and endocrine processes is established by a small, paired hypothalamic nucleus, the suprachiasmatic nucleus. The suprachiasmatic nucleus is comprised of individual neuronal oscillators coupled to constitute a network that functions as a circadian pacemaker. The precise output of the pacemaker is modulated by photic and nonphotic neural afferents to provide maximal adaptation. This output acts predominantly through connections to hypothalamus and, to a lesser extent, to thalamus and basal forebrain. Although limited, these connections orchestrate the precise pattern of behavioral and physiological processes that represent the circadian contribution to adaptation.

Suprasegmentals

Suprasegmental features of speech are associated with stretches that are larger than the segment (whether vowel or consonant), in particular *pitch*, *stress*, and *duration* (Lehiste 1970). Respectively, these terms refer to the sensation of higher and lower tone, to the prominence patterns of words, and to durational differences between segments, whether between different segments or between pronunciations of the same segment in different contexts. In general, speech can be analyzed from two points of view: the phonetic reality, most readily accessible as the acoustic speech wave form, but equally present in the articulatory behavior of the speaker and the perceptual analysis of the auditory signal by the listener, and the discrete mental representation which serves as the set of instructions from which the phonetic signal is built by the speaker. One way of structuring a discussion of this topic is to take these three suprasegmental features as a point of departure, consider their somewhat varied manifestations at the different stages of the speech chain, that is, their articulation, acoustics, and perception, and tabulate the ways in which they function in languages. This approach would reveal that the terms pitch, stress, and duration do not refer to concepts at a single stage in the speech chain. Stress is largely a phonological notion (cf. section on the foot). Pitch is a perceptual concept, the articulatory correlate of pitch being rate of vocal cord vibration, and the acoustic correlate, in the usual case, being periodicity in the speech signal, the repetition of nearly the same pattern of vibration. Another approach takes the phonological representation as the starting point, and refer to the phonetic features that are involved in their realization, which is what will be done here.

Recently, the phonological object of study that corresponds to the traditional suprasegmental features has come to be known as *prosody*. Prosodic structure has two components. First, there is a hierarchical compartmentalization of the segment string into phonological constituents, like the syllable and the intonational phrase, called the *prosodic hierarchy* (Selkirk 1978, Nespor and Vogel 1986, Hayes 1989). Second, overlaid on the string of segments, there is a *tonal structure*, which is synchronized in specific ways with the segmental and prosodic structure (Pierrehumbert and Beckman 1988, Ladd 1996). All languages have both of these structural components.

1. The Prosodic Hierarchy

The phonological structure of an English sentence like *Too many cooks spoil the broth* does not just consist of a linear segment string [tuː meni kʊks spɔɪl ðə brɔθ]. The segments are grouped in a hierarchical set of constituents, where constituents at each rank include those of the rank below. There are seven syllables and five feet (*Too*, *many*, *cooks*, *spoil*, and *broth*), each of which is also a phonological word; next, there are three phonological phrases (*Too many cooks*, *spoil*, and *the broth*), two intonational phrases (*Too many cooks* and *spoil the broth*), and one utterance (*Too many cooks spoil the broth*).

The *foot* captures the notion stress. It is a constituent which in the unmarked case consists of a stressed (or strong: S) and an unstressed (or weak: W) syllable, with languages choosing between *trochees* (S–W) and *iambs* (W–S). Often, there are restrictions on segmental contrasts in weak syllables, as in Russian, which has five vowels in stressed syllables but only three in unstressed syllables, and in English, which, depending on the variety, has between 13 and 17 monophthongs and diphthongs in stressed syllables, but only three in unstressed syllables (cf. the final syllables in *villa*, *folly*, and *fellow*; Bolinger 1986, p. 347ff.). Commonly, feet are disyllabic. English, a trochaic language, also has marked feet: a monosyllabic foot occurs in *cooks* and *manifest*, where *-fest* occurs after the disyllabic foot *mani-*; a trisyllabic foot occurs in *cavity* and *university*, where the foot *-versity* occurs after the disyllabic foot *uni-*. One of the feet of a word is selected to bear *primary stress* or *main stress* ['], the others having *secondary stress* [ˌ]. In English, the primary stress is on the rightmost branching foot, as shown by *'mani ˌfest*, *uni'versity*, and *ˌApaˌlachi'cola*, but there are many exceptions, like *'salaˌmander*, *ˌperso'nnel*. Other languages will make other choices. For instance, Bengali, Czech, Finnish, Icelandic, and Pintupi (Australia) always have the primary stress on the first trochee, that is, all words have initial stress, and secondary stresses may be found on alternate syllables, as in Pintupi ['jumaˌɽiŋkaˌmaraˌtʲuɽaka] 'because of mother-in-law.' Foot structure assignment may take place *left-to-right*, as in Pintupi, where odd-syllabled polysyllabic words end in trisyllabic feet, or *right-to-left*, and instead of a trochee, the foot may be an iamb. In

quantity-sensitive languages, long vowels, or long vowels and closed syllables, do not tolerate being in a weak position, and will thus interrupt any regular count through the word. Hawaiian is a quantity-sensitive trochaic language which assigns feet right-to-left, so that [ko'hola] 'reef' has penultimate stress, but [ˌkoho'laː] 'whale' has final stress. When a language has *extrametricality*, the regularities obtain minus an edgemost (usually final) syllable. Finally, within limits imposed by the typology of the language, some words may have exceptional stress, in which case the foot structure is marked in the underlying representation. English is a quantity-sensitive, trochaeic, right-to-left language with extrametricality and exceptions (cf. Hayes 1985).

Stressed positions in phonological representations not only attract more phonological contrasts, as the English and Russian vowel systems show, but also lead to less casual articulation than unstressed positions. The intensity at the higher end of the frequency spectrum tends to fall off less steeply (even *spectral balance*), spectral targets of vowels are approached more closely (less *vowel reduction*), and their duration is longer; overall intensity measures like RMS intensity appear to be unreliable indicators of stress (e.g., Beckman 1986, Sluijter 1995). Stressed syllables also have different pitch characteristics from unstressed syllables. These are caused by the fact that stressed syllables attract *intonational pitch accents*, tones, or tone complexes, which (together with boundary tones, see below) make up the tonal structure of the language. The presence of a pitch accent on a stressed syllable makes that syllable *accented*, as indicated by capitalization. When said in isolation, an English word like *theory* is pronounced *THEory*, while there may also be a pitch accent on a secondary stress before the primary stress, so that *Japanese* will be *JapaNESE* or *JAPANESE*. English has a number of different pitch accents, like H*, L*, L*H, etc., where the starred tone is time-aligned with the stressed syllable. While in isolation, the pronunciation will be *THEory*, in *SET theory* the syllable *the-* is unaccented, because in compounds only the first constituent is accented. Other reasons for *deaccentuation* are stress shift and lack of focus (see below).

A frequently applied diagnostic for the *phonological word* is syllabification, more specifically the extent to which consonants syllabify as onsets with vowels to their right. The phonological word may be smaller or larger than the morphological word. In many languages, it is smaller in compounds, where each constituent is a separate syllabification domain (e.g., English *cat's eye* syllabifies as ['kæts.ˌaɪ], not as *['kæt.ˌsaɪ]); it is larger in cases of cliticization (e.g., English *What is he* ['wɔt.si] *saying?*). The *phonological phrase* may determine the distribution of accents, favoring first and last accents. Although *TOO MANY*! will have two accents, *Too many COOKS* is likely to lose the pitch accent on *many*.

The term *stress shift* is applied to cases where such rhythmic deaccentuation leads to the sole presence of a pitch accent on a foot with secondary stress, as in *JAPANESE*, but *JAPANESE FURniture* (Gussenhoven 1991). The *intonational phrase* typically comes with *boundary tones* at its edges. For instance, the intonational phrase *Too many cooks* might end with a H-tone, pronounced after the pitch accent on *cooks*. Boundaries of this type are often felt to correspond with a comma in writing. The utterance, finally, roughly corresponds with the intuitive notion of spoken sentence. Instead of, or in addition to, the intonational phrase, the phonological phrase and the utterance may also be provided with boundary tones.

In (1), a full prosodic representation is given, together with frequently used symbols; the subscript *I* in the tonal structure indicates a boundary tone.

(1)

The choice of tones is one of many possible combinations, each of which will produce a different *intonation contour*. At the higher ranks, some optionality also exists in the phrasing, depending on style, constituent length, and sometimes language variety. Thus, *spoil the broth* may form a single phonological phrase, as shown by varieties like American English which allow stress shift in verb-object combinations, like *MAINtain ORder* (cf. *ORder to maintain*). The sentence can also be pronounced as a single intonational phrase.

The constituents in the prosodic hierarchy often define the context of segmental restrictions. For instance, syllable-final obstruents are voiceless in Turkish; voicing of Dutch [s] occurs between a sonorant segment and a vowel if [s] occurs at the end of a prosodic word; in Kimatuumbi, all vowels are shortened except any long vowel that ends up in the last word in the phonological phrase. Higher rank prosodic constituents in particular tend to undergo (phonetic) *preboundary lengthening*, which is usually confined to the final syllable.

There is no consensus on how many prosodic constituents there are, in part due to apparent differences between languages. For instance, Japanese has an *accentual phrase*, which seems to lie halfway

between PW and ϕ. A *clitic group* has been claimed for Italian and English, for instance, providing a level between PW and ϕ. A constituent below the syllable is the *mora*, which captures quantity contrasts. A syllable with a short vowel has one mora, one with a long vowel or diphthong two. A geminate consonant adds one mora, a single consonant none. Disyllabic words in Finnish, which has quantity contrasts in vowels and consonants in stressed syllables, may have two moras (CVCV), three (CVVCV or CVCCV), or four (CVV-CCV). *Exhaustive parsing* refers to the ideal situation in which each constituent includes all and only the segments included in the constituents of the rank below. For instance, the inclusion of [m] in the syllable [mɛ] implies that it is also included in the foot [mɛni] and the phonological word [mɛni] (which makes the structure distinct from that of *Tomb any*). A violation occurs in (1) for the syllable *the*, which lacks the normal properties of F and PW, and is directly included in the ϕ.

2. Tonal Structure

The tonal structure can be thought of as a string of tones arranged in parallel to the segmental structure provided by the string of consonant and vowels, that is, as an *autosegmental* representational tier (Goldsmith 1976). It varies greatly across languages. There are two ways in which a typology can be set up, a morphosyntactic one ('How do tones signal what words, phrases, or clause types are used?') and a phonological one ('Where are tones located and how many contrasting tones are there?). A frequently applied morphosyntactic criterion is whether the tone(s) enter into the specification of (also segmentally specified) words or morphemes. If they do, the language is a *tone language*, examples of which can readily be found in Asia (Sino-Tibetan languages, Japanese), Africa (Bantu languages, Khoi-San languages, Nilo-Saharan languages), and many languages in the Americas. Examples of tonal distinctions ([ˋ] = low, [ˊ] = high, [¯] = mid) of this kind are Japanese [hásì] 'chopsticks,' [hàsí] 'bridge,' [hàsī] 'end,' Mandarin (Sino-Tibetan) [má:] 'mother,' [mǎ:] 'hemp,' [mà:] 'horse,' [mâ:] 'vituperate,' Mamvu [máàkà] 'type of seasoning' vs. [màákà] 'cat.' Frequently, tone is involved in the morphology in particular in languages spoken in Africa, as shown by Makonde [nìndì tálèékà] 'I cooked' vs. [nìndà tàlèékà] 'I will cook' and Mamvu [áfù] 'man,' [àfú] 'men' (all examples from Kaji 1999). About half of the languages in the world fall in this class (Maddieson 1978). If they do not use tone to determine the identity of morphemes, they are not tone languages; sometimes non-tone languages are referred to as *intonation languages*, but this term incorrectly suggests that tone languages do not use tone intonationally.

In nontone languages, tones are used to indicate discourse meanings, like 'interrogativity,' 'finality,' 'continuation,' etc. This is illustrated by English *There's no cutlery*: when *cutlery* is spoken with a low-to-high rise, the sentence is meant as a question; with falling-rising pitch it could either be a reminder or again a question, while a high-to-low fall signals a statement of fact. Many tone languages use tone in this intonational way, like Japanese, which distinguishes a L-tone in statements from a H-tone in questions utterance-finally. By contrast, some languages, like the Western Aleut dialect of Unangan, would appear to restrict their tonal structure to the insertion of specific initial and a final boundary tones at the beginning and end of every intonational phrase, and perhaps one more at the end of the utterance. Here, the only function of tone is to mark the phrasing. There are thus widely varying functional claims made by the phonologies of different languages on pitch variation. Not all acoustic variation, however, is due to differences in phonological representation. Speakers of all languages will also use pitch variation to signal universal meanings. Variations in overall pitch range, for example, may signal such general meanings as surprise, interest, emphasis, etc., many of which have an ethological origin (Ohala 1994).

A phonological typology of tone might be based on tonal density: how many locations are specified for tone, that is, have tonal *associations*? In other words, languages differ in the selection of the *tone bearing unit*: in the 'densest' case they specify every mora for tone, and in the sparsest case they just mark the phrasing. When more than one tone is associated with a syllable, like HL or LH, the combination is known as a *contour tone*, while a single tone is a *level tone*.

After edges of prosodic constituents, stressed syllables rank as a popular location for tone. In (1), all tones are intonational. The Venlo Dutch sentence (2a) also has intonational boundary tones and an intonational pitch accent (H*), but the second H-tone on the word for 'play' is a lexical tone, whose presence makes this word distinct from (the segmentally identical) word for 'rinse,' given in (2b). The difference comes out in that the syllable [spϕ:] has high pitch in (2a) but falling pitch in (2b), where the boundary tone spreads to the second mora of the stressed syllable. Thus, although (2a) and (2b) differ in pitch, they have the same intonation.

(2)

Languages that, like the Dutch dialect of Venlo, restrict the lexical tonal contrasts to one per word are

called *pitch accent languages*. (Observe the different meaning of 'pitch accent' from that given earlier.) Most of these use the syllable with word stress for this location (*metrical pitch accent languages*), but the location may also be arbitrary, as is in Japanese (*lexical pitch accent languages*), where the HL-tone complex is located on one of the syllables of accented words. (Unaccented words are unaccented because they—again arbitrarily—do not have this tone complex on any of their syllables.) In Japanese, the accented syllable has none of the phonetic characteristics of stressed syllables (Beckman 1986). Metrical pitch accent languages can also be found in Europe (Norwegian, Swedish, Central Franconian dialect of German, Limburgian dialect of Dutch, Serbocroatian dialects, Basque dialects, Lithuanian; cf. van der Hulst 1999).

The number of tonally specified locations is usually greater than the number of tones. For instances, moras may be specified by a *spreading* tone: when a tone spreads (left or right), it specifies more than one tone bearing unit. Also, suffixes may have a tone with the opposite value from the tone of the stem (*polar rule*), etc. Moras, syllables, or words that are unspecified for tone are pronounced with a pitch that results from an *interpolation* between the two pitches specified at the nearest locations to the right and to the left. If a language just has an initial L-tone and a final H-tone in the intonational phrase, for instance, the pitch in the phrase may begin low, and rise towards the end. In fact, the pitches indicated in the unaccented Japanese word for 'end' are due to the interpolation between an initial LH tone complex of the accentual phrase and a final L-tone of the utterance, and both pitches are thus due to intonational tones, the mid pitch on the second syllable being a curtailed interpolation between H and L.

A second typological question concerns the number of *contrasting tones*. While most languages, and most probably all nontonal languages, contrast H with L, some languages have three or even four contrasting level tones.

Both the prosodic hierarchy and the autosegmental tonal structure are *nonlinear* forms of representations, differing radically from the linear segment string given at the beginning of Sect. 1.

3. The Expression of Focus

Languages frequently exploit prosodic structure for the expression of *focus*, the marking of information status in sentences. Languages appear to vary in the kind of information status which is marked (counter-presupposition, counter-assertiveness, topichood), but a common operationalization of focus is the answer to a question. Thus, if *Sue doesn't like cheese* is an answer to *Who doesn't like cheese?*, the focus is *Sue*, since it expresses the information the question seeks to elicit, while the rest of the sentence is outside the focus. However, if it is an answer to *Why are you changing the menu?*, the whole sentence is focus. The latter type is called *broad focus*, sentences with unfocused constituents having *narrow focus* (Ladd 1996). Prosodic encoding of focus distribution may take several forms. One is phrasing, in which case the beginning or end of a medium-rank prosodic constituent coincides with, respectively, the beginning or end of the focus constituent (e.g. Japanese, Bengali). Some languages use different types of intonational pitch accent for focused and non-focused parts of sentences (e.g., Italian), while others deaccent non-focused parts (Germanic), or de-accent *and* use different pitch accents for broad and narrow focus (Bengali) (Hayes and Lahiri 1991). Lastly, accentuation may signal other meanings than focus. If sentence (1) were to lose its accent on *spoil*, it would lose its implicit conditional status ('If there are too many cooks …') and imply that the number of cooks that actually end up spoiling the broth is too large.

Supreme Courts

Supreme courts are courts of final appeal within national judicial systems. There is a degree of ambiguity about which institutions properly may be called both a 'court' and 'supreme.' Civil law countries have, effectively, three (or more) separate court systems covering different areas of the law, with separate institutions at the head of each, of which only the supreme civil court is called a 'court.' Federal systems commonly have, along with a national supreme court, separate supreme courts for their states or provinces. The development of supranational courts (e.g., the European Court of Justice), further complicates the matter, as these have become the courts of final appeal on some matters. Among these many institutions that arguably function, in one way or another, as 'supreme courts,' this article focuses on national, not supranational or sub-national, courts, and on courts whose cases arrive principally by way of appeal from lower courts.

Over the latter part of the twentieth century scholarly interest in these courts has grown significantly due to several developments. The growing capacity of rights-advocacy and other organizations to pursue sustained litigation, growing complaints about bureaucratic abuses, and a weakening of centralized governmental power have encouraged many supreme courts, in a wide array of countries, to intervene increasingly frequently and actively in the policy process (Epp 1998, Tate and Vallinder 1995). At the same time, many observers have contended that strong and independent supreme courts play a key role in fostering the conditions for constitutional democracy, the rule of law, and the protection of individual and minority rights (Henkin and Rosenthal 1990, Stotzky 1993), as well as property rights and economic development. These are heavy burdens to bear, and the capacity of supreme courts for achieving a wide range of policy goals is often exaggerated. Although supreme courts are not without significant influence, their power is constituted and thus also limited by their countries' particular political, social, and economic structures. Nonetheless, the conditions favoring active policy intervention by supreme courts show no signs of abating, and scholarly attention to them is likely to increase.

1. Institutional Structure

1.1 The Main Types

Supreme courts take a wide variety of forms, and are related to other political institutions in a wide variety of ways, but nonetheless fall within two main types reflecting the broad division between the common law and civil law traditions (see *Legal Systems, Classification of*; *Common Law*; *Civil Law*). In common-law countries, a single national supreme court has general jurisdiction over a wide range of cases in virtually all areas of the law arising in lower courts. These courts are frankly recognized as law-making bodies (through their development of caselaw), and traditionally have been valued for their roles in checking executive discretion and lending coherence and consistency to their country's caselaw. They exercise these roles almost exclusively in cases arising out of concrete disputes between two or more parties; the losing party in a lower court may appeal the decision to a superior court, and a small proportion of these appeals ultimately reaches the country's supreme court where review, in theory, is confined to disputes over law (and not facts) (see *Appeals: Legal*). This model is found today in countries throughout the former British empire, particularly in the United States, Canada, Australia, India, and in Africa, particularly Ghana, Kenya, Nigeria, as well as South Africa.

In some common-law countries, particularly the USA and countries following its model, the supreme court possesses the power of judicial review to strike down legislation as unconstitutional, but typically only incidentally to resolving disputes between two or more parties (a system known as 'concrete review') (see *Judicial Review in Law*). In other common-law countries—those with parliamentary sovereignty, particularly Britain—the supreme court has no such power but nonetheless exercises relatively broad authority to check administrative discretion. Following the enormous symbolic influence of the US Supreme Court's attack on racial segregation and its creation of new individual rights in the 1950s and 1960s, some supreme courts in common-law countries, particularly Canada and India, shifted markedly from the British to the American model by increasingly exercising the power of judicial review, particularly in the area of individual rights (Epp 1998; Knopff and Morton 1992). Under the growing influence of European law, even the Appellate Committee of the House of Lords,

Britain's supreme court, has made decisions that appear to be edging toward a frank exercise of judicial review, a trend that is likely to be reinforced as Britain's new bill of rights gains authority.

Civil law systems, by contrast, have been heavily influenced by the French Revolution's efforts to limit the power of courts and to foreclose the development of an independent, powerful, and active judiciary headed by a single supreme court. Consequently, the supreme judicial power in many civil law countries is divided into three (or more) distinct institutions, each with a specialized jurisdiction (Jacob et al., 1996, Merryman 1985). Thus, in France, the ordinary judiciary, which is headed up by the Court of Cassation, traditionally has been strictly forbidden from exercising judicial review or in any other way challenging legislative or administrative acts. The value of some mechanism for checking administrative acts was quickly recognized, however, resulting in the creation of a separate administrative court, the Contentious Section of the Council of State (hereafter, the Council of State), which now functions as the supreme court for the administrative court system. With the growing interest in constitutionalism after World War II, many civil law countries added a separate constitutional court with the power of judicial review over legislation, reflecting the belief that the ordinary supreme court was insufficiently statesmanlike, too conservative, or too tied to a prior regime, to give meaningful effect to constitutional provisions (Cappelletti 1989, p. 145, Favoreu 1990, Merryman and Vigoriti 1967) (see *Constitutional Courts*). In countries in which the constitutional court decides challenges to existing laws, that court and the ordinary supreme court have at times developed sharply conflicting interpretations of the validity of particular laws, which has led to significant tensions between these courts (see e.g., Krug 1997, Merryman and Vigoriti 1967). The civil law model—with multiple courts of last resort—has been adopted throughout much of Europe, many parts of Africa, the Middle East, and Latin America.

The strength of the pressures favoring active supreme court participation in the policy process are evident in the history of the French system. The French Court of Cassation originated as a legislative tribunal with power only to quash incorrect judicial interpretations of law, but over time it adopted a forthright appellate function and eventually was formally converted into the ordinary court system's supreme court; it has since engaged in significant judicial policy-making (Merryman 1985); (for parallels in Britain, see Stevens 1978). Similarly, although the Council of State is not a part of the regular judiciary, it has evolved to a position of great independence within the administrative branch, adjudicates the legal claims of individuals against the state bureaucracy, exercises judicial review over administrative regulations (which constitute a substantial proportion of French law), and has served as a model for supreme courts elsewhere (Brown and Bell 1993, Hill 1993, Merryman 1985). Although formally there is no doctrine of *stare decisis* in civil law systems, in practice the decisions of the Court of Cassation and the Council of State gain wide adherence in lower courts and constitute a body of 'jurisprudence' that is similar in many ways to caselaw (Merryman 1996).

The institutional structures of supreme courts in Latin America mix elements of the US and French models (see e.g., Barker 1986). Thus, most Latin-American countries have a single supreme court with the power of judicial review and with general jurisdiction over appeals from a variety of ordinary courts, but many deny to the inferior courts the power of judicial review, and even the supreme court's power of judicial review in most of these countries is limited to suspending the application of a law in a particular case, not invalidating the law itself. Some countries in the region follow the French model by denying the supreme court jurisdiction over the administrative courts; some countries' supreme courts hear constitutional issues that are referred by the legislature, and Columbia has both a regular supreme court and a separate constitutional court.

1.2 Agenda-setting, Workload, and Internal Structure

The workload of many supreme courts has increased tremendously in recent years, providing significant opportunities for creative judicial policy-making (McWhinney 1986). To better manage rising caseloads, some countries have created intermediate appellate courts and have granted their supreme court significant discretion over which cases to decide. Such reforms acknowledge and enhance the policy-making role of the supreme court, and courts that have this discretion typically use it to expand their policy-making activities by building a coherent agenda that commonly has focused on constitutional issues (Kagan et al. 1977, Pacelle 1991). Granting the supreme court discretion over its judicial agenda is more typical of common law than civil law systems, as appellate review traditionally has been viewed in the former as an extraordinary resort, whereas in the latter it is viewed as a regular aspect of the judicial process (Damaska 1986, Shapiro 1981). Countries that have not granted discretion over case selection to their supreme courts—for instance, India and France—are virtually forced by rising caseloads to expand the number of judges on the court; this is often accompanied by a division of the court into several panels (or 'chambers' or 'benches') specializing in different areas of the law.

Supreme courts differ, too, in how decisions are issued. The decisions of common-law supreme courts typically report significant disagreements among the

deciding justices. Some, like the supreme courts of Canada and the United States, issue a single majority opinion along with dissenting opinions; others report separate ('*seriatim*') opinions written by each of the justices. Civil law courts, by contrast, present a public face of consensus that conceals any politically motivated disputes among the judges. Modes of publication differ as well: generally, the larger the court's caseload, the smaller the percentage of decisions that is published. Although the most important decisions typically are published, a body of research shows that in lower courts decision-making patterns in published and unpublished decisions differ significantly.

These various internal structures provide senior supreme court justices with different opportunities and constraints for manipulation of the decision agenda. Thus, in courts that are divided into separate panels, the chief justice may influence outcomes in particular cases through exercise of authority to assign justices and cases to particular panels. In courts that meet as a whole, as in the USA, the chief justice or the senior justice in the majority similarly may influence case outcomes by exercising authority to assign the responsibility for writing the majority opinion (see e.g., Epstein and Knight 1998, pp. 125–35).

2. *Supreme Courts in the Political Process*

2.1 *Political Influences on Supreme Courts and their Legitimacy*

Supreme courts are political institutions and are influenced by the political process; but the ways in which they are political, and the nature and paths of political influence vary considerably. Although countries have adopted a wide array of constitutional and statutory provisions aimed at striking a balance between judicial independence from undue political manipulation and judicial responsiveness to widespread popular values, the effects of these measures are strongly shaped by several key factors related to the broader structure and distribution of political and organizational power in each society.

First, the more centralized is governmental power, particularly in the executive, the greater is the degree of direct manipulation of the supreme court by officials in these other institutions. At one extreme, military coups or the exercise of emergency powers by governing regimes are commonly associated with sharp limitations on the authority of a country's supreme court and direct manipulation of the court by the regime (Tate 1993). At the other extreme, in countries in which governing power is greatly divided either by a federal structure or an American-style separation of powers, or both, the paths of influence on the supreme court are more attenuated, affording the supreme court greater room for maneuver. Between these ends of the continuum lie many intermediate instances. The supreme courts of Latin-American republics and Japan, where political power is highly centralized, rarely challenge governmental policies or intervene in the policy process (Itoh 1989, Stotzky 1993, Verner 1984). Nonetheless, even supreme courts in pluralistic systems—e.g., the United States and Canada—rarely challenge directly the key policies favored by the national governing coalition.

Second, political influences on supreme courts are conditioned by the degree of pluralistic conflict over selection of justices and the degree of diversity in the pool from which justices are drawn (see *Judicial Selection*). At one extreme, in a pattern more typical of common law than civil law countries, are courts whose appointment processes are subject to open political conflict between competing factions and whose justices are drawn from a relatively diverse population that includes politicians, government officials, and law professors. Thus, in the United States, the constitutional requirement for Senate confirmation of nominations made by the President has afforded the opportunity for open, pluralistic conflict over appointments to the Supreme Court (Maltese 1995). At the other extreme are systems that insulate appointment processes from popular pressure and which draw judges from an insular elite, a pattern typical of civil law countries. In some civil law countries, the judiciary is largely self-regulating; judges are selected by competitive examination after receiving specialized legal training, and they advance through the judicial hierarchy on the basis of seniority and the approval of superior judges. In other civil law countries, the executive dominates judicial recruitment and promotion to the supreme courts. Often the two factors are found together, resulting in highly-insular supreme courts.

For instance, in Chile the Supreme Court annually evaluates and ranks all of the country's judges, and appointments to the Court are made by the executive from a short list of nominees selected by the Court itself from among the lower judiciary; the system discourages the development of diversity of opinion and creativity within the judicial ranks, and, as a consequence, the Court has remained very quiescent over most of its history (Stotzky 1993, Vaughn 1992–93). Although the differences between civil law and common law patterns of appointment to supreme courts thus loom large, the dichotomy does not account for all variations. In the common-law world, the process of appointment to the US Supreme Court is notoriously open and conflictual, while for the British higher judiciary it is highly insular. In France, judges on the Court of Cassation are drawn exclusively from inferior courts; by contrast, members of the Council of State are drawn not only from inferior administrative tribunals but also from the admin-

istrative bureaucracy and academia (Brown and Bell 1993, pp. 78–80). In general, the insularity of the recruitment process in continental Europe appears to be gradually eroding, with potentially significant implications for the judicial role.

Third, the degree of popular legitimacy of supreme courts and the nature and diversity of external coalitions of support for them place constraints on direct manipulation of these courts by other governmental officials. Some supreme courts have gained significant popular legitimacy, while others remain relatively unsupported; judicial legitimacy, ironically, may be cultivated by courts themselves through active intervention in the policy process that attracts external coalitions of support (Gibson et al. 1998). The ability of courts to cultivate supporters, however, is constrained by the extent of litigational resources and organizational pluralism in civil society; strong societies composed of numerous litigation-advocacy organizations are a key condition for the development of active judicial agendas (Epp 1998). Where coalitions of support are diverse and politically strong, they have played key roles in supporting supreme courts against measures aimed at curbing their power. This is clear, for instance, in comparing the limited success of attacks on the US Supreme Court prior to 1937 (Ross 1994) with the Gandhi government's relatively greater influence over the Supreme Court of India in the 1970s (Baxi 1980, Epp 1998). In general, judges in common-law countries tend to be accorded relatively high status and respect, while the civil law tradition has cultivated a lasting and deeply-entrenched disrespect for the judicial role and for judges (Merryman 1996).

Although the various factors just summarized are conceptually distinct, they are mutually reinforcing in practice. Governing systems in which political power is decentralized have tended to accord greater symbolic status to their judges, particularly to their supreme court justices; have tended to develop pluralistic and even conflictual appointment processes that select justices from a diverse population; have tended to cultivate broad coalitions of support around their supreme courts; and their supreme courts have tended to be relatively actively engaged in the policy process. By contrast, governing systems in which political power is centralized have tended to accord their judges, and even their supreme court justices, the lowly status of legal bureaucrats; have tended to select these justices through an executive-dominated process from highly insular pools of legal professionals; and, as a consequence, these courts have developed highly formalistic decision processes that yield politically-acquiescent decisions and which rarely cultivate support in the broader population. The latter extreme is exemplified by the insular judicial bureaucracies of Latin America that have few sources of popular support—a pattern that is surely compounded by the effects of economic inequality on the degree of organizational pluralism in civil society.

2.2 The Growth in Policy Intervention by Supreme Courts, and the Limits of their Power

Supreme courts, particularly in governing systems in which political power is not highly centralized, have increasingly intervened in the policy process in recent decades, in areas ranging from individual rights to environmental policy. Judges in active policy-making supreme courts commonly have developed relatively high degrees of individuality, and, consequently, these courts are subject to relatively open internal conflict that has made possible the quantitative study of decision-making patterns. Several partially conflicting strains have developed in these studies. One, called the 'attitudinal model,' posits that justices' votes directly reflect their political attitudes toward judicial policies; this theory, although originally based on studies of the US Supreme Court (Segal and Spaeth 1993), has now been applied elsewhere as well (Morton et al. 1995). A second strain of research, sometimes labelled 'new institutionalism,' rejects the claim that justices' decisions directly reflect their policy preferences (Clayton and Gillman 1999). One variant, influenced by rational choice theory, posits that in attempting to achieve their policy goals, supreme court justices temper the raw exercise of their preferences through strategic action that takes into account the preferences of other actors (and thus also of certain institutional norms) (Epstein and Knight 1998). A second variant of new institutionalism emphasizes the influence of legal norms: these studies show that many decisions, particularly in the agenda-setting process, are constrained by legal factors and are reached unanimously (Perry 1991), and that legal assumptions establish the foundations and boundaries of judicial decision-making and thereby constrain the choices recognized by the justices (Gillman 1993).

The extent to which supreme courts are capable of effecting substantial changes in governmental policy, too, remains a matter of dispute. It is clear that supreme courts have no enforcement authority of their own and thus depend for implementation of their decisions on the actions of public officials, private individuals and organizations. On this basis, Gerald Rosenberg (1991) has argued that policy reform decisions of the US Supreme Court have led to actual reforms only in very limited circumstances, particularly when they are aided by sympathetic officials or a sympathetic population, or are subject to implementation by market forces. Michael McCann (1994), however, has shown that judicial decisions provide strategic resources that may be used by social movements, organized groups, and public officials to substantial effect (albeit often in ways unanticipated by the judiciary) (see *Law, Mobilization of*). In some countries, indeed, particular supreme court decisions undoubtedly have led to substantial policy changes. In the USA, time-series analyses have revealed that major decisions by the US Supreme Court have significantly

influenced news media attention to particular issues (Flemming et al. 1997). Taken as a whole, the increasing policy intervention of supreme courts, and of courts in general, has contributed to the 'judicialization' or 'legalization' of policy and administrative processes (see e.g., Tate and Vallinder 1995).

3. The State of Social Scientific Research on Supreme Courts

Research on supreme courts has advanced remarkably in the late twentieth century. Scholars have developed sophisticated quantitative databases of decision-making patterns and of relations between supreme courts and some aspects of governmental systems and societies at large. Additionally, research agendas are increasingly based on social scientific theories and thus increasingly attempt to explain rather than merely to describe. Yet important gaps remain. The cognitive revolution in psychology has as yet been largely ignored in studies of supreme court decision-making. Scholarly attention, moreover, is often directed exclusively to courts' internal decision-making processes even though it is widely recognized that judicial policies are commonly transformed in the implementation process. Most of the existing social scientific research on supreme courts has focused on a handful of highly active courts, particularly those of the United States and Canada, while many other courts, particularly the supreme courts of cassation in the civil-law world, have been largely ignored. Finally, although research on supreme courts in many parts of the world has expanded in the 1990s, only a few truly comparative studies have been done.

Nonetheless, our understanding of supreme courts has grown. The body of social scientific research suggests both that supreme courts may contribute to the broader goals that many observers in recent years have pinned on them—the protection of individual and minority rights and the cultivation of constitutional normal more generally—but also that the extent to which they support these goals is conditioned by a range of factors, particularly the degree to which political power in the governing system is centralized, and the degree to which these courts enjoy popular legitimacy and are supported by coalitions of organizations in civil society.

Surprise Examination

Examinations, and tax audits, are not always announced in advance. There are 'surprise' examinations. What is more, it seems that there might be surprise ones consistent with it being announced that they will occur in some specified period of time. There is, however, a line of argument to the conclusion that it is impossible to have a surprise examination when it has been announced ahead of time that it will occur in some specified period of time. This is very hard to believe, which is why the line of argument constitutes a paradox.

This article starts by stating the line of argument and various attempts to identify the fallacy. It concludes with a short discussion of some related issues concerning cooperative social arrangements, a matter often raised under the heading of the backwards induction paradox. This article does not discuss certain technical issues to do with self-reference sometimes raised in the context of the surprise examination paradox (for these see, e.g., Shaw 1958).

1. *The Paradox*

Suppose that on Monday morning the head of a school makes two announcements to the students.

(a) An examination will be held at 14:00 one afternoon this week.

(b) You will not know until shortly before 14:00 on the day which afternoon it is.

The examination will, that is, be a surprise one.

The argument to paradox runs as follows.

Suppose that the examination is held on Friday. In this case, it will be known in advance when the examination is to be held. For it will be known on Thursday after 14:00 that as the only day left to hold the examination is Friday, the examination has to be on Friday. It follows that the examination cannot be held on Friday consistent with the announced conditions (a) and (b). Now suppose that the examination is held on Thursday afternoon. After 14:00 on Wednesday, it will be known that the only afternoons left to hold the examination are Thursday and Friday. But Friday has just been ruled out as a possible day to hold a surprise examination, so that leaves Thursday as the only possible day. But then the students will know after 14:00 on Wednesday that the examination has to be on Thursday. But this is to say that Thursday as well as Friday can be ruled out as a possible day for a surprise examination. Suppose next that the examination is held on Wednesday. On Tuesday, after 14:00, it will be known that the only afternoons left for the examination are Wednesday, Thursday, and Friday. Thursday and Friday are not possible days for a surprise examination, by the reasoning just given, which leaves Wednesday as the only possible day. But then, if the examination is held on Wednesday, it will be known in advance that it is on Wednesday: Wednesday can, that is, be ruled out as a possible day for a surprise examination. Repeating the same reasoning rules out Monday and Tuesday. It follows that it is impossible to hold an examination under the announced conditions, that announcing that the examination will be held in a given period, and that it will be a surprise one makes it impossible for it to be a surprise one.

There is clearly a fallacy somewhere in this reasoning but it has proved hard to say exactly where it goes wrong. This is part of the reason the paradox has generated a large literature (see Kvanvig 1998).

2. *Replies that Draw on the Possibility of Doubt About (a) or (b)*

2.1 *Uncertainty About (a)—the Examination Being Held at All*

In most discussions of the paradox, it is granted that the examination cannot be held on the last day and still be a surprise. The focus of the discussion is on where the argument goes wrong *after* the step where Friday is excluded. However, as Quine (1953) points out, the matter is not that simple. If there is some doubt about whether or not the conditions set by the head will be satisfied, the argument that rules out the last day can fail. In particular, if there has been no examination by late Thursday afternoon and the students find themselves, perhaps as a result of this fact or perhaps for some other reason, in doubt about whether condition (a) will be satisfied, about whether, that is, there will be an examination at all in the week in question, they do not know that there will be an examination on Friday. There maybe, for all they know, no examination at all. In this case, if the head proceeds to hold the examination on the Friday at 14:00, both conditions set down will be satisfied. The examination will have been held at 14:00 on one day in the week in question (which satisfies condition (a)), and the students will not have known in advance which day it was to be (which satisfies condition (b)).

However, as many commentators point out, the students might be in a position to be certain that the examination will be held in the week in question. Perhaps they know that holding the examination some time during that week is an unshakable prerequisite for government registration of the school. However, it seems that it would still be possible that the examination should be a surprise. There must, therefore, be something more to say about where the argument to the conclusion that a surprise examination is impossible goes wrong. The mistake cannot simply be the possibility of doubt about the examination being held in the relevant period, because the paradox survives the removal of that doubt.

2.2 *Uncertainty About (b)—the Examination Being a Surprise*

Suppose that it is certain that the examination will be held in the week in question, in which case the students can rule out Friday as a possible day for a surprise examination. This is consistent with it being a matter of doubt whether or not the examination will be a surprise one. Now suppose that there is doubt about this condition—(b)—being satisfied. Wright and Sudbury (1977) point out that this undermines the students' reasoning on Thursday morning in the case where Monday through Wednesday prove to be exam-free. The students cannot argue that Friday is excluded as a possible day for the examination to be held on the ground that then they would know in advance when the examination was to be held. For, if there is doubt about (b), they must allow that maybe the examination will not be a surprise. They must, therefore, allow that there are two possible days for the examination to be held: Friday, in which case (b) will be violated, or Thursday. In this case, the head can hold the examination on Thursday consistent with (a) and (b). This is because the students cannot, on Thursday morning, rule out Friday owing to doubt about the examination being a surprise. In effect, the head can exploit doubt about the examination being a surprise—which leaves Friday as a possible day for the examination in the students' minds—to ensure that it is a surprise by holding it on Thursday.

In sum, doubt about (a) would make it possible for the examination to be held on Friday consistent with (a) and (b). Doubt about (b), even in the absence of doubt about (a), would make it possible to hold the examination on Thursday consistent with (a) and (b).

The obvious question to ask at this point is what happens when there is no doubt about either (a) or (b). Could it not be the case that it is certain that the examination will be held on one afternoon of Monday through Friday, and certain that the students will not know in advance which afternoon it is? Isn't there still a paradox to be addressed? In order to address this question, it is necessary to draw a distinction between whether there is doubt on some matter and whether there *would* be doubt on some matter were certain things to happen.

3. *What is Open to Doubt vs. What Would be Open to Doubt*

It is not open to doubt given current evidence that Hitler died in the bunker, but were certain discoveries to be made, it would become open to doubt. Similarly, for most people who are here and now awake, it is not open to doubt that they are here and now awake, but were they to have the experience as of waking up from an extraordinarily life-like dream, it would be open to doubt. What is here and now open to doubt is distinct from what would be open to doubt were certain things to happen.

The view that the points made in the previous section do not dispose of the surprise examination paradox arises from the conviction that a surprise examination is possible when it is beyond doubt both that the examination will occur during the week and that the students will not know in advance. How then, runs the challenge, can we dispose of the paradox by pointing out that when there is doubt about (a) or (b), the student's reasoning fails at some key point or other? However, on careful inspection, the failure of the students' reasoning does not depend on there actually being doubt about (a) or (b). It depends on it

being the case that there would be doubt were certain things to happen.

Provided it is the case that were Friday morning to come without the examination having so far taken place, there would then be doubt about the examination happening in the week in question, that is, about (a), the students' cannot rule out the examination being held on Friday. If there would, *should Friday morning arrive before the examination makes its appearance*, be doubt on that Friday morning about (a), the head can hold the examination on Friday without violating either (a) or (b)—as was noted above. This does not require that there be, at any stage, actually any doubt. It requires simply that were Friday morning to arrive without an examination having been held, there would be doubt about (a).

A similar point applies to the role of doubt about the examination being a surprise, that is, of doubt about (b). There need not actually be any doubt that the examination will be a surprise. The students' reasoning would be undermined simply by the fact that there would be doubt should enough days pass without the examination taking place. As was noted above, should Thursday morning arrive without there having been an examination and were this to mean that there would then be doubt about (b), the students cannot rule out Friday even if they are certain of (a). It is not required that there ever actually be any doubt about (b). All that is required is that should certain things come to pass, there would be doubt about (b).

It might be suggested that it could be built into the paradox that not only is there no doubt at any stage about (a) and (b), there would be no doubt about them no matter how many days pass without an examination. But this would be to build something absurd into the statement of the paradox. There would *have* to be doubts about one or both of (a) and (b) should enough days pass without the examination having taken place. For example, should Friday morning arrive without the examination having taken place, the students would *know* that one or both of (a) and (b) are open to doubt. It would be inconsistent of them to hold in that eventuality both that it is beyond doubt that the examination will take place on one of the designated days and that they cannot know in advance which it is. For example, if it would still be certain that the examination will take place on one of the designated days should Friday morning arrive without the examination having been held, they would know that should this happen, the examination would not be a surprise (for a longer development, see Jackson 1987).

4. The Backward Induction Paradox

4.1 The Rationality of Cooperation

There are parallels between the style of argument in the surprise examination paradox and certain arguments concerning the rationality or otherwise of cooperative social arrangements. Many cooperative arrangements that have both costs and benefits to the involved parties rest on the basis of expected returns in the future to all parties to the arrangement. The Robinsons work with the Smiths on something that advantages the Smiths in the expectation that in the future the Smiths will work with the Robinsons on something that advantages the Robinsons. A classic example is helping with building houses. It is much easier to build a house when there are a number of workers to lift heavy beams and the like. So the Robinsons give of their time to help the Smiths build the Smiths' house, but do so in the expectation that the Smiths will later help the Robinsons build the Robinsons' house. But why, in terms of self-interest, should the Smiths later help the Robinsons; they already have their house? The answer is that there will be other opportunities for cooperation, and the Smiths can expect to benefit from some of them.

This intuitively appealing answer can be challenged by a 'backwards induction.' It will not be rational (in the sense of being advantageous) for the 'giving' party to cooperate on the *last* occasion for possible cooperation, because there is no prospect of their being the 'receiving' party in the future. But then, it seems, there is no reason for the giving party to cooperate on the second last occasion either, assuming rationality on the part of both parties. The only reason for the giving party to cooperate on the second last occasion is in the hope of being the receiving party on the last occasion, and that could only happen if the giving party on the last occasion is irrational. Similar reasoning applies to the third last, fourth last, etc. occasions, so yielding the conclusion that it is never rational to be a giving party in a cooperative arrangement.

It would be a mistake to reply to this argument by challenging the self-interest conception of rationality it employs. The puzzle is that it clearly is in parties' self-interest sometimes to cooperate when they are the givers, in the expectation of being receivers in the future. The error in the argument is that it neglects the kind of epistemological points we saw to be crucial in diagnosing the error in the surprise examination paradox. Although it would be irrational for the giving party to cooperate on the *known* last occasion for cooperation, normally it is not known when the last occasion for cooperation is. Similarly, there may be doubt about all parties being rational.

4.2 Sequences of Prisoner's Dilemmas

A special version of the backwards induction paradox is sometimes deployed to argue that it is rational to defect throughout a sequence of prisoner's dilemmas as well as in a one-off prisoner's dilemma. A prisoner's dilemma is defined as follows. There are two parties, X

and Y. If they both cooperate, they each do better than if they both defect. However, X and Y each do better if they defect, independently of whether or not the other cooperates or defects—defecting dominates cooperating, as it is put (see Resnick 1987).

Most game theorists accept that this means it is rational for each to defect despite the fact that if they both defect, they each end up worse off than if they both do the irrational thing of cooperating. What has proved harder to accept is the claim that, in a sequence of prisoner's dilemmas of known length involving rational players, it would be rational to defect throughout. Surely it would be rational, sooner or later, for X and Y to start cooperating in order to set up an expectation of cooperation which means that, at least sometimes, they end up both cooperating, which is better for each than their both defecting?

A backwards induction argument has been used to resist this thought. Clearly, runs the resistance, it is not rational to cooperate at the last prisoner's dilemma—engendering expectations of future cooperation has no pay off in that case. But cooperation at the second last prisoner's dilemma is only rational if it leads to cooperation at the last prisoner's dilemma, so this means that cooperation at the second last cannot be rational *unless* it leads to irrationality at the last prisoner's dilemma. But that is to say that if X and Y are steadfastly rational, defection is rational at the second last prisoner's dilemma as well as at the last. Repeating the reasoning delivers the result that it is rational to defect throughout the sequence of prisoner's dilemmas.

A full discussion of this last backwards induction argument is beyond the scope of this article (but see Pettit and Sugden 1989 and Bicchieri 1998). But it should be noted, first, that belief in rationality, or lack of it, is crucial to the argument, and, second, that if cooperating at early stages in a sequence of prisoner's dilemmas sets up certain expectations, these early stages will not strictly speaking be prisoner's dilemmas, for taking into account the longer term benefits means that they will not be cases where defecting dominates cooperation.

Survey and Excavation (Field Methods) in Archaeology

1. The Term 'Archaeology'

The term 'archaeology' comes from the Greek word, *arkhaiologia*, meaning the 'discussion or discourse about ancient things.' By definition, archaeology is the science by which the remains of the ancients can be methodically and systematically studied to obtain as complete a picture as possible of ancient culture and society, and thereby to reconstruct past ways of life. An antiquarian doctor of Lyon, Jacques Spoon, first used the term 'archaeology,' in the seventeenth century. Archaeology is a discipline that involves the scientific method of study, observation, recording, and experiment. Archaeologists study in detail the complete life of cultures and their patterns of change in an attempt to delineate the causes and effects of the cultural process. The fascination of archaeology lies in the solving of long-standing problems and in the discovery of the meaning of things. The excitement of archaeology lies in the new problems which recent findings produce.

2. The History of Archaeology

The earliest 'archaeologist' was the sixth century BCE King Nabonidus of Babylon who excavated a temple down to its foundations which had been laid thousands of years before. Even the Roman emperor Augustus was a collector of 'giants' bones and ancient weaponry. With time, Europeans began to collect burial urns, chipped flint stone and ground stone tools which some believed were amulets. In 1719 the Austrian Prince d'Elboef led the first excavation to Herculaneum, which had been destroyed along with Pompeii in AD 79 when Mount Vesuvius erupted. Thereafter when pieces of classical sculpture began to turn up, artists began to study their shapes and decoration and collectors began to collect, proudly display, and discuss their forms. With time, more people began to describe what they recognized as ancient monuments

and excavations were undertaken to retrieve more and more objects. In the mid eighteenth and early nineteenth centuries digging for ancient objects became the pursuit of gentlemen of the leisured class and professionals: they became known as antiquarians and formed clubs to discuss the merits of ancient artifacts.

Archaeology as a pursuit using scientific systems of recovery began in the nineteenth century, along with the growing realization that humankind had an ancient past that could be investigated in a methodical way. The names of most important archaeologists from the early days include Sir William Matthew Flinders Petrie in Egypt, Robert Koldewey in Babylon, the duplicitous Heinrich Schliemann in the Aegean at Troy, Mycenae and Tiryns, and General Augustus Pitt-Rivers in Britain. Later pioneers were Sir R. E. Mortimer Wheeler in Britain and India, George Andrew Reisner and Sir Leonard Woolley in the Near East, Max Uhle and Alfred Vincent Kidder in America, and François Bordes and André Parrot in France.

In the present day, archaeology has grown into a multidisciplinary, methodical, problem-oriented search for the past. It now involves above-ground research as well as excavation, and a host of specialists is required, depending on the site. Background research as well as excavation has become meticulous. The object study of pottery, for example, involves not only typologies but sophisticated scientific testing by neutron activation analysis to understand the chemical components and to identify the sources and, cultural patterns as well as to assess trade relationships.

Archaeological questions extend far beyond the excavation and interpretation of any single cultural group, geographic region, or chronological period of time. In theory, all archaeological study is aimed toward an explanation that will provide a conceptual basis for the reconstruction of the past, and the where, how, and why of the changes that took place.

3. *The Importance of Archaeology*

Archaeology is unique in that it encompasses the whole world over the past 2.5 million years in order to reconstruct the past. It includes the research of all kinds of sites—underwater wrecks or port installations, caves, jungles, deserts, and mountain-top sites; wherever past activity has taken place. Archaeology wants to discover where and when humankind developed and began to practice art, agriculture, and technology and became urbanized. It is our route to our understanding of ourselves, for in order to know where we are going we have to reconstruct and understand the past and where we have come from.

Archaeology continues to give us a broad and long-term view about the past and the events that conditioned us. There is an implosion of new answers to research on how, where, and when humankind began, our development of technology, the arts, the expression of our ideas in writing, how we harnessed the environment brought about the domestication of plants and animals, and developed agricultural systems. Archaeology helps us to understand the processes of becoming urbanized how we developed complex societies, and to understand our basic needs.

4. *Archaeological Sites*

Archaeology covers a wide diversity in time, space, subject matter, and approach. An archaeological site can be any place that has been a scene of past human activity, including a briefly settled campsite, a shipwreck, a monumental city, or the evidence of any number of different combinations of human remains. Any place where human beings have established themselves, even momentarily, is considered a site.

As each archaeological site is a unique time capsule, each has its own distinct character and problems. Types of sites are often labeled by their prehistoric or historic context, their function, their general topographic nature, or according to whether they are composed of one or many levels of occupation. Sites represent a body of data relevant to their setting and their cultural patterning and must be interpreted both in relation to this local setting and as a link between cultures. Sites may be small or large. Small sites are far more numerous throughout the world and may range from hunting or fishing stations to small village communities. There are prehistoric plains or riverside terraces such as Olduvai Gorge in Tanzania, Africa; there are caves such as Chou Kou Tien near Peking, China where the Peking Man was found; or those containing Upper Paleolithic art, like Lascaux in France.

Large sites are generally cities, temples, large tells—artificially built-up mounds in the Middle East with one city built on top of the other (known as *höyük* in Turkish or *tepe* in Persian). The ancient mound of Jericho, Israel is particularly important, revealing evidence dating back to 8000 BCE. A more recent tell of the Mississippi Basin was built by the Mound Builders of North America in about 1300 CE. There are monumental cities such as classical Rome, Meso-American Tikal in Guatemala, or Angkor Vat in Cambodia. There are sacred areas reserved for ritualistic functions such as Stonehenge in England, or the statues of Easter Island. There are cemeteries and tombs such as those of Mycenae in Greece, the Pyramids in Egypt, or the mounds of Ohio, Illinois or Mississippi. Famous sites also include underwater shipwrecks and harbors discovered worldwide off the shores of the Mediterranean, or near Oslo, Norway, where early Viking ships have been recovered.

The selection of a site for excavation therefore depends upon what the excavator–principal investigator wants to find, and what problems will be answered by excavation. What is the nature of the evidence? It usually involves a problem to be solved—how has the site been built up over time? What is its environment and how has this changed? Using a research design, a review process is undertaken which includes the preliminary analysis of the site, the evaluation of the probable results, the examination of the costs, and the evaluation of organizational abilities and needs to carry out the tasks involved.

5. *Archaeological Studies*

Many types of archaeology have evolved over the years. There are Old World (Eastern Hemisphere) and New World (Western Hemisphere) prehistoric specialties, based on the stone tools humankind produced. The Paleolithic, Mesolithic, Neolithic, Bronze Age, and Iron Age are specialties. These are broad artificial classifications with subdivisions. As far as the discipline in which it has received attention, Old World archaeology is a separate subject in some schools, or is associated with departments of classics or Near Eastern studies, history, or art history. In the New World prehistoric specialists may concentrate on the Paleolithic, Archaic, and Woodland periods. Then both Old and New World archaeology moves into historical archaeology. In the Old World there are experts who are devoted to classical archaeology (the worlds of Greece and Rome) or Biblical archaeology (the areas encompassed by the Holy Land).

Similarly, many kinds of specialties have developed in archaeology, for example, industrial archaeology; the study of manufacturing and salvage archaeology; the rescue work done before a modern construction takes place such as land development, or urban renewal, or when a pipeline, road, or dam is built. There are also technical specialties of people who concentrate on specific techniques such as ceramics, lithics, paleobotany, palynologists (specialists in pollen), and dendrochronologists (specialists of tree ring growth) among many others, including computer specialists who lend support to all these areas.

Since the 1960s in America, archaeology as a subdiscipline also has been associated with anthropology. As anthropology is the study of humanity, anthropologists generally observe the behavior of present-day people in order to explain and reconstruct their behavior patterns. In so doing, they have to make assumptions about past behavioral patterns as set against the environment of the present.

Anthropology is divided into several subfields among which are social and/or cultural anthropology, physical or biological anthropology, linguistic anthropology, which includes the interpretation of oral history, demographic anthropology, ethnic anthropology, cognitive and symbolic anthropology, enthnoarchaeology, and archaeo-astronomy (the study of ancient astronomical events).

6. *Dating Systems in Archaeology*

The term 'culture' is used when assuming that a group of people exhibit shared behavior. Archaeologists want to be able to establish accurate space and time frameworks or dates for the cultures they are researching. In short archaeologists want to establish the site context, culture, and chronology. Laboratory methods provide what are known as absolute dating methods, and relative dates are ascribed to archaeological strata based on the site deposition or stratigraphy and the discovery of cultural artifacts similar to those found at other sites.

Absolute dating is a date given in specific years, in terms of chronometrical dating or the calendar. A date given as BP is a date before 1950. BC means 'before Christ' (although nowadays BCE is used, meaning 'before the Common Era'). CE (Common Era) is used instead of the old term AD, meaning *Anno Domini*, or after the birth of Christ. Absolute dates can be established by laboratory analyses like radiocarbon dates (C-14), potassium-argon, thermoluminesence (TL), archaeomagnetism, and palaeomagnetism, among others. These are geochronologic methods used for determining the absolute date of a deposit.

Relative dates are based on the stratigraphic deposition—the principles of superposition, association, and correlation. Superposition assumes that the uppermost stratum (soil level) was deposited last and the lowest stratum was deposited first; thus the reasoning assumes that lower strata are generally older than the layers above them. Association assumes that the artifacts found in the same closed and sealed archaeological context are contemporary and are therefore presumed to be culturally and temporally associated. Correlation assumes that, once cultural associations have been determined, artifacts can be cross-culturally correlated with artifacts from other site cultures and they can be expected to have been manufactured at the same time, and therefore to possess the same relative date.

Archaeologists use seriation as a method of relative dating. Seriation involves the ordering of specific artifact types from an earlier to a later time sequence by the use of a typology. In creating a type series, the archaeologist assumes that artifacts have formal attributes that can be measured like raw material, length, width, thickness, color, weight, and so on, and that these nonrandom attribute factors were used as a standard by the maker. Therefore, a typology is comprised of types which are a cluster of attributes in a class of objects and these can be given relative dates that can be used to date the stratification.

Once associations have been defined cultural levels can be inferred. A cultural level represents the choices of a particular social group, such as the classical Greeks. The data collected in such a cultural level depict a known and recognizable set of ideas that are then represented as the cultural products of that society.

7. *Archaeological Survey*

Survey includes exhaustive historical research, map-reading, geomorphologic and geographic analysis, aerial photography, and ground-level surveys, including electronic and magnetic surveying techniques. Historical research includes all previous research of the area—excavation reports, artifact studies, and the conclusions drawn by previous researchers. In-depth bibliographic research provides essential background information.

All archaeologists are concerned with surveying as a means of planning and laying out the area to be studied or excavated. Surveying is generally the first step in all archaeological projects, and is often the last step before the completion of the excavation. Using maps, aerial photos, and whatever background information is available, ground level surveys can be undertaken on foot to understand the physical features of the site as well as the artifacts—in short, all the material cultural remains of the site or the culture. The site is then located according to Global Positioning Systems on a topographic government map with a scale of 1:50,000, and its location is established and officially reported.

As a branch of engineering, surveying is the science that accurately determines the shape, area (size), and positions of a site's surface by the measurement of certain points. It includes the measurements of horizontal distances and elevations, and determines the direction and relationships of angles by the use of optical instruments. There are several principal classes of survey: *geodetic* surveys, *photogrammetric* (picture-measured) aerial surveys, and *plane* surveys. Geodetic surveys are used for the study of large areas like countries or continents, and take into account the curvature of the earth's surface. Satellite photographs have become important to the archaeological analyses of large landforms. Photogrammetric surveys are the science of taking detailed vertical or oblique photographs from an aircraft for the reliable measurement of the earth's features. Plane surveying is used for small areas of archaeological focus in which the curvature of the earth's surface is not measured. The preliminary survey also consists of a systematic walking over the site recording standing structures and features as well as artifact materials and scatters. Depending upon what type of survey is to be conducted, artifact concentrations may be collected, processed and studied to indicate the type of site and its artifact range. The survey should establish the site size, what kind of site it may be, its time span, and, if possible, its depth of deposit.

Depending on the site, three principal types of survey are usually conducted before excavation: (a) the land survey for the proper planning and laying out of the site which includes the site grid; (b) The topographic survey which is the measurement of elevations representing the surface of the area; and (c) the ongoing excavation survey, which is made during excavation to control the location of archaeological structures, features, and objects and providing these with elevations. Anomalies and physical features are then thoroughly mapped and described as well as factors like vegetation and soils.

Decisions then may be taken as to what additional surveying equipment will be used to look at the subsurface features. Electrical resistivity meters and magnetic surveying by using any number of different magnetometers are instruments that are linked to computer-processing programs; they help to determine what disturbances or structures exist in the area. Only when the comprehensive survey has been completed can the researcher decide if excavation is justified, and if it is, where it is to begin, and what course it is to take.

8. *Excavation and Ethical Considerations*

Even before a site is excavated, preservation and consolidation measures must be seriously considered and implemented. How will the site be left after the excavation is completed? As excavation is destruction, one of the most important considerations is the site's stratigraphy, its depth of deposit, and its characteristics. We need to conserve and protect the excavated sites and monuments from all periods and in all parts of the world. Furthermore we need to protect sites against the threats from human intervention, mass tourism, and building development, as well as from the elements of natural deterioration and neglect. Looting is an age-old problem. There are those who clandestinely excavate to sell artifacts at an enormous profit. Although artifact-rich countries have the legislation to prevent the illegal excavation and export of their country's patrimony, they lack consistent regulatory measures to police looters, dealers, and the exporters of their antiquities. If we are to preserve our common human heritage, the protection of cultural patrimony has to become everyone's priority.

There have been changes in the ethical standards observed by archaeologists today. Ethical standards in archaeology may be defined as the obligations of a professional or an amateur to the excavation, to the country, State or area in which it is located, to the public at large, and to fellow archaeologists. Today's archaeologists strive to work and live according to a

high standard of behavior, applying their knowledge to enhance the reputation and achievements of archaeology as a whole and for the benefit of human knowledge. Many archaeological associations have drawn up ethical codes that have been accepted by international archaeological societies. The codes of the Archaeological Institute of America and the Society of Professional Archaeologists are among these.

Who will be responsible for the care and upkeep of the site over time? And what should be done to care for site artifact collections? Where are they going to be stored, who is going to study them and on what time schedule? What is to be their final disposal—a museum, reburial, and, if the latter, where will they be buried? Today the archaeologist has the responsibility of addressing such issues and these should be best addressed before excavation takes place.

9. *Excavation*

Excavation is the deliberate recovery of buried objects in relation to the layer or stratum and other associated objects in its original deposit. The principle of excavation is that artifacts, nonartifactual materials, and architectural features are not randomly distributed, but are deposited by people. Their position in the earth reflects the cultural, economic, and social behavior of humankind that can be studied by means of excavation. This is the basis for the functional reconstruction of the site. It is only through excavation that the archaeologist can collect and extract a wide range of physical information or obtain a sense of the people who lived, worked, and perhaps worshipped at a site. The archaeologist does this by describing the evidence the people left behind—the architectural features and objects. It is only through excavation that we can align these physical features in time and space so that the functional reconstruction of the processes involved can be determined. In this way we can better understand and interpret the causes, changes, and processes which the ancients used to bring about change.

Excavation is the method of removing objects and uncovering stationary features that have been concealed by later deposits. It involves the removal of layers or strata in reverse order to the way in which they were laid down, gradually revealing each successive stage in the history of the people who used the site. Because excavation is the means by which information is unearthed, it must be conducted methodically so that whatever is found can be seen and studied within its own context. The main objectives of excavation are to uncover the position of objects as well as floral and faunal data, and to plot their location on a horizontal plan. It also involves the meticulous recording and sequencing of successive layers on the vertical section by position and depth measurements. Finally, the goal is to relate such data to the total environment of the site and to assess its relationship to other sites in the area.

10. *Modern Developments in Archaeology*

Major developments in archaeology took place in the late 1990s with the advent of computer technology—remote sensing, web pages, virtual reality, computer simulations, digital cameras, and the greater use of the hard sciences including DNA analysis.

In the 1960s American archaeologists began to challenge the traditional archaeological academy and argued that the discipline had become simplistic. As a result of this critique the 'new archaeology' was developed, emphasizing the importance of the processes within the society being studied. This was known as 'processual archaeology,' and it emphasized the value of objective, logical explanation and the descriptive processes that can produce testable assumptions. They believed that culture should be studied as sets of systems and subsystems as they relate to the environment, the economy, and patterns of subsistence. They also emphasized that the interrelationships between different sectors of the society should be explainable so that specific developments could be established throughout time.

They failed to stimulate the traditionalist majority who practiced archaeology as they had before and who believed that there were no universal laws governing human behavior.

The merit to the then-new approach to archaeological data opened the way to a vast array of new theories including Marxist, neo-Marxist positivist, structuralist, post-structuralist, post-processualist, deconstructionist, and probabilist views along with other theoretical constructs. The post-processual school of archaeologists still adheres to a so-called interpretative archaeology, which insists on emphasizing history, philosophy and, whenever possible, literary studies. Interpretative archaeologists place importance on the fundamental uniqueness and diversity of culture, believing there is no one governing law that can apply either to archaeological research or to the interpretation of the past. These theories hold some truth, provide stimulating hypotheses for our explanation of the past and are used by many who thoughtfully interpret the probabilities of the evidence. Now archaeologists are wrestling with the ideas of multivariate explanations—and many continue to build idealized models for their interpretations.

11. *Conclusion*

By and large, archaeologists are dedicated researchers and teachers. As for future directions in theory and research, evaluation can be said to drive archaeological standards. By clearly specifying the outcomes

in measured ways, archaeologists will change the way they excavate and publish. In the training of students, field directors hope they will train people who possess the qualities and attributes desired in a competent archaeologist. As an archaeological project is expected to foster a shared sense of a shared mission between the field researcher and the principal investigator, both will strive to reach a common goal. Archaeology is best taught through active learning processes, and principal investigators help students by gauging their progress and identifying and overcoming barriers to the excavation as a whole. The developmental process of archaeology is most effective when the goals are known so that the whole team can work together toward the shared goals, collaboratively devising strategies to overcome any obstacles. Our understanding of the past is in a constant state of change due to new discoveries and advances in our knowledge. It will never be finished.

Today archaeology has developed into a complex discipline with a vast literature and a range of specialties that are well beyond the competence of a single researcher. More and more data are being produced, museums are overwhelmed with objects and, even with the advent with the computer, many artifacts have remained unanalyzed or unregistered. There is a crisis in the discipline due to the fact so much data has been produced, and as excavation involves the destruction of the site, archaeologists must be aware that the discipline may self-destruct unless it puts its house in order. It faces considerable challenges and risks ahead and it must develop an international dialogue among its leadership that is committed to a strategy which will ensure the saving of the past for the future.

Survey Research: National Centers

National centers for survey research are a rare species among the masses of survey research centers, companies and offices. However, the impact of the few centers on the development of systematic survey research and its methodology cannot be overestimated. Four centers in three different countries will be examined as blueprints or models. These are, in chronological order, the National Center for Opinion Research (NORC, Chicago), the Institute for Social Research (ISR, Ann Arbor), the National Center for Social Research (NATCEN, London), and the German Society of Social Science Infrastructure Institutes (GESIS, Mannheim). The focus is on survey research; thus surveys must be defined clearly and distinguished from other instruments for social research, like tests and census. Next, national centers for survey research will be distinguished from survey research centers, institutes, companies, and census offices at large. The four model centers will then be portrayed with some emphasis on their history and their impact on survey research.

1. Social Surveys

Surveys are defined in this article as *observing societal facts using interviews as the source of information and systematic sampling as the base for selecting information sources* (cf. de Heer et al. 1999), and they are quantitative instruments to identify distributions of societal characteristics. Questions or items in a survey are understood as indicators pointing to a latent construct or dimension. Psychological tests, including many marketing studies, differ in two ways from surveys: they focus on characteristics of individuals or small groups but not societal characteristics. In most cases the selection of the respondent is not based on systematic sampling. Survey research is, on the contrary, neither interested in information about a single individual nor in small, identifiable groups. Information gathered on the individual level in a survey will be aggregated across groups and even societies. A population census may share items or question wording with survey research studies. However, census studies are not designed to identify latent constructs. By its name, a census is an investigation involving all members of a given population not a sample.

Survey research, hence, requires among others specific methods and techniques for designing sampling frames, dealing with nonresponse, and constructing and validating measurement instruments which must be in turn suitable for complex statistical modeling across all strata of a society. Survey research is a complex, often high-tech, production process. Consider as an example a National General Social Survey like the American GSS or the German ALLBUS (Davis and Smith 1992, Davis et al. 1994).

The target is to collect data from about 3,000 respondents. To do so, one has to contact up to 6,000 households and to identify whether they are eligible and willing to participate. Up to 600 interviewers in 630 sampling points will collect the data. About 50–100 other staff will back them up, supervise the process, or edit the incoming data. The whole process will be directed and supervised by 5–10 senior social researchers. The goal is to collect from each and every respondent all information as accurately as possible. The result will be about 1.2 million different information units (answers to questions, etc. by all respondents).

This complexity of the survey production process requires adequate organizational and professional production structures. Big survey research companies like Gallup, Harris, Infratest-Burke, Inra, or Mori to name but a few and famous, provide such organizational and professional structures for polls, big market surveys, etc. In the public, nonprofit domain, independent, academic survey research centers serve the academic communities, governments, and even compete with private companies on many sectors.

It is the integration of academic methodological standards and perspectives into the applied survey research process, which makes academic survey research centers different from private companies' research units. Publishing rigorous methodological research, going beyond the 'it works' to find out 'how and why it works,' is thus a must for an academic survey research institute. Hence it is no coincidence that the two most prominent survey research centers today, ISR and NORC, are also centers of methodological excellence. However, methodological research, important as it may be for survey research, is a very small area in the sea of modern social research. It is almost always interdisciplinary and cooperative. In short, methodological survey research is not suited for a career at a university. National research centers by their very size and their mission to accomplish high quality surveys provide a natural base for long-term high quality methodological research also.

National centers for survey research cover national and international issues, which are quite distinct from regional centers. In addition such centers have a broad focus on methods, target audience, and topics. Funding and organization differ from center to center and from nation to nation.

The term 'national center' as it is used here does not exclude several centers within one nation, nor does it imply that the word 'national' in the name immediately qualifies an institute to be a national center. They also serve as hosts for important national surveys. Studies like the General Social Survey (NORC), the Panel Study of Income Dynamics (ISR), British Election Studies (NATCEN), or the German General Social Survey (ZUMA/GESIS) are cornerstones of their countries' social science information systems. Finally, they have an enormous impact on the development of multinational survey research: NATCEN, NORC, ZUMA are founding members of the International Social Survey Programme (ISSP, www.issp.org), ISR hosts the World Value Survey.

Rigorous methods, the public as an audience, free distribution of major nationwide data sets, intensive, published methodological research, and an international perspective are what mark national centers for survey research.

Today, 88 years after the first survey (de Heer et al. 1999, p. 28) centers which truly qualify are still very small in number. This is despite the enormous growth in interviews conducted around the globe (in 1978 the gross revenue of the survey industry was estimated at $4 billion; de Heer et al. 1999, p. 32); the annual turnover reported by ESOMAR in 1998 was about $13 billion with an increase of 10 percent since 1997 (www.esomar.nl).

There are actually only a handful institutions worldwide which can be counted as a national center for survey research: in the US the National Opinion Research Center (NORC, Chicago, founded 1941), the Survey Research Center in the Institute for Social Research (ISR, Ann Arbor, 1946), in Great Britain the National Center for Survey Research (NATCEN (formerly SCPR), London, 1969), the Norwegian Social Science Data Services (NSD, Bergen, 1971), the German Social Science Infrastructure Institutes (GESIS, Mannheim, an umbrella organization for ZUMA in Mannheim, Zentralarchiv in Cologne and the Social Science Information Center in Bonn, 1986).

Other institutes like social science data archives, for instance the Roper Center, ICPSR, or the Essex Archive (cf. CESSDA, www.nsd.uib.no/cessda/ or www.ifdo.org), or the numerous social research institutes listed in clearing houses (www.abacon.com/sociology/soclinks with references to other lists) either do not carry or contract out major national surveys or are not heavily involved in methodological survey research apart from secondary data analysis. Hence they are not covered in this section.

In the following, short bios of the four centers will be presented. These bios will not go into the history of these institutes; rather their current standing will be emphasized. In concluding, the impact to these centers on survey research will be outlined at the beginning of the twenty-first century.

2. *NORC: National Opinion Research Center, Chicago*

NORC was established in 1941 as a nonprofit corporation through a grant from the University of Denver and the Field Foundation. In 1947, NORC moved to the University of Chicago campus (www.norc.uchicago.edu). The center conducts survey research in the public domain as well as for private

organizations. It is an independent nonprofit organization with strong ties to the University of Chicago.

NORC has a reputation for both complex surveys and innovations in survey research methodology. It is the birthplace of surveys conducted for the benefit of the sociological profession at large, the General Social Survey (GSS) (Davis and Smith 1992). The first GSS was conducted as early as 1972. A GSS is a generalized tool which repeatedly measures important characteristics. It is released immediately after completion to the social science community. Thus researchers, students, and other interested parties have up-to-date survey data to hand which they can analyze on their own terms. Such a complex, long-term enterprise requires a strong and well-equipped infrastructure, like the one provided by NORC as a national survey research center. Other strongholds of NORC are methodological studies concentrating on measurement error. Norman Bradburn and Roger Tourangeau are but two among the number of researchers who contributed to this field from the 1980s.

3. *ISR: Institute for Social Research, Ann Arbor*

Shortly after NORC moved to Chicago, in 1948, researchers from the Survey Research Center and the Research Center for Group Dynamics founded ISR in Ann Arbor (www.isr.umich.edu). From its very beginning ISR advocated interdisciplinary research. Its continuous studies range from National Election Studies to the Panel Study of Income Dynamics. It provides major databases as well as substantial contributions in group dynamics and political science to the scientific community. ISR is also a world leader in survey research methodology and statistics. Researchers like Kish, Schuman, Converse, Presser, Groves, Couper, Singer, and Schwarz pave the way for modern survey research processes in areas such as sampling statistics, response error, household-non-response, and survey cognition processes.

Another impact area of ISR is training and data publishing. Since 1962 ISR has hosted the Inter-university Consortium for Political and Social Research (ICPSR) which was founded as an archive for quantitative social science data. From a safe haven for key punched cards ICPSR developed the world's largest survey data publisher/distributor where researchers have access to thousands of data files.

ISR offers three training programs open to researchers worldwide. These are the Summer Institute in Survey Research Techniques, the ICPSR Summer Program in Quantitative Methods and, more recently, the Research Center on Group Dynamics Program in Experimental Methodology and Statistics. The institute puts much emphasis on international cooperation and knowledge dissemination in all its activities.

Apart from a healthy competitive attitude, NORC and ISR are complementary institutes with strong ties to their respective universities (NORC—University of Chicago, ISR—University of Michigan at Ann Arbor). NORC puts more emphasis on fielding many complex studies, while ISR concentrates on specific studies. ISR is very strong in survey methodology, while NORC is stronger in survey process management and sampling design. Both provide a base for international cooperation.

4. *NATCEN: National Centre for Social Research, London*

NATCEN, formerly SCPR, was founded in 1969. Today, it is Britain's largest nonprofit survey research organization (www.natcen.ac.uk). It is the home of British Social Attitudes as Britain's general social survey, of the British Elections studies, and major health surveys, to name but a few. Within the tradition of British social research, NATCEN conducts both quantitative and qualitative studies. Among its divisions are a Survey Methods Centre (research, consulting, and teaching) and joint centers with universities like CASS (Centre for Applied Social Surveys) which hosts a survey item bank. Researchers at NATCEN are leading in applied survey research. Among their innovations is the International Social Survey Programme (ISSP) initiated by Roger Jowell and the first ever deliberative poll. It will be the 'command and engine room' of the European Social Survey to come in 2002.

NATCEN is the only center among the survey research centers discussed here which names itself a 'national center.' However, it is a national center not by Her Majesty's appointment, but *de facto* due to the specific structure of the British science funding system. As an independent charitable trust it forms the base for collaborative mid-range and long-range projects like CREST, the Centre for Research into Elections & Social Trends. Funded as a research center of the Economic and Social Research Council (ESRC), it is a joint venture of Nuffield College in Oxford and NATCEN in London. The above-mentioned CASS, on the other hand, is an ESRC research center joining NATCEN with the University of Southampton.

5. *GESIS: German Society of Social Science Infrastructure Institutes, Mannheim, Cologne, and Bonn*

Founded in 1986 by act of the federal government and all states, GESIS comprises three major centers: ZUMA, Center for Survey Research and Methodology in Mannheim, the Zentralarchiv in Cologne, and the Information Center (www.gesis.org). Together

these three centers form a comprehensive national survey research center as a permanent infrastructure for the social sciences.

ZUMA consults academics in all areas of quantitative survey methods; it runs continuous research streams in areas like standardization of demographics, intercultural survey research, and, recently in web surveys. It is, among others, the home of ALLBUS, the German General Social Survey, the German ISSP, and a participant in the German Social Welfare Studies. Together with researchers from five other European institutes it will be part of the European Social Survey 'engine room' (see above). It is also the birthplace of the German Standard Demography, now a major project of the German Census Office, ZUMA, and other professional groups. The center bridges the gap between German Official Statistics and the social science profession by providing and/or enabling access to official microdata.

The Zentralarchiv, founded as early as 1960, is the German national archive for quantitative survey data. It played a major role in establishing the international archive network. The archive also provides training courses in survey methods.

The Information Center provides in-depth bibliographies of German social science publications, keeps record of ongoing research projects, and serves as a platform for information interchange between Eastern and Western Europe.

Taken together the three centers form a unique infrastructure for their national scientific community. Access to all services is free, products are nominally charged.

The three institutes were independent and differently funded units until the National Science Board (*Wissenschaftsrat*) voted to form a unified national survey research center, namely GESIS. As a social science infrastructure it has a strict supportive function for academic research. Substantive research is different than in America or Britain, and is not a core issue of GESIS. However, as a dedicated social science infrastructure GESIS is fully funded by the federal government and all German states.

6. *Conclusion*

National centers for survey research are defined as institutions that provide databases, methodological research, and training for their scientific community. In addition, national centers focus on the national rather than the regional level and bridge national research with international. There may be more institutions around the globe than the four introduced here. Many others may fulfill one or other of the functions. However, the core of a national center for survey research is dedicated methodological studies embedded into long-term methodological and substantial research programs.

In looking back to get a vision of the future, one could arguably say that the fast progress one could observe in survey research technology and methodology since the 1950s was caused by the very existence of the two American centers. Others countries still lag behind the United States both in advancement of scientific knowledge and in survey engineering. Germany, for instance, where ZUMA was founded as late as 1974 with limited capacities (no fieldwork staff, no own surveys), had to bridge a huge methodological and technological gap since the 1980s. The founding of GESIS as a national center was a late but not too late remedy. It is thus no coincidence that the lack of national centers or their substitutes correlates with the standards of survey research in a country. Because all modern societies need sound information about their own state, efforts should be made to either found more national centers or to transform existing ones into real or virtual transnational centers. Finally, in view of the new survey technologies, like net-based multimedia surveys, and their likely abuse and misuse, national centers become even more indispensable as a means to sort good methods and data from information rubbish.

Surveys and Polling: Ethical Aspects

Polls and surveys are used to investigate opinions and attitudes, and to obtain factual information. Two broad aspects of ethical practice with respect to polls and surveys can be distinguished. The first has to do with the extent to which research designs, instruments, data collection procedures, and analysis permit valid and reliable conclusions. The second pertains to the researcher's obligations toward others, especially respondents, but clients and the larger public as well. Because polls and surveys are really indistinguishable

except in terms of location, with polls typically carried out by commercial organizations and surveys by academic institutions (Schuman 1997), the present discussion of ethical practices is intended to apply to both.

Although the discussion is framed in terms of the code of ethics of one organization in a particular country—the Code of Ethics of the American Association for Public Opinion Research (AAPOR), a professional organization including academic, commercial, and government survey researchers among its members—the principles presented here apply much more generally. But because the legal requirements for protecting respondent confidentiality, as well as the ability to do so in practice, vary from one country to another, such variations are not discussed here. Also excluded from the discussion are the fundamentally different ethical issues raised by administrative uses of data gathered for statistical purposes (see, for example, Seltzer 1998).

1. *Standards for the Conduct of Research*

AAPOR's Code of Ethics, which obligates members to adhere to the Code and is one of the few such instruments to provide a mechanism for punishing violations, is necessarily couched in general terms, simply asserting that members will 'exercise due care' in carrying out research and 'take all reasonable steps' to assure the validity and reliability of results. In May 1996, AAPOR adopted two more specific statements, one defining a set of performance standards that embody current 'best practices' in the field of survey research, the other a set of practices that are universally condemned. Members are urged to adhere to the first and refrain from the second. Among the 'best practices' are scientific methods of sampling, which ensure that each member of the population has a measurable chance of selection; follow-up of those selected to achieve an adequate response rate; careful development and pretesting of the questionnaire, with attention to known effects of question wording and order on response tendencies; and adequate training and supervision of interviewers. Among practices defined as 'unacceptable' are fund raising, selling, or canvassing under the guise of research; representing the results of a poll of self-selected or volunteer respondents (for example, readers of a magazine who happen to return a questionnaire, callers to an 800- or 900-number poll, or haphazard respondents to a web-based survey) as if they were the outcome of legitimate research; and 'push polls,' which feed false or misleading information to voters under the pretense of taking a poll. For example, a push-poll might ask if the respondent would object to learning that candidate X has been accused of child abuse, has defaulted on a loan, etc. Revealing the identity of individual respondents to anyone without their permission, and misleading the public by selecting or manipulating methods of research or analysis to reach a desired conclusion, are included among 'unacceptable' practices but they are also mentioned in the AAPOR Code.

2. *Standards for Dealing with Clients, the Public, and Respondents*

2.1 *Obligations to Clients*

Ethical behavior toward clients requires, in the first place, undertaking only those research assignments that can reasonably be accomplished, given the limitations of survey research techniques themselves or limited resources on the part of the researcher or client. Second, it means holding information about the research and the client confidential, except as expressly authorized by the client or as required by other provisions of the Code. Chief among the latter is the requirement that researchers who become aware of serious distortions of their findings in public must disclose whatever may be needed to correct these distortions, including a statement to the group to which the distorted findings were presented. In practice, this provision of the Code may obligate researchers to issue a corrective statement to a legislative body, a regulatory agency, the media, or some other appropriate group if they become aware of the release of such distorted results.

2.2 *Obligations to the Public*

The AAPOR Code of Ethics attempts to satisfy the profession's obligations to the larger public by mandating the disclosure of minimal information about a poll or survey whose findings are publicly released. The elements that must, at a minimum, be disclosed are the following: (a) who sponsored the survey, and who conducted it; (b) the exact wording of questions asked, including the text of any preceding instruction or explanation to the interviewer or respondent that might reasonably be expected to affect the response; (c) a definition of the population under study and a description of the sampling frame; (d) a description of the sample selection procedure, making clear whether respondents were selected by the researcher or were self-selected; (e) size of sample and, if applicable, completion rates and information on eligibility criteria and screening procedures; (f) a discussion of the precision of the findings, including, if appropriate, estimates of sampling error and a description of any weighting or estimating procedure used; (g) which results, if any, are based on parts of the sample rather than the entire sample; (h) method, location, and dates of data collection. Together, these items of information communicate some idea of the error likely to

be associated with estimates from a given survey, or, conversely, the degree of confidence warranted by the results. The Code requires this information to be included in any report of research results, or, alternatively, made available at the time the report is released. In other words, researchers are not required by the Code of Ethics to follow the best professional practices, but they are required to disclose the practices they used. Thus, the Code relies on the 'marketplace of ideas' to drive out bad practices over time.

2.3 Obligations to Respondents

Few, if any, surveys put respondents at physical or psychological risk in ways that psychological experiments or, particularly, medical research may do. Ordinarily, the biggest risk to survey respondents comes from the possibility that their identity will be disclosed, either inadvertently, because adequate precautions were not taken to maintain the confidentiality of the data, or deliberately, as a result of special efforts by an 'intruder' to obtain the identity of one or more respondents. Thus, survey organizations have a special responsibility both to protect the confidentiality of the data they collect and to inform respondents of the risks that remain. These are two of the ethical issues that will be discussed in this section; the third arises from declining survey response rates and attempts to compensate for these by special persuasion strategies, including the offer of refusal conversion payments.

2.3.1 Informed consent in surveys and polls. One important purpose of informed consent is to protect respondents from harm. Another purpose, less often cited, is to give them meaningful control over information about themselves, even if the question of harm does not arise. For example, informing potential respondents of the voluntary nature of their participation in the interview is essential to ethical survey practice, even if this leads some potential respondents to refuse to participate. Similarly, obtaining the respondents' permission to record an interview should be standard practice, even though no harm is likely to come to them as a result. Currently, many states permit such recording with only the interviewer's consent.

At present, obtaining informed consent, which may be defined as the 'knowing consent of an individual or his legally authorized representative … without undue inducement or any element of force, fraud, deceit, duress, or any other form of constraint or coercion,' is not legally mandated for participation in most surveys in the United States. Even those surveys that are subject to federal rules for the protection of human subjects are exempt unless they collect respondent identification and disclosure of responses could reasonably be damaging to respondents' good reputation, employability, or financial standing or could put them at risk of civil or criminal liability (*Federal Register* 1991, 28:012). (Surveys of populations that are seen as especially vulnerable, such as minors or incapacitated or institutionalized adults, are required to institute special procedures for obtaining informed consent, however.) But surveys conducted by federal agencies *are* subject to the Privacy Act of 1974, which requires the disclosure of some information to respondents—for example, the principal purpose for which the survey is to be used (Duncan et al. 1993).

Although informed consent is not *legally* required for most surveys in the United States, some major professional associations (for example, the American Statistical Association and the American Sociological Association) do make mention of it in their ethical codes. AAPOR, however, does not, noting only that 'We shall strive to avoid the use of practices or methods that may harm, humiliate, or seriously mislead survey respondents.'

It is not difficult to understand this omission. Although full disclosure of sponsorship and purpose, for example, may be highly desirable from an ethical point of view, it may seriously bias responses to a survey. It may do so not only because some people will choose not to participate in surveys sponsored by certain organizations or with a particular purpose, but also because those who do participate may distort their responses in order to thwart or advance the purpose as they understand it. From another standpoint, the issue is how much detail should be communicated in order to 'inform' respondents— should they, for example, be told in advance that they are going to be asked their income near the end of the interview? Although Presser (1994) argues persuasively that the uses to which a survey will be put are often impossible to predict and even harder to communicate to respondents with any accuracy, he acknowledges that in the end, there 'may be no escaping the conflict of ethical obligations with research ends' (Presser 1994, p. 454).

2.3.2 Protection of respondents' confidentiality. As has already been noted, probably the most important source of danger to survey respondents comes from identification of their responses, that is, from deliberate or inadvertent breaches of confidentiality. The more sensitive the information requested—for example, HIV status or whether the respondent has engaged in some illegal activity—the greater the harm that a breach of confidentiality might entail. Not unexpectedly, respondents require strong assurances of confidentiality when they are asked to provide such data about themselves (Singer et al. 1995).

A variety of threats to the confidentiality of survey data exist. Most common is simple carelessness—not

removing identifiers from questionnaires or electronic data files, leaving cabinets unlocked, not encrypting files containing identifiers. Although there is no evidence of respondents having come to harm as a result of such negligence, it is important for data collection agencies to raise the consciousness of their employees with respect to these issues, provide guidelines for appropriate behavior, and ensure that these are observed.

Less common, but potentially more serious, threats to confidentiality are legal demands for identified data, either in the form of a subpoena or as a result of a Freedom of Information Act (FOIA) request. Surveys that collect data about illegal behaviors such as drug use, for example, are potentially subject to subpoena by law-enforcement agencies. To protect against this, researchers studying mental health, alcohol and drug use, and other sensitive topics, whether federally funded or not, may apply for Certificates of Confidentiality from the Department of Health and Human Services. Such certificates, which remain in effect for the duration of the study, protect researchers from being compelled in most circumstances to disclose names or other identifying characteristics of survey respondents in federal, state, or local proceedings (42 C.F.R. 2a.7, 'Effect of Confidentiality Certificate'). The Certificate protects the identity of respondents; it does not protect the data.

However, when surveys are done expressly for litigation, demands for data from one party or the other are not uncommon, and this protection may not be available. Several such cases are reviewed by Presser (1994). In one, the case was settled before the data were to be produced; in two others, the courts ordered the researchers to turn over raw data, including respondent identifiers, to the defendants. Presser (1994) discusses several actions that might be taken by professional survey organizations to enhance protections of confidentiality in such cases—for example, mandating the destruction of identifiers in surveys designed for adversarial proceedings. If this became standard practice, individual researchers would be better able to defend their own use of such a procedure.

A final threat to data confidentiality that should be mentioned here is what is known as 'statistical disclosure.' So far, the discussion has been in terms of explicit respondent identifiers—name, address, and social security number, for example. But there is increasing awareness that even without explicit identifiers, re-identification of respondents may be possible given the existence of high-speed computers, external data files to which the survey data can be matched, and sophisticated matching software. Longitudinal studies may be especially vulnerable to such re-identification.

There are essentially two ways to reduce the risk of statistical disclosure: restricting access to the data, for example by enclave or bonding arrangements, or restricting the data that may be released, for example, by top-coding age and income and releasing detailed data only for large geographic areas. Although guidelines for reducing the risk of statistical disclosure exist (Federal Committee on Statistical Methodology 1994), some researchers believe that the best way to safeguard confidentiality is to create synthetic data sets derived from the actual information provided by respondents (Rubin 1987).

In view of the diverse threats to confidentiality reviewed above, there is a growing consensus among researchers that absolute assurances of confidentiality should seldom, if ever, be given to respondents (Duncan et al. 1993). The 'Ethical Guidelines for Statistical Practice' of the American Statistical Association (ASA), for example, caution statisticians to 'anticipate secondary and indirect uses of the data when obtaining approvals from research subjects.' At a minimum, the Guidelines urge statisticians to provide for later independent replication of an analysis by an outside party. They also warn researchers not to imply protection of confidentiality from legal processes of discovery unless they have been explicitly authorized to do so, for example, by a Certificate of Confidentiality. Research by Singer (1978) and Singer et al. (1995) suggests that for surveys on nonsensitive topics, neither the response rate nor data quality is likely to suffer as a result of such qualified assurances of confidentiality. For those collecting sensitive data, researchers should make every effort to obtain a Certificate of Confidentiality, which would permit them to offer stronger assurances to respondents. Even such Certificates, however, cannot guard against the risk of statistical disclosure.

2.3.3 Efforts at persuasion. An issue that merits brief discussion here is the dilemma created by the need for high response rates from populations that spend less time at home, have less discretionary time, and are less inclined to cooperate in surveys. This dilemma leads survey organizations to attempt more refusal conversions and to make greater use of refusal conversion payments. Respondents see both practices as undesirable (Groves et al. 1999). They also regard the paying of refusal conversion payments as unfair, but awareness of such payments does not appear to reduce either the willingness to respond to a future survey or actual participation in a new survey (Singer et al. 1999).

2.3.4 Polling on the Net. Polls and surveys conducted on the Internet have shown explosive growth in the last several years, and such surveys bring an entirely new set of ethical problems to the fore, or bring new dimensions to old problems. For example, maintenance of privacy and confidentiality in such surveys requires technological innovations (for example, 'secure' websites, encryption of responses) beyond those

required by older modes of data collection. Other ethical issues simply do not arise with older modes of conducting surveys—for example, the possibility that a respondent might submit multiple answers, thus deliberately biasing the results—and these, too, call for new technical solutions requiring sophisticated knowledge of computer hardware and software. These problems, and proposed solutions, are too new to permit more than brief mention of them here.

3. Concluding Observations

A number of developments in recent years have increased ethical dilemmas for survey researchers. There is growing demand for information about individuals on the part of both business and government. At the same time, there is growing concern about personal privacy on the part of the public. Technological developments have made safeguarding privacy and confidentiality increasingly difficult, and for this as well as other reasons, there is increasing reluctance on the part of the public to participate in polls and surveys, including government censuses. How these dilemmas are resolved in the next few years will have profound implications for the future of survey research.

Survival Analysis: Overview

1. Failure-time Data and Representation

The term survival analysis has come to embody the set of statistical techniques used to analyze and interpret time-to-event, or failure-time data. The events under study may be disease occurrences or recurrences in a biomedical setting, machine breakdowns in an industrial context, or the occurrence of major life events in a longitudinal-cohort setting. It is important in applications that the event of interest be defined clearly and unambiguously. A failure-time variable T is defined for an individual as the time from a meaningful origin or starting point, such as date of birth, or date of randomization into a clinical trial, to the occurrence of an event of interest. For convenience, we refer to the event under study as a failure.

A cohort study involves selecting a representative set of individuals from some target population and following those individuals forward in time in order to record the occurrence and timing of the failures. Often, some study subjects will still be without failure at the time of data analysis, in which case their failure times T will be known only to exceed their corresponding censoring times. In this case, the censoring time is defined as the time elapsed from the origin to the latest follow-up time, and the failure time is said to be right censored. Right censorship may also arise because subjects drop out the study, or are lost to follow-up. A key assumption underlying most survival analysis methods is that the probability of censoring an individual at a given follow-up time does not depend on subsequent failure times. This independence assumption implies that individuals who are under study at time t are representative of the cohort and precludes, for example, the censoring of individuals at time t because, among individuals under study at that time, they appear to be at unusually high (or low) risk of failure. (This assumption can be relaxed to independence between censoring and failure times conditional on the preceding histories of covariates.) The

reasonableness of the independent censoring assumption, which usually cannot be tested directly, should be considered carefully in specific applications.

The distribution of a failure time variate $T > 0$ is readily represented by its survivor function $F(t) = P(T > t)$. If T is absolutely continuous, its distribution can also be represented by the probability density function $f(t) = -dF(t)/dt$ or by the hazard, or instantaneous failure rate, function defined by

$$\lambda(t) = \lim_{\Delta t \downarrow 0} P(t \leqslant T < t + \Delta t \mid T \geqslant t)/\Delta t = f(t)/F(t^-). \tag{1}$$

Note that

$$F(t) = \exp\{-\int_o^t \lambda(u)\,\mathrm{d}u\}, \quad \text{and}$$

$$f(t) = \lambda(t)\exp\{-\int_o^t \lambda(u)\,\mathrm{d}u\}$$

for $0 < t < \infty$

In a similar way, the distribution of a discrete failure time variate T, taking values on $x_1 < x_2 < \cdots$, can be represented by its survivor function, its probability function $f(x_i) = P(T = x_i)$, $i = 1, 2 \ldots$, or its hazard function $\lambda(x_i) = P(T = x_i | T \geqslant x_i) = f(x_i) | F(x_i^-)$. Note that

$$F(t) = P(T > t) = \prod_{i \mid x_i \leqslant t} [1 - \lambda(x_i)] \tag{2}$$

as arises through thinking about the failure mechanism unfolding sequentially in time. To survive past time t where $x_j \leqslant t < x_{j+1}$, an individual must survive in sequence each of the points $x_1, \ldots, x_j$ with conditional probabilities $1 - \lambda(x_i)$, $i = 1, \ldots, j$.

It is often natural and insightful to focus on the hazard function. For example, human mortality rates are known to be elevated in the first few years of life, to be low and relatively flat for the next three decades or so, and then to increase rapidly in the later decades of life. Similarly, comparison of hazard rates as a function of time from randomization for a new treatment compared with control can provide valuable insights into the nature of treatment effects. Hazard function modeling also integrates nicely with a number of key strategies for selecting study subjects from a target population. For example, if one is studying disease occurrence as it depends upon the age of study subjects, hazard function models readily accommodate varying ages at entry into the study cohort since the conditioning event in (1) specifies that the individual is surviving and event-free at age t. Again one needs to assume that selected subjects have hazard rates that are representative (conditional on covariates) of those at risk for the target population.

2. Estimation and Comparison of Survival Curves

Suppose that a cohort of individuals has been identified at a time origin $t = 0$ and followed forward in time. Suppose that failures are observed at times $t_1 < t_2 < \cdots < t_k$. Just prior to the failures observed at time t_j, there will be some number, r_j, of cohort members that are under active follow-up. That is, the failure and censoring times for these r_j members occur at time t_j or later. Of these r_j individuals, some number, d_j, are observed to fail at t_j. The empirical failure rate or estimated hazard at t_j is then d_j/r_j, and the empirical survival rate is $(1 - d_j/r_j)$. The empirical failure rate at all times other than $t_1, \ldots, t_k$ in the follow-up period is zero. The Kaplan and Meier (1958) estimator of the survivor function F at follow-up time t is

$$\hat{F}(t) = \prod_{\{t_j \leqslant t\}} (1 - d_j/r_j) \tag{3}$$

the product of the empirical survivor rates across the observed failure times less than or equal to t. Note that $\hat{F}$ estimates the underlying survivor function F at those times where there are cohort members at risk. For (3) to be valid, the cohort members at risk at any follow-up time t must have the same failure rate operating as does the target population at that follow-up time. Thus, the aforementioned independent censoring assumptions are needed.

The hazard rate estimators d_j/r_j, $j = 1, \ldots, k$ can be shown to be uncorrelated, giving rise to the Greenwood variance estimator

$$\mathrm{var}\,\{\hat{F}(t)\} = \hat{F}(t)^2 \sum_{\{t_i \leqslant t\}} d_j/\{r_j(r_j - d_j)\} \tag{4}$$

for $\hat{F}(t)$. In order to show asymptotic results for the estimator $\hat{F}(t)$, for example that $\hat{F}(t)$ is a consistent estimator of $F(t)$, it is necessary to restrict the estimation to a follow-up interval $[0, \tau)$ within which the size of the risk set (i.e., number of individuals under active follow-up) becomes large as the sample size (n) increases. Under these conditions, $n^{1/2}\{\hat{F}(t) - F(\mathrm{t})\}$; $0 \leqslant t < \tau$ can be shown to converge weakly to a mean-zero Gaussian process, permitting the calculation of approximate confidence intervals and bands for F on $[0, \tau)$. Applying the asymptotic results to the estimation of $\log\{-\log F(t)\}$, which has no range restrictions, is suggested as a way to improve the coverage rates of asymptotic confidence intervals and bands (Kalbfleisch and Prentice 1980, pp. 14, 15).

Consider a test of equality of m survivor functions $F_1, \ldots, F_m$ on the basis of failure-time data from each of m populations. Let $t_1 < t_2 < \cdots < t_k$ denote the ordered failure times from the pooled data, and again let d_j failures occur out of the r_j individuals at risk just prior to time t_j, $j = 1, \ldots, k$. Also, for each sample $i = 1, \ldots, m$, let d_{ij} denote the number of failures at t_j, and r_{ij} denote the number at risk at t_j^-. Under the null

hypothesis $F_1 = F_2 = \cdots = F_m$ the conditional distribution of $d_{1j},\ldots, d_{mj}$ given $(d_j, r_{1j},\ldots, r_{mj})$ is hypergeometric from which the conditional mean and variance of d_{ij} are respectively $u_{ij} = r_{ij}(d_j/r_j)$ and $(V_j)_{ii} = r_{ij}(r_i - r_{ij})d_j(r_j - d_j)r_j^{-2}(r_j - 1)^{-1}$. The conditional covariance of d_{ij} and $d_{\ell j}$ is

$$(V_j)_{i\ell} = r_{ij}r_{\ell j}d_j(r_j - d_j)r_j^{-2}(r_j - 1)^{-1}. \tag{5}$$

Hence the statistic $v_j' = (d_{1j} - u_{1j},\ldots, d_{mj} - u_{mj})$ has conditional mean zero and variance V_j under the null hypothesis. The summation of these differences across failure times,

$$v = \sum_1^k v_j \tag{6}$$

is known as the logrank statistic (Mantel 1966, Peto and Peto 1972). The contributions to this statistic across the various failure times are uncorrelated, and $v'V^{-1}v$ generally has an asymptotic chi-square distribution with $m-1$ degrees of freedom where $V = \sum_1^k V_j$ and a 'prime' denotes vector transpose.

This construction also shows that a broad class of 'censored data rank tests' of the form $\sum_1^k w_j v_j$ also provide valid tests of the equality of the m survival curves. In these tests, the 'weight' w_j at time t_j can be chosen to depend on the above conditioning event at t_j, or on data collected before t_j, more generally. The null hypothesis variance of these test statistics is readily estimated by $\sum_1^k w_j^2 V_j$, again leading to an asymptotic chi-square $(m-1)$ test statistic. The special case $w_j = \hat{F}(t_j^-)$ generalizes the Wilcoxon rank sum test to censored data in a natural fashion (e.g., Peto and Peto 1972, Prentice 1978) and provides an alternative to the logrank test that assigns greater weight to earlier failure times. More adaptive tests can also be entertained (e.g., Harrington and Fleming 1982).

3. *Failure-time Regression: The Cox Model*

3.1 *Model Development*

The same type of conditional probability argument generalizes to produce a flexible and powerful regression method for the analysis of failure-time data. This method was proposed in the fundamental paper by Cox (1972) and is referred to as Cox regression or as relative risk regression.

Suppose that each subject has an associated vector of covariates $z' = (z_1, z_2,\ldots)$. For example, the elements of z may include primary exposure variables and confounding factor measurements in an epidemiologic cohort study, or treatment indicators and patient characteristics in a randomized clinical trial. Let $\lambda(t; z)$ denote the hazard rate at time t for an absolutely continuous failure time T on an individual with covariate vector z. Now one requires the censoring patterns, and the cohort entry patterns, to be such that the hazard rate $\lambda(t; z)$ applies to the cohort members at risk at follow-up time t and covariate value z for each t and z. The Cox regression model specifies a parametric form for the hazard rate ratio $\lambda(t; z)/\lambda(t; z_0)$, where z_0 is a reference value (e.g., $z_0 = 0$). Because this ratio is nonnegative, it is common to use an exponential parametric model of the form $\exp\{x(t)\beta\}$. The vector $x(t) = \{x_1(t),\ldots, x_p(t)\}$ includes derived covariates that are functions of the elements of z (e.g., main effects and interactions) and possibly product (interaction) terms between z and t. The vector $\beta' = (\beta_1,\ldots, \beta_p)$ is a p-vector of regression parameters to be estimated. Denoting $\lambda_0(t) = \lambda(t; z_0)$ allows the model to be written in the standard form

$$\lambda(t; z) = \lambda_0(t)\exp\{x(t)\beta\}. \tag{7}$$

As in previous section let $t_1 < t_2 < \cdots < t_k$ denote the ordered distinct failure times observed in follow-up of the cohort, and let d_j denote the number of failures at t_j. Also let $R(t_j)$ denote the set of labels of individuals at risk for failure at t_j^-. We suppose first that there are no ties in the data so that $d_j = 1$. The conditional probability that the ith individual in the risk set with covariate z_i fails at t_j, given that $d_j = 1$ and the failure, censoring (and covariate) information prior to t_j, is simply

$$\frac{\lambda(t_j; z_i)}{\sum_{\ell \in R(t_j)}\lambda(t_j; z_\ell)} = \frac{\exp\{x_i(t_j)\beta\}}{\sum_{\ell \in R(t_j)}\exp\{x_l(t_j)\beta\}}. \tag{8}$$

The product of such terms across the distinct failure times

$$L(\beta) = \prod_{j=1}^k \frac{\exp\{x_j(t_j)\beta\}}{\sum_{\ell \in R(t_j)}\exp\{x_\ell(t_j)\beta\}} \tag{9}$$

is known as the partial likelihood function for the relative risk parameter β.

If one denotes $L(\beta) = \prod_{j=1}^k L_j(\beta)$, then the fact that the scores $\partial \log L_j(\beta)/\partial\beta$, $j = 1,\ldots, k$ have mean zero and are uncorrelated (Cox 1975) suggests that, under regularity conditions, the partial likelihood (9) has the same asymptotic properties as does the usual likelihood function. Let $\hat{\beta}$ denote the maximum partial likelihood estimate that solves $\partial \log L(\beta)/\partial\beta = 0$. Then, $n^{1/2}(\hat{\beta} - \beta)$ will generally converge, as the sample size n becomes large, to a p-variate normal distribution having mean zero and covariance matrix consistently estimated by $-n^{-1}\partial^2 \log L(\hat{\beta})/\partial\hat{\beta}\partial\hat{\beta}'$. This result provides the usual basis for tests and confidence intervals on the elements of β.

Even though we are working with continuous models, there will often be some tied failure times. If the ties are numerous, it may be better to model the data using a discrete failure-time model. Often, however, a simple modification to (9) is appropriate.

When the d_j are small compared with the r_j, the approximate partial likelihood (Peto and Peto 1972, Breslow 1974)

$$L(\beta) = \prod_{j=1}^{k} \frac{\exp\{s_j(t_j)\beta\}}{[\sum_{\ell \in R(t_j)} \exp\{x_l(t_j)\beta\}]^{d_j}} \tag{10}$$

is quite adequate for inference, where $s_j(t_j) = \sum_{i \in D_j} x_i(t_j)$ and D_j represents the set of labels of individuals failing at t_j. Efron (1977) suggested an alternate approximation that is only slightly more complicated and is somewhat better. Both the Breslow and Efron approximations are available in software packages.

3.2 Special Cases and Generalizations

Some special cases of the modeled regression vector $x(t)$ illustrate the flexibility of the relative risk model (7). If one restricts $x(t) = x$, to be independent of t, then the hazard ratios at any pair of z-values are constant. This gives the important proportional hazards special case of (7). For example, if the elements of z include indicator variables for $m-1$ of m samples and $x(t) = (z_1,\ldots, z_{m-1})$ then each e^{β_j}, $j = 1,\ldots, m-1$ denotes the hazard ratio for the jth sample compared with the last (mth) sample. In this circumstance the score test for $\beta = 0$ arising from (9) reduces to the logrank test of the preceding section.

The constant hazard ratio assumption, in this example, can be relaxed by defining $x(t) = \{g(t)z_1,\ldots, g(t)z_{m-1}\}$ for some specified function g of follow-up time. For example $g(t) = \log t$ would allow hazard ratios of the form t^{β_j} for the jth sample compared with the mth. This gives a model in which hazard ratio for the jth vs. the mth population increase ($\beta_j > 0$) or decrease ($\beta_j < 0$) monotonely from unity as t increases. The corresponding score test would be a weighted logrank test for the global null hypothesis. More generally one could define $x(t) = \{z_1,\ldots, z_{m-1}, g(t)z_1,\ldots, g(t)z_{m-1}\}$. This model is hierarchical with main effects for the sample indicators and interactions with $g(t)$. A test that the interaction coefficients are zero provides an approach to checking for proportionality of the hazard functions. Departure from proportionality would imply the need to retain some product terms in the model, or to relax the proportionality assumption in some other way.

As a second special case consider a single quantitative predictor variable z. Under a proportional hazards assumption one can include various functions of z in the modeled (time independent) regression vector $x(t) = x$ for model building and checking, just as in ordinary linear regression. The proportionality assumption can be relaxed in various ways including setting $x(t) = \{xI_1(t),\ldots, xI_q(t)\}$ where $I_1(t),\ldots, I_q(t)$ are indicator variables for a partition of the study follow-up period. The resulting model allows the relative risk parameters corresponding to the elements of $x = x(z)$ to be separately estimated in each follow-up interval. This provides a means for testing the proportionality assumption, and relaxing it as necessary to provide an adequate representation of the data.

The above description of the Cox model (7) assumed that a fixed regression vector z was measured on each study subject. It is important to note that (7) can be relaxed to include measurements of stochastic covariates that evolve over time. This does not complicate the development of (9) or (10). Specifically, if $z(t)$ denotes a study subject's covariates at follow-up time t, and $Z(t) = \{z(u); u < t\}$ denotes the corresponding covariate history up to time t, then the hazard rate $\lambda(t; Z(t)\}$ can be modeled according to the right side of (7) with $x(t)$, comprising functions of $Z(t)$ and product terms between such functions and time.

Careful thought must be given to relative risk parameter interpretation in the presence of stochastic covariates. For example, the interpretation of treatment effect parameters in a randomized controlled trial may be affected substantially by the inclusion of postrandomization covariates when those covariates are affected by the treatment. However, careful use of such covariates can serve to identify mechanisms by which the treatment works.

3.3 Survivor Function Estimation

The cumulative 'baseline' hazard function $\Lambda_0(t) = \int_0^t \lambda_0(u)\mathrm{d}u$ (7) can be simply estimated (Breslow 1974) by

$$\hat{\Lambda}_0(t; \hat{\beta}) = \sum_{t_j \leqslant t} \left[d_j \Big/ \sum_{\ell \in R(t_j)} \exp\{x_\ell(t_j)\hat{\beta}\} \right]. \tag{11}$$

If $x(t) = x$ is time-independent, the survivor function $F(t; z) = p\{T > t|z\} = \exp\{-\Lambda_0(t)e^{x\beta}\}$ is estimated by

$$\hat{F}(t; z) = \exp\{-\hat{\Lambda}_0(t; \hat{\beta})\mathrm{e}^{x\hat{\beta}}\} \tag{12}$$

A slightly more complicated estimator $\hat{F}(t; z)$ is available if x is time-dependent.

A practically important generalization of (7) allows the baseline hazard to depend on strata $s = s(z)$, or more generally $s = s(z, t)$ so that

$$\lambda(t; z) = \lambda_{0s}(t) \exp\{x(t)\beta\} \tag{13}$$

where s takes integer values $1, 2,\ldots, m$ indexing the strata. This provides another avenue for relaxing a proportional hazards assumption. The stratified partial likelihood is simply a product of terms (9) over the various strata.

3.4 Asymptotic Distribution Theory

The score function $U(\beta) = \partial \log L(\beta)/\partial\beta$ from (9) involves a sum of terms that are uncorrelated but not

independent. The theory of counting processes and martingales provides a framework in which this uncorrelated structure can be described, and a formal development of asymptotic distribution theory. Specifically, the counting process N for a study subject is defined by $N(t) = 0$ prior to the time of an observed failure, and $N(t) = 1$ at or beyond the subject's observed failure time. The counting process can be decomposed as

$$N(t) = \Lambda(t) + M(t) \tag{14}$$

where, under independent censorship,

$$\Lambda(t) = Y(t)\int_0^t \lambda\{u; Z(u)\}\mathrm{d}u \tag{15}$$

and $M(t)$ is a locally square integrable martingale. Note that in the 'compensator' Λ the 'at risk' process Y is defined by $Y(t) = 1$ up to the time of failure or censoring for the subject and zero thereafter. The decomposition (14) allows the logarithm of (9), and its derivatives, and the cumulative hazard estimator (11), to be expressed as stochastic integrals with respect to martingales, to which powerful convergence theorems apply. Anderson and Gill (1982) provide a thorough development of asymptotic distribution theory for the Cox model using these counting process techniques, and provide weak conditions for the joint asymptotic convergence of $n^{1/2}(\hat{\beta}-\beta)$ and to $\hat{\Lambda}_0(\cdot, \hat{\beta})$ to Gaussian processes. The books by Fleming and Harrington (1991) and Andersen et al. (1993) use the counting process formulation for the theory of each of the statistics mentioned above, and for various other tests and estimators.

4. Other Failure-time Regression Models

4.1 Parametric Models

Parametric failure-time regression models may be considered as an alternative to the semiparametric Cox model (7). For example, requiring $\lambda_0(t)$ in (7) to be a constant or a power function of time gives exponential and Weibull regression models respectively. The maximum partial likelihood estimate $\hat{\beta}$ of the preceding section is known to be fully efficient within the semiparametric model with $\lambda_0(t)$ in (7) completely unspecified. While some efficiency gain in β estimation is possible if an assumed parametric model is true, such improvement is typically small and may be more than offset by a lack of robustness.

Of course there are many parametric regression models that are not contained in the Cox model (7). One such class specifies a linear model for the logarithm of time to failure,

$$\log T = \alpha + x\beta + \sigma u \tag{16}$$

where $x = x(z)$ is comprised of functions of a fixed regression vector z. The parameters α and σ are location and scale parameters, β is a vector of regression parameters and u is an error variate. Because regression effects are additive on log T, or multiplicative on T, this class of models is often referred to as the accelerated failure-time model. If the error u has an extreme value distribution with density $f(u) = \exp(u - \mathrm{e}^u)$, then the resulting model for T is the Weibull regression model previously mentioned. More generally, any specified density for u induces a hazard-function model $\lambda(t; z)$ for T to which standard likelihood estimation procedures apply, and asymptotic distribution theory can be developed based again on counting process theory.

4.2 A Competing Semiparametric Model

The model (16) has also been studied as a semiparametric class in which the distribution of the error u is unspecified. Prentice (1978) considered the likelihood for the censored data rank vector based on the 'residuals' $v(\beta_0) = \log T - x\beta_0$ to generate a linear rank statistic

$$\sum_{j=1}^{k}(x_j - \bar{x}_j)w_j v_j(\beta_0) \tag{17}$$

for testing $\beta = \beta_0$. In (17), $v_j(\beta_0)$ is the jth largest of the uncensored $v(\beta_0)$ values, x_j is the corresponding modeled covariate value, $\bar{x}_j$ is the average of the x-values for the individuals having 'residual' equal or greater than $v_j(\beta_0)$, and w_j is a weight, usually taken to be identically equal to one (logrank scores). An estimator of $\hat{\beta}$ of β in (17) can be defined as a value of β_0 for which the length of the vector (17) is minimized. The calculation of $\hat{\beta}$ is complicated by the fact that (17) is a step function that requires a reranking of the residuals at each trial value of β_0. However, simulated annealing methods have been developed (Lin and Geyer 1992) for this calculation, and resampling methods have been proposed for the estimation of confidence intervals for the elements of β (Parzen et al, 1994). See Ying (1993) for an account of the asymptotic theory for $\hat{\beta}$.

The model (16) implies a hazard function of the form

$$\lambda(t; z) = \lambda_0(te^{-x\beta})\mathrm{e}^{-x\beta}. \tag{18}$$

This form suggests a time-dependent covariate version of the accelerated failure-time model (e.g., Cox and Oakes 1984, Robins and Tsiatis 1992) given by

$$\lambda\{t, Z(t)\} = \lambda_0\left\{\int_0^t \mathrm{e}^{-x(u)\beta}\mathrm{d}u\right\}\mathrm{e}^{-x(t)\beta} \tag{19}$$

which retains the notion of the preceding covariate

history implying a rescaling or acceleration, by a factor $e^{-x(t)\beta}$, of the rate at which a study subject traverses the failure-time axis.

5. Multiple Failure Times and Types

5.1 Multiple Failure Types and Competing Risks

Suppose that individuals are followed for the occurrence of a univariate failure time, but that the failure may be one of several types. The type i specific hazard function at follow-up time t, for an individual having preceding covariate $Z(t)$ can, for example, be specified as

$$\lambda_i\{t; Z(t)\} = \lambda_{0i}(t) \exp\{x(t)\beta_i\} \tag{20}$$

where λ_{0i} is a baseline hazard for the ith failure type and β_i is a corresponding relative risk parameter. Estimation of $\beta_1, \beta_2, \ldots$, under independent censorship is readily based on a partial likelihood function that is simply a product of terms (9) over distinct failure types (e.g., Kalbfleisch and Prentice 1980, Chap. 7). In fact, inference on a particular regression vector β_i and corresponding cumulative hazard function Λ_{0i} is based on (9) upon censoring the failures of types other than (i) at their observed failure times. Accelerated failure time regression methods similarly generalize for the estimation of type-specific regression parameters.

Very often questions are posed that relate to the relationship between the various types of failure. It should be stressed that data on failure time and failure type alone are insufficient for studying the interrelation among the failure mechanisms for the different types, rather one generally requires the ability to observe the times of multiple failures on specific study subjects.

5.2 Recurrent Events

Suppose that there is a single type of failure, but that individual study subjects may experience multiple failures over time. Examples include multiple disease recurrences among cancer patients, multiple job losses in an employment history study, or multiple breakdowns of a manufactured item. The counting process N at follow-up time t is defined as the number of failures observed to occur on the interval $(0, t]$ for the specific individual. The asymptotic theory of Andersen and Gill (1982) embraced such counting processes in which the failure rate at time t was of Cox model form

$$\lambda\{t; H(t)\} = \lambda_0(t) \exp\{x(t)\beta\}. \tag{21}$$

In this expression, the conditioning event $H(t)$ includes the individual's counting process history, in addition to the corresponding covariate history prior to follow-up time t. Hence the modeled covariate $x(t)$ must specify the dependence of the failure rate at time t both on the covariates and on the effects of the individual's preceding failure history. Various generalizations of (21) may be considered to acknowledge these conditioning histories in a flexible fashion. For example, λ_0 can be stratified on the number of preceding failures on the study subject; or the argument in λ_0 may be replaced by the gap time from the preceding failure (Prentice et al 1981).

A useful alternative to (21) involves modeling a marginalized failure rate in which one 'forgets' some aspects of $H(t)$. For example, one could replace $H(t)$ in (21) by the covariate history $Z(t)$ and the number $s = s(t)$ of failures for the individual prior to time t. A Cox-type model $\lambda_{0s}(t) \exp\{x(t)\ \beta_s\}$ for the resulting failure rate function would allow one to focus on covariate effects without having to model the timing of the s preceding failures. While the parameters β_s can again be estimated using the score equations from a stratified version of (9) a corresponding sandwich variance formula is needed to acknowledge the variability introduced by the nonincreasing conditioning event (Wei et al. 1989, Pepe and Cai 1993, Lawless and Nadeau 1995).

5.3 Correlated Failure Times

In some settings, such as group randomized intervention trials, the failure times on individuals within groups may be correlated, a feature that needs to be properly accommodated in data analysis. In other contexts, such as family studies of disease occurrence in genetic epidemiology, study of the nature of the dependency between failure times may be a key research goal.

In the former situation, hazard-function models of the types described above can be specified for the marginal distributions of each of the correlated failure times, and marginal regression parameters may be estimated using the techniques of the preceding sections. A sandwich-type variance estimator is needed to accommodate the dependencies between the estimating function contributions for individuals in the same group (Wei et al 1989, Prentice and Hsu 1997).

If the nature of the dependence between failure times is of substantive interest it is natural to consider nonparametric estimation of the bivariate survivor function $F(t_1, t_2) = p(T_1 > t_1, T_2 > t_2)$. Strongly consistent and asymptotically Gaussian nonparametric estimators are available (Dabrowska 1988, Prentice and Cai 1992), though these estimators are nonparametric efficient only if T_1 and T_2 are independent (Gill et al. 1995). Nonparametric efficient estimators away from this independence special case can be developed through a grouped data nonparametric maximum likelihood approach (Van der Laan 1996), though this estimation problem remains an active area of investigation.

5.4 Frailty Models

There is also substantial literature on the use of latent variables for the modeling of multivariate failure times. In these models, failure times are assumed to be independent given the value of a random effect, or frailty, which is usually assumed to affect the hazard function in a multiplicative (time-independent) fashion.

One of the simplest such models arises if a frailty variate has a gamma distribution. This generates the Clayton (1978) bivariate model with joint survivor function

$$F(t_1, t_2) = \{F_1(t_1)^{-\theta} + F_2(t_2)^{-\theta} - 1\}^{-1/\theta} \qquad (22)$$

where θ controls the extent of dependence between T_1 and T_2 with maximal positive dependence as $\theta \to \infty$, maximal negative dependence as $\theta \to -1$, and independence at $\theta = 0$ (e.g., Oakes 1989).

Nielsen et al. (1992) generalize this model to include regression variables and propose an expectation-maximization algorithm with profiling on θ for model fitting. Andersen et al. (1993) and Hougaard (2000) provide fuller accounts of this approach to multivariate failure-time analysis.

6. Additional Survival Analysis Topics

Space permits only brief mention of a few additional survival analysis topics: Considerable effort has been devoted to model building and testing aspects of the use of failure-time regression models. The monograph by Therneau and Grambsch (2000) summarizes much of this work in the context of the Cox model (7).

The cost of assembling covariate histories has led to a number of proposals for sampling within cohorts, whereby the denominator terms in (9) are replaced by suitable estimates, based on a subset of the subjects at risk. These include nested case-control sampling in which the denominator at t_j is replaced by a sum that involves the individual failing at t_j and controls randomly selected from $R(t_j)$, independently at each distinct t_j, and case-cohort sampling in which the denominator summation at t_j consists of the failing individual along with the at risk members of a fixed random subcohort (see Samuelson (1997) for a recent contribution).

Considerable effort has also been directed to allowing for measurement error in regression variables, particularly in the context of the Cox model (7) with time-independent covariates. Huang and Wang (2000) provide a method for consistently estimating β in (7) under a classical measurement error model, and provide a summary of the literature on this important topic.

Testing and estimation on regression parameters has also been considered in the context of clinical trials under sequential monitoring. The recent book by Jennison and Turnbull (2000) summarizes this work.

Additional perspective on the survival analysis literature can be obtained from the overviews of Anderson and Keiding (1999) and of Oakes (2000). Goldstein and Harrell (1999) provide a description of the capabilities of various statistical software packages for carrying out survival analyses.

Sustainability Transition: Human–Environment Relationship

The reconciliation of society's human developmental goals with the planet's environmental limits over the long term is the foundation of an idea known as sustainable development. This idea emerged in the early 1980s from scientific perspectives on the interdependence of society and environment, but even as it garnered increasing political attention and acceptance around the world, its scientific base weakened. The decade of the 1990s has seen an effort to re-engage the scientific community around the requirements for a sustainability transition. Beyond its commonplace meaning as a transition towards a state of sustainable development, a sustainability transition was studied as a series of interlinked transitions, as a process of adaptive management and social learning, and as a set of indicators and future scenarios.

1. *Sustainable Development*

The origins of sustainable development can be traced back through the 1980 World Conservation Strategy and the 1972 Stockholm Conference on the Human Environment to the early days of the international conservation movement (O'Riordan 1988, Adams 1990). But the contemporary linking of environment and development is little more than a decade old, stemming from *Our Common Future*, the 1987 report of the World Commission on Environment and Development (also known as the Brundtland Commission). The Commission defined sustainable development as the ability of humanity 'to ensure that it meets the needs of the present without compromising the ability of future generations to meet their own needs' (WCED 1987). An extraordinarily diverse set of groups and institutions have taken this widely accepted statement of sustainable development and projected upon it their own hopes and aspirations. While sharing a common concern for the fate of the earth, proponents of sustainable development differ in what they think is to be sustained, what is to be developed, how each is related to the other, and for how long a time.

The most common view as to what is to be sustained are planetary life-support systems, particularly those supporting human life (Kates 1994). These systems include natural resources as well as environments that provide aesthetics, recreation, pollution absorption and cleansing, and other ecosystem services (Daily 1997). Contrasting this anthropocentric view is one of sustaining nature itself in all its biodiversity and assemblages of life forms. These ought to be sustained, not only for their utilitarian service to humans, but because of the moral obligations of humanity arising either as 'stewardship'—still acknowledging the primacy of humans—or as a form of 'natural rights' in which earth and its other living things have equal claims for existence and sustenance. Also for some, cultural diversity is seen as the counterpoint to biological diversity, and various communities that include distinctive cultures, particular groups of people, and specific places need to be sustained.

The most common view of what is to be developed is the economy that provides employment, needed

income, desired consumption, and the means for investment in physical and human capital, as well as environmental maintenance and restoration. An alternative emphasis is on people-centered human development which focuses on the quantity of life, as seen in the survival of children and their increased life expectancy, and the quality of life through education and equal opportunity. Finally, some discussions of what is to be developed emphasizes society itself, addressing the well-being and security of national states, regions and institutions.

The relationship between what is to be sustained and what is to be developed also differ. Some conceptual statements, provide equal emphasis for both; others, while paying homage to sustainable development, seem to be saying 'sustain only,' 'develop mostly,' or 'sustain or develop subject to some minimal constraint on the other.' Similarly the implied time horizons for sustainable development differ. There is universal acceptance that such time horizons are intergenerational, but these then range between a single generation of 25 years, several generations, or as an unstated, but implicit, forever. Each of these time periods present very different prospects and challenges for sustainable development. Over the space of a single generation, almost any development appears sustainable; over an infinite forever none does.

At the century's end, the difficulties of actually delivering on these diverse hopes that people around the world have attached to the idea of sustainable development had become increasingly evident. In part, these difficulties reflected political problems, grounded in questions of financial resources, equity and the competition of other issues for the attention of decision-makers. In part, they reflect the differing views about what should be developed, what should be sustained and over what period. Additionally, however, the political impetus that carried the idea of sustainable development so far and so quickly in public forums has also increasingly distanced it from its scientific and technological base.

2. *Interlinked Transitions*

Thus during the 1990s several groups of scientists sought to reinvigorate their historic connection with the concept of sustainable development by focusing not on the larger concept, with all its actual and implied diverse meanings, but on a sustainability transition. The interest in transitions arose in part from the widespread perception that the continuation of current trends in both environment and development would not provide for the desired state of sustainable development. To the extent that transitions represent breaks in such trends, there was growing interest in identifying the needed or desired transitions in the relationships between society and environment.

There was also widespread interest in the post-Cold War world in the nature of transitions themselves. Attention was focused on the economic transition from state to market control and on the civil society transition from single-party, military or state-run institutions to multiparty politics and a rich mix of nongovernmental institutions (Mathews 1997). Earlier transitions had also been identified, such as that in settlement patterns from rural to urban; in agricultural productivity from increases in production derived from additional land to increases derived from greater yields; and in health from early death by infectious diseases to late death by cancer, heart attack, and stroke. For the environment, significant transitions were seen for biogeochemical cycles in a shift from dominance by natural processes to dominance by human releases; for specific pollutants from increasing to decreasing rates of emissions; and for land cover in temperate zones a change from deforestation to reforestation (Turner et al. 1990).

But the greatest interest lay in the successful confirmation of the 'demographic transition'—the change in population regimes from ones of high birth and death rates, to ones of low birth and death rates. The demographic transition appeared credible because it met scientific criteria: it was partly supported by theory, matched well the data and had predictive power (Kates 1996). It was also seen as both needed and desired because of the widespread consensus that rapidly growing population made more difficult human development, while further stressing the natural systems that needed to be sustained.

On a global scale, at the century's end, the transition in birth rates was more than halfway towards birth stability, the 2.1 births required to achieve eventual zero population growth, with an average of less than three children for each woman of reproductive age, compared with five at the post World War II peak of population growth. The death transition was even more advanced, with life expectancy at birth having increased from 40 years to 66 years, about three-quarters of the way to the stabilizing stage of the transition, when life expectancy is likely to reach 75 years. Mid-range projections (in 1998) foresaw further slowing of population growth rates with 8.9 billion people in the world by 2050 and stabilizing to 9.5 billion by the century's end (United Nations 1999).

Thus, in the first major conceptualization of the 'sustainability transition' Speth (1992) set forth a series of five inter-linked transitions (demographic, technological, economic, social and institutional) as collective requirements for a sustainability transition. In addition to the desired demographic transition, Speth saw the need for a transition towards technologies that were environmentally benign and reduced sharply the consumption of natural resources, and the generation of waste and pollutants. For the economy, the desired transition was towards one in which prices reflected their full environmental costs. A social transition

would move towards a fairer sharing of economic and environmental benefits both within and between countries. All of these transitions required a fifth: a transition in the institutional arrangements between governments, businesses and people that would be less regulation-driven and more incentive-led, less confrontational and more collaborative. To these five, Gell-Mann (1994) further suggested an ideological transition towards a sense of solidarity that can encompass both the whole of humanity and the other organisms of the biosphere and an informational transition that integrates disciplinary knowledge and disseminates it across the society.

Together, Speth and Gell-Mann present these transitions as requirements for a more sustainable world: if each individual transition is completed successfully the result would constitute a sustainability transition. And all of these transitions may be underway as there are some trends in each of the desired directions. To investigate this concept they organized a major, albeit uncompleted, research effort known as the '2050' project (World Resources Institute, Brookings Institutions, Santa Fe Institute) that sought to track these transitions and understand their interactions.

3. *Adaptive Management and Social Learning*

A different approach was adopted by the National Academy of Sciences (USA) Board on Sustainable Development (1999). It too adopted a two generation, to the year 2050, time horizon. But in *Our Common Journey: A Transition Toward Sustainability*, the Board doubted that any specific set of trends or transitions constituted necessary or sufficient conditions for sustainability. It argued that the pathway to a sustainability transition could not be mapped in advance. Instead, it would have to be navigated adaptively through trial and error, and conscious policy experimentation (Holling 1978, Lee 1993) and a process of social learning (Social Learning Group 2001) as well other devices such as indicators and scenarios (described below).

What could be selected were goals for a sustainability transition. In the Board's judgment, the primary goals of a transition toward sustainability over the next two generations should be to meet the needs of a much larger but stabilizing human population, to sustain the life-support systems of the planet, and to reduce hunger and poverty substantially. Specific targets for these goals for human well-being and environmental preservation have been defined over the past few decades through extensive processes of international political debate and intergovernmental action.

In the area of human needs, internationally agreed-on targets exist for providing food and nutrition, nurturing children, finding shelter and providing an education, although not for finding employment. Thus, there is an implicit hierarchy of needs that favors children and people in disasters, and favors feeding and nurturing first, followed by education, housing and employment.

Compared with targets for meeting human needs, quantitative targets for preserving life-support systems are fewer, more modest and more contested. Global targets now exist for ozone-depleting substances and greenhouse gases, and regional targets exist for some air pollutants. Absolute prohibitions (zero targets) exist for ocean dumping of radioactive wastes and some toxics, for the taking and/or sale of a few large mammals (whales, elephants and seals), migratory birds when breeding or endangered, and certain regional fishing stocks. Water, land resources and ecosystems such as arid lands and forests have, at best, qualitative targets to achieve sustainable management or restoration. International standards exist for many toxic materials, organic pollutants and heavy metals that threaten human health, but not for ecosystem health.

A major action and research agenda was developed in *Our Common Journey* based on both current scientific understanding and the requirements of an emerging sustainability science. For the core sectoral areas of sustainable development identified more than a decade ago by the Brundtland Commission—human population and well-being, cities, agriculture, energy and materials, and living resources—the Board identified concrete goals and appropriate next steps to accelerate major transitions underway or needed in each sector. To create a research agenda of what might be called 'sustainability science,' the Board would promote the creation of usable knowledge from scientific understanding; would seek to integrate global and local perspectives to shape a 'place-based' understanding of the interactions between environment and society; and initiate focused research programs on a small set of understudied questions that are central to sustainability transition.

4. *Indicators and Scenarios*

The largest scientific effort to date has been the creation of indicators of sustainable development and to use them to track a transition toward sustainability. It sought to make more realistic the diverse meanings of sustainable development by attempting to develop indicators of the different values so implied. A major effort was launched by the Scientific Committee on Problems of the Environment (Moldan et al. 1997) and an important alternative effort by the so-called Balaton Group (Meadows 1998). These scientific efforts complemented similar efforts by various local, national, and international groups to create indicators as ways of expressing desired values for sustainable

Table 1
Sustainable development in the USA: an experimental set of indicators

Economic	Environmental	Social
Capital assets	Surface-water quality	Population of USA
Labor productivity	Ratio of renewable water supply to withdrawals	Life expectancy at birth
Domestic product	Fisheries utilization	Births to single mothers
Income distribution	Acres of major terrestrial ecosystems	Children living in families with only one parent present
Consumption expenditures per capita	Invasive alien species	Educational achievement rates
Unemployment	Conversion of cropland to other uses	Educational attainment by level
Inflation	Soil-erosion rates	Teacher training level and application of qualifications
Investment in R&D as a percentage of GDP	Timber growth to removals balance	People in census tracts with 40 percent or greater poverty
Federal debt to GDP ratio	Outdoor recreational activities	Crime rate
Energy consumption per capita and per $ of GDP	Contaminants in biota	Participation in the arts and recreation
Materials consumption per capita and per $ of GDP	Quantity of spent nuclear fuel	Contributing time and money to charities
Homeownership rates	Identification and management of superfund sites	
Percentage of households in problem housing	Metropolitan air quality nonattainment	
	Status of stratospheric ozone	
	Greenhouse-gas emissions	
	Greenhouse climate response index	

futures (http:}}iisd1.iisd.ca/measure}compendium.htm and United Nations Commission for Sustainable Development 1996). A set of 40 economic, environmental and social indicators for the USA that use existing data sets are shown in Table 1 (http://www.sdi.gov/reports.htm).

In contrast to indicators such as these that can inform society to what extent progress is being made in a transition toward sustainability, alternative pathways for a transition were explored through long-range development scenarios that reflect the uncertainty about how the global system might unfold. While they are rigorous, reflecting the insights of science and modeling, these scenarios are told in the language of words as well as numbers because assumptions about culture, values, lifestyles, and social institutions require qualitative description. Sets of scenarios were created that reflect current trends and reform proposals, various forms of social and environmental breakdown, and more fundamental transitions or transformations (Raspin et al. 1997, Hammond 1998). Based on these and other data, the National Academy of Science's Board (USA) on Sustainable Development (1999) concluded that:

> Although the future is unknowable … a successful transition toward sustainability is possible over the next two generations. This transition could be achieved without miraculous technologies or drastic transformations of human societies. What will be required, however, are significant advances in basic knowledge, in the social capacity and technological capabilities to utilize it, and in the political will to turn this knowledge and know-how into action.

R. W. Kates

Sustainable Development

In the late 1980s, the World Commission on Environment and Development (WCED), otherwise known as the Brundtland Commission, defined sustainable development as 'development that meets the needs of the present without compromising the ability of future generations to meet their own needs' (WCED 1987). Since then, sustainable development has received significant attention from the global community at the local, national, and international level amid concerns about climate change, biodiversity loss, tropical deforestation, and other environmental depletion and degradation problems.

This article discusses briefly the emergence of the concept of sustainable development and provides a broad definition of sustainable development. Two distinct interpretations of sustainable development—*weak* and *strong* sustainability—are compared and contrasted. Recent advances in three areas of the literature that are relevant to understanding sustainable development and to designing appropriate policy responses are examined. These are: ecological functioning and resilience; environmental Kuznets' curve (EKC) and the environment–growth debate; and endogenous growth, technological innovation, and resource dependency. For each area, the basic concept is explained and the implications for sustainable development are discussed. Finally, the policy issues and options for achieving sustainable development are discussed. Four key options are identified: measuring the ecological and economic impact of declining natural resources; improving our estimates of the economic costs of depleting natural capital; establishing appropriate incentives, institutions, and investments for sustainable management of natural capital; and encouraging interdisciplinary collaboration between the relevant social and behavioral sciences undertaking research on sustainable development.

1. Concept of Sustainable Development

1.1 Definition of Sustainable Development

The broad concept of sustainable development (Pearce and Barbier 2000) encompasses considerations of equity across and within generations, taking a longer-term perspective and accounting for the value of the environment in decision-making (Pearce et al. 1989). As noted by Turner (1997), the concept of sustainable development has been challenged on several grounds: as an oxymoron, as a means of imposing a particular political position, as an approach to divert attention from more pressing socioeconomic problems, and given the history of the human–environment relationship (see *Human–Environment Relationships*). However, sustainable development continues to receive increasing international recognition and it has become a key guiding principle for the global society at the start of the new millennium (National Research Council 1999).

There have been a substantial number of diverse and wide-ranging interpretations of sustainable development, both across and within scientific disciplines. Pearce et al. (1989) provide a collection of

such definitions, and for summaries of recent developments see Goldin and Winters (1995) and Pearce and Barbier (2000). In general, sustainable development implies that economic development today must ensure that future generations are left no worse off than present generations. This means that future generations should be entitled to at least the same level of economic opportunities—and thus at least the same level of economic welfare—as is currently available to present generations. As Pezzey (1989) succinctly states, the welfare of society should not be declining over time.

1.2 Total Capital Stock

The total stock of capital employed by the economic system, which includes physical, human, and natural capital, determines the full range of economic opportunities and welfare available to both present and future generations. Natural capital comprises of natural resources and environments and provides various goods and services to society. For example, tropical forests provide *direct use benefits* in the form of timber, fruits, and nuts, *indirect use benefits* such as recreation, watershed protection, biodiversity protection, carbon storage, and climate maintenance, and *nonuse benefits* which include existence and bequest values (Barbier et al. 1994). Sustainable development requires managing and enhancing the total capital stock so that its aggregate value does not decline over time. Therefore, society must decide how best to use its total capital stock today to increase current economic activities and welfare, and how much it needs to save or even accumulate for the welfare of future generations.

However, it is not simply the aggregate stock of capital in the economy that matters but also its composition. In particular, whether present generations are 'using up' one form of capital to meet the needs of today. For example, much of the recent interest in sustainable development has risen out of concern that current economic development may be leading to the rapid accumulation of physical and human capital, but at the expense of excessive depletion and degradation of natural capital. The major concern has been that the irreversible depletion of the world's stock of natural wealth will have detrimental implications for the welfare of future generations (see *Consumption, Environmentally Significant*).

While generally it is accepted that economic development around the world is leading to the irreversible depletion of natural capital, there is widespread disagreement as to whether this necessarily implies that such development is inherently unsustainable. From an economic standpoint, the critical issue of debate is not whether natural capital is being irreversibly depleted. Instead, as argued by Mäler (1995), the more crucial issue for sustainable development is whether we can compensate future generations for the current loss of natural capital, and if that is the case, how much is required to compensate future generations for this loss? This depends on whether natural capital is considered to have an unique or essential role in sustaining human welfare and whether special 'compensation rules' are required to ensure that future generations are not made worse off by natural capital depletion today.

1.3 Weak and Strong Sustainability

Two distinct interpretations of sustainable development are referred to commonly in the literature as 'weak' and 'strong' sustainability. According to the *weak sustainability* view, there is essentially no inherent difference between natural and other forms of capital, and hence the same optimal depletion rules ought to apply to both. That is, as long as the natural capital that is being depleted is replaced with even more valuable physical and human capital, then the value of the aggregate stock—comprising human, physical, and the remaining natural capital—is increasing over time. Maintaining and enhancing the total stock of all capital alone is sufficient to attain sustainable development.

In contrast, proponents of the *strong sustainability* view argue that physical or human capital cannot substitute for all the environmental resources comprising the natural capital stock, or all of the ecological services performed by nature. This view questions whether human, physical, and natural capital comprises a single homogeneous total capital stock. *Uncertainty* over many environmental values, in particular the value that future generations may place on increasingly scarce natural resources and ecological services, further limits our ability to determine whether we can compensate adequately future generations for irreversible losses in *essential* natural capital today. Thus, the strong sustainability view suggests that environmental resources and ecological services that are essential for human welfare and cannot be substituted easily by human and physical capital should be protected and not depleted. Maintaining or increasing the value of the total capital stock over time in turn requires keeping the nonsubstitutable and essential components of natural capital at least constant over time.

2. Aspects of Sustainable Development

2.1 Ecological Functioning and Resilience

The ecological economics literature has called attention to the important role of *ecological functioning* and *resilience* in sustaining human livelihoods and

welfare (Perrings et al. 1992) (see *Ecological Economics*). By ecological functioning, ecologists usually mean those basic processes of ecosystems, such as nutrient cycling, biological productivity, hydrology, and sedimentation, as well as the overall ability of ecosystems to support life. Ecologists consider the collective range of *life-support functions* to be the key characteristic that defines an ecosystem, as well as the source of the many key ecological resources and services that are important to human welfare (e.g., drinking water, food, and soils).

Although there is some dispute in the ecological literature over precise interpretations of the term *ecological resilience*, ecologists generally use this term to mean the capacity of an ecosystem to recover from external shocks and stresses (e.g., drought, fire, earthquakes, pollution, biomass removal) (Holling 1986, Walker 1992). As the health of an ecosystem usually is determined by its capacity to deliver the life-support functions appropriate to its stage of ecological succession, then the ecological resilience of the system is linked inherently to its ecological functioning. That is, if an ecosystem is resilient, then it should recover sufficiently from any human-induced or natural stresses and shock and function normally. However, if ecosystems are insufficiently resilient to recover from persistent problems of environmental degradation then the ability of ecosystems to function normally and deliver important biological resources and ecological services will be affected. At some threshold level of ecological functioning, ecosystems that are subject to persistent environmental degradation and disruption begin to malfunction, breakdown, and ultimately, collapse (see *Human–Environment Relationship: Carrying Capacity*).

The loss of ecosystem functioning and resilience will lead to a decline in the availability of some economically important biological resources and ecological services (see *Extinction of Species*). For example, the loss of fish stocks as the result of pollution impacting on marine systems, the inability of rangeland pastoral systems to recover from drought, and the decline of the watershed protection function of degraded forests. At first these ecological and welfare impacts may be localized, but if they occur on a sufficiently great enough scale, they may generate wider national, regional, or even global effects, such as climate change (see *Climate Change, Economics of*). Although the scale of such impacts and their ultimate effects on human welfare are often uncertain and difficult to determine, the irreversible loss of key biological resources and ecological 'services' through the disruption and breakdown of ecosystems could constitute a growing problem of *ecological scarcity* (Barbier 1989). The rising 'scarcity' of ecological resources and services will mean that they will increase in value relative to human-made goods and services produced in economic system. Moreover, persistent and rising ecological scarcity may be an indicator of more widespread and frequent disruptions to the functioning and resilience of ecosystem, and increase the likelihood of ecological collapse and catastrophe on ever widening scales (Daily and Ehrlich 1992, Meadows et al. 1992, UNPF 1993).

2.2 Implications of Ecological Functioning and Resilience for Sustainable Development

Given the rate at which ecological disruption is occurring globally as a result of the cumulative impacts of pollution, habitat modification, and conversion and over-exploitation of some biological resources, the ecological functioning and resilience upon which many important ecological resources and services depend may be undermined. Thus, not only is there a danger of depleting essential ecological components of natural capital, but the widespread disruptions to the functioning and resilience of ecosystems may mean that these essential components are being lost irreversibly. Therefore, the ecological economics literature generally endorses the strong sustainability view.

Ensuring sustainable development first will require identifying those essential ecological resources and services that are most at risk from current patterns of economic activity and development. Second, it is necessary to take appropriate policy measures to protect the irreplaceable components of natural capital. Finally, it is important to maintain the functioning and resilience of the key ecosystems on which they depend. This implies a fundamental rethinking in the way in which countries currently manage their environments, as well as the relative importance of policies for environmental protection in the process of economic development. The additional costs that are required to adjust current patterns of economic activity and development could be significant, especially in the short and medium term, and may constrain such a comprehensive shift in policy.

2.3 Environmental Kuznets' Curves and the Environment–Growth Debate

There has been a long-standing debate about the relationship between economic growth and the environment. An early view was expressed in the publication of the Club of Rome's *Limits to Growth* in 1972 that there exists a *trade-off* between economic growth (measured by rising real per capita incomes) and the environment, whereby an improvement in one implies a reduction in the other (Meadows et al. 1972, Daly 1987). The modern sustainable development debate has focused more on the potential *complementarity* between growth and the environment, where growth is considered compatible with improved environmental quality (see *Cassandra/Cornucopian Debate*).

A recent extension to this literature looks at the analysis of *environmental Kuznets' curves* (EKC). This is the hypothesis that there exists an 'inverted U' shaped relationship between a variety of indicators of environmental pollution or resource depletion and the level of per capita income (Kuznets 1955, Grossman and Kreuger 1995, Shafik 1994). The implication of this hypothesis is that environmental degradation should be observed to increase initially, but to eventually decline, as per capita income increases. To some extent, this combines the two previous views on the relationship between economic growth and the environment. That is, at low incomes there exists a trade-off between economic growth and environmental quality, while at higher incomes economic growth is complementary to improved environmental quality.

Pearce and Barbier (2000) and Stern et al. (1996) provide a review of the relevant empirical studies. These studies suggest that EKC relationships are more likely to hold for only a few pollutants with short-term and local impacts, such as sulphur dioxide (SO_2) and to a lesser extent solid particulate matter (SPM) (see *Air Pollution*). In addition, even when an EKC relationship is estimated, the 'turning point' on the curve where environmental degradation starts to decline with per capita income is very high relative to the current per capita GDP levels of most countries. This is a particular problem for less developed countries with low per capita income levels (see *Environment and Development*). However, several recent studies have also demonstrated that EKCs are highly susceptible to structural economic shifts and technological changes, which are in turn influenced by policy initiatives such as the Montreal Protocol and the Second Sulphur Protocol.

2.4 Implications of EKCs for Sustainable Development

Recent EKC studies have revived the wider 'growth vs. the environment' debate. Some commentators have argued that the empirical evidence of EKCs supports the general proposition that the solution to combating environmental damage is economic growth itself (Beckerman 1992). For example, the EKC literature offers limited evidence that for certain environmental problems, particularly air pollutants with localized or short-term effects, there is an eventual reduction in emissions associated with higher per capital income levels, which may be attributable to the 'abatement effect' that arises as countries become richer (Panayotou 1997). Also, both the willingness and the ability of political jurisdictions to engage in and enforce improved environmental regulations, to increase public spending on environmental research and development, or even to engage in multilateral agreements to reduce emissions may also increase with per capita income levels (see *Greening of Technology and Ecotechnology*).

Other commentators have been more cautious, noting that conclusive evidence of an EKC relationship applies only to a few pollutants, which makes it difficult to support more general growth-environment linkages. It has also been noted that, even for those pollutants displaying EKC characteristics, aggregate global emissions are projected to rise over time, demonstrating that the existence of an EKC relationship for such pollutants does not imply necessarily that, at the global level, any associated environmental damage is likely to disappear with economic growth. Therefore, the recent EKC literature should not be taken to imply that economic growth on its own will foster environmental improvement automatically. As Panayotou (1997) concluded, 'when all effects are considered, the relationship between growth and the environment turns out to be much more complex with wide scope for active policy intervention to bring about more desirable, and in the presence of market failures, more efficient economic and environmental outcomes.' Or, as Arrow et al. (1995) have succinctly put it: 'economic growth is not a panacea for environmental quality; indeed it is not even the main issue.'

2.5 Endogenous Growth, Technological Innovation, and Resource Dependency

Another recent advance in the literature with important implications for sustainable development looks at *endogenous growth*, *technical innovation*, *and resource dependency*. A key feature of recent endogenous growth models is that technological innovation, that is, the development of new technological ideas or designs, is *endogenously* determined by private and public sector choices within the economic system (hence the term 'endogenous' growth) rather than determined outside (i.e., 'exogenous') to the system (Romer 1990). This implies that the level of technology in an 'endogenous growth' economy can be advanced perpetually through public and private investments, such as research and development expenditures and increases in human capital skills. Since *technical innovation* adds to physical capital already used in production, the economy can potentially 'sustain' growth rates indefinitely. Furthermore, as the economy develops, its growth rate should eventually diminish until it reaches its long-run growth rate (Barro and Sala-I-Martin 1995).

The recent debate over the role of innovation in economic growth has led to empirical studies across countries and regions in the factors underlying long-term economic growth. Empirical evidence seems to support the notion that rich countries have higher rates of savings or more 'effective' institutions, and

implies that persistently bad government policies and ineffective institutions are inhibiting the long-run growth prospects of low-income countries. In addition, poor countries may fail to achieve higher rates of growth because they fail to generate or use new technological ideas to reap greater economic opportunities.

Institutional and policy failures in poor economies are important determinants of their inability to innovate sufficiently to achieve higher long-term growth rates. Another important factor may be the structural economic dependence of these economies on their natural resource endowments (see *Environmental Vulnerability*). Recent explanations as to why *resource dependence* may be a factor in influencing economic growth point to a number of possible fundamental linkages between environment, innovation, and long-term growth relevant to poor economies. Previous studies of an economy's dependence on natural resources and its long-run growth (Dasgupta and Heal 1979, Stiglitz 1974) have been extended by Barbier (1997) to include an endogenous growth economy in order to determine whether an economy's dependence on an exhaustible natural resource is necessarily a binding constraint on long-term growth. The results of the analysis show that sufficient allocation of human capital to innovation will ensure that in the long run resource exhaustion can be postponed indefinitely, and the possibility exists for sustained long-term per capita consumption. However, when negative feedback effects between the rate of resource utilization and innovation exist, the conditions under which it is possible to sustain per capita consumption over the long run are much more stringent and again assume that the economy is able to build up sufficient human capital and to innovate.

2.6 Implications of Endogenous Growth Theory, Technical Innovation, and Resource Dependency for Sustainable Development

Endogenous growth theory offers some support for the weak sustainability view. That is, provided that obstacles such as persistent policy distortions, political instability, and institutional failures can be overcome, any economy—even a low-income and resource dependent developing country—should be able to foster endogenous innovation to substitute human and physical capital for a declining natural capital base in order to sustain economic opportunities and welfare indefinitely. The key appears to be developing effective policies and institutions, including the necessary public and private investments to enhance research and development and human capital skills.

Unfortunately, in most low-income countries current economic policies and investments in agriculture, forestry, and other resource-based sectors have led to rapid changes—frequently with adverse economic consequences—in resource stocks and patterns of use. Demographic trends have often worsened the relationship between population and resource carrying capacity in many regions, and chronic environmental degradation may itself be contributing to social conflict and political instability, thus undermining the social and economic conditions necessary to foster long-term innovation and development (Homer-Dixon 1995). In addition, the type of 'resource-saving' innovations envisioned in most endogenous growth models are likely to be technologies to abate pollution and other waste products, and to conserve the use of raw material and energy inputs. However, many ecological resources and services, such as biodiversity, amenity services, and ecological functions, are less amenable to substitution by the conventional resource-saving innovations developed in the economic process. Thus, innovations are less likely to lead to opportunities for the substitution of the more unique, and possibly essential, range of ecological resources and services, including the general life-support functioning and resilience of ecosystems.

3. Policy Issues and Options for Sustainable Development

This section discusses the policy issues and options for sustainable development. There are some important areas of common ground for policy makers that make good progress towards sustainable development, regardless of the viewpoint on strong and weak sustainability. For example, as there exists considerable scope for substituting human and physical capital for natural capital through conservation and substitution of resource inputs, reducing pollution, and improving environmental protection, then designing policies for sustainable development must begin with these basic objectives in mind. To do this requires progress in four areas.

First, it is important to improve existing efforts to measure the economic and ecological consequences of natural capital depletion and degradation. That is, in order to consider how well an economy is substituting physical and human capital for natural capital, it is necessary to measure how much the value of the natural capital stock has been 'depreciated' through current efforts to use environmental resources and services to promote greater levels of consumption and investment in the economy. Determining the 'sustainable' level of income and consumption, that is, accounting for the increases in the total available goods and services in the economy *net* of the depreciation in the value of the natural capital stock, is an important economic approach to measuring sustainability. Equally, determining the ecological 'limits' to exploitation of the natural capital stock, including ecological thresholds, carrying capacities, and key ecological goods, services and natural environments

that might be considered 'essential,' are important ecological contributions to measuring sustainability.

Second, many of the resources and services of our natural capital endowment are either 'unpriced,' meaning that unlike other goods and services in our economy there are no markets for them, or they are 'underpriced,' meaning that where markets do exist for some environmental goods and services the prices in these markets do not necessarily reflect their true contribution to human welfare. As long as environmental goods and services continue to be 'unpriced' and 'underpriced,' then their contribution to human welfare relative to other goods and services in the economy is effectively 'undervalued.' Thus, in order to promote better policies for sustainable development it is necessary to determine the correct economic values for environmental goods and services and to develop a variety of economic tools for assessing these values (see *Resources and Environment: Contingent Valuation*).

Third, determining an appropriate 'mix' of human, physical, and natural capital to ensure sustainable development is ultimately about designing appropriate incentives, institutions, and investments for efficient and sustainable management of the natural environment. In order to promote sustainable development it is important to determine the causes of environmental degradation, particularly where the failure of institutions, markets, and government policy are the main contributing factors, and to demonstrate how correcting these failures can lead to improved incentives and investments for efficient and sustainable management of natural capital (see *Environmental Policy: Protection and Regulation*).

Finally, in order to make genuine progress towards sustainable development, it is necessary for the conventional social and behavioral sciences, such as economics and ecology, to work together towards a common goal of sustainable development.

Sustainable Transportation

The concept of sustainable transportation applies the idea of societal sustainability to a particular area of human activity: the movement of people and goods. Sustainability, or sustainable development, has been adopted by the United Nations agencies as an overarching goal of economic and social development (UNCED 1992). Although there are several alternative definitions of sustainability, the most widely cited definition and the one generally recognized as initiating the global consideration of the subject, is that of the World Commission on Environment and Development (also known as the Brundtland Commission).

> Sustainable development is development that meets the needs of the present without compromising the ability of future generations to meet their own needs. (WCED 1987, p. 43)

This and most other definitions constitute a normative concept of intergenerational responsibility or fairness. It is also significant that the context of the Brundtland definition was the issue of economic development and resulting conflicts with the environment. The concept of sustainability balances the right of less advantaged nations to economic development, with the imperative to preserve the resources, especially the environmental resources, that future generations will need for their own well-being. Thus, a concept of equity, both intergenerational and international, has been inherent in the idea of sustainability since its inception.

Sustainability pertains to the responsibility of an entire generation of society to future generations; whether it can meaningfully be applied to a single area of human activity such as transportation has been a subject of debate. That is, sustainability must be satisfied by the integral activities of a society and so, in this sense, it is not possible to judge whether one sector of society is sustainable on its own. On the other hand, it would not be possible for society to achieve sustainability, at least not in the long run, if even one sector were not sustainable. Thus, sustainable transportation may be considered a necessary but not sufficient condition for the sustainability of society.

Economic development has been central to the issue of sustainability since its inception. Economists have argued that the Bruntland definition implies non-decreasing well-being, and some have suggested that measures such as gross domestic product or real consumption per capita may be appropriate measures of sustainable growth. Others argue that well-being must be defined more broadly to include other areas of human development, such as education, health, environmental quality, and social justice (e.g., Pearce et al. 1994). In this broader view, the human institutions passed from one generation to another are just as important a resource as any other institution.

The question of how to translate the Brundtland imperative into a measurable and verifiable concept is still being worked out. In the economic literature, efforts to resolve this question have revolved around the concepts of weak and strong sustainability. The doctrine of weak sustainability holds that manufactured capital (machinery, buildings, infrastructure, etc.) is perfectly substitutable for natural capital (natural and environmental resources). This view holds not only that manufactured capital can be substituted for resources such as coal or iron ore, but that it can be substituted for environmental functions such as the ability of the air to absorb pollution or even the atmospheric and ocean processes that produce the global climate. Strong sustainability, on the other hand, maintains that there are limits to the substitutability of manufactured and natural capital. In particular, it maintains that there are certain environmental processes and functions that must be protected and preserved because they cannot be replaced by created capital. Ecosystems and biodiversity are often-cited examples of irreplaceable environmental processes.

How economic growth and expanding human welfare could continue indefinitely in the face of intensifying environmental impacts and finite natural resources is a central question for theorists and researchers. Human activity, and especially economic activity, are inextricably linked to the environment by the ever-expanding quantities of natural resources extracted, processed and consumed (Pearce and Warford 1993). Because mass and energy must be conserved due to the laws of nature, all the resources and energy used must end up somewhere in the form of waste (unless recycled). A useful way to conceive of the relationship between human activity and the environment is to imagine a coefficient of environmental intensity that relates total environmental damage to the total level of activity, perhaps measured, albeit incompletely by gross domestic product. Similarly, one can imagine a coefficient of natural resource requirements for input to the world economy. Because emissions controls, recycling, and greater energy efficiency can change the environmental coefficient, technological change and behavioral change clearly must play a key role in achieving sustainability. If the environmental coefficient can be reduced as fast or faster than the growth of human activity, and if increasing efficiency and

recycling can similarly reduce the requirements for energy and other natural resource inputs, then it should be possible for human well-being to expand in a sustainable way.

The above line of reasoning identifies sustainability not as an equilibrium or final state of being able to continue indefinitely, but as a steady state in which the rate of improvement exceeds the rate of exhaustion of manufactured capital, natural resources, environmental services, and human and institutional capital. In this view, sustainability requires reducing demands on the environment per unit of activity as fast as or faster than the growth in activity. It requires increasing the efficiency of energy and resource use, or expanding the scope of useful resources at a rate at least as fast as the growth of human activity. It may even be interpreted more broadly as a matter of improving human institutions faster than challenges emerge to threaten them. While these concepts can and have been applied to transportation, a comprehensive theory of sustainable transportation that is measurable and verifiable is still yet to emerge.

1. *Sustainable Transportation and Economic Development*

Throughout history, the expansion and improvement of transportations systems has been an engine of economic development (Greene and Wegener 1997). The fast and reliable movement of persons and commodities contributes more than simply a reduction in the costs of production. It facilitates the reorganization of production and consumption to permit specialization, scale economies, inventory reduction, and more. Today, transportation activity continues to increase at roughly the rate of economic growth in both the developed and developing economies.

Motorized transport is the source of essentially all the demands transportation imposes on natural and environmental resources. The motorization of transport, fully accomplished in the developed economies during the twentieth century, is now proceeding rapidly in the developing world. In 1950, 90 percent of the world's 50 million motor vehicles could be found in Europe or the United States. Today, half of the world's roughly 700 million vehicles are to be found outside of those countries. The developing economies own more than one-third of the world's motor vehicles, and vehicle ownership outside of the developed economies is growing at twice the rates seen in the developed economies. The global potential for motorization is enormous. In developed economies, motor vehicle ownership rates average 500 per 1,000 persons. In the US, there is more than one motor vehicle per person of driving age. Ownership rates in the developing economies are about one-twentieth as high.

Expansion of modern, motorized transportation in the developing economies appears to be essential to their sustainable development. The World Bank has identified three broad types of sustainability in considering transport investments in developing countries: (a) economic and financial sustainability; (b) environmental sustainability; and, (c) social sustainability (World Bank 1996). These categories reflect the view that to be sustainable, transportation systems must have stable financing in the context of market economies, must address the many adverse impacts of transportation on health and ecosystems, and must serve the mobility needs of the poor as well as those with the ability to pay.

2. *Environmentally Sustainable Transport*

Transportation systems have diverse and widespread impacts on the environment, affecting climate, air and water quality, noise, habitats, and biodiversity. Worldwide, transportation accounts for one-fourth of global carbon dioxide emissions. Scientists have concluded that the accumulation of carbon dioxide and other less common anthropogenic greenhouse gases in the world's atmosphere since the onset of the industrial revolution are now having a perceptible impact on the earth's climate. While it is not yet clear what the impacts on climate will be, they are likely to include increases in storm activity, changes in the patterns of rainfall, a general warming leading to higher sea levels, and other potentially harmful or even catastrophic effects. The quantity of carbon dioxide emission produced by transportation depends on the carbon content of the transportation fuels and the energy efficiency of transport systems. Today, motorized transport is entirely dependent on fossil fuels. The combustion of fossil fuels is the predominant source of greenhouse gas emissions from human activities. A typical passenger car adds 1 to 2 tonnes of carbon to the atmosphere each year. Despite 50–100 percent increases in the fuel economy of automobiles over the past 30 years, there appears to be no prospect of reducing global greenhouse gas emissions from transportation for at least 20 to 30 years. Clearly, continuing to force alterations in the earth's climate systems in unpredictable ways does not satisfy the sustainability doctrine.

Transportation is a major source of local and regional air pollution. In Europe and the United States, transportation vehicles emit roughly 45 percent of nitrogen oxides and 40 percent of volatile organic compounds that mix in the atmosphere to form ozone, a pollutant that exacerbates a variety of respiratory problems and causes damage to vegetation as well. Air pollutants from transport have an immediate impact on human health and on vegetation. Ozone pollution has been observed to change the distribution of tree species in forests, retard the growth of vegetation,

and damage crops. Prolonged exposure to ozone is strongly believed to reduce biodiversity of plant communities and diminish variability in their gene pools (NRC 1997). Emissions of oxides of nitrogen and sulfur from motor vehicles contribute to acid rain with widespread negative impacts on terrestrial and aquatic ecosystems. Volatile organic compounds also include a number of toxic pollutants, including known and suspected carcinogens, such as benzene, formaldehyde, cyanide, and dioxin.

Transportation vehicles produce significant quantities of fine particulate pollution via several mechanisms. Vehicle tailpipe emissions contain particles produced by incomplete combustion. Particles and aerosols are formed when certain motor vehicle emissions react in the air. Finally, dust from roads is a major source of air-borne particulate matter. Fine particulate matter can be inhaled deeply into the lungs, contributing to a variety of respiratory problems. Epidemiological studies have correlated elevated morbidity and mortality rates with long-term, low-level exposure to fine particulates, as well as to episodes of acute pollution, suggesting that particulate pollution may be the most serious form of motor vehicle pollution from the perspective of human health (NRC 1997).

Since the 1950s, enormous technological progress has been made in reducing the pollutant emissions from new transportation vehicles. A properly operating motor vehicle manufactured in 2000 produces 1 percent to 10 percent of the pollution (depending on the pollutant) of a car made 35 years earlier. Still, even this rate of progress has been insufficient to achieve air quality standards in many urban areas because the growth of travel has outpaced the rate of technological improvement. Further significant improvements in conventional vehicles and fuels will be made from 2000 to 2010. Yet achieving sustainability will probably require entirely new energy sources and propulsion technologies ultimately.

3. *Solid Waste*

Transportation infrastructure and vehicles generate enormous amounts of solid waste. Some of this waste, such as iron and steel, has a long history of recycling. Other components like plastics most often end up in landfills or incinerators. Waste oil and fluids, batteries, and other components often contain toxic materials that pose serious health and environmental hazards if not properly disposed of. The maintenance and reconstruction of transportation facilities also generate substantial quantities of mostly asphalt and concrete waste. Not only increased recycling, but life-cycle management of materials for transportation systems has been recognized as essential to achieving sustainable transportation systems (OECD 1997).

4. *Noise*

It may seem odd to include noise among the issues affecting transportation's sustainability. Noise, after all, is inherently transitory and its impacts on society and the environment would seem to be also. On the other hand, transportation systems operate more or less continuously, generating noise around the clock. Studies carried out in Europe have shown that about 20 percent of the population are exposed to daytime transport noise exceeding acceptable levels (65 dB(A)) (European Commission 1995). Another 170 million are exposed to noise levels that cause serious annoyance as defined by the World Health Organization. Road noise is the dominant source, followed by rail and air transport. Furthermore, data for the 1980–95 period showed no significant improvement in exposure to traffic noise for the population of Europe. The principal impacts of transportation noise are annoyance, interference with work and sleep and, less commonly, hearing loss. Estimates of the costs of noise pollution in Europe range between 0.1 percent and 2 percent of GDP.

5. *Natural Resources*

Transportation is a major consumer of two critical, limited resources: land and petroleum. Worldwide, transportation accounts for 56 percent of global petroleum consumption and between 1973 and 1997 was responsible for all of the increase in world oil consumption (IEA 2000). Recent assessments of the world's supplies of conventional petroleum indicate that sometime between 2005 and 2025, the world will have consumed half of all the conventional petroleum that is known or believed to exist (EIA 2000 and USGS 2000). Once this point is passed, it is virtually certain that production of conventional petroleum will begin to decline, and unconventional energy sources will have to be substituted at an increasing rate. The world's transportation system, which is 97 percent dependent on petroleum for energy, will not be sustainable unless it can make a transition to alternative energy sources. While there are more than adequate resources of fossil fuels that can be converted to transport fuels (e.g., coal, oil shale, and tar sands), the greater environmental impacts associated with using these fuels raises serious questions about the sustainability of a motorized world transport system based on fossil fuels.

Perhaps even more serious are the questions raised by transportation systems' expanding direct and indirect uses of land. Not only does transportation infrastructure such as road, airports, and railroad tracks, occupy millions of hectares of land, but the infrastructure and vehicles that use it have significant impacts on surrounding ecosystems. Linear transportation structures serve as deadly barriers to the

migration and movements of species, and alter water flow and groundwater. But perhaps more importantly, transportation infrastructure indirectly alters the patterns and density of human settlements, with even more pervasive impacts on ecosystems and biodiversity (NRC 1997).

6. *Sustainable Communities*

Transportation is recognized as a key element of sustainable communities (PCSD 1997). Human development patterns and the transportation systems that serve them are strongly interdependent. Transportation choices made by present generations will constrain the opportunities of future generations because built environments can be changed only slowly and at great cost. The high level of mobility provided by automotive transport has engendered dispersed low-density development, sometimes referred to as sprawl. The area of built-up urban land in the United States increased by an estimated 14 million acres between 1982 and 1992, driven in large part by the expansion of highway infrastructure (BTS 1996, p. 162).

As demand for mobility has continued to grow, while the land available for expanding transportation infrastructure in urban areas has not, chronic congestion has become a major problem in cities around the world. Increasing levels of traffic congestion are not only a source of stress and waste the time of present generations, but can restrict the opportunities for mobility of future generations. If the capacities of transportation systems cannot be expanded to accommodate future growth without incurring unacceptable trade-offs, the options available to future generations will be diminished.

7. *Safety*

Safety must also be included in assessing the sustainability of transportation systems (e.g., Black 2000). While absolutely compelling as a human tragedy, the sense in which transportation safety is a sustainability issue may be less obvious. Globally, there are about 700,000 motor vehicle fatalities annually, and many millions of serious injuries. On the other hand, fatality rates (e.g., per 100,000 vehicle miles) are generally declining. In developed economies such as the United States, recent years have seen declines in total fatalities even while motor vehicle travel and population size continue to grow. In countries undergoing rapid motorization, however, total fatalities are increasing at the same time rates are declining. When both fatalities and fatality rates are increasing, the sustainability of transportation systems is in question. The resource at issue is human life itself, and the needs of future generations would clearly appear to be threatened by increasingly unsafe transportation systems. Where both total fatalities and fatality rates are declining, an argument can be made for sustainability. Without a doubt, safety is the single most important problem facing transportation. Yet, to date there is little agreement on how safety should be interpreted in the context of the sustainability doctrine.

8. *Equity*

Equity among generations is clearly integral to the concept of sustainability. For sustainability to exclude equity considerations among individuals within a generation would be inherently inconsistent. The Charter of European Cities and Towns Towards Sustainability states that the goals of sustainable development are '…to achieve social justice, sustainable economies, and environmental sustainability' (Greene and Wegener 1997). Furthermore, the context of the Brundtland sustainability definition was clearly the need to preserve the global environment while permitting developing countries the economic development that is their right. Clearly social justice and particularly equity have been integral to the concept of sustainability. It has been argued that the concept of intergenerational fairness embodied in sustainability, in fact arises from a societal commitment to equality of opportunity among contemporaries (Howarth 1997). Exactly how equity concerns are to be incorporated in an operating definition of sustainability has yet to be resolved, as have the implications for transportation. At a minimum, equity considerations include the interests of developing economies to pursue higher levels of mobility, as well as the needs of disadvantaged citizens for access to mobility in all societies.

9. *Measuring Sustainability*

If policies are to be formulated and implemented to achieve sustainable transportation, indicators must be found to measure it (OECD 1994). If the steady-state concept of sustainability is accepted, these indicators should show:

whether the world's environmental resources are being reduced by transportation's impacts on air or water pollution;

whether the global climate is being altered by greenhouse gas emissions;

whether habitats are being destroyed through direct or indirect land-use impacts; and

whether the generation of solid waste is increasing or being restrained by recycling.

Indicators must show whether the fundamental natural resources required for transportation, such as energy and land, are being expanded as fast or faster than they are being consumed, and whether trans-

portation systems are being developed and managed so as to enhance social equity by improving access to mobility for all. Until the consequences of transportation for sustainability are made visible measuring them, progress toward sustainable transportation will be limited.

Symbolic Boundaries: Overview

1. Definition and Intellectual Context

'Symbolic boundaries' are the lines that include and define some people, groups and things while excluding others (Epstein 1992, p. 232). These distinctions can be expressed through normative interdictions (taboos), cultural attitudes and practices, and more generally through patterns of likes and dislikes. They play an important role in the creation of inequality and the exercise of power. The term 'symbolic boundaries' is also used to refer to the internal distinctions of classification systems and to temporal, spatial, and visual cognitive distinctions in particular (see *Expression and Interaction: Microfoundations of Expressive Forms*). This article focuses on boundaries within and between groups. It discusses the history, current research, and future challenges of work on this topic.

The literature on symbolic boundaries has gained importance since the 1960s due to a convergence between research on symbolic systems and indirect forms of power. Writings by Pierre Bourdieu, Mary Douglas, Norbert Elias, Erving Goffman, and Michel Foucault on these and related topics have been influential internationally across several disciplines, but particularly in anthropology, history, literary studies, and sociology. In North America, a renewed cultural sociology has produced wide-ranging empirical research agendas on symbolic boundaries and inequality. In other fields including community, cognition, deviance, gender, immigration, knowledge and science, nationalism, professions, race and ethnic studies, and social movements, issues of boundaries have gained analytical prominence, although some authors analyze boundary work without using the language of symbolic boundaries.

2. History

Two of the founding fathers of sociology played central roles in shaping the literature on symbolic boundaries: Emile Durkheim and Max Weber. Their contributions are reviewed before turning to the 'neo-classical' writings of Mary Douglas, Norbert Elias, and Thornstein Veblen, which illustrate the lasting influence of Durkheim and Weber on this literature up to the 1960s. While Durkheim brings attention to classification systems and their relationship with the moral order, Weber is more concerned with their impact on the production and reproduction of inequality.

One of the most widely used examples of symbolic boundaries is taken from Durkheim's later work, *Les formes élementaires de la vie religieuse* (*The Elementary Forms of Religious Life* 1965 [1911]). In this book, Durkheim argues that the distinctiveness of the religious experience from other types of experiences rests in the fact that it involves a symbolic distinction between the realms of the sacred and the profane (pp. 234, 250). The meanings of these realms are mutually exclusive and are defined relationally, through interdictions and rituals that isolate and protect the former from the latter (e.g., a Roman Catholic sinner cannot receive communion until he is purified through confession) (p. 271).

The distinction between the sacred and the profane extends to the whole universe of objects and people in which it takes place. For instance, the status of members of a community is defined by the types of relationship they have with sacred objects (e.g., Roman Catholic women cannot celebrate mass). In this sense, religious systems provide a cosmology, i.e., a general interpretation of how the world is organized and how its elements relate to one another and to the sacred. This cosmology acts as a system of classification and its elements are organized according to a hierarchy (counterpoising for instance the pure with the impure). The belief invested in this 'order of things' structures people's lives to the extent that it limits and facilitates their action. In Durkheim's words, 'the power attached to sacred things conducts men with the same degree of necessity as physical force' (p. 260).

Moving beyond the religious realm, Durkheim points to the existence of a moral order, i.e., a common public system of perception of reality that regulates, structures, and organizes relations in a community. This system operates less through coercion than through intersubjectivity (p. 238). In fact, Durkheim defines society by its symbolic boundaries: it is the sharing of a common definition of the sacred and the profane, of similar rules of conducts and a common compliance to rituals and interdictions that defines the internal bonds within a community. Hence, he posits that the boundaries of the group coincide with those delimitating the sacred from the profane.

Unlike Durkheim, Max Weber is more concerned with the role played by symbolic boundaries (honor) in the creation of social inequality than in the creation of social solidarity. In *Wirtschaft und Gesellschaft*

(1922; *Economy and Society* 1978), he describes human beings as engaged in a continuous struggle over scarce resources. In order to curb competition, they discriminate toward various groups on the basis of their cultural characteristics, such as lifestyle, language, education, race, or religion (Chap. 2). In the process, they form status groups whose superiority is defined in relation to other groups. They cultivate a sense of honor, privilege relationships with group members, and define specific qualifications for gaining entry to the group and for interacting with lower status outsiders (e.g., opposing miscegenation). They invoke their higher status and shared rules of life to justify their monopolization of resources. Hence, cultural understandings about status boundaries have a strong impact on people's social position and access to resources.

Thornstein Veblen's *The Theory of the Leisure Class* (1979 [1899]) parallels Weber's writings on status groups. Veblen is also concerned with the mechanisms that produce boundaries between status groups. This American economist suggests that habits of thought ('classifying and demarcating') are central to these mechanisms and are often organized around notions of superiority and inferiority concerning employment, consumption, and leisure. In his words, 'the concept of dignity, worth, or honor, as applied either to persons or conduct, is of first-rate consequence in the development of class and class distinctions' (p. 15). For instance, idleness symbolizes status because it signifies pecuniary status. It is a way for 'successful men to put their prowess in evidence.' Evidence of nonproductive consumption of time includes 'quasi-scholarly or quasi-artistic accomplishments.' Also, 'refined tastes, manners, and habits of life are useful evidence of gentility because good breeding requires time, application, and expenses' (p. 49) and are therefore not available to those 'whose time and energies are taken up with work.'

Veblen also developed the concept of 'conspicuous consumption' in the context of an acerbic critique of the excesses of the business class. He argues that the possession and display of wealth confers honor: as an invidious distinction, it symbolizes ranking within a group. This way of manifesting superiority is more common when predatory aggression or war are less frequent. Veblen's analysis assumes that there is a usual tendency to change standards of sufficiency as one's pecuniary situation improves, so that one becomes restless with creating 'wider and ever-widening distance' between herself and the average standard.

Also paralleling Weber's work is the work of German sociologist Norbert Elias, *Über Den Prozess der Zivilisation* (*The Civilizing Process* 1982 [1939]). Elias analyzes the historical emergence of a boundary between civilized and barbarian habits by using evidence from Western manner manuals written between the late middle ages and the Victorian period. His attention centers on 'natural' bodily functions such as spitting, defecating, eating, and blowing one's nose to show an 'advance in the threshold of self-control' over time. He demonstrates the growing centrality of shame and embarrassment in instituting norms of behavior in public and private. At a more general level, he shows transformations in standards of behavior and feelings and in personality structures (what he calls 'habitus' or habits emerging from social experience). He argues that these vary across hierarchical groups in society and that these variations are key to pacification and the exercise of power.

To turn now to the lasting influence of Durkheim's work, in *Purity and Danger* (1966), Mary Douglas is concerned with the order-producing, meaning-making, and form-giving functions of classification systems and the role of rituals in creating boundaries grounded in fears and beliefs. In *Natural Symbols* (1970), she takes on the idea of a correspondence between classification systems and social organization advanced by Durkheim and Mauss (1963 [1903]). She describes the structure of binary symbolic systems as 'reflecting' that of group structures. Like Elias, she is also concerned with the moral order and centers her attention on the system of social control as expressed through the body and through the observable artifacts of everyday life (food, dirt, and material possessions). She argues that the very basis of order in social life is the presence of symbols that demarcate boundaries or lines of division.

One of Douglas' main concerns is how communities differentiate themselves from one another and how they are internally differentiated. She distinguishes groups on the basis of their degree of social control and of the rigidity of their grid (by which she means the scope and coherent articulation of their system of classification or the extent to which it is competing with other systems). In societies with high social control and great cultural rigidity (i.e., what she calls high grid and group), there is a concern to preserve social boundaries; the role structure is clearly defined and formal behavior is highly valued and well-defined in publicly insulated roles. Through 'the purity rule,' formality screens out irrelevant organic processes, 'matters out of place.' Douglas suggests that the more complex the system of classification and the stronger the pressure to maintain it, the more social intercourse pretends to take place between disembodied spirits, i.e., the more the purity rule applies.

3. *Current Theory and Research*

In the contemporary literature on symbolic boundaries, both the neo-Weberian and neo-Durkheimian heritage remain strong. The question of how boundaries intersect with the production of inequality has attracted great interest in recent years, following the publication of Pierre Bourdieu's impressive corpus. In

the United States in particular, cultural sociologists have been working to assess some of Bourdieu's theoretical claims and to use his work as a stepping stone for improving our understanding of the cultural aspects of class, gender, and racial inequality. Other important developments concern the study of identity through boundary work, and research on moral order, community, and symbolic politics. As is argued in the final section of this article, social scientists will soon face the challenge of integrating work from a wide range of fields that have used the concept of boundaries to various ends.

3.1 Culture and Inequality

In the last 20 years, a large neo-Weberian literature emerged around the study of processes of closure, as illustrated most notably by the work of Frank Parkin and Randall Collins. Parkin (1979) drew on Weber to propose an analysis of class relationship that focuses on the distributive struggle for monopolizing or usurping resources within and across classes—with an emphasis on the right of ownership and credentialism, i.e., the use of educational certificates to monopolize positions in the labor market. Equally inspired by Durkheim, Collins (1998) extended his earlier work on credentialism and interaction rituals to analyze how intellectuals compete to maximize their access to key network positions, cultural capital, and emotional energy, which generates intellectual creativity. These authors' contributions intersect with those of Pierre Bourdieu and his collaborators, although their ideas followed an independent path of development.

In *Reproduction* (1977 [1970]), Pierre Bourdieu and Jean-Claude Passeron proposed that the lower academic performance of working class children cannot be accounted for by their lower ability but by institutional biases against them. They suggest that schools evaluate all children on the basis of their familiarity with the culture of the dominant class (or cultural capital), thus penalizing lower-class students. Extensive vocabulary, wide-ranging cultural references, and command of high culture are valued by the school system and students from higher social backgrounds are exposed to this class culture at home. Hence, children of the dominated classes are overselected by the educational system. They are not aware of it, as they remain under the spell of the culture of the dominant class. They blame themselves for their failure, which leads them to drop out or to sort themselves into lower prestige educational tracks.

This work can be read as a direct extension of Karl Marx and Friedrich Engels' 'dominant ideology thesis,' which centers on the role of ideology in cementing relations of domination by camouflaging exploitation and differences in class interests. However, Bourdieu and Passeron are more concerned with classification systems than with representations of the social world itself, i.e., with how representations of social relationships, the state, religion, and capitalism contribute to the reproduction of domination. Implicitly building on the work of Antonio Gramsci, they made inroads in analyzing the subjective process of consolidation of class domination, focusing on the shaping of cultural categories. The control of subjectivity in everyday life through the shaping of common sense and the naturalization of social relations is the focus of their attention. They broaden Marx and Engels by suggesting that crucial power relations are structured in the symbolic realm proper, and are mediated by meaning. They *de facto* provide a more encompassing understanding of the exercise of hegemony by pointing to the incorporation of class-differentiated cultural dispositions mediated by both the educational system and family socialization.

In *Distinction* (1984 [1979]), Bourdieu applies this analysis to the world of taste and cultural practice at large. He shows how the logic of class struggle extends to the realm of taste and lifestyle, and that symbolic classification is key to the reproduction of class privileges: dominant groups define their own culture and ways of being as superior. Thereby they exercise 'symbolic violence,' i.e., impose a specific meaning as legitimate while concealing the power relations that are the basis of its force (Bourdieu and Passeron 1977 [1970], p. 4). They define legitimate and 'dominated' cultures in opposition: the value of cultural preferences and behaviors are defined relationally around binary oppositions (or boundaries) such as high/low, pure/impure, distinguished/vulgar, and aesthetic/practical (p. 245). The legitimate culture they thereby define is used by dominant groups to mark cultural distance and proximity, monopolize privileges, and exclude and recruit new occupants to high status positions (p. 31). Through the incorporation of '*habitus*' or cultural dispositions, cultural practices have inescapable and unconscious classificatory effects that shape social positions.

A large American literature applying, extending, assessing, and critiquing the contributions of Bourdieu and his collaborators developed in the wake of their translation in English (for a review, see Lamont and Lareau 1988). For instance, DiMaggio (1987) suggests that boundaries between cultural genres are created by status groups to signal their superior status. Lamont (1992, Chap.7) critiqued Bourdieu (1979) for exaggerating the importance of cultural capital in upper-middle class culture and for defining salient boundaries *a priori* instead of inductively. By drawing on interviews with professionals and managers, she showed that morality, cultural capital, and material success are defined differently and that their relative importance vary across national contexts and by subgroups. Lamont also showed variations in the extent to which professionals and managers are tolerant of the lifestyles and tastes of other classes, and argued that cultural *laissez-faire* is a more important

feature of American society than French society. High social and geographic mobility, strong cultural regionalism, ethnic and racial diversity, political decentralization, and relatively weak high culture traditions translate into less highly differentiated class cultures in the United States than France.

Other sociologists also argue that cultural boundaries are more fluid and complex than cultural capital theory suggests. In particular, in his study of group variation in home decoration, Halle (1993) suggests that art consumption does not necessarily generate social boundaries. He finds that the meaning attached to living room art by dwellers is somewhat autonomous from professional evaluations, and is patterned and influenced by a wide range of factors beyond class—including neighborhood composition. He also finds that cultural consumption is less differentiated than cultural capital theory suggests—with landscape art being appreciated by all social groups for instance. Finally, he suggests that 'the link between involvement in high culture and access to dominant class circles … is undemonstrated' (p. 198). For his part, Hall (1992) emphasized the existence of heterogeneous markets and of multiple kinds of cultural capital. He proposes a 'cultural structuralism' that addresses the multiplicity of status situation in a critique of an overarching market of cultural capital.

Bryson (1996), Erickson (1996), and Peterson and Kern (1996) suggest that cultural breadth is a highly valued resource in the upper and upper-middle classes, hence contradicting Bourdieu's understanding of the dominant class which emphasizes exclusively the boundaries they draw toward lower class culture. Bryson (1996) finds that musical exclusiveness decreases with education. She proposes that cultural tolerance constitutes a multicultural capital more strongly concentrated in the middle and upper classes than in the lower classes. Erikson (1996) suggests that although familiarity with high status culture correlates with class, it is useless in coordinating class relations in the workplace. She writes that the 'culture useful for coordination is uncorrelated … with class, popular in every class' (p. 248) and that 'the most useful overall cultural resource is variety plus a well-honed understanding of which [culture] genre to use in which setting' (p. 249). For their part, Peterson and Kern (1996) document a shift in high status persons from snobbish exclusion to 'omnivorous appropriation.' These studies all call for a more multidimensional understanding of cultural capital as a basis for drawing boundaries, and counter Bourdieu's postulate that the value of tastes is defined relationally through a binary or oppositional logic.

3.2 Identity and Boundary Work

The growing literature on identity is another arena where the concept of symbolic boundaries has become more central. In particular, sociologists and psychologists have become interested in studying boundary work, a process central to the constitution of the self.

Social psychologists working on group categorization have been studying the segmentation between 'us' and 'them.' Brewer's (1986) social identity theory suggests that 'pressures to evaluate ones' own group positively through in-group/out-group comparison lead social groups to attempt to differentiate themselves from each other.' This process of differentiation aims 'to maintain and achieve superiority over an out-group on some dimension' (Tajfel and Turner 1985, pp. 16–17). While these authors understand the relational process as a universal tendency, sociologists are concerned with analyzing precisely how boundary work is accomplished, i.e. with what kinds of typification systems, or inferences concerning similarities and differences, groups mobilize to define who they are.

The concept of boundary work was proposed originally by Gieryn in the early 1980s to designate 'the discursive attribution of selected qualities to scientists, scientific methods, and scientific claims for the purpose of drawing a rhetorical boundary between science and some less authoritative residual non-science' (1999, pp. 4–5). In recent years, sociologists have become interested in analyzing this process by looking at self-definitions of ordinary people, while paying particular attention to the salience of various racial and class groups in boundary work. For instance, Newman (1999) analyzes how poor fast-food workers define themselves in opposition to the unemployed poor. Lamont (1992) studies the boundary work of professionals and managers, while Lamont (2000) examines how workers in the United States and France define worthy people in opposition to the poor, 'people above,' blacks, and immigrants, drawing moral boundaries toward different groups across the two national context. Lichterman (1999) explores how volunteers define their bonds and boundaries of solidarity by examining how they articulate their identity around various groups. He stresses that these mappings translate into different kinds of group responsibility, in 'constraining and enabling what members can say and do together.' Binder (1999) analyzes boundaries that proponents of Afrocentrism and multiculturalism build in relation to one another in conflicts within the educational system. Finally, Gamson (1992) analyzes how the injustice frames used in social movements are organized around 'us' and 'them' oppositions.

Jenkins's (1996) study of social identity provides useful tools for the study of boundary work. He describes collective identity as constituted by a dialectic interplay of processes of internal and external definition. On the one hand, individuals must be able to differentiate themselves from others by drawing on criteria of community and a sense of shared belonging within their subgroup. On the other hand, this internal

identification process must be recognized by outsiders for an objectified collective identity to emerge. Future research on the process of collective identity formation may benefit from focusing on the dynamic between self-identification and social categorization.

3.3 Moral Order, Community, and Symbolic Politics

A third strand of work on symbolic boundaries presents more palpable neo-Durkheimian influences. Several empirical studies have centered on moral order and on communities. Wuthnow (1987, p. 69) writes 'Order has somehow to do with boundaries. That is, order consists mainly of being able to make distinctions—of having symbolic demarcations—so that we know the place of things and how they relate to one another.' A recent example of this neo-Durkheimian line of work is Alexander's (1992) semiotic analysis of the symbolic codes of civic society. The author describes these codes as 'critically important in constituting the very sense of society for those who are within and without it.' He also suggests that the democratic code involves clear distinctions between the pure and the impure in defining the appropriate citizen. His analysis locates those distinctions at the levels of people's motives and relationships, and of the institutions that individuals inhabit (with 'honorable' being valued over 'self-interested' or 'truthful' over 'deceitful' in the case of the democratic code).

It should be noted that the last decades have produced several studies of status politics that documented precisely how groups sharing a lifestyle made such distinctions, engaged in the maintenance of the moral order, and simultaneously bolstered their own prestige. Particularly notable is Gusfield (1963) who analyzed the nineteenth century American temperance movement in favor of the prohibition and the Eighteenth Amendment to the constitution. Gusfield understands this movement as a strategy used by small-town Protestants to bolster their social position in relation to urban Catholic immigrants. Along similar lines, Luker (1984) describes the worldviews of anti-abortion and pro-choice activists. She shows that they have incompatible beliefs about women's careers, family, sexuality, and reproduction, and that they talk past one another and define themselves in opposition to one another. The literature on social movements includes numerous additional studies that focus on the process by which categories of people are turned into categories of enemies (Jasper 1997, Chap. 16).

4. Challenges and Future Directions

Two main challenges concerning the study of boundaries are pointing at the horizon of sociological scholarship. They concern (a) a necessary synthesis of the various strands of work that speak to boundary issues across substantive areas; and (b) the study of the connection between objective and subjective boundaries.

The concept of boundaries is playing an increasingly important role in a wide range of literatures beyond those discussed above. For instance, in the study of nationalism, citizenship, and immigration, scholars have implicitly or explicitly used the boundary concept to discuss criteria of membership and group closure within imagined communities (e.g., Anderson 1983, Brubaker 1992). Some of these authors are concerned with the established rules of membership and boundary work. Yet others study national boundary patterns, i.e., the ways in which nations define their identity in opposition to one another (Saguy 2000).

The concept of boundary is also central in the study of ethnicity and race. The relational process involved in the definition of collective identity ('us' vs. 'them') has often been emphasized in the literature on these topics. The work of Barth (1969) for instance concerns objective group boundaries and self-ascription, and how feelings of communality are defined in opposition to the perceived identity of other racial and ethnic groups. Along similar lines, Bobo and Hutchings (1996) understand racism as resulting from threats to group positioning. They follow Blumer (1958) who advocates 'shift[ing] study and analysis from a preoccupation with feelings as lodged in individuals to a concern with the relationships of racial groups…[and with] the collective process by which a racial group comes to define and redefine another racial group' (p. 3).

Finally, gender and sexual boundaries are also coming under more intense scrutiny. For instance, Epstein (1992) points out that dichotomous categories play an important part in the definition of women as 'other' and that much is at stake in the labeling of behaviors and attitudes as feminine or masculine (also see Gerson and Peiss 1985). Those who violate gender boundaries in illegitimate ways often experience punishment in the workplace. More recently, Tilly (1997) argues that dichotomous categories such as 'male' and 'female' (but also 'white' and 'black') are used by dominant groups to marginalize other groups and block their access to resources. He extends the Weberian scheme by pointing to various mechanisms by which this is accomplished, such as exploitation and opportunity hoarding. He asserts that durable inequality most often results from cumulative, individual, and often unnoticed organizational processes.

Because these various literature all deal with the same social process, boundary work, it may be appropriate at this point to begin moving toward a general theory of boundaries by, for instance, identifying similarities and differences between boundaries drawn in various realms—moral, cultural, class, racial, ethnic, gender, and national boundaries. This could be

accomplished by focusing on a number of formal features and characteristics of boundaries, such as their visibility, permeability, boundedness, fluidity, and rigidity. We may also want to compare embedded and transportable boundaries; explicit and taken-for-granted boundaries; positive and negative boundaries; and the relationship between representations of boundaries and context. Social scientists should also think more seriously about how different types of boundaries can combine with one another across local and national contexts (e.g., how cultural or moral boundaries combine with race, gender, or class boundaries).

A second challenge will be to understand the connection between objective boundaries and symbolic boundaries. Students of objective boundaries have focused on topics such as the relative importance of educational endogamy vs. racial endogamy among the college educated; racial hiring and firing; the extent of residential racial segregation; the relative permeability of class boundaries; and the process of creation of professional boundaries. Lamont (1992) has argued that symbolic boundaries are a necessary but insufficient condition for the creation of objective boundaries. More empirical work is needed on the process by which the former transmutes into the latter.

Symbolic Interaction: Methodology

The term 'symbolic interactionism' (SI) was coined in an article by Blumer (1937). SI presented a radical break from the traditional, macrostructural theories of sociology. SI rejected the scientific method and its reliance on predetermined hypotheses. SI's goal was not predicting about society, as structuralist methodologies did, but understanding the nature of the social world. In basing its research in the real world of everyday life, SI relied heavily on the theoretical work of the pragmatists, especially that of Mead (1934).

1. *Blumer and Naturalistic Research*

In his book containing reprints of his earlier articles, Blumer (1969) applies a methodology, naturalistic research, to the theoretical work of Mead. In symbolic interactionism, theory and methodology are intertwined very closely. Mead's social pragmatism advocated a study of society that takes place in small group interaction; namely, the relation of self and others. This reciprocal interaction is derived, for Mead, through the use of symbols, primarily language but others as well. Thus, society, for Mead, is a consensual, intersubjective world where the sharedness of meanings among its members allows some stability in an ever-changing flux (cf. Adler and Adler 1980).

Blumer, who was first a student and then a colleague of Mead at the University of Chicago, followed the latter's theoretical ideas and stated that society exists in action, in the reciprocal exchange of symbols, and the meaning these have for the members of society. If society is to be found in the interactional processes of its members we should study it in 'the real world,' i.e., the world created by societal members in their interaction, rather than in artificial settings or hypothetical situations. For Blumer, it follows that rather than constrain the study of social processes with controlled variables we should proceed with minimal intervention by the researcher. Also, in trying to maintain the integrity of the phenomenon under investigation we should not fit the 'real world' to our method, as typical in survey research, but should adapt out methodology to the world and thus use flexible data collection strategies. Finally, the model of the study should not be predetermined and then tested, but should be everchanging to fit the changes and events in the real world.

For Blumer the naturalistic research has two phases: exploration and inspection. Exploration allows the researcher to gain a clearer understanding of the study, what methods to use, and to conceptualize the area of study in order to be able to talk from facts rather than speculations (Blumer 1969). Exploration should be flexible and change as necessary to understand the topic at hand and thus should rely on a multiplicity of methods including observation, interviewing, life histories, and personal documents. Exploration is the first step of naturalistic inquiry for Blumer but must be complemented by another, more analytic step, inspection. This latter step aids the researcher in developing an analytic understanding of the elements of inquiry and their relations. This understanding is sensitizing rather than definitive, since the world studied is a process, i.e., ever changing. Furthermore, inspection allows for the testing of theoretical propositions. Thus, naturalistic research uses exploration to define the parameters of the study, then turns to inspection to develop sensitizing concepts about the study, finally developing theoretical concepts about society and its members (Hammersley 1989).

1.1 *The Chicago School*

Blumer mentioned some works of the Chicago School and particularly *The Polish Peasant in Europe and*

America (Thomas and Znaniecki 1918–20) as exemplars of the naturalistic method. Indeed, many works of the Chicago School are considered the antecedents of SI, since they tended to rely on some facet of the naturalistic method. Both Mead and Blumer were at the University of Chicago in the 1920s and 1930s when the school had great influence on American sociology. Among many other important contributors to the naturalistic studies of the Chicagoans, besides W. I. Thomas, who was one of the theoretical leaders (but left as early as 1918), Robert Park must be mentioned. He was an ex-journalist trained in philosophy and took some courses from the pragmatists, John Dewey and William James. From his previous profession Park brought an understanding of studying the real world 'out there,' thus, being the inspirator of many studies of naturalistic nature. It must be noted that the Chicago School has been criticized for saying very little about their methods in their writings (Hammersley 1989) and for not really being a school of thought at all (Becker 1999). Some of the most notable works from the Chicago naturalistic tradition are *The Ghetto* (Wirth 1928), *The Delinquent Gang* (Thrasher 1927), *The Gold Coast and the Slum* (Zorbaugh 1929), *The Hobo: The Sociology of the Homeless Man* (Anderson 1923). For a detailed study of the Chicago School see Faris (1967) and Bulmer (1984).

2. *Other Methods Based on Mead*

While Blumer's adaptation of Mead's theories is the methodological mainstay of SI, there are other methodologies based on SI, and these will be mentioned next. Analytic induction was first discussed by Znaniecki (1928). It was later used, with minor variations by Lindesmith (1937, 1968) (he was a graduate student of Blumer), Cressey (1950) (a student of Lindesmith), Becker (1963) (see Hammersley 1989), and others. Analytic induction, according to Znaniecki, recognizes the fact that objects in the world are open to an infinite number of description and, thus, our account of them must be selective; this selectivity will be based on the interest at hand, which for sociologists is primarily social and cultural systems; commonly used sociological methods relying on pre-identification (deductive) or superficial description (inductive) will not work, only analytic induction will accomplish the task. The researcher will select a small number of cases (10–12, usually) and study them in depth, continually defining and redefining the event and formulating and reformulating theoretical propositions until they will fit all cases. Negative cases must also be examined (this was Lindesmith's idea).

Another student of Blumer, Strauss, together with Glaser, developed another SI method, grounded theory (Glaser and Strauss 1967). Closely related both to Blumer's methodology and to analytic induction, grounded theory placed more emphasis on the generation and development of theory. Relying on the inductive method, grounded theory is akin to Blumer's inspection, only much more elaborate. Rather than relying on a priori population, in analytic theorizing one continues to study new cases until the point of saturation, generating theoretical categories.

Not all SI methods followed the constructionist approaches outlined above. A notable exception came from the Iowa School of Sociology. Kuhn (1964) adopted a much more deterministic approach to Mead's discussion of the self and the nature of the 'me,' the various roles and images we have of ourselves. The methodology he adopted to discover the nature of the self was called the Twenty Statements Test (TST), a series of open-ended questions about the self. Kuhn felt that rather than use the oblique method of observing people one ought to ask them directly about the nature of their inner feelings and they would honestly disclose them to the researcher. The results of TST would be used, by Kuhn, to outline generic laws that would apply to human beings in different situations. Other positivistic oriented symbolic interactionists are Sheldon Stryker, described as a 'structural role theorist,' who influenced numerous students at the University of Indiana and Carl Couch, who was a stalwart of the discipline, with his 'Behavioral Sociology' at the University of Iowa (cf. Reynolds 1993).

In the 1960s and 1970s a plethora of theoretical approaches, largely based on the naturalistic method, appeared. Some were based on basic Meadian tenets, such as dramaturgy (Goffman 1959), and labeling (Becker 1963). Others based their constructionist approach not only on the ideas of Mead but on those of the phenomenologists (Husserl, Schutz,Heidegger, Dilthey) and the existentialists (Merleau-Ponty, Sartre), and ordinary language philosophers (Wittgenstein). They are phenomenological sociology, existential sociology, ethnomethodology, and the sociology of emotions (see Douglas et al. (1980) for a survey of these sociologies and a list of references to them; also, see Adler et al. (1987)).

3. *Postmodern-informed Symbolic Interactionism*

More recently, with the influence of postmodernism on the social sciences, the methodology of SI has undergone some dramatic changes (Marcus and Fischer 1986, Dickens and Fontana 1994). Again, the closeness of theory and methodology in SI affects methodological approaches to SI. Postmodernism (Lyotard 1984) advocates a disenchantment with metatheories, claiming all we can possibly know about society is much smaller in scope, and it is relative due to its historical, temporal, regional nature, as well as other elements. Thus, society becomes fragmented and

we should question and deconstruct all overarching metatheories and reduce the scope and intent of our studies to our immediate surroundings, to the details of everyday life.

These beliefs impact the naturalistic method of SI in a number of ways. First, we can no longer claim to be aiming at universal laws of human behavior since that would be a metatheory. Second, metatheories come under scrutiny and are deconstructed, i.e., their basic assumptions are rendered problematic and questioned. This leads to the questioning of the role of the researcher and author in terms of authority of selectively choosing data to record and report, thus biasing the study. Postmodern-informed interactionism attempts to remedy this authorial bias by the use of polyphony, by this meaning to allow the many voices of the respondents to speak for themselves. Additionally, researchers disclose as much information as possible about themselves—role, interest, possible bias, and more. This is only a partial solution to the authorial influence, which is ultimately, irremediable, as we cannot help but to perceive and report selectively.

Other methodological changes take aim at the relation between the researcher and the researched. Traditionally, interactionists have attempted to remain as neutral and invisible as possible in order not to influence the study. Postmodern-informed interactionists make their presence felt in an attempt to establish a one-to-one partnership with the respondents. In so doing researchers are no longer aloof observers collecting data but become a part of the interaction and influence the research findings. Now data stems from a negotiated process between researcher and respondent (Gubrium and Holstein 1997) (notice that this goal contradicts the previous goal of reducing authorial bias).

Another change involves the notion of 'value free' research. Some postmodern-informed interactionists wish to overthrow traditional sociology (Clough 1998, Denzin 1997, 1999a) which they consider patriarchal, instead they envision a new researcher who is a 'feminist, communitarian reseacher … who builds collaborative, reciprocal, trusting, and friendly relations with those studied' (Denzin 1997).

4. *Current Trends*

Postmodern-informed interactionists not only have made dramatic methodological changes from Blumerian interactionism but are experimenting with radically different reporting styles, which are closely intertwined with the new methodological ethos. Some of these styles include poetry and performances, as well as the writing of short stories about one's personal past (autoethnographies). While some of these reports are highly engaging (Richardson 1997, Denzin 1999b), they raise a question about standards—should these works be judged and evaluated by the standards of sociology or poetry and literature? Some interactionists have been highly critical of postmodern-informed interactionism (Seidman 1991, Shalin 1993, Best 1995, Prus 1996). As a result the field of interactionism is currently divided in many groups with different methodological approaches.

Adler and Adler (1999), in describing the varied groups of interactionists at the turn of the millenium, use the metaphor of 'the ethnographers' ball' and sit the factions at various tables. We will rely upon the Adlers' description in the following section. The first table sits the 'postmodern-informed' ethnographers, next to them is the 'autoethnography group,' a bit further down sit the 'interpretive discourse analysts' who attempt to integrate interactionism, ethnomethodology, and postmodernism. At another table the Adlers have the 'classic interactionists,' in the wake of the old Chicago School. Next to them sit the 'no mo pomo' (Adler and Adler 1999), the Blumerian group critical of the new postmodern influence. Near by are the followers of Erving Goffman, the 'dramaturgists,' studying everyday life by using the metaphor of the theater. They are followed by the 'grounded theorists,' next to the 'conversational analysts' who are continuing the work of ethnomethodologists such as the late Harvey Sacks and others. Next, the Adlers have a table for those who practice 'the extended case study,' using ethnography to do applied research. Finally we see the 'visual interactionists' who capture symbolic interaction through the eye of the camera lens. As the Adlers themselves say, 'the list can go on' (Adler and Adler 1999).

We would add to the Adler's list three more tables, before we run out of room in the ballroom. One would be the 'phenomenological/existential' table sitting Jack Douglas and his former students at the San Diego campus of the University of California. Another table, right next to the postmodernists, would be the 'feminist interactionists' who are 'united in their criticisms of "Eurocentric masculinist approaches"' (Collins, quoted in Denzin 1997). Finally, there would be a table of 'theoretical interactionists' who have written extensively in the area without actually engaging in ethnographic work (cf. Lyman and Scott 1989).

The methodology of Symbolic Interactionism has become the methodologies of symbolic interactionism, and can no longer be grouped under Blumer's guiding ideas, yet their diversity is exaggerated and exacerbated by rivalry among various subgroups. By and large, while differing in some methodological points, the great majority of interactionists still wish to study the real world and the meaning that its members make of it and how they manage to maintain and achieve social order as a negotiated interactional accomplishment.

Symbolism in Anthropology

Symbolism, as it is known and practised in anthropology, is the positive side of a negative effect called 'the subject,' or 'subjectivity.' The symbol and its symbolism live a life of their own, even in the efforts to determine what they may be or mean, so that the whole meaningful life of our species is compounded within their parameters. It is because it is difficult or well-nigh impossible to separate the life of symbols from our own that the social sciences have come into existence. What we identify as 'symbolic' is a recollective fantasy or educated guess as to what may have been going on as it was being formulated, and the lived or thought continuity it presupposes is a cumulative reprojection, or collective daydream, compounded of such educated guesses. It is the scholar's or the writer's way of dealing with 'the emotions.'

The secret of this has very much to do with 'yes' and 'no.' For it was Gregory Bateson who demonstrated that analogy is not exclusive to human beings, that the dog that wishes to be friendly will deliver 'the bite that is not a bite,' affirming positive intention by not

closing its teeth on one's hand. We, it seems, invented 'no,' or at least 'delivered' it. The simplest version is a joke: 'Hurt me!' said the masochist. 'No,' said the sadist, smiling in his teeth. Ever since, we have had the subject to contend with.

'Hurt me!' said the phenomenologist; 'No,' said the anthropologist. Symbolism gives us a deniability of the spoken word in the action of writing or reading it, and a deniability of the written word in the action of speaking from it. We know from ourselves it is that way, and we are a very quick study.

In its most radical determination, anthropological symbolism is concerned with the human ability to reflect ideas, emotions, and perceptions in representational form, hence to reflect upon itself. As an analyzable artifact of cultural or psychological experience, symbolism renders conscious what might otherwise be thought to be unconscious or subconscious. As a totalizing perspective, integrating or at least classifying the whole of a personal, interpersonal, cultural, and social conceptualization of things, symbolism essays the whole compass of the concept. It is world-in-the-person and person-in-the-world. 'DENY ME, CRUCIFY ME' said God. 'NO,' said the being, smiling in its teeth, and just now suddenly HUMAN.

The problems of psychology pertain to the individual person or personality, those of sociology involve a collective or consensual entity, and anthropology defines itself through the differences and similarities that these two polarities share in common. As a conjoint therapy, a medium through which each of these functions is determined by means of the other, symbolism takes on a life of its own, becomes its own mythology about itself.

That might help to explain why anthropologists like Edward Sapir, Alfred Kroeber, Gregory Bateson, Margaret Mead, and especially Ruth Benedict, took such a deep interest in psychological problems. And also why psychologists beginning with Freud, Jung, and Adler, tried to capture anthropology within the net of their all-too-specific visions. It is as though the medium of symbolisation, a self-reflexive agency come into its own, simultaneously divided the two approaches and assimilated each to the other. Or as though the very medium of interpretation stole its message back from those who sought to interpret or dissect it.

In the fine phrasing of the Urapamin people of Papua New Guinea, according to Joel Robbins, 'the eye steals it and eats it.' Interpretation is a thief, and not necessarily a visual one. Another anthropologist, F. E. Williams, was told in Papua that 'The sky has no mouth, the sea has no mouth; only old men have mouths.' Just how much of hermeneutical theory was made in envy of the spoken word? The favorite form of Melanesian immortality is what they call 'the talk that never dies.'

Treated formalistically, subjected to its own definition of itself, it becomes, instead, the symbolism that never lives. The structuralism and ethnosemantics of the 1960s shifted the interpretative message into the symbols, signs, and markers themselves, grounded in schemes for the classification of things, and ultimately the classification of classification itself. The economy or self-condensing advantage of the structuralist shift in emphasis is easily misunderstood in that structuralism and semiotics do not deny the reflexive (e.g., 'psychological') ramifications of symbolism so much as they incorporate them within their analytic designs. The so-called 'poststructuralist' or 'postmodern' approaches have basically nothing to add to this, for in 'unpacking' the 'text,' pretending lived social reality as an imaginary diagram or document, one is subversively packing it.

An alternative approach was suggested in the writings of Sir Edmund Leach and Mary Douglas in which the significative and self-classifying properties of symbolization became secondary to the liminal categorization of properties developed from their usage. It was the anomalies, ambivalences, and ambiguities encountered in classification, and thus only indirectly classification itself, that motivated, and so defined, symbolism. (Thus the consumption of pork would have been proscribed in the ancient Middle East because the pig was an anomalous creature, one that 'divideth the hoof but cheweth not the cud.') The result was a theory of symbolism that was forced to deny its subject matter as a means of affirming it. Victor W. Turner noted that the possibility of an 'anti-structure,' as he called it, is a necessary concomitant of anything that could be called structural. ('Deny the liminal, the reality between the words,' challenged Turner. 'No,' said the ardent symbolist, smiling in his teeth.)

'What is the representational or reflectional status of a symbolism that compromises its own ability to mean or represent, and so exists through the riddle it makes of its own existence?' Essentially all subsequent approaches to symbolism in anthropology devolved from the point of that impasse, offering alternative solutions to the problem by denying or qualifying certain of its drawbacks. One might, for instance, argue that there is no definable symbolism, but only an evolutionary or historical process, thereby postponing the subject of the enquiry indefinitely. In that case the symbolist would have to be what Claude Levi-Strauss called a *bricoleur*, a crafty opportunist anxiously fitting together what the inevitable process was casually taking apart. *Bricolage* would be a form of the Hegelian or Marxian dialectic, but, alas, the dialectic would also be a form of *bricolage*.

Another alternative was posed in the American conception of a 'cultural system,' which has its only unity in a sort of either/or proposition. Either symbolism is metaphorical to its own usage, an open invitation to what Clifford Geertz has called its 'understanding,' or it is not. In his classic study of American kinship, David M. Schneider defined the

symbol as that which stands for what it is not, and it was but a step from this to his later conclusion that 'kinship' simply does not exist. ('Deny *relationship*,' said the anthropologist, 'it is only a function of the *person*.' 'No,' said the informant, smiling in his teeth.)

Is misunderstanding simply a more arcane version of what Geertz and the phenomenologists have called 'understanding?' It would be impossible to form substantive conclusions about anthropological symbolism and what it means without in some way participating in the very effect one was trying to cast into relief. It would likewise be very difficult to live within or experience a kind of 'construction of reality' without in some way penetrating or disqualifying the facade it is said to impose. Virtually any example of symbolism one could know or imagine would have to correspond with some version of the anti-symbolic insight, and thus give the lie to Max Weber's famous dictum about human beings 'suspended in webs of meaning that they themselves have created.' Should Weber have added '… or uncreated,' and smiled in his teeth?

The thing that stands for what it is not is also not what it stands for. The prescient quality of the symbol, and of the symbolism on which it is founded, has just that little to do with content and form, with the kinds or varieties of its usage and recognizable categorization. The lesson in this, which has whole semiotic literatures at its beck and call, is not simply moronic, but actually oxymoronic, like a breath of fresh air. It is more clearly analogous to the lyrics of an American 'country' song: 'Just what part of "no" don't you understand?' Is the metaphor really a metonym in disguise, or is it the other way around; is the 'syntagmatic chain,' a code phrase for the ways convention strings symbols together, a sort of learner's permit for the paradigmatic, the illusion of all the meanings coming together at once? 'There are no easy horses,' says another country song, 'but you've got to learn to ride.' 'Americans,' said the cowboy–humorist Will Rogers, 'are lucky enough not to get all the government they pay for.' Are symbolists even luckier?

The symbolism, or theory of symbolism, that does not partake of the emotional quality it engenders is just another sign, a part of 'no' that, properly misunderstood, might well become a 'yes.' We affirm our denials symbolically, as they say. If we can have no emotions that are not part of the process of determining what they themselves might be, then symbol and emotion are like siamese twins, joined at the hip. They are in a physical relationship; no kind of therapy or 'talking cure' will be able to cut them apart, but only, if lucky, make them feel better about their plight. Denial is also emotional, very strongly and suggestively so, but writing a theory of denials would be like photocopying the air instead of breathing it.

A large part of the 'symbolic' problem seems to be that the predominant mental ethos in what we like to pretend to ourselves as a 'modern world civilization' has excused itself from the insights of the medieval nominalist philosophers. These were the gadflies who insisted, against the worship of essences, the Platonic Realism of their own version of civilization, that there is nothing in what we know save in the names we give to it. We know the names of the stars and their constituent elements and processes. We have given very fancy names to the molecules that make us up, and to their processes and transformations, and are lucky enough not to get all the ones we pay for. But, according to Peter Abelard, we would know very little else.

'The *named* is the mother of the myriad creatures' said Lao Tsu. Phenomenalism, epistemology, and, of course, symbolism, have a very ancient reading in the texts of Aristotle, the Arabic and Jewish, Indian, and Chinese philosophers, and even Heraclitus. But it would seem that the medieval problem of symbolism began with the assertion, by Berengar of Tours, that the Holy Christian Sacrament is but a symbol. He may have smiled in his teeth but was very nearly killed for this. He meant that the accidental properties of things (including the names we give them), and not their essences or substances (whatever those might be) make up the whole reality by which we know them. Thanks to his protector, Fulk the Black of Anjou, Berengar lived to a ripe old age. But he committed symbolic suicide for the medieval church.

Dying by design may be the first and the last thought of the would-be suicide, and of the architect of gothic cathedrals. It was no accident that Berengar's insight happened in medieval times, and provoked the theologies of sacramental doctrine into being. It was no accident either that the subsequent scientific revolution built virtual gothic cathedrals of the accidental properties of things, the matter of 'substance' having gone to subatomic particles, energies, uncertainty-principles or worse, committing real homicide instead of symbolic suicide. 'Understand me,' said Berengar. 'No,' said modern world civilization, smiling in its nuclear fallout. Lucky enough not to get all the Berengar it has paid for.

Not surprisingly, it was a twentieth-century philosopher, Ludwig Wittgenstein, who completed Berengar's 'sentence.' The sacrament, or anything else, is a symbol because 'We picture facts to ourselves.' In other words, important as understanding or even interpretation may be, the essential fact is what Wittgenstein called 'making *sense* of things.' This means that sense is a total phenomenon, and that reason, logic, and even the *overstanding* of a problem that we call an 'explanation,' are its derivative qualities. The whole perspective is in the picture, and no abstraction or ideal quality, however profound, is ever-more useful or effective than the sense that models its meanings for us.

More to the point of this definition, sense gives the gift of deniability to logic and rational ordering. This

would have to mean that all of Einstein's conclusions about general and special relativity were beholden to the 'thought experiments,' through which he imagined them to himself, the 'picture facts.' It would mean that the chemistry of DNA is the micromanagement of Watson and Crick's 'double helix' model, and that all subsequent determinations of subatomic structure are footnotes to the initial mistake of the Bohr atom.

It means that the fossil itself is a cartoon of the reconstructions that we make of it and call a 'dinosaur,' and that everything that we may remember about the past lies in the future of the present moment, that anything we may know of culture or through our own version of it, is a by-product of the initial invention of the concept. We make a solid object of its sense, we 'make book on it.' Imaginal deniability suggests that 'culture' and symbolization enjoy a positive (e.g., 'double negative') relation to each other, that each lives a life of its own within the shadow of the other. 'Deny me, dissect me, disqualify me,' said the culture. 'No,' said the symbol, smiling in its teeth.

The English reformer John Wycliffe suggested that neither substance nor accident have very much to do with Berengar's symbolic sacrament, that what the partaker is after is an 'indwelling of Christ in the soul,' a better sense of Christ's sacrifice, or denial of his life, in the body. The self-denial in Christ's sacrifice is essential to its meaning, or self-affirmation. Likewise, metaphor, the pictorial essence of sense in the symbol, is language's way of falling on its sword. And of liking it.

If what we call 'consciousness' is the mind's way of surprising itself, then symbolism is the reaction it has when it will not take 'no' for an answer. No surprise/no consciousness; no consciousness/no symbol. Everything in the world of letter and number, and even the picture, has the quality of marks, usually in black and white. Everything else has the quality of surprise. Then consciousness itself has no other birth, and no death, and no other phenomenology either that would not come as a surprise. If consciousness begins in pain, as in the joke quoted, then, never mind the change of subject, it would have to finish in satisfaction.

Put more bluntly, this means that if pain is the consequence of taking the human subject too seriously, then symbolism would be the consequence of passing it off as a joke. Then morphine, *pace* Christ, would be the sufferer's best friend, for with morphine 'all the pain is there, I can feel it in my bones, but, insofar as I cannot sense it, I quite honestly don't give a damn,' said the human subject, smiling in its teeth.

We have plenty of subjects in anthropology, and the surprising thing is that we have no valid ethnography about how or why the subject should take itself seriously, care or not care about its culture. Not even in Colin Turnbull's work on the *Ik*. And this makes it difficult to either care or not care about anthropology itself. We have all too many anthropological studies of the ideological substitute for care or concern, the backlash of symbolization. The target of pity becomes a pathetic (e.g., phenomenological) subject when forced to turn that pity back on itself, and an object or willing tool when it lashes out against its plight. The giver of pain or of pity becomes an empathetic subjector. 'Hurt me,' implores the pathetically cultural masochist. 'I am hurting,' says the ideological sadist, smiling in his teeth. Symbolism does not come from inspired self-rejection; it goes there.

Symbolism does not merely encourage personal solipsism; it positively enjoins it, and forces the solipsist to make the necessary compromises or adjustments in attitude. 'Every man his own priest,' was the motto of the Reformation; 'every person their own guru, world-renouncer, and inventor of the world,' sings the modern-day choir in response, 'we are all hurting.' The quality of mercy is strained through the sieve of cognition. Symbolism may or may not be the live wire, nature's way of short-circuiting the human race, but it is definitely culture's way of short-circuiting anthropology.

Symbolism is the edged weapon, the most ancient, *pace* language, part of our technology; it is the distinction that cuts the person as the person cuts the distinction. Without the cutting tool, linguistic or whatever, we could not establish figure against ground, or ground against figure; we would not be grounded at all for want of knowing the difference between the two.

Without the essential tension between affirmation and denial, what the symbolism 'stands for' and how it does not do so, the yes-and-no that Peter Abelard called *sic et non*, its significance would indeed be a mere construction. The so-called 'interpretation' merely dramatizes, and the so-called 'construction' deconstructs, an effect that is in fact causal to their very possibilities, like the trick that 'emotion' plays upon our feelings and sensibilities. ('How do you *feel* about yourself? Tell me about it.') Symbolism is both affirmation and denial at the same time, and the tension between its alternative propositions is the time-space, what Mikhail Bakhtin called the 'chronotope,' of our lives. It is the conscience, the judgment, the question and the answer, the argument and the satisfaction.

In effect, symbolism makes the person necessary in a way that biology or biological evolution could never do by itself. It sustains an adversarial counterpoint without which the fictions of individual and collective, conviction and apathy or their moral and ethical surrogates, would be the empty idealities or meaningless categorizations that marry contemporary political ideologies to social science thinking. How, then, might one propose? Smiling, in one's teeth?

Symbolism (Religious) and Icon

1. Religious Symbols: Their Nature and Functions

1.1 Symbols, Transcendence, and Salvation

Religious symbols arise out of the tension which exists between consciousness and the world. Indeed, the *raison d'être* of religious symbolism is to transcend that tension and move beyond, into 'the other,' into the world of transcendence. Religious symbols in other words are bridges between consciousness, the world, and the sacred. They are not just boundaries between the sacred and the profane, they are also means and processes of their inversion and transformation. Through symbols the material becomes spiritual and the spiritual becomes empirical and is communicated in visible form. As Eliade (1959, p. 12) put it: 'By manifesting the sacred any object becomes *something* else, yet it continues to remain *itself*, for it continues to participate in the surrounding cosmic milieu.' To transcend the world is to give it meaning at another level and attempt to transform it through symbols. A symbol, as Geertz (1975, p. 91) defines it, may be 'any object, act, event, quality, or relation which serves as a vehicle for a conception.' For Geertz, as for Sperber (1975), to symbolize is to conceptualize. Religious symbols, thus, serve as vehicles of conceptualization of this world in terms of another world. Along with conceptualizing the sacred they also serve as means to separate it and conceal it from the profane. In mediating transcendence, symbols function at the same time as vehicles of transformation and stabilization of the world, but the conservative or revolutionary political function of symbols is a matter of degree and depends on political and socioeconomic conditions.

There is an intentional and existential element in religious symbolism which links ultimate reality, social reality, and the quest for salvation which is innate in the human condition and, in one sense or another, underpins all religions. The limitations posed by the human biological, psychological, and social life and above all death, become embodied in religious images which transcend these limitations and give meaning to an otherwise chaotic reality. From this premise Marx, following Feuerbach, and without any theoretical elaboration of the symbolic, produced a reductionist, compensatory theory of religion and understood all religious symbols to be projections and epiphenomena of unfulfilled material needs and limitations imposed by socioeconomic conditions. Freud also produced a reductionist theory of religious symbols in the framework of his psychoanalytic theory. Religious symbolism underwent sophisticated analysis, especially in anthropology during the twentieth century, but its religious meaning *per se* and the problem of salvation were rarely taken on board. Reductionist interpretations of religious symbols have declined in the last decades of the twentieth century but the postmodernists have been criticized for their extreme relativism (Gellner 1992). Weber (1948, p. 280) did not get involved in the analysis of symbols and rituals but he argued that 'the world images that have been created by ideas have, like switchmen, determined the track along which action has been pushed by the dynamic of human interest.' He made these images central to his sociology of religion and explored them as an integral part of human action in the pursuit of salvation. The symbolic representation of salvation then, as pursued within the various religious images of the world in various social and historical contexts, form the general framework of the functions and meanings of religious symbols.

Durkheim (1915 p. 47) described 'sacred things' as 'set apart and forbidden.' Yet in the context of salvation the world of the sacred and that of the secular must be, and are, brought into interaction. Salvation means that chaos, limitation, and disunity are surmountable and God meets humankind. Within the Abrahamic faiths especially, salvation means to bring everything under the unity of God. The forces of evil and death must, and can, be overcome. A bridge between God and humans must be built with the initiative of God and the synergy of humankind. Because of this symbols, as tools of transcendence and salvation, are essentially ambiguous. Their ultimate function is to mediate, reveal, express, and com-

municate that which in essence cannot be fully grasped, spoken of, or communicated. God is both: known and unknown, present and absent, hidden and revealed, God and humans. As Martin (1980, p. 7) points out, 'To transcend is to go beyond. So we must name it and refuse to name it.' What Rudolf Otto (1953) has called *mysterium tremendum et fascionum* cannot be contained in ordinary human knowledge and logic. So the believer's attitude to the sacred is basically one of faith, awe, fascination, and submission.

For the same reason the sacred is not subject to the ordinary rules of formal logic. The nonlogical, the miraculous, and the extraordinary are basic properties of the sacred. Leach (1976, pp. 69–71) calls the logic involved in religious discourse 'mytho-logic' and argues that 'One characteristic feature of such nonlogic (mytho-logic) is that metaphor is treated as metonymy.' Sacred agents can be here, there, and everywhere simultaneously and according to the believer this is not just metaphorical language. It expresses (describes) true properties of divine agents which human agents cannot possess because they are limited, because they are human. Unlike humans, gods can do anything they please, whenever they please. If their doings are to make sense at all they must be in terms of some general scheme of salvation. They are not subject to biological and physical constraints (Christ walking on the water or moving through closed doors). The anthropomorphic, physical features of divine agents are usually represented in exaggerated and distorted form. The Hindu pantheon is characteristic for its multisemic, multiform, and weird symbolic representation. God Siva's commonest representation, for instance, is the 'linga' (the phallus curved on stones) and the sacred bull. Victor Turner (1968, p. 580) describes trickster gods as agents of liminality and antinomian character with ambiguous sexual characteristics. Thus the Greek god Hermes was represented as hermaphrodite and was symbolized by ithyphallic statues and the Yoruba god Eshu is represented with a long headdress curved as a phallus.

Christian symbolism is full of ambiguity and paradox which makes sense primarily in terms of salvation and the Kingdom. God the Son 'begotten' of God the Father, becoming man in Christ, being born of a virgin, dying on the cross, rising from the dead and ascending into heaven, and coming again in glory to judge the quick and the dead: all this is part of the *Nicene Creed* which is the symbol of the Church. The body and blood of Christ, 'eaten' and 'drunk' by Christians, are symbols of reconciliation (redemption) between humans and God. Adam is restored through Christ, the new Adam, who is God-Man (indivisible and without confusion according to the christological doctrine). A dominant, condensed symbol (Turner 1967, pp. 28–30, Douglas 1970, p. 10, Firth 1973, pp. 87–93), which reenacts and represents all that and more, is the Christian liturgy or Eucharist. The point to be stressed here is that religious symbols as units do not make sense in isolation and are systematically related in terms of corresponding schemes of salvation which at the same time correspond to world images and social experience. That may, of course, be above all a theological interpretation of religious symbolism which may be rejected by many sociologists, anthropologists, and psychologists. David Martin (1980), however, has demonstrated that a deep and very sophisticated sociological analysis and interpretation of Christian symbolism can take place by encompassing transcendence in the context of the general soteriological scheme of Christianity. The point to be stressed, in any case, is that without taking seriously the implications for salvation no sociological, anthropological, or psychological interpretation of religious symbolism will be adequate. Indeed, reductionist interpretations may distort the essential anthropological meaning of religious symbols.

1.2 Symbols, Boundaries, Inversion, and Power

Religious symbolism acquired specific cultural significance and potency within what have been called axial civilizations (Eisenstadt 1986). In the monotheistic religions of Judaism, Christianity, and Islam transcendence and unity, and the eschatology implicit in them, became central cultural forces with a cosmic historical dialectic. Transcendence and the pursuit of salvation necessitate boundaries. To go beyond is to move from one boundary to the next, from one set of conditions to another or from one status to another. To be redeemed means to be reborn. The Kingdom of God makes good sense in the context of imperfect, unjust, and corrupt human kingdoms. The heavenly city, where 'there shall be tears no more, no sorrow, no death' (Rev. 21:4), is the opposite of earthly cities where sin, death, suffering, injustice, misery, and tears abide. So the polar oppose of the city of God is the city of Babylon. Within the Kingdom there is unity and divine bliss. Divisions of any kind, injustice, and biological and social boundaries do not apply. Blood bonds and other social bonds as well as divisions of all kinds are characteristic of this fallen world. There are no churches or temples in heaven but the sacred and the profane realms, though separate, are interdependent because the Kingdom, where God shall be all in all, has not come yet. The two kingdoms are separated by ambiguous symbolic boundaries of which paradox and inversion are basic characteristics. Sacred symbols function as sacred markers which challenge or reinforce the powers of this world with a power of their own.

Entering a church, a synagogue, a mosque, or any sacred place one crosses a boundary: the boundary between the world of everyday life and that of another world of sacred, cosmic power and significance. Within the sacred places there are other boundaries

designating a hierarchy of meaning reaching up to the highest, the most sacred and the ineffable. In those specifically sacred parts, the holy of holies, only persons of special sacred status may enter in order to perform specific ritual acts. These acts guarantee that the holiness, the perfection, and the autonomy of the sacred are protected and maintained, while symbolically mediated to the secular world. In the Christian Eucharist the priest carries out the sacrifice of Christ on behalf of Christ, the congregation, and humankind. So hierarchy and status become intertwined from the highest to the lowest levels and transition from one status to another require *rites de passage* (Van Gennep 1960). Such rites symbolize losing the old status and entering a new one and involve what Turner (1969, p. 80) has called a state of liminality, a state 'betwixt and between,' rich in ambiguous symbolism linked 'to death, to being in the womb, to invisibility, to darkness, to bisexuality, to the wilderness … .' In the early church, to be baptized meant to enter the community of the saints, to pass from death to life. Immersion in, and rising out, of the water stood for purification, death, and resurrection. This is symbolized by stripping off the old clothes and putting on new white robes. The color white has transcultural symbolic significance linked to life and to light, as black signifies darkness and death.

Martin (1980), Leach (1976), Douglas (1970), Turner (1969), and others have shown that inversion and status reversal are central mechanisms in religious symbolism. Christ, the Lord and Master of all, washes the feet of the disciples. Humility and hierarchy go together, as the irreconcilable tension between hierarchy and its total abolition are endemic in Christianity. Biological and social reproduction and family and social bonds are counteracted by the concept of virginity and the forming of celibate brotherhoods and sisterhoods. Being born again means entering spiritually and physically the community of the elect. 'Those who will lose their life will gain it.' God defeats death through death. Such inversions and logical contradictions form the substance of religious symbolism.

Symbolic boundaries link the spiritual power that 'moves mountains' and the powers of this world which permeate the human condition. Again, in most religions, this is through paradox and inversion. For Christianity, 'the infinite power of the Almighty' is demonstrated by Christ's suffering on the cross and by icons like that of the Pantocrator in Daphni outside Athens. A thin and weak man like Ghandi could challenge the British Empire by advocating nonviolence. Mary Douglas (1970, pp. 37–53) mentions the 'bog Irish' in London and the Apocryphal characters of old Eleazar in ancient Israel (2 Macc. 6:18) as exercising symbolic religious power against secular power, one by abstaining from meat on Friday and the other by refusing to eat pork on pain of death. The ultimate clash between the powers of this world and the power of heaven and glorious and total victory of the latter over the former is depicted most colourfully in the book of Revelation. Yet for Christianity, as for all religions, the tension between the two kingdoms is always present because the Kingdom of God is yet to come. There is a specific kind of formidable power which is generated through martyrdom which the powers and the rulers of this world seem to fear most. Millenarists down the centuries have celebrated the imminence of the Apocalypse by burning their homes and possessions, by weird behavior, by noise and ecstasy or by total silence, or, paradoxically, by adopting rigid absolute rules in their effort to reject all rules. But the Apocalypse remains in the future and nonviolent religious movements like early Christianity became in time powerful Churches embodying both sacred and secular power. However, as long as the Kingdom is not fully and finally here, religious symbols will continue to reveal and conceal the sacred, and their eschatological pull will continue to move the world.

2. *Icon*

Icons represent the sacred in condensed pictorial form. In iconography the holy is grasped not by reasoning but by feeling. As Langer (1980, p. 15) argues 'the thing we do with images is to envisage a story.' Icons speak to the heart and according to St John of Damascus 'they are to the eye what speech is to the ear' (Uspenski 1976, p. 9). Religious images engage the emotions and express and communicate the sacred directly. Iconography, in most religions, is anthropomorphic and this is true of 'primitive,' Indian, Egyptian, Hindu, Buddhist, Greco-Roman as it is of Christian religion. Central feature of icons is the human body although in certain religions it is presented in a distorted form. In Hinduism, for instance, God *Visnu* is invariably represented with four hands which symbolize his various attributes. In Judaism, the making of images of God or idols are strictly prohibited (Ex. 20:4, Dt. 4:15–18, Dt. 27:15) so iconography did not develop. In Islam, although the Qur'an does not prohibit divine images, pictorial representations were forbidden from the beginning so abstract, geometric, decorative designs and calligraphy developed instead (Schimmel 1987, p. 64).

In a restricted sense, icons refer to the specific form of iconography which developed within Eastern Christianity during the Byzantine period. They constitute the almost exclusive type of religious art in the Orthodox Church to the present day as frescoes, mosaics but mostly painted on wood (Sendler 1988, Kokosalakis 1995). Icons developed out of the early Christian iconography of the catacombs which, in large part, conveyed coded messages of basic Christian themes. Christ, for instance, was represented as fish, which in Greek is ΙΧΘΥΣ, which is an acronym for:

Ιησούς, Χριστός, Θεού, Υιός, Σωτήρ (Jesus Christ Son of God Savior). By the fourth century icons could be found in most Christian communities and constituted a central part of Christian teaching parallel to biblical texts. The formalization of the Christian doctrine during the fourth and fifth centuries consolidated with it the basic themes of Christian iconography: Christ, the Virgin, the saints, and various biblical themes. The representation of Christ in particular went through a long evolution and for certain icons, especially of the Virgin, it was believed that they were not made by human hand (αχειροποίητοι).

By the end of the sixth century icons occupied a central place in collective and private worship in Byzantium but their theological meaning became explicit during the iconoclastic period (AD 726–843) when Byzantine society was shaken to its foundations. Devotion to icons had led to excesses and Emperor Leo III, supported by some bishops and certain heretical groups who rejected external worship, issued the first decree against icons in AD 726. There followed a long period of theological controversy and social unrest which, apart from religious, had also serious political and economic etiology. Icons were finally and decisively reinstated in AD 843 by Empress Theodora and since then have occupied a central place in Orthodox theology and worship.

Icons in the Orthodox Church are religious symbols *par excellence* with central cultural significance. They are related to neoplatonic ideas about the expression of spiritual reality in matter with a substantive religious meaning around the concept of the person/image which refers directly to both the creation of humans in the image of God (κατ' εἰκόνα) and their salvation through the incarnation of the word of God. Icons embody the universal and the particular simultaneously. Some icons are attributed thaumaturgical powers by the faithful. In Eliade's (1959, pp. 24–29) terms such icons constitute 'theophanies.' Orthodox pictorial art adopted the inverted, two-dimensional perspective so that the image enters the viewer instead of the viewer entering the image. For the Orthodox Church, icons are windows of revelation and vehicles of direct communication with divine agents.

Symptom Awareness and Interpretation

Physical symptoms often are ambiguous and open for subjective interpretation. Even though people certainly have some awareness of their internal states, that awareness and the accuracy of interpreting internal sensations may be fairly limited (Pennebaker 1982). Many authors state that people are poor at tracking physiological processes. Nevertheless, they hold the belief that they are able to do so. In general, individuals are motivated to maintain an understanding of their bodily condition. Both vague internal states and information about possible diseases lead to interpretive activities. Understanding the processes that guide symptom identification and interpretation

at the initial stage of the occurrence and also during the course of disease has been found to be critical for understanding how people act upon symptoms and disease.

Traditionally, mainly fields such as psychophysiology and the medical sciences dealt with questions related to symptom awareness and interpretation. Pennebaker (1982), in his groundbreaking book, brought the information processing perspective to the area. This approach has proven useful in understanding phenomena of symptom awareness and interpretation. Specifically, Pennebaker proposed that symptoms or sensations are best understood as representing information about internal states. Taking the information processing perspective, this article will emphasize the role of the following aspects: (a) information organization and mental representation of symptoms, (b) knowledge activation and use, and (c) an explanation and attribution of symptoms. Throughout, the behavioral implications of the reviewed research for disease-management, help-seeking behavior, and compliance and adherence to medical regimens will be illustrated taking selected diseases as examples (hypertension and diabetes). Finally, open questions and probable directions of future theory and research will be addressed.

1. *Information Organization: The Mental Representation of Symptoms*

Given the quantity of information that is available to individuals at any given time, it is functional for the organism to organize and reduce the incoming data. This is achieved by cognitively (re)structuring, synthesizing, and organizing the incoming information. Cognitive psychology has introduced several theoretical constructs in this context, namely schemata, cognitive sets, prototypes, expectancies, and scripts. Studies on the structure of illness schemata consistently found five dimensions according to which symptom and illness experiences are organized (Lau and Hartman 1983): illness schemata include information about the identity or label of the disease, its consequences (i.e., the symptoms), its causes, its duration, appropriate treatments, and expectations about its curability. Cognitive structures such as illness schemata or prototypes help to organize information from internal sensations (symptoms) and disease-related information gathered from the external environment.

Certainly, the most relevant model of symptom perception within the tradition of information processing has been proposed by Leventhal et al. (1984). Their approach is rooted in cognitive psychology and builds on the work on cognitive schemata and prototypes (see *Health and Illness: Mental Representations in Different Cultures*). In specific, Leventhal et al. (1984) propose that individuals tend to construct their own individual representation of symptoms or illness and that this idiosyncratic representation will, in turn, influence their behavior (e.g., help-seeking, adherence, and compliance). Specifically, they proposed that illness representations (or schemata) are a function of an individual's semantic knowledge about symptoms and disease and specific contextual factors such as the nature of somatic changes and the situations in which these occur. This semantic knowledge accumulates across the life span and is acquired through the media, through personal experience, and from family and friends who have had experience with the disease. People's common sense models of illness strongly influence which symptoms a person will search for and will ultimately perceive. Work by Meyer et al. (1985) on hypertension illustrates this point. Hypertensives hold one or a combination of disease models about high blood pressure. As Meyer et al. (1985) demonstrated, some patients hold the belief that hypertension is a disease of the heart, others believe that it is an arterial disorder, and a third group might associate hypertension with emotional upset. Importantly, the kind of belief patients hold affects the way they monitor their body: Symptoms that are consistent with their specific illness belief are more likely to get noticed (see *Hypertension: Psychosocial Aspects*). The common sense model of illness approach has also been used successfully to explain such phenomena as placebo effectiveness and mass psychogenic illness (MPI). For example, Pennebaker (1982) stated that placebos are effective because they change the way in which individuals process sensory information. Individuals who are worried about their condition—after taking a (placebo) drug—change their focus from sensations that may signal illness to sensations that signify improved health.

In addition to general concepts of illness, people also hold organized conceptions—termed disease prototypes—for particular diseases (Bishop 1991, Bishop and Converse 1986). For example, a person may have a disease prototype of heart disease. Similar to general illness conceptions, prototypes of specific diseases help people organize and evaluate information about bodily sensations that might otherwise not be interpretable. Thus, a person who holds the belief that he or she is vulnerable to heart disease is more likely to interpret chest pain in accord to his or her prototype of heart disease than a person who does not hold this belief (Bishop and Converse 1986). This latter person might instead regard the chest pain as signaling a gall bladder problem.

Altogether, organized representations of illness-related knowledge and experiences strongly determine symptom awareness and interpretation, and the expectations individuals generate respecting their consequences and causes. This has important implications for health behavior as the kind of beliefs patients hold about symptoms and disease may lead them to alter or fail to adhere to their treatment regimens (e.g., see *Patient Adherence to Health Care Regimens*).

2. Knowledge Activation and Use

2.1 The Role of Knowledge Activation in Symptom Awareness

What directs individuals to become aware of a symptom and how to interpret it? As noted above, individuals use hypotheses and subjective theories (their prototypes) about diseases to interpret initially ambiguous symptoms. Once a plausible hypothesis is identified, information to verify the hypothesis is sought. This is performed by selectively scanning stored knowledge for matching evidence. Given the rather vague nature of many symptoms, confirming evidence often can easily be found.

The accessibility of knowledge stored in memory has been demonstrated to increase when it has been recently primed. Mechanic (1972), for example, documented a common phenomenon in medical schools, the medical students' disease. He reported that about 70 percent of first-year medical students perceive symptoms of those illnesses studied in their courses. Obviously, studying the symptoms leads students to focus on their own internal states and to compare what they hear with their concrete personal experience at the moment. Vague, ambiguous physical sensations are then interpreted in accordance with the disease that was made salient in their course.

Importantly, Leventhal et al. (1980) showed that this process can work both ways. They proposed the symmetry rule, which holds that individuals will (a) seek symptoms when given a diagnostic label (such as in the medical students disease) and (b) seek a diagnostic label when experiencing symptoms, that is, the perception of a change in internal sensation creates a pressure for finding a label. Similarly, being provided with a label of a specific disease generates pressure for a perceptual referent. Schachter and Singer's (1962) classic study can be regarded as evidence for the symptom-to-label part of the symmetry rule since it shows that people will come up with a specific interpretation or label for their somatic sensations that can explain their condition (see below, attribution of symptoms). Bishop's (1991) and Bishop and Converse's (1986) studies on differences in symptom perception as a function of differential beliefs about hypertension mentioned earlier can also be interpreted as reflecting the symptom-to-label part of the symmetry rule.

The second part of the symmetry rule (that people will seek symptoms when given a label) is consistent with findings by Meyer et al. (1985) on hypertension. Hypertension is largely a symptomless disease. However, many patients erroneously believe that they can tell when their blood pressure is high (e.g., they believe their blood pressure to be high when their face gets warm, their heart beat increases, or they are feeling tense) (Baumann and Leventhal 1985). In fact, though, the correlation between beliefs about level of blood pressure and actual blood pressure is low (Meyer et al. 1985). In accord with the label-to-symptom part of the symmetry rule, the authors found that patients in hypertension treatment became more likely to perceive their blood pressure the longer they were in treatment (even though high blood pressure, in fact, is unsymptomatic).

Importantly, illness representations strongly influence the way patients will act upon (subjectively perceived) symptoms. Taking hypertension as an example, patients have been found to treat their condition based on their belief that they are able to detect when their blood pressure is high and when it is not. When they 'feel fine,' they may discontinue taking medication, and when they believe their blood pressure is high they might take it. A similar phenomenon has been documented for the self-management of diabetes. Both hyperglycemia and hypoglycemia produce unpleasant bodily sensations that can be vividly described by patients (Hampson 1997). Diabetes patients often fail to self-monitor their blood glucose level and instead, like hypertension patients, rely on what their blood glucose level 'feels like.' However, the relation between symptom experience and acute blood glucose levels is also often imprecise, and patients are misled by their illness belief. Hence, diabetes patients need to be advised that their illness management should not rely on subjective perceptions of their blood glucose level. Instead, in deciding when to take measures to increase or decrease their blood glucose level, they should rely exclusively on testing their blood glucose (Hampson 1997, see *Diabetes: Psychosocial Aspects*).

2.2 The Role of Knowledge Activation in Symptom Interpretation

What determines which knowledge will be activated and used in order to *interpret* perceived symptoms? The evaluation of symptoms is very subjective and has been found to be influenced by the nature of their attributes. Symptom attributes can include such aspects as how salient (noticeable) and how unexpected they are, or which consequences they may have for one's life. Not all features of a physical sensation receive equal attention. Most likely, symptoms that are visible or cause pain draw most attention. Similarly, symptoms that affect highly valued parts of the body (e.g., the eyes, face, or heart) usually are interpreted as being more serious and as more likely to require attention than symptoms that affect less valued organs. In sum, symptoms that hurt, symptoms that change quickly, and symptoms that are incapacitating are more likely than their opposites to be interpreted as signs of a serious illness and therefore more likely to induce a person to seek medical treatment (Safer et al. 1979).

This selective attention to symptoms can have its costs, however, when symptoms that are not salient

but nevertheless serious remain unnoticed. For example, people with heart attacks often wait for several hours until they seek help (Matthews 1982). As a consequence, 70 percent of all deaths due to heart attacks occur in the first few hours. Matthews noticed that a person will wait longer before seeking help the less salient the first symptoms are, the more depressed and exhausted the person is, and the more effortful the activity is that they are engaged in at the time of symptoms' onset. The latter effect can also be explained by Pennebaker's (1982) *Competition of Cues Model*. In his model, Pennebaker states that external and internal sensory information compete for people's attention. The likelihood with which internal sensory perceptions are perceived then is a function of the proportion of external to internal information. When people are focused externally, for example, in a highly distracting environment or during a vigorous physical activity, they are slower at noticing symptoms. In contrast, when the external environment lacks stimuli, attention is more likely directed toward the body. This increases the likelihood that cues that suggest illness are noticed (Pennebaker 1982). In one study, for example, Pennebaker demonstrated that people are more likely to cough during boring parts of a movie than during more interesting parts. Apparently people focus their attention more on their internal states when there are few external stimuli, and are therefore more likely to notice itching or tickling in their throats to which they then respond with coughing.

Altogether, the awareness and interpretation of internal sensations is a function of the relation between external and internal stimuli. And it is also a function of the beliefs that individuals hold. The beliefs cause them to selectively attend to specific internal information or contextual information, i.e., not all knowledge is used in evaluating internal states.

3. *Explanation and Attribution of Symptoms*

It has been suggested that people are 'common-sense' medical scientists who search for the meaning of somatic events and search to attribute it to a specific cause. Research has been presented which demonstrates that sometimes not the mere presence of symptoms impact on behavioral implications, but rather the attributions made for these symptoms. For example, almost two-thirds of the people who seek medical attention for low-level symptoms have been found to suffer from anxiety or depression instead. This may occur because symptoms of these emotional disorders are mistakenly thought to be indicative of a physical disease. Attributions of symptoms have also been found to affect adherence to medical regimens. For example, in their study on HIV-infected women, Siegel and Gorey (1997) found decreased adherence to medication and even discontinuation of medication intake when symptoms were attributed to side effects of the medicine taken. According to the authors, adherence was reduced because these symptoms were interpreted as evidence that the medication was making them sicker or had more risks than benefits. Similarly, failure of medications to relieve symptoms also negatively influenced adherence because they are interpreted as not having any effects.

3.1 *What Guides Symptom Attribution?*

Valins (1966) was the first to suggest that the mere belief that a change in physiological 'arousal' had occurred would lead individuals to seek for information to label this change. In a recent demonstration, McCaul et al. (1992) found that students who were informed falsely that they were at risk for gum disease reported higher rates of gum bleeding (a symptom of gum disease) 2 days later than students in the control group who were informed that they had no gum disease. Mechanic's notions on the medical students' disease and Schachter and Singer's (1962) study on the attribution of physical arousal mentioned earlier also fit into this conception: When persons have access to a certain sickness label (e.g., because they just read about it or met a sick person) they will be particularly likely to attribute their physical sensations to this disease.

The explanation and attribution of symptoms is, however, also influenced by motivational factors. Specifically, it has been shown to be governed by optimistic tendencies that support a positive view of oneself and one's physiological condition (Weinstein 1980, see *Health Risk Appraisal and Optimistic Bias*). This means that an individual will be less likely to interpret a novel symptom (e.g., bleeding of a mole) as a sign of a serious, life-threatening disease (e.g., skin cancer) and will be more declined to neglect it or to attribute it to a nonserious cause (e.g., a scratch). In general, the optimistic bias results in selectively seeking information that confirms the less threatening hypothesis. Obviously, this benign hypothesizing results in delay to seek help (e.g., see *Illness Behavior and Care Seeking*).

3.2 *The Influence of Mood, Emotions, and Stress*

Mood, emotions, and life stressors may be a further important determinant of symptom attribution and in consequence of care seeking and adherence. People who are in a positive mood report fewer symptoms (Salovey and Birnbaum 1989). People in a bad mood, however, report more symptoms, are more pessimistic that any actions they might take would relieve their symptoms, and perceive themselves as more vulnerable to future illness. In the presence of life stress, ambiguous physical sensations (e.g., fatigue, headaches, or stomachaches) have been found to be

interpreted as signs of stress instead of illness (Cameron et al. 1995). Hereby, stress attributions are more likely for sets of symptoms that are unfamiliar, novel, and ambiguous (Pennebaker 1982).

3.3 Individual Differences in Symptom Attribution

The attribution of perceived symptoms is further determined by both individual and cultural differences. Age and gender as well as ethnic and racial differences in symptom attribution have been documented (e.g., see *Aging and Health in Old Age*; *Culture as a Determinant of Mental Health*; *Health and Illness: Mental Representations in Different Cultures*; *Gender and Physical Health*). For example, identifying initially ambiguous symptoms as signs of a beginning disease is particularly difficult in the elderly. First, older individuals experience more physical complaints than younger persons. They therefore have to evaluate the significance of new symptoms against an increasingly complex background of age related somatic changes (Leventhal and Crouch 1997). Second, distinguishing symptoms that can be attributed to normal aging from symptoms that signal serious disease can be a complex task in old age. Importantly, the 'wait and see' strategy that is widely used at all ages in an attempt to rule out benign causes of ambiguous bodily signals may be more dangerous in old age because of a less vigorous immune protection. Discounting and ignoring treatable symptoms and waiting to seek help can delay diagnosis and treatment of potentially life-threatening disorders and can create unnecessary risk for morbidity and mortality. In sum, older individuals may be at greater risk because they are more likely to make aging attributions and because it has more serious consequences when they delay seeking treatment for a serious disease (Leventhal and Crouch 1997).

4. Remaining Questions

Much progress has been made in the theoretical understanding of the mental representation of symptom sets and diseases and the behavioral implications of these beliefs. Most research in this area has so far focused on just a few diseases: asthma, diabetes, and hypertension. As a consequence, the mental representation of these diseases and their consequences for self-management is, by now, quite well understood. Much more research is needed, however, with regard to the understanding of diseases that until now have received less research attention (e.g., allergies).

Clearly, social and cultural factors shape both the awareness and interpretation of physical symptoms and the behavioral responses chosen for controlling them. A key area for future work is to understand the self-regulatory processes of symptom perception and interpretation within the social and cultural context in which they occur. With a marked increase in the proportion of older people in many countries, research in this area has to move more strongly into the direction of taking a life-span perspective. A better understanding of age-related changes in the awareness and interpretation of symptoms will be vital in the process of optimizing the self-management of chronic diseases. At the same time, with many chronic diseases on the rise among children (e.g., asthma and allergies), more knowledge is needed to understand how they perceive and interpret symptoms and how contextual factors of their life situation can be worked into a better adherence to problematic medical regimens.

B. Knäuper

Synapse Formation

Formation of specialized contacts, the so-called synapses, between presynaptic axonal terminals of neurons and their postsynaptic targets, such as neurons and muscle cells, is a decisive step in building the nervous system. It enables rapid formation transfer between contacting cells via spatially and temporally restricted activation of postsynaptic receptors by neurotransmitters secreted from the nerve terminals. Considerable progress in the understanding of this complex phenomenon came from studies of synaptogenesis of the vertebrate neuromuscular junction (Fig. 1A). During the last decade investigations of glutamatergic neuron-neuron contacts in mammalian brains (Fig. 1B) and the neuromuscular junction in *Drosophila* highlighted the diversity of molecular interactions and universality of certain principles underlying formation of different types of synapses. These two issues are addressed in the present article.

1. *Approaching the Target*

Growth cones are guided to their targets by attractive and repulsive cues that can be diffusible or integrated into the cell surface or the extracellular matrix (Mueller 1999). Semaphorins, ephrins and their receptors constitute large groups of guidance molecules that evoke repulsive and adhesive responses, often bidirectionally in the interacting cells. Cell adhesion molecules of the immunoglobulin superfamily promote neurite outgrowth via homophilic and heterophilic interactions with a variety of extracellular matrix and membrane-bound molecules. Recently, the L1 immunoglobulin superfamily molecule has also been found to be involved in ephrin receptor mediated repellent signaling. Netrins compose a family of proteins that can attract or repel axons, acting via distinct netrin receptors. Binding of recognition molecules to receptors activate signal transduction mechanisms, mostly involving receptor and non-receptor tyrosine kinases. These signals have been shown to converge in the regulation of activities of several small guanosine triphosphate (GTP) binding proteins of the Rho subfamily. Two of these proteins, Cdc42 and Rac1, are under the control of attractive guidance cues, whereas Rho is under control of repulsive guidance cues (Hall 1998). Recent studies show that one and same molecule can evoke attractive or repulsive responses depending on the internal state of the cell. For instance, three different extracellular cue molecules—recognition molecule netrin-1 brain-derived neurotrophic factor (BDNF) and neurotransmitter acetylcholine—induce attractive or repellent turning of the growth cones depending on the intracellular level of cyclic adenosine monophosphate (AMP) (Ming et al. 1997).

2. *Selecting the Target*

Selection of the appropriate postsynaptic target and search strategies of axonal growth cones are interrelated processes. Removal of the repulsive cues or their axonal receptors often results in a decrease in axon bundling, so-called defasciculation, indicating that axon–axon interactions are no longer favored over axon–substrate interactions. This enables the fibers to grow into the regions that normally are not invaded and there form ectopic synapses. At the *Drosophila* neuromuscular junction, the immunoglobulin superfamily molecule fasciclin II promotes and semaphorin II inhibits promiscuous synaptogenesis. These molecules are expressed by all muscles in wild-type flies. A more restricted expression is seen for netrin B which is synthesized by a subset of muscles where it attracts some axons and repels others. Underexpression of repellent molecules or overexpression of adhesion-promoting fasciclin II upregulate formation of promiscuous and ectopic synapses. These experiments argue against the view that pre- and postsynaptic partners have unique complementary labels, and show that the relative balance of adhesive and repellent molecules controls the number of the synapses formed (Winberg et al. 1998). This is also demonstrated by genetic deletion of semaphorin IIIa and its receptor, neuropilin, which resulted in defasciculation and abnormal spreading of cranial nerves in mice. Also, more synapses were formed on wild-type hippocampal neurons expressing the neural cell adhesion molecule (NCAM), the closest mammalian homolog of fasciclin II, when compared to

Figure 1
Formation and differentiation of the vertebrate neuromuscular junction (A) and excitatory neuron–neuron connection (B). The numbers 1–4 refer to four consecutive stages of maturation, during which accumulation of synaptic vesicles in presynaptic active zones and clustering of postsynaptic receptors occur. For the neuromuscular junction (A), after the growth cone (stage 1) establishes contact with a muscle fiber, it is a simple bulbous enlargement (stage 2). During further maturation, extracellular material is accumulated in the synaptic cleft forming the basal lamina, multiple junctional folds are formed, and nerve terminals are coated by glial processes (stages 3–4). For the neuron–neuron synapse (B), induction of a synapse by dendritic filopodium (stage 1) is followed by retraction of the filopodium and formation of the shaft synapse (stage 2) that can be further transformed into stubby (stage 3) and to spine synapse (stage 4). For mature synapses (stage 4) the localization of some molecules is shown. Indicated in (A) synaptic vesicle and active zone proteins are common for these types of synapses. A more detailed description of protein functions and involved molecular interactions is given in the text

neighboring neurons from NCAM-deficient mice maintained in co-cultures. However, NCAM-deficient neurons maintained in a no-choice situation— separately from NCAM-expressing cells—receive normal numbers of contacts. This implies that NCAM mediates one of several signals which are integrated by the developing axon to confer preference for contact formation at sites where the integrated signal is optimal (Dityatev et al. 2000).

Cooperative actions of some N-acetyl-galactosamine-terminated glycoconjugates, N-cadherin and BDNF are known to regulate formation of synapses of retinal axons in the chick optic tectum. Lamina-specific connections in the hippocampus illustrate that synaptogenic cues can be expressed by 'guidepost' cells that are not definitive synaptic targets but transient targets for growing axons. Such 'guidepost' cells, for instance, are Cajal–Retzius cells which occupy the *stratum lacunosum-moleculare* and calbindin-positive interneurons occupying the *stratum radiatum* of the hippocampus. During early development, entorhinal axons form synapses onto Cajal–Retzius cells before the dendrites of pyramidal cells reach the molecular layer. Calbindin-positive interneurons are preferred targets for commissural axons. Later, most of guidepost cells die and synapses are transferred to the pyramidal dendrites (Sanes and Yamagata 1999).

3. *Exchanging Signals*

When an axon approaches its postsynaptic target, it releases anterograde signals and receives retrograde influences from the postsynaptic side. As discussed below, anterograde signals can induce clustering of postsynaptic receptors at synaptic sites and down-regulation of receptor expression at nonsynaptic sites. Also, when neonatal muscles, destined to become fast- or slow-twitch, are denervated and cross-reinnervated with each other's nerves, they acquire contractile characteristics appropriate for their new innervation. Such 'conversion' of postsynaptic cells is mediated by acetylcholine release and electrical activity inducing changes in expression of proteins encoding fiber type-specific isoforms of contractile proteins.

Retrograde signaling plays an important role in elimination of incorrect or excessive synaptic inputs. Most vertebrate muscle fibers are initially innervated by more than one motor axon, retaining only a single input during early postnatal life. Similarly, projections from both eyes initially overlap in the lateral geniculate nucleus, with eye-specific laminae forming from the initially diffuse projections late in embryogenesis. These processes appear to depend on postsynaptic electrical activity. First, competition and selection of afferents could then arise due to limited amounts of maintenance factors released from postsynaptic cells and taken up by axons in an activity-dependent manner. Nitric oxide and neurotrophic factors, like BDNF, nerve growth factor (NGF) and fibroblast growth factor 2 (FGF2), are among the favorite candidate molecules mediating retrograde strengthening of synapses. Second, electrical activity can evoke release of proteases such as thrombin or plasminogen activator, destabilizing cell interactions at the nerve terminal unless they are protected by endogenous inhibitors. Interestingly, the heparan sulfate proteoglycan agrin, implicated in clustering of nictotinic acetylcholine receptors (AChRs) at the neuromuscular junction, may function also as a protease inhibitor. Third, postsynaptic activity can redistribute the localization of adhesion molecules leading to retraction of axons and loss of synapses via downregulation of adhesive interactions in inappropriate sites, whereas synaptic strengthening should involve accumulation of adhesion molecules, such as NCAM, or changes in their molecular configuration as has been shown for cadherins, which dimerize upon depolarization. Such dimers are protected from proteolytic degradation and can form transsynaptic associations (Tanaka et al. 2000).

4. *Postsynaptic Differentiation*

Maturation of synaptic contacts leads to the accumulation of transmitter receptors at postsynaptic sites. If AChRs are uniformly distributed in immature muscles at a density of $1000\,\mu m^{-2}$, their expression in the mature muscles exceeds $10000\,\mu m^{-2}$ at the synapse, whereas the density drops to $10\,\mu m^{-2}$ extrasynaptically. Many molecules have been reported to promote clustering of AChRs *in vitro*. Of these, only one has so far been implicated in synaptogenesis *in vivo*. This is the nerve-derived alternatively spliced isoform of agrin that interacts with the transmembrane protein tyrosine kinase MuSK. A crucial effector of receptor clustering downstream of MuSK is the cytoplasmic protein rapsyn that bears distinct domains responsible for association with the membrane, multimerization, and interaction with receptors. Functionally similar synapse-associated proteins were discovered in neuronal synapses (Garner et al. 2000). They bear protein motifs called PDZ domains that can bind ligand- or voltage-gated ion channels and adhesion molecules. In *Drosophila*, discs-large protein interacts with and determines synaptic localization of fasciclin II and Shaker type of voltage-gated K^+ channels. In vertebrates, the PDZ domain-containing postsynaptic density protein (PSD-95), glutamate receptor interacting protein (GRIP), and Homer interact with N-methyl-D-aspartate (NMDA), α-amino-3-hydroxy-5-methyl-isoxazole-4-propionic acid (AMPA) and metabotropic glutamate receptors, respectively. PSD-95 can also interact with voltage-gated K^+ channels, the synaptic cell adhesion molecule neuroligin, and kainate receptors, whereas GRIP interacts with ephrin B ligands. These complexes

are linked to the postsynaptic cytoskeletal matrix and signaling cascades. For example, PSD-95 and GRIP are likely to couple glutamate receptors to the Ras GTPase-activating protein SynGAP and GDP-GTP exchange factor GRASP1, respectively.

Differential expression of transmitter receptors in postsynaptic sites at the vertebrate neuromuscular junction is achieved not only by clustering of diffusely distributed receptors, but also by transcriptional activation of AChR genes in the muscle in subsynaptic nuclei, and transcriptional repression of AChR expression in nonsynaptic nuclei. Repression of synthesis is regulated by postsynaptic activity, inducing entry of Ca^{2+} and activation of protein kinase C. Critical targets of this kinase are transcriptional factors (myoD, myf5, MRF4, and myogenin) that down-regulate transcription of AChRs by binding to the so-called E-box containing sequences in several AChR subunit genes. These repressive signals can be counteracted at synaptic sites by the nerve-derived neuregulin that is incorporated into synaptic basal lamina and activates synthesis of AChRs in myocytes. Neuregulin acts via the epidermal growth-factor-related receptor tyrosine kinase and downstream cascades of effector molecules, including Ras, Raf, and Erk kinases. These effectors regulate the activity of transcription factors of the ets family, which can bind to N-box elements in some AChR subunit genes. Neuregulins also trigger synthesis of some receptors in the central nervous system and some proteins are likely to be synthesized locally at synaptic sites in dendrites.

5. *Presynaptic Differentiation*

Spontaneous and evoked neuromuscular transmission has been seen to begin within minutes after an axon contacts the postsynaptic cell. However, the synaptic activity is initially low, not only because of the small number of postsynaptic receptors, but also because only few vesicles are released. During maturation of a synapse, synaptic vesicles increase in number and become clustered at active zones, whereas some cytoskeletal elements characteristic of the growing axon are lost. These changes are accompanied by an increase in synaptic volume that leads to a prominent increase in synaptic activity. The factors that induce presynaptic differentiation are unknown, but several molecules, which can be retrogradely released or are present in extracellular matrix, have been implicated in stimulating clustering and release of synaptic vesicles. They include neurotrophic factors, BDNF and FGF2, and extracellular matrix molecules such as agrin and synaptic isoforms of laminin. As for the postsynaptic site, presynaptic differentiation involves redistribution of synaptic machinery, and changes in expression of different isoforms of synaptic proteins. Accumulation and mobilization of vesicles is mediated by synapsins and the PDZ domain-containing proteins Piccolo and Rim. Possibly, assembly of pre- and postsynaptic components in neuron–neuron connections depends on formation of transsynaptic molecular complexes. Thus, postsynaptically localized neuroligin, associated with PSD-95, can bind to presynaptically localized β-neurexin associated via CASK with two PDZ domain-containing proteins, Veli and Mint1. The latter molecule interacts with N-type Ca^{2+} channels that are responsible for the entry of Ca^{2+} and transmitter release at the nerve terminals.

6. *Synaptogenesis as a 'Never Ending Story'*

Formation and loss of synapses continue during the whole lifespan of animals. It is likely that high cognitive functions, such as learning and memory, utilize the mechanisms evolved to wire the brain during early development. Indeed, many molecules involved in early synaptogenesis, such as cell adhesion molecules of the immunoglobulin superfamily, integrins, cadherins, and ephrin receptors, have proved to play important roles in long-term potentiation and depression of synaptic connections, underlying learning and memory in adults (see *Long-term Depression (Cerebellum)*; *Long-term Depression (Hippocampus)*; *Long-term Potentiation (Hippocampus)*; *Memory: Synaptic Mechanisms*). However, synaptogenesis in the adult brain occurs in the context of a very different milieu than that of early development. Mature synapses are subject to more severe constraints for further modifications, due to reduced NMDA receptor-mediated currents, and well-developed inhibitory circuitry. Additional restrictions are imposed by the established adhesive interactions within and outside of synapses, and a firm extracellular matrix enriched in repellent signals, thus possibly reducing structural plasticity. It remains to be seen which mechanisms active during development contribute to the formation of synapses in the adult brain and which mechanisms were additionally 'invented' to provide stability, but also flexibility in synaptic activity underlying learning and memory.

Synapse Ultrastructure

The chemical synapse, which is the primary location for communication between neurons, is characterized by the apposition of two neuronal membranes with unequal membrane densities and a cluster of synaptic vesicles close to the synaptic site. Synaptic ultrastructure refers to the study of the physical components that make up the chemical synapse. This article examines some of the important findings in this area and considers the potential functional relevance of changes in synaptic ultrastructure that have been observed following neuronal activation, neural lesions, learning, and memory.

1. *Why is Synaptic Ultrastructure Important?*

Ramon y Cajal (1893; cited in Bliss and Collingridge 1993) theorized that learning and memory formation resulted from the formation of new synapses. Others speculated that learning might result from changes in the relative strength or efficacy of existing synapses. Donald Hebb (1949) postulated that one neuron's involvement in firing a second neuron would strengthen the connection between the two neurons. The most likely location for this type of change in connective strength is the synapse. At the time of Hebb's proposal there was little evidence to suggest that synapses were capable of change, either anatomically or physiologically. Based on advances in research methodology, however, it is clear that synapses are indeed capable of these types of changes.

As a result of this early research (Cajal 1893, Hebb 1949), the structure and functioning of the synapse has become an area of intense study. While neuronal, axonal, and dendritic changes are also undoubtedly important, the synapse probably represents the primary location for activity dependent neural plasticity. Research on synapses includes examining synaptic chemical transmission (see *Synaptic Transmission*), how synapses form (see *Synapse Formation*), and the differences in synaptic connections throughout the brain. While describing specific synaptic components has also been an important pursuit, quantifying the number and dimensions of synapses is the primary goal of research on synapse ultrastructure.

Quantifying synapses may be especially important for functional reasons when synapses change in number or dimension following neural activation, neural lesions, learning, and memory formation. While a comprehensive review of the literature in this area is beyond the scope of this article, the basic components of the synapse are described, some of the research examining the structural plasticity of the synapse is discussed, and a series of ultrastructural changes that may support the anatomical storage of information is proposed.

2. *Basic Ultrastructural Components of the Synapse*

The following is a brief description of the basic physical components of the synapse. The synapse can be divided into presynaptic components, the synaptic cleft, and postsynaptic components. The presynaptic component usually arises from the end of an axonal branch and the postsynaptic component is usually a dendrite or a dendritic spine. Although many other synaptic contact types exist (e.g., axo-axonic (axon to axon), axosomatic (axon to neuron cell body), etc.), the majority of synapses in the more plastic commonly studied regions of the brain (e.g., the hippocampus and cerebral cortex) consist of axon terminals contacting dendritic spines.

The synaptic junction contains a specialized area referred to as the active zone where synaptic transmission is known to take place. This area is composed of two plasma membranes separated by a cleft, with

Figure 1
Basic ultrastructural components of the synapse

dense structural specializations (referred to as densities, dense projections, or thickenings; see Fig. 1). The presynaptic axon terminal contains synaptic vesicles situated within the presynaptic dense projections. These dense projections are tufts of electron dense material assumed to be essential for vesicular release. The postsynaptic element contains the postsynaptic density (PSD), which is comprised of various proteins (Bloomberg et al. 1977) and is associated with actin, a calcium calmodulin dependent protein kinase (Cohen et al. 1985). While PSDs are also associated with other kinases etc., actin may play a particularly important role in synaptic ultrastructural change as it is involved in maintaining the structure of the postsynaptic element (see Sect. 3.2). The PSD is also the site of postsynaptic neurotransmitter receptors and is considered integral to modulation of synaptic events (Seikevitz 1985).

Gray (1959) proposed that chemical synapses come in two basic morphological types (Type I and Type II). Type I synapses are thought to be excitatory, house round vesicles, and have a wider PSD region (asymmetric synapses). Type II synapses are thought to be inhibitory, house oblong or oval vesicles and have a smaller PSD (symmetric synapses).

3. *Ultrastructural Plasticity of the Synapse*

It has become clear that neuronal growth, changes in connectivity, and changes in activity are associated with modulation of the structure of synapses (Bailey and Kandel 1993). Changes have been observed in synaptic number, synaptic curvature, synaptic size, and synaptic configuration (e.g., perforated synapses, see Sect. 3.4). Please note that this article does not include a consideration of the ultrastructure of dendritic spines (see Harris and Kater 1994 for review).

3.1 *Quantifying Synaptic Number*

When examining the ultrastructure of synapses in a given brain region the initial analysis usually involves some estimate of the total number of synapses in that region. In early research synapses were often counted on a single plane within the region of interest. That is, researchers used an electron microscope to photograph one large two-dimensional area and simply counted how many synapses were present. Gundersen (1977) and others began to realize that this form of counting involved a serious bias. Coggeshall and Lekan (1996) point out that considering only one plane biases the synaptic counts because the number of two-dimensional synaptic profiles observed depends not only on the actual number of whole synapses but also on the size, shape, orientation, etc. of the synapses. As a result, the method of using stereological dissectors to estimate synaptic number was developed. Put simply this involves examining a series of micrographs (photographs) that move through the tissue in three dimensions. Synapses are only counted once when they first appear which rules out the bias identified above and includes all synapses present (see Geinisman et al. 1996b for more details). Synaptic number in a brain region is assumed to important functionally as more synapses would yield stronger connections between neurons (Petit 1995).

3.2 *Changes in Synaptic Curvature*

Changes in synaptic curvature are also known to occur following various forms of synaptic activation (see Petit 1995 for review). Markus and Petit (1989) evaluated synaptic curvature using four possible states: concave (presynaptic element protrudes into the postsynaptic element), flat (no curvature), convex (postsynaptic element protrudes into the presynaptic element), and irregular (w-shaped or more than one curvature). One possible explanation for curvature changes is that plastic internal actin and myosin cytoskeletal networks may create changes in response to activity dependent calcium influx. Fifkova (1985) found that cytoskeletal networks that contain only highly plastic actin structures are found exclusively in developing neurons and mature dendritic spines (see Deller et al. 2000 for an update on this research).

Functionally, curvature is thought to effect synaptic efficacy by increasing contact area and the probability of the transmitters reaching their target (see Markus and Petit 1989 for review). Computer modeling experiments have also suggested that concave shaped syn-

apses, seem to confine the diffusion of presynaptic intracellular calcium (Ghaffari et al. 1997). This would lead to higher calcium concentrations in the presynaptic terminal and an increased probability of vesicular (transmitter) release (see *Synaptic Transmission*).

3.3 Changes in Synaptic Size

Most researchers have theorized that larger synapses are stronger synapses. Conceivably, more neurotransmitter could be released (presynaptically), more postsynaptic receptors could be present, and more conductance through to the postsynaptic cell could occur (Petit 1995). A recent study used cultured cortical neurons to study the effect of synaptic size on the quantal capacity of the synapse (Mackenzie et al. 1999). By imaging Ca^{2+} and then conducting morphological analyses on the same synapse, Mackenzie et al. concluded that synaptic size correlates positively with the amplitude of the postsynaptic response. This suggests that larger synapses create larger synaptic signals.

3.4 Changes in Synaptic Configuration

One of the main changes in synaptic ultrastructure is the transition of some synapses from a continuous synapse to a perforated synapse. A perforated synapse can be defined as any synapse with a discontinuous or segmented PSD (Geinisman et al. 1991). Carlin and Siekevitz (1983) proposed that at some optimal size the postsynaptic material would perforate, eventually segment, and potentially new simple synapses would form. There is, however, evidence against the notion that synapses split to form new simple synapses. Jones et al. (1991) found few double-headed spines, axo-spinous non-perforated synapses lying adjacent to one another, and spinules completely traversing the presynaptic terminals of perforated synapses. Functionally, perforations may indicate synapses ready to divide and this may lead to more synapses and a larger neural signal (Toni et al. 1998). Alternatively, perforations may allow calcium channels to be located closer to the vesicular release apparatus, which could result in greater neurotransmitter release (Jones et al. 1991).

4. Changes in Synaptic Ultrastructure following Neural Events

As mentioned in Sect. 1, a comprehensive review of the literature on changes in synaptic ultrastructure is beyond the scope of this article. As a result synaptic changes following the onset of disease and other models are not discussed. The following is a selection of findings associated with models that involve activation of synapses primarily in the hippocampal formation due to its involvement in learning and memory (see *Hippocampus and Related Structures*).

4.1 Long-term Potentiation

Bliss and Lomo (1973) are credited with the discovery of long-term potentiation (LTP), which has proven to be a popular model system for learning and memory (see *Long-term Potentiation (Hippocampus)*). Put simply LTP is a sustained increase (hours, days, or weeks) in the amplitude of the response evoked in a cell, or population of cells, following tetanic (repeated) stimulation of those cells. The ultrastructural characteristics of synapses have been shown to change following the induction of LTP (Geinisman et al. 1991, Desmond and Levy 1983, Weeks et al. 1999). It is not clear, however, what role, if any, these changes play in the enhanced neural signal observed during the maintenance of LTP (see Sect. 3.2–3.4 for some possibilities).

While LTP can be induced in several brain regions, the majority of the research on changes in synaptic ultrastructure following LTP has been conducted in the hippocampus. Geinisman et al. (1996a) found more numerous axo-dendritic synapses (synapses directly on the dendritic shaft) 13 days following the induction of LTP in the rat dentate gyrus (a sub-region of the hippocampus). Functionally, these axo-dendritic synapses may have a more direct effect on the soma and could therefore combine to create a potentiated signal (see Harris and Kater 1994 for discussion). Desmond and Levy (1983) analyzed synaptic curvature in the rat dentate gyrus and found that the number of concave shaped synapses increased as early as 2 minutes after the induction of LTP. General increases in synaptic size following LTP have also been reported (Chang and Greenough 1984, Desmond and Levy 1988). These studies found an enlargement of the presynaptic and postsynaptic elements, and an increase in length of the presynaptic dense projections and postsynaptic density (PSD).

Geinisman et al. (1991) found an increase in the number of perforated synapses per neuron following the induction of LTP in the rat dentate gyrus. Importantly, the significant increase in perforated synapses observed at 1 hour post-induction was no longer evident at 13 days post-induction (Geinisman et al. 1996a). Buchs and Muller (1996) utilized calcium accumulation markers to identify activated synapses and found that these activated synapses were more perforated following LTP induction. Toni et al. (1999) reported an increase in synaptic perforations in activated synapses during the first 30 minutes following *in vitro* LTP induction in the rat CA1 area (another sub-region of the hippocampus). At 60 minutes post-induction, they found an increase in the proportion of double synapses (two spines connected to the same

presynaptic terminal) suggesting that perforated synapses may eventually split to form new simple synapses. Contradictory evidence has come from Sorra and Harris (1998) who did not find any ultrastructural changes 2 hours post-LTP induction in area CA1 of the rat.

In a series of experiments, Weeks et al. (1999, 2000, 2001) considered the pattern of synaptic ultrastructure at 1 hour, 24 hours, and 5 days post-LTP induction. LTP was associated with an increase in concave shaped synapses at 24 hours. Synapses were larger overall at 1 hour and 5 days but not different at 24 hours. These differences in length were particularly evident in concave-shaped synapses, which were longer at 1 hour, shorter at 24 hours, and longer at 5 days. The proportion of perforated synapses was increased at 1 hour post-LTP induction but did not differ from controls at later time periods. Taken together and added to the other research in this area these results form a model of ultrastructural remodeling that occurs in activated synapses following LTP. Synapses appear to initially grow in size, become concave in shape and perforate by 1 hour post-LTP induction, either split or form new smaller concave synapses at 24 hours and then grow again in size by 5 days.

4.2 Learning and Memory

Synaptic ultrastructure has also been shown to change following learning. Reempts et al. (1992) found an increased number of concave perforated synapses in the rat dentate gyrus following the acquisition of a one-way active avoidance task. Concave synapses were also found to be increased in size relative to controls following training. This result is similar to the findings at 1 hour post-LTP induction (Weeks et al. 2000).

Synapse ultrastructure was also analyzed following the hippocampus-dependent trace eye-blink conditioning in the rabbit (see *Classical Conditioning, Neural Basis of*; *Eyelid Classical Conditioning*). Geinisman et al. (2000) found that while the number of synapses did not change following conditioning the PSDs were significantly larger in the trained animals. Geinisman et al. speculated that this increase in size might represent the addition of signal transduction proteins (thus increasing synaptic strength).

Learning that involves the cerebellum (see *Cerebellum: Associative Learning*) has also been associated with changes in synaptic ultrastructure. Kleim et al. (1996) found that motor skill learning caused synaptogenesis (formation of new synapses) in the rat cerebellum (see *Motor Control Models: Learning and Performance*). The number of synapses per purkinje cell increased in rats after they learned to navigate an aerial maze compared to motor controls. Further, the number of multiple varicosities (clusters of synapses) increased following learning as did the amount of branching in the purkinje cell processes. Kleim et al. also found that as the number of synapses increased, their average size decreased. This result is similar to the changes observed in the rat dentate gyrus 24 hours post-LTP induction (Weeks et al. 1999).

4.3 Synaptic Ultrastructure Following Neural Lesions

Reactive synaptogenesis (formation of new synapses after a neural lesion) in the hippocampus was examined by Anthes et al. (1993). Following ipsilateral entorhinal cortical lesions (see *Hippocampus and Related Structures*), synapses were quantified in the rat dentate gyrus at 3, 6, 10, 15, and 30 days post-lesion. Results showed that the lesions caused an initial 88 percent synaptic loss at day 3, which was followed by rapid synaptogenesis from day 6 through to day 15. Anthes et al. speculated that, following the loss of entorhinal input, previously dormant or suppressed fibers and their synapses became active in the absence of the primary innervation. Interestingly, synaptic size was found to decrease during the phase of rapid synaptogenesis. As synaptogenesis returned to baseline levels (approximately day 15), synaptic size also returned to control or pre-lesion levels. Another important finding was that the number of perforated synapses was greatest at the peak of synaptogenesis (days 10–15) and returned to control levels by day 30 post-lesion. Despite the differences in the length of time post-lesion, the sequence of synaptic structural changes observed by Anthes et al. is very similar to that observed by Weeks et al. (2001) following LTP (see Sect. 4.1).

5. Proposed Sequence of Synaptic Ultrastructural Change

There are limitations to the scope of the sequence of synaptic ultrastructural changes proposed. This sequence is based primarily on changes observed at excitatory, axo-spinous (axon to dendritic spine) synapses. Therefore, these modifications may not take place in inhibitory, axo-dendritic, or axo-somatic synapses, etc.

The data required to make a detailed comparison between the synaptic structural changes associated with LTP, reactive synaptogenesis, learning, and memory is far from complete but it is tempting to speculate about a common mechanism. One intriguing possibility, which was suggested by the growth of clusters of synapses observed by Kleim et al. (1996), is that a subset of synapses become involved or recruited in the various forms of neural plasticity. This subset of synapses then follows a sequence of structural changes (an initial increase in size, concavity, and perforations, then a decrease in size but an increased number of synapses, followed by a return to baseline levels) to

produce more numerous and stronger synapses within the activated groups of afferent fibers. This finding directly supports Hebb's (1949) postulate (see Sect. 1) and allows for lasting ultrastructural change in synapses that form activated networks within the nervous system. These activated networks may then form a basis for learning, memory, and other psychological processes.

Synaptic Efficacy, Regulation of

Multiple biological signals and mechanisms regulate the efficacy of synaptic transmission, thus providing rich combinatorial possibilities for modifying neural communication. These processes have been studied particularly well in invertebrate preparations, whose large neurons and relatively simple neural circuits permit detailed mechanistic and functional analyses.

1. *Multiple Processes Regulate Synaptic Efficacy*

The processes regulating synaptic efficacy vary along several dimensions, including (a) the nature of the change itself (e.g., an increase or decrease in efficacy); (b) mechanisms of induction —that is, the nature of the neural signals that initiate the synaptic change; (c) mechanisms of expression, the proximal causes of synaptic changes; (d) mechanisms of maintenance, the steps involved in their persistence; and (e) time course, ranging from transient forms of regulation lasting only a few seconds, to relatively permanent long-term changes persisting a day or more.

2. *Simple Forms of Synaptic Regulation*

2.1 *Decreases and Increases of Synaptic Efficacy*

Simple forms of synaptic regulation include decreases and increases in synaptic efficacy. Synaptic depression is typically expressed as a decrease in the amplitude or other parameters of a postsynaptic potential (PSP) at a given synaptic connection (Fig. 1). Other things being equal, the larger the synaptic potential, the greater the influence a presynaptic neuron exerts on its postsynaptic target neuron. Hence, in synaptic depression, the presynaptic neuron exerts less control over its postsynaptic target. Facilitation, enhancement, augmentation, and potentiation all refer to an increase in synaptic strength, often expressed as an increase in PSP amplitude (Fig. 1).

Synaptic regulation has been studied most extensively at chemical synapses. However, changes in the efficacy of electrical synapses can also occur.

2.2 *Mechanisms of Induction*

A separate but related issue is the type and locus of cellular activity necessary to induce, or trigger, the change in synaptic efficacy.

Homosynaptic changes arise from activity that occurs at the same ('homo') synapse that is modified. Thus, homosynaptic depression is a decrease in synaptic strength ('depression') that arises from activity at that synapse (hence, 'homosynaptic'). In contrast, heterosynaptic changes arise from activity in neurons other than those being modified. Both are instances of non-associative induction mechanisms, in that only one type or locus of neural activity is involved in triggering the synaptic change.

In contrast, conjunctive or associative mechanisms of synaptic regulation depend on activity in more than one cell. Associate mechanisms are of particular interest from a theoretical perspective, because they involve a more advanced regulatory logic: changes in synaptic strength occur if and only if two conditions are met (see *Associative Modifications of Individual Neurons*).

2.3 *Regulation of Synaptic Efficacy in the* Aplysia *Siphon-withdrawal Circuit*

The following four examples illustrate these different forms of induction as well as certain other aspects of synaptic regulation in the context of the gill- and siphon-withdrawal circuit of the marine mollusk *Aplysia* (Fig. 2).

As detailed by Eric Kandel and colleagues (Kandel and Schwartz 1982, Kandel and Pittenger 1999), the *Aplysia* gill- and siphon-withdrawal reflex to a tactile siphon stimulus is mediated in part by the LE siphon sensory neurons, which connect both directly and indirectly to LF_S and other siphon and gill motor neurons. The strength of LE sensorimotor connections can be modified in several ways (see *Memory: Synaptic Mechanisms*). Similar changes have also been found at connections of *Aplysia* tail mechanosensory neurons.

2.3.1 Homosynaptic depression and homosynaptic facilitation. Low-frequency activation of LE siphon sensory neurons depresses transmitter release at sensorimotor connections and hence also depresses the postsynaptic response (Fig. 1; Castellucci and Kandel 1976). Functionally, homosynaptic depression contributes to behavioral habituation of the gill-and siphon-withdrawal reflex. The siphon is a small fleshy spout that expels seawater from the mantle cavity. A

Figure 1
Homosynaptic depression and heterosynaptic facilitation at *Aplysia* sensorimotor synapses **A.** Simplified circuit and experimental arrangement. Siphon sensory neurons (SN) project monosynaptically and polysynaptically to gill and siphon motor neurons (MN). Extracellular stimulation of the connective, which carries input from tail and head to the abdominal ganglion, activates facilitatory interneurons (Fac.) that produce heterosynaptic facilitation at sensorimotor connections (asterisk) by enhancing transmitter release. **B.** Example of homosynaptic depression (left) and heterosynaptic facilitation (right). Intracellular stimulation evokes an action potential in the sensory neuron that elicits a monosynaptic excitatory synaptic potential (EPSP) in the motor neuron. With repeated stimulation, the amplitude of the EPSP declines (synaptic depression). Connective stimulation (Conn. Stim.) increases the EPSP amplitude (heterosynaptic facilitation). Source: Castellucci and Kandel 1976. © American Association for the Advancement of Science. Adapted with permission

tactile stimulus to the siphon causes both the gill and the siphon to withdraw. After repeated taps of the siphon, however, the amplitude and duration of the reflex diminish. Habituation is an important and ubiquitous form of learning that enables an organism to screen out stimuli of little consequence.

In addition to homosynaptic depression, *Aplysia* sensorimotor connections exhibit post-tetanic potentiation (PTP) in response to high-frequency activation, which is due at least in part to homosynaptic facilitation (Clark and Kandel 1984).

2.3.2 Heterosynaptic facilitation and heterosynaptic inhibition. In *Aplysia* siphon-withdrawal circuits, strong noxious stimuli (e.g., tail shock) activate a group of facilitatory interneurons (e.g., L29 cells) that synapse onto LE siphon sensory cells. Activation of facilitatory interneurons modifies sensory cells and increases their transmitter release via multiple mechanisms. Because this increase in synaptic efficacy is regulated by an extrinsic input, it is an example of heterosynaptic facilitation (Fig. 1; Castellucci and Kandel 1976). Behaviorally, presynaptic facilitation contributes to sensitization of the siphon-withdrawal reflex, increasing its amplitude and duration. With very strong stimuli, heterosynaptic inhibition can also be induced.

2.3.3 Activity-dependent enhancement of presynaptic facilitation. In this associative mechanism (also termed activity-dependent neuromodulation and activity-dependent extrinsic modulation), activity in sensory neurons enhances the heterosynaptic presynaptic facilitation normally evoked by facilitatory interneurons (Hawkins et al. 1983). The facilitation is greater than can be accounted for by a simple combination of a homosynaptic increase (PTP arising from sensory neuron activity) and heterosynaptic facilitation (arising from activation of facilitatory interneurons) and thus is associative. This mechanism is believed to contribute to classical conditioning of the siphon-withdrawal reflex, in which a siphon tap conditioned stimulus (CS) that activates siphon sensory neurons is paired with a tail shock unconditioned stimulus (US) that activates neuromodulatory facilitatory interneurons. Such pairings result in greater synaptic

Figure 2
Four induction mechanisms for synaptic facilitation at *Aplysia* sensorimotor connections. In each case, the synapse being strengthened is the sensorimotor connection from the siphon sensory neuron (SN) to the siphon motor neuron (MN), as indicated by the asterisk. The locus of cellular activity critical for the induction of facilitation is indicated by shading of the cell or synapse. **A.** High-frequency activity of the SN alone (shaded) produces homosynaptic facilitation (e.g., PTP). **B.** Activity in facilitatory interneurons enhances transmitter release from the SN, resulting in heterosynaptic facilitation. **C.** Conjoint activation of the sensory neuron and the facilitatory interneuron produces even greater facilitation, indicating activity-dependent enhancement of heterosynaptic facilitation. **D.** Conjoint activity in the presynaptic SN and postsynaptic MN produces Hebbian facilitation

facilitation and a greater increase in the siphon-withdrawal response than that produced by unpaired CS and US presentations.

2.3.4 Hebbian facilitation. Hebbian facilitation (Hebb 1949) also contributes to increases in synaptic efficacy at LE-LF_s connections (Glanzman 1995). The critical inductive signal for Hebbian facilitation is conjoint activity of the presynaptic sensory neuron and activity or large depolarization of the postsynaptic motor neuron. The associative properties presumably arise from a glutamate N-methyl-D-aspartate (NMDA)-type receptor, which acts as a molecular 'AND-gate' that requires both neurotransmitter binding *and* large postsynaptic depolarization (to remove Mg^{2+} block of the channel) in order for Ca^{2+} influx to occur through the channel and trigger synaptic change (see *Associative Modifications of Individual Neurons*; *Long-term Potentiation (Hippocampus)*). Behaviorally, Hebbian facilitation also contributes to classical conditioning of the reflex. The tactile siphon CS activates siphon sensory neurons, and the tail shock US activates and depolarizes siphon motor neurons, thereby providing the key conjunctive events.

2.4 Expression, Maintenance, and Time Course of Synaptic Regulation

In principle, increases and decreases in synaptic efficacy can result from either a presynaptic expression mechanism (e.g., a decrease in transmitter release from the presynaptic cell), or a postsynaptic expression mechanism (e.g., a decrease in the sensitivity or number of transmitter receptors on the postsynaptic target cell), or both.

Although the mechanisms for expression and for maintenance and duration of synaptic regulation are logically and biologically separable, they are often functionally related and will be considered together here. Four broad categories of mechanisms allow the regulation of synaptic efficacy to span a wide range of temporal domains: (a) transient regulation, which is voltage- and Ca^{2+}-dependent, lasting milliseconds to seconds; (b) short-term regulation, involving second-messenger mediated covalent modifications of pre-existing proteins, typically lasting minutes to an hour; (c) intermediate-term regulation, dependent on protein synthesis, persisting several hours; and (d) long-term regulation, dependent on both RNA synthesis and protein synthesis, persisting for hours and days (Fig. 3).

2.4.1 Transient, voltage- and Ca^{2+}-dependent presynaptic regulation. As demonstrated by studies at the squid giant synapse, which permits intracellular stimulation and recording from both presynaptic and postsynaptic elements, transmitter release is regulated by the voltage of the presynaptic terminal, which in turn influences the basal concentration of intracellular Ca^{2+}, the ion responsible for transmitter release. Depolarization of the presynaptic terminal elevates intracellular Ca^{2+} concentrations and increases release, whereas hyperpolarization decreases intracellular Ca^{2+} concentrations and decreases release. Axo-axonic synapses (connections from one neuron onto presynaptic terminals of another) can depolarize or hyperpolarize presynaptic terminals, thereby regulating release and producing presynaptic facilitation or inhibition, respectively. This form of synaptic regulation is typically transient, as it is dependent on the continuation of the afferent axo-axonic input, so it allows a moment-to-moment gating of information flow. Homosynaptic spike activity can also influence residual Ca^{2+} levels and thus modify transmitter release relatively directly.

Figure 3
Maintenance of Enhanced Synaptic Efficacy. Four classes of mechanisms allow the regulation of synaptic efficacy to span a wide range of temporal domains, illustrated here by four examples of presynaptic facilitation. **A.** Transient voltage- and Ca^{2+}-dependent facilitation. Activation of presynaptic ionotropic receptors depolarizes the presynaptic terminal, increasing basal Ca^{2+} levels and enhancing transmitter release. The facilitation terminates quickly (within milliseconds to seconds) after afferent activity subsides and the terminal repolarizes. **B.** Short-term covalent modifications, as occur at *Aplysia* sensorimotor connections. Facilitatory inputs elevate concentrations of second messengers (e.g., cAMP), activate protein kinases, and phosphorylate substrate proteins, enhancing transmitter release. Short-term facilitation persists beyond the termination of afferent facilitatory input, but subsides on a time scale of minutes as substrate proteins are dephosphorylated. **C.** Intermediate-term facilitation at *Aplysia* sensorimotor connections lasting a few hours requires translation of mRNA to protein but not transcription of DNA to RNA. **D.** Long-term facilitation at *Aplysia* sensorimotor connections. Here the second messenger cascade regulates gene expression as well as protein synthesis, leading to relatively permanent synaptic facilitation lasting a day or more

2.4.2 Short-term regulation via second-messenger mediated covalent modifications. Short-term regulation of synaptic efficacy, lasting minutes to approximately an hour, typically involves second-messenger cascades and the subsequent covalent modification of pre-existing proteins, often via kinase-dependent phosphorylation. For example, in short-term facilitation at *Aplysia* sensorimotor connections, facilitatory interneurons activate both the cAMP-dependent protein kinase (PKA) and protein kinase C (PKC) in sensory cells. In the cAMP-dependent cascade, the facilitatory transmitter (e.g., serotonin), the 'first messenger,' binds to a receptor coupled to G-protein that activates the enzyme adenylyl cyclase. Adenylyl cyclase activation converts adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP), the 'second messenger.' cAMP in turn activates PKA by binding to the regulatory subunits of the kinase, causing them to dissociate from the catalytic subunits. The freed catalytic subunits then phosphorylate the substrate proteins, invoking conformational and functional changes. Similarly, in the

PKC cascade, serotonin activates phospholipase C via a separate G-protein coupled receptor, which in turn elevates the levels of the second messenger diacylglycerol and activates PKC. Together, these two second-messenger cascades produce a broadening of sensory neuron action potentials, enhanced Ca^{2+} influx, and an enhancement of spike-release coupling, thereby increasing transmitter release.

Second-messenger cascades modify a variety of substrate proteins, allowing for coordinated regulation of multiple steps involved in synaptic transmission. Because substrate phosphorylation persists even after the brief input from facilitatory interneurons terminates, synaptic facilitation is maintained beyond the presence of sensitizing stimulus itself. However, biochemical mechanisms for substrate dephosphorylation also exist. Hence, covalent modifications of substrate proteins by themselves are not well suited for more permanent maintenance of synaptic changes.

2.4.3 Intermediate-term and long-term regulation of synaptic efficacy involve translation and transcription. Intermediate-term (lasting hours) and long-term forms of synaptic regulation (lasting a day or more) typically require the recruitment of additional steps to those implicated in short-term regulation. The relationship among these different forms of cellular memory has been particularly well studied at *Aplysia* sensorimotor connections. Unlike short-term facilitation, certain forms of intermediate-term facilitation require the synthesis of new proteins (translation of mRNA to protein). Long-term facilitation involves not only protein synthesis, but also the modification of gene expression (transcription of DNA to RNA) (Montarolo et al. 1986). These forms of synaptic regulation are thus distinct on a mechanistic as well as phenomenological level.

With repeated sensitizing stimuli or their analogs (e.g., serotonin application) used to induce long-term facilitation, PKA phosphorylates not only substrate proteins involved in short-term facilitation at the synapse, but also the transcriptional activator cAMP-response element binding protein (CREB) in the sensory neuron nucleus. CREB then binds to and activates the promoter element CRE (the cAMP response element), inducing gene expression. The new gene products involve not only 'effector' molecules directly involved in the expression of long-term facilitation, but also additional transcription factors, such as C/EBP, that regulate the expression of other genes, thereby producing a cascade of gene regulation. Interruption of this gene cascade at early time points by inhibitors of RNA or protein synthesis blocks subsequent long-term facilitation, but leaves short-term facilitation intact. In contrast, inhibition of RNA and protein synthesis at later time points has little effect. Thus the dynamics of macromolecular synthesis in long-term facilitation mimic the time-sensitivity of long-term memory itself. cAMP and CREB have been implicated in neural substrates of memory in other systems, such as *Drosophila* (see *Memory in the Fly, Genetics of*).

Just as short-term facilitation involves the coordinated facilitation of several processes involved in transmitter release, long-term facilitation involves multiple effector genes. Enhanced expression of the enzyme ubiquitin carboxyterminal hydrolase promotes the degradation of the inhibitory regulatory subunits of PKA, thereby making the kinase persistently active, even after cAMP levels return to baseline. Other gene products lead to the growth of new sensory neuron synaptic terminals (which does not occurn short-term facilitation), thus providing a stable, enduring substrate for long-term memory. Structural changes in sensory neurons are accompanied by corresponding growth in postsynaptic targets, providing further evidence for the coordinated regulation of synaptic efficacy on multiple levels.

3. *Functional Consequences of Simple Synaptic Regulation*

3.1 *Modulation of Input–Output Pathways*

The functional consequences of simple forms of synaptic regulation can be relatively straightforward in circuits where there is a relatively uniform direction of information flow from input to output. For example, as described above, decreases in synaptic strength at *Aplysia* sensorimotor connections contribute to decreases in the siphon-withdrawal response (e.g., habituation), and increases in synaptic strength contribute to increases in the siphon-withdrawal response (e.g., sensitization and classical conditioning).

3.2 *Reconfiguration of Multifunctional Networks*

In other instances, however, even relatively simple forms of synaptic change can have more complex functional consequences. Many neural networks (or their components) are multifunctional networks, participating in more than one behavior. Because the operation of such networks depends on interactions among multiple non-linear processes at the cellular, synaptic, and network levels, regulation of synaptic efficacy can profoundly alter network operation, reconfiguring the network into functionally distinct modes.

3.2.1 Escape swimming in Tritonia. One interesting example is the reconfiguration of a premotor network from a resting reflex withdrawal circuit into a rhythmic central pattern generator (CPG) swim circuit in the marine mollusk *Tritonia* (Katz and Frost

1996). None of the three major interneuron types in this circuit have endogenous bursting properties; the oscillation of the network instead arises from, and hence depends upon, their synaptic interactions. The dorsal swim interneurons (DSIs) are essential elements of the CPG circuit for escape swimming. DSI activity contributes directly to the generation of the swim motor program; in addition, it rapidly enhances the synaptic efficacy and excitability of a second interneuron, C2. C2 has been implicated in the reconfiguration mechanism; its activity disinhibits the DSI neurons, enabling rhythmic dorsal flexions. Thus, the rapid enhancement of C2 contributions may functionally rewire the network, allowing the reconfiguration from simple reflex withdrawal to rhythmic swimming to occur. Because the regulation of C2 synaptic efficacy develops and decays dynamically with DSI activity, it may also play a role in the cycle-by-cycle generation of the swim rhythm itself.

3.2.2 CPGs in lobster stomatogastric ganglion. The gastric mill CPG and pyloric CPG in the lobster stomatogastric ganglion are also polymorphic networks that can be functionally reconfigured to produce fundamental variations in output under different circumstances (Harris-Warwick and Marder 1991). Such alterations arise both from regulation of synaptic efficacy in the circuit and from changes in the intrinsic properties of the component neurons. For example, stimulation of the anterior pyloric modulator (APM) neuron activates the pyloric motor pattern by enhancing the plateau potential capabilities of pyloric CPG neurons. The platean maintains neurons in a depolarized state and so allows them to fire repetitively. As a consequence, a brief excitatory synaptic input that was previously ineffective can trigger a transition of the neuron to the tonically active plateau condition. In the plateau state, neurons also actively resist hyperpolarization, thus rendering inhibitory inputs less effective. The combined enhancement of synaptic excitation and diminution of inhibition result in a more active network.

Modulatory transmitters produce bursting pacemaker potentials in the anterior burster (AB) neurons, the most important pacemaker of the pyloric CPG. Synaptic interactions within the stomatogastric ganglion are mediated partly by non-spiking release, which varies continuously with membrane potential. Hence, larger bursting potentials enhance transmitter release from AB terminals, increasing AB inhibition of certain postsynaptic CPG targets and removing them from the functional circuit, thereby altering the pyloric network and rhythm. Because different modulatory amines exert different effects on AB bursts, the anatomical circuit can be sculpted in a variety of ways to yield a number of different functional networks.

4. Qualitative Regulation of Synaptic Efficacy

The decreases and increases in synaptic efficacy described above involve primarily quantitative modifications of synaptic strength, rendering synapses either more or less potent. However, regulation of synaptic efficacy can also involve a number of qualitative changes in synaptic transmission, thus extending the range of adaptive mechanisms that the nervous system utilizes.

4.1 Regulation of Transmitter Type

An important additional form of synaptic regulation involves changes in the type, rather than the amount, of transmitter that a neuron releases. Such changes can arise either from shifts in the relative release of different co-transmitters resulting from different rates and patterns of neural firing, or from changes in transmitter synthesis (Simerly 1990). Release of one co-transmitter or another can produce qualitative changes in the overall functional effect of synaptic transmission on a particular postsynaptic target (e.g., from excitation to inhibition), rather than simple quantitative changes in a pre-existing synaptic response. Regulation of the transmitter type can also effectively add or remove a particular postsynaptic pathway from operation, thus allowing functional rewiring of the neural circuit without the need for anatomical reorganization. In principle, similar molecular switching might be accomplished by regulation of the relative number or sensitivities of different postsynaptic receptors (see *Long-term Potentiation (Hippocampus)*).

4.1.1 Lobster stomatogastric ganglion. Changes in co-transmitter release affect the pyloric CPG in the lobster stomatogastric ganglion. The inferior ventricular nerve (IVN) cells evoke both excitatory and inhibitory responses in the AB neurons, the most important pacemaker of the pyloric CPG, as described above. At low frequencies of IVN activation, one (unknown) excitatory transmitter is released, and the frequency of the pyloric rhythm increases. In contrast, at higher frequencies, the inhibitory transmitter histamine is preferentially released, and the pyloric rhythm is disrupted. In a variation on this theme, the neuromodulatory transmitter dopamine changes the sign of the synaptic connection between certain identified neurons in the CPG from inhibitory to excitatory by reducing the efficacy of the inhibitory synapse and uncovering a weak electrical connection.

4.1.2 Feeding in Aplysia. Differential release of co-transmitters may also provide for intrinsic self-regulation of a network. For example, the motor neurons in the feeding circuit of *Aplysia* use a variety of

peptide co-transmitters that modulate neuromuscular transmission, extending the dynamic range over which the muscles can operate effectively. High frequency activation of motor neuron B15 enhances the co-release of small cardioactive peptide B. This neuromodulatory peptide increases the amplitude and quickens relaxation time of the muscle, thereby enabling larger muscle contractions to be driven at a higher rate. Similarly, in the leech, the myogenic heart muscle is innervated by heart excitatory motor neurons that co-release acetylcholine and FMRFamide, a modulatory peptide that regulates amplitude and duration of heart beat. Amines also modulate the amplitude of potentials at many crustacean neuromuscular junctions.

4.2 Regulation of Synaptic Plasticity: Metaplasticity

An additional form of synaptic regulation, recently termed 'metaplasticity' (Abraham and Bear 1996), is manifested as a modification of the ability of the synapse to undergo changes in synaptic efficacy, rather than as a change in synaptic efficacy *per se*. For example, long-term potentiation (LTP) not only increases the population spike evoked in dentate granule cells of mammalian hippocampus by afferent stimulation, it also reduces non-linear response properties so that synaptic efficacy is less affected by the recent history of activity at that synapse. LTP thus increases the fidelity as well as the gain of the system (Berger and Sclabassi 1985). Regulation of more long-lasting forms of synaptic plasticity also occurs at hippocampal synapses, involving, for example, shifts in the tendency of synapses to exhibit LTP or long-term depression (LTD).

Metaplasticity has recently been implicated at identified inhibitory synapses of the siphon-withdrawal circuit of *Aplysia* (Fischer et al. 1997). The inhibitory interneuron neuron L30 exhibits multiple forms of synaptic enhancement that control the gain of the siphon-withdrawal reflex, including frequency facilitation during initial phases of high-frequency activation and synaptic augmentation and potentiation that persist after activation. Tail shock reduces the baseline strength of L30 connections onto L29 cells; it also attenuates augmentation/potentiation while leaving frequency facilitation relatively intact. Behaviorally, tail shock decreases the inhibition normally produced by cutaneous stimuli, perhaps by reducing augmentation of L30 inhibition, thus suggesting a functional role for metaplasticity within a defined neural circuit.

5. Regulation of Synaptic Efficacy and of Other Neural Properties

Although not the explicit subject of this article, changes in neural excitability and other intrinsic neural properties can occur in addition to modifications of synaptic efficacy. Synaptic and non-synaptic changes can co-occur in the same neurons, and can be functionally and even mechanistically related. For example, both *Aplysia* mechanosensory cells and *Hermissenda* type B photoreceptors exhibit learning-related increases in excitability (increased firing to a given stimulus), as well as enhanced synaptic strength (Schuman and Clark 1994). These two modifications work in concert to increase both the number and the potency of the synaptic signals conveyed to their postsynaptic targets. Similarly, as described above, reconfiguration of the *Tritonia* escape swim CPG and the pyloric CPG in lobster stomatogastric ganglion involve both synaptic and non-synaptic forms of neural regulation.

One important distinction between regulation of synaptic efficacy and of other neural properties is the greater specificity that synaptic changes may exhibit. Because any given neuron may form pre- or postsynaptic contacts with thousands of other cells, the ability to modify only selected connections of a neuron confers a high degree of precision in the modification of neural pathways. In contrast, intrinsic changes such as enhanced excitability are often expressed cell-wide or nearly cell-wide, enhancing responses to virtually all inputs and enhancing virtually all outputs. In *Aplysia* siphon sensory cells, several short-term forms of synaptic plasticity, including heterosynaptic facilitation, heterosynaptic inhibition, and Hebbian facilitation, exhibit synapse specificity (Clark and Kandel 1984, Clark 2001). Synapse specificity is perhaps not surprising in short-term regulation, which involves covalent modifications of pre-existing proteins. However, long-term heterosynaptic facilitation, which depends on regulation of transcriptional and translational events, is also in part synapse-specific (Clark 2001, Martin et al. 1997). Synapse-specific long-term facilitation raises the intriguing question of how new gene products are preferentially utilized at facilitated synapses, compared with other synapses of the same neuron. An emerging answer, consistent with comparable findings in hippocampal LTP, is that synapse-specific long-term facilitation involves synaptic tagging and depends in part on local protein synthesis. According to this hypothesis, relatively short-lived, local regulatory events at treated synapses allow the subsequent capture of new gene products that are shipped cell-wide, thus conferring the specificity. Irrespective of the particular mechanistic details, long-term synapse-specific facilitation provides an additional illustrative example of the rich interplay and elegance of the multiple biological processes involved in synaptic regulation.

Synaptic Transmission

As explained in detail by J. C. Eccles in 1964, nerve cells communicate via specialized regions of close juxtaposition that were first named 'synapses' by C. S. Sherrington, who used this term to denote the anatomical region where the axon terminal of one neuron contacts another neuron. Sherrington always used synapse in its functional sense (for example, to account for the one-way conduction in the reflex arc). However, it must now be considered from an anatomical perspective as well since, despite variations, there are common structural features consistent with some of the physiological properties of synapses. For example, given that there is a high resistance gap of 200 Å width separating neuronal membranes at most synapses, as first claimed by Rámon y Cajal, current generated by one cell cannot spread significantly to the next one. Thus, it is advantageous for postsynaptic terminals to utilize a chemical mediator to secure transmission. This concept was only established after decades of controversy and efforts to distinguish between electrical and chemical models, for both excitation and inhibition. Yet, although it is beyond the scope of this overview, electrotonic interactions between nerve cells, in the periphery and in the brain, can indeed occur, due to either (a) areas of continuity between them via gap junctions (Bennett 1977); or (b) the channeling of currents in adjacent cells by an unusually high external resistance. The second case is called ephaptic or, better stated, field effect transmission (Faber and Korn 1989). These two electrical modes, which should not be confused, allow signaling to occur instantaneously, and are well suited for the mediation of rapid behaviors, such as escape. In contrast, the hallmark of chemical synapses is the irreducible delay (-1 msec) between the incoming stimulus and the postsynaptic response, which reflects activation of the presynaptic machinery involved with transmitter release (Katz 1969, Llinas 1982). Chemical synapses, however, have remarkable adaptive advantages, such as: (a) variable gain; (b) a large repertoire of polarity and kinetics, resulting in excitations and inhibitions of different durations, depending upon their specific chemistry; and (c) the ability to store information on a long-term basis, due to plastic properties which have become a paradigm for studies of learning and memory.

1. Integrative Properties of Neurons and Synaptic Correlates

Since any behavior is ultimately produced by combined activity in neuronal assemblies, it is of critical interest to understand how each individual neuron reacts to incoming signals initiated in cells connected to it through synaptic junctions, as in a simple reflex chain (Fig. 1A). In fact, information is distributed widely in the nervous system, such that a single neuron may both have many targets and receive inputs from numerous presynaptic axonal terminals, according to the principles of divergence and convergence, respectively. Recording electrodes inserted in the various

Figure 1
Integrative properties of neurons and mode of generation of action potentials

parts of a neuron (soma, dendrite, axon), in combination with anatomical studies of the synapses contacting these loci, have revealed electrical signals whose polarity reflects their function. The signals are named excitatory postsynaptic potentials (EPSPs), and inhibitory postsynaptic potentials (ISPSs). Due to nerve cell cable properties, which are determined by the membrane resistivity and capacitance, signals generated at a distance from the axon are attenuated there, but nevertheless contribute to the summation of responses at the so-called trigger zone (Fig. 1B), which decides whether or not some information will be passed on to the next neuronal relay. This essential integrative property of the cell can be quite complex, with there being multiple trigger zones (Llinas et al. 1969), and summation not always being algebraic (non-linear). Yet, whatever the rules are in a given neuronal subtype, the tonic and phasic bombardment of a cell by incoming inputs can only bring it to such a decision when excitation dominates inhibition and reaches a critical value, the threshold for generating an action potential (Fig. 1C) that will propagate along the axon towards the next synaptic relay. It can already be noted that reaching threshold is the result of the collective activity of large populations of inputs, each of which may, however, act randomly, as will be described below. This cooperative nature of the nervous system pertains whether it is viewed from a molecular, synaptic, network, or behavioral perspective.

2. *What Synapses Have in Common*

The meaning of the term 'synapse' has evolved over time, in parallel with the development of the morphological and physiological tools available for studies of the brain. Today, its strict definition requires electron microscopic demonstration of ultrastructural features associated with chemical transmission. A comparison of central synapses with the neuromuscular junction (nmj), which was the Holy Grail of pioneering studies, allows one to recognize their basic unity.

At the frog nmj, the terminals of the motor axon occupy the end plate, a specialized depression in the muscle membrane, which forms folds. Opposite the crest of each fold, where transmitter receptors are the

Figure 2
Presynaptic and postsynaptic components of quantal transmission

most abundant, the axon terminal contains dense bands and spherical organelles that package 5,000–10,000 molecules of the transmitter acetylcholine (Kuffler and Yoshikami 1975) and are called synaptic vesicles. It was later demonstrated that the opening of synaptic vesicles (exocytosis) takes place at the borders of the bands, which therefore were designated active zones (Couteaux and Pecot-Dechavassine 1970). An equivalent term for physiologists is 'release site,' as vesicle openings were observed there (Heuser et al. 1974). The motor end plate can thus be considered as a number of synaptic units, each represented by a dense band with its associated vesicles and a postsynaptic density (for review, see Peters et al. 1991).

Synapses in the central nervous system (CNS) have more restricted apposition zones. They most often consist of synaptic boutons (Fig. 2A, B) that contain the vesicles and are separated from the postsynaptic element by the 10–20 nm wide cleft. The plasma membranes on both sides exhibit marked densities which, together with the assembly of vesicles, are referred to as a synaptic complex (Palay 1958). Here the analog of the active zone is the presynaptic grid, formed by electron-opaque densities called presynaptic dense projections, which are arranged in triangular arrays and, in *en face* view, take the form of an 'egg box.' This structure is postulated to 'guide' the vesicles towards the plasma membrane (Pfenninger et

al. 1972). As at the nmj, the postsynaptic membrane facing this release apparatus contains the receptors which, however, are restricted to localized clusters (Triller et al. 1985). Thus, as further shown by physiological studies, the basic functional unit of synaptic transmission is a complex containing the presynaptic active zone and its neighboring synaptic vesicles, together with the aggregate of ligand-gated receptors in the opposing postsynaptic membrane. It thus corresponds to the synaptic complex.

At either type of chemical synapse, the depolarization of the terminals associated with a presynaptic action potential opens voltage sensitive Ca^{++} channels, with the consequent Ca^{++} influx initiating a cascade of molecular events that can culminate in the opening of a vesicle fused to the plasma membrane at the release site and the rapid discharge of its contents into the cleft (Fig. 2B). The postsynaptic receptors are thus exposed to a high concentration of transmitter, on the order of mM, albeit briefly (Fig. 2C, double arrow). Consequently, the ligand-gated channels open nearly synchronously, allowing specific ions to flow down their electrochemical gradient. However, as each individual opened channel in the postsynaptic receptor matrix closes randomly, the postsynaptic current, which is the sum of all individual channel activity, decays exponentially. This 'population' phenomenon is illustrated in Fig. 2C, where the summed current rises rapidly and relaxes slowly, a time course typical of those at the so-called fast synapses used by the brain for information processing. At the nmj, the contents of one vesicle open about 1000 receptor-channels, while at central synapses the number can be much less.

One should note that in the CNS the current flow through synaptic channels can be either inward (i.e., directed towards the cell interior) and excitatory, or outward and inhibitory, depending upon the selectivity of the channel, i.e., which ion(s) it allows to pass. Furthermore, in most neuronal systems, glycine and γ-aminobutyric acid (GABA) are inhibitory, and glutamate and acetylcholine are excitatory, although a given transmitter can have either function, depending upon the type of channel associated with that transmitter's receptor (Hille 1984).

3. *Why Synaptic Potentials Fluctuate in Integer Steps*

With a recording electrode placed at the nmj, Katz and colleagues made two related discoveries. First, at rest, spontaneous potentials of similar amplitudes occur randomly. Second, when the nerve is stimulated repeatedly, the resulting evoked endplate potentials fluctuate in amplitude in a steplike manner from trial to trial. Furthermore, amplitude histograms show that the apparently discrete size classes are integer (1, 2, 3, … n) multiples of a basic unit which corresponds in time course and average size to the spontaneous event (del Castillo and Katz 1954). These elementary 'miniature' endplate potentials were thus called 'quanta,' since they are representative of the basic unit of the evoked response. Remarkably, the underlying statistics of transmitter release, which account for the variable number of quanta issued after each impulse (based on experiments conducted in a low concentration of extracellular calcium ($[Ca^{2+}]_0$), satisfied the Poisson process. Release occurred with statistical independence at any one of a large number, n, of 'quantal units available for release' at the junction, with a low release probability (p) that was identical for each unit. Finally, it was postulated that each quantum corresponded to the action of the transmitter packaged in one synaptic vesicle, and since n is large in the Poisson equation, it was assumed to represent the total number of vesicles ready to be released (Katz 1969).

Despite difficulties inherent to the analysis of signals recorded from brain cells, such as the inability to relate any miniature response to one of the numerous junctions impinging on the neuron being investigated, and the low signal to noise ratio, the conclusion illustrated in Fig. 3A, namely that responses evoked by activating a single presynaptic neuron are quantal, was also reached for central synapses (Korn and Faber 1991, Redman 1990, see also Jonas et al. 1993). However, a statistical formulation other than the Poisson most often provides a better description of the amplitude fluctuations. Here the statistics are either a simple binomial model, where n is finite and p is relatively large, or a compound binomial, where p may be different at individual releasing units (see also below). Regardless of the mathematical details (Martin 1977 and see below), n is smaller than originally thought. Also, in experiments combining physiological recordings with anatomical reconstructions of the cells studied, the value derived for this parameter turned out to be equivalent to the number of active zones or release sites in the activated presynaptic terminals. The result lead to the 'one vesicle' hypothesis, according to which a presynaptic action potential causes the exocytosis of the contents of at most one vesicle at each active zone (reviewed in Korn et al. 1990). Despite controversies about multivesicular release, for example during development, this concept is still commonly used for interpreting experimental data (see Stevens 1993).

4. *Consequences of Quantal Transmission*

At the skeletal nmj, neurotransmission in normal Ca^{++} has a high safety factor (large n and p), such that a presynaptic impulse always leads to muscle contraction. On the other hand, the full implications and richness of the quantal nature, and hence uncertainty of transmitter release, are better exploited, albeit still puzzling, at central synapses. From a functional point

Figure 3
Binomial model of transmitter release

of view, the most novel feature is that communication across central synapses is not guaranteed systematically even when p is relatively high: after each impulse, a synapse flips a coin. This probabilistic aspect is exemplified in Fig. 3A, 3B, which stress that each synaptic unit operates in an 'all or none' manner. It also shows that over a large number of trials the average response amplitude equals the $n \cdot p \cdot q$, product, where n and p are presynaptic parameters, and q, the size of a quantum, is proportional to the number of channels opened by a single exocytotic event. This product defines the so-called synaptic weight or strength of a connection between two neurons, which is a dynamic term, as it can be modulated pre- or postsynaptically. Indeed, persistent increases in synaptic weights are considered to underlie higher-order processes such as learning and memory, from invertebrates to primates. For example, activity-dependent long-term potentiation (LTP; Bliss and Collingridge 1993) in mammalian hippocampus, which is considered a well-suited candidate for a memory mechanism, can result from an increase in any one of the three quantal parameters (Stevens 1993). The reverse form of plasticity is long-term depression (LTD; Bear and Abraham 1996) (first described in the cerebellum), which may be a cellular correlate of erasing memory traces. It presumably represents a second mechanism for allowing neurons to respond preferentially to selected subsets of their inputs.

Since a neuron may receive information from thousands of junctions, the binary mode of transmission illustrated in Fig. 2A may be better suited for computational purposes than having a graded process at each site, which would lead to excess or redundant information. Along this line, a synapse can be viewed metaphorically as a symbolic communication system with, according to the scheme of Shannon and Weaver, the encoding process localized to the release site. Knowledge of p and n then allows calculation with the classical entropy equation of the amount of information, in bits, at a connection between neurons. For example, with a given value of p, the increased reliability of neuronal connections with larger ns is counterbalanced by a decreased number of bits per quantum (Korn and Faber 1987).

5. *Diversity of Synapses*

Central synapses exhibit a great deal of structural and functional heterogeneity, which is built upon the scaffolding described above. For example, the transmitter at adjacent contacts on to a given postsynaptic could be an amino acid such as glycine or acetylcholine, a biogenic amine such as serotonin or dopamine, or a peptide such as somatostatin, substance P, or Vasoactive Intestinal Peptide (VIP), and, furthermore, combinations of these substances may be packaged in one terminal ending (Hokfelt et al. 1984). The consequences of this colocalization and of the cotransmission that is often associated with it are not yet resolved, particularly in puzzling cases where two classical transmitters with the same function can be released together (Jonas et al. 1998). In addition, there are multiple receptor subtypes for most transmitters, and more than one may be colocalized to the same postsynaptic locus (Somogyi 1998). Some are ionotropic, with binding causing channel opening or closing, while others are metabotropic, which means that the ligand-bound receptor activates an intracellular metabolic cascade which can modulate kinases or channel activity. In fact, listing the differences

Figure 4
'Latent' synapses and mechanisms of short-term modifications of synaptic efficacy

between synapses is almost an insurmountable task. One would first have to consider constitutive variations in pre- or postsynaptic parameters, namely the probability of release, the kinetics and conductances of single channels. The mechanisms for limiting the duration of action of a transmitter such as its diffusion in the synaptic cleft, its uptake by activated terminals or glia, its chemical inactivation, and receptor desensitization once the channels have opened, add another layer of complexity (Johnston and Wu 1995). One then would have to factor in the synergistic or antagonistic effects of the growing inventory of modulators (Kaczmarek and Levitan 1987), which can influence these various functions in normal and pathological conditions, as well as during development. This diversity may confer a higher degree of functional uniqueness to individual synapses and neurons than is commonly recognized. In any case, it influences the richness of animal behaviors and higher functions which result from activity in complex neuronal assemblies that are synchronized via their synaptic connectivity.

Some elements of synaptic diversity and their functional implications deserve mention. First, although most junctions are fully operational in the normal brain, some of them may remain silent, either because a presynaptic action potential does not evoke transmitter release, or because the postsynaptic receptors are unresponsive (Fig. 4A). These may be viewed as 'latent' rather than 'silent' synapses, because they may be turned on in specific circumstances, such as during learning (Malenka and Nicoll 1997). Second, by virtue of the close packing of synapses, the transmitter released at one of them can diffuse laterally and interact with the postsynaptic receptors of its neighbors (Fig. 4B). This spillover may violate the principle of independence of individual junctions and result in synergistic interactions (Korn et al. 1990), and it may contribute to phenomena such as LTP. Finally, synaptic strength can vary on a millisecond timescale when a presynaptic neuron discharges repetitively (Fig. 4C), and this plasticity can be expressed as either a facilitation or depression (Johnston and Wu 1995, Markram and Tsodyks 1996). Both processes are presynaptic in origin, due to a corresponding change in the release probability, and typically meet the functional requirements of the related networks. For example, facilitation may contribute to recruit neuronal targets that are otherwise weakly excited.

6. *Quantal Analysis and its Limitations*

A statistical dissection of postsynaptic electrical recordings, based on the quantal hypothesis, remains an unsurpassed tool for understanding how different classes of nerve cells communicate with each other. The models used, and their corresponding mathematical formulations, are the same as used in game theory and many branches of the social, behavioral and political sciences; that is, the laws of chance. Stated otherwise, the release of a packet of transmitter after an impulse is equivalent to rolling dice. Despite their apparent complexity, these laws are quite straightforward. For all models, the average number of units released over a large series of trials, which is called *mean quantal content* or m,

$$p_1 + p_2 + \ldots p_n = \sum_{i=1}^{n} p_i$$

where p_1 is the release probability at each site. This is the essence of the *compound binomial release model*, which encompasses all others that assume independent probabilities of release.

If there were no ambiguities about *quantal size*, q, i.e., the magnitude of the postsynaptic response to a quantum, amplitude distribution histograms of evoked responses would have discrete peaks corresponding to transmission *failures*, single quantum responses, doublets and so on, and these distributions could be described with one of the quantal models.

For a compound binomial:

$$\begin{aligned} p_x = {} & p_1 p_2 \ldots p_x (1-p_{x+1}) \ldots (1-p_n) \\ & + p_1 p_3 \ldots p_{x+1} (1-p_2)(1-p_{x+2}) \ldots (1-p_n) \\ & + (1-p_1) \ldots (1-p_{n-x})(p_{n-x+1}) \ldots p_n, \end{aligned}$$

where each line represents one way to get x successes and $(n-x)$ failures. For example, in the first line, units 1 to x release quanta, whereas the other units ($x+1$ to n) do not. The probability of failure for one quantal unit is $(1-p_1)$.

For a simple bionomial:

$$p_x = \left(\frac{n}{x} \right) p^x (1-p)^{(n-x)}$$

where

$$\left(\frac{n}{x} \right) = \frac{n!}{(n-x)!x!}$$

gives the number of combinations by which x quanta can be released out of an available pool of size n.

For a Poisson:

$$p_x = \frac{e^{-m} m^x}{x!}$$

with $m = np$

As developed elsewhere (Martin 1977), most investigators have relied on the two latter models and on indirect methods derived from them rather than trying to fit the distributions. These methods involve either counting the number of failures, n_0, in N trials or measuring the coefficient of variation, CV, of the amplitude distribution, since according to a Poisson:

$$\begin{aligned} m &= -\ln n_0/N \text{ (method of failures)} \\ &= \mathrm{CV}^2 \text{ (coefficient of variation method).} \end{aligned}$$

In rare cases, m can be determined directly, by counting quanta or by averaging miniature events arising from the same synapses. Corresponding expressions allow the last two methods to be applied to a binomial process if p is finite (see Martin 1977). Also, since the binomial $\mathrm{CV} = ((1-p)/np)^{1/2}$ and is independent of q, it has been used as a tool for identifying the pre- vs. postsynaptic locus of a change in synaptic strength, but this approach is liable to misinterpretations (Faber and Korn 1991).

Correct application of these tools requires the accurate identification of the quantal response, which is often difficult at central connections due to quantal variance, distortion by cable properties, and instrumental noise. As a consequence, discrete peaks in amplitude histograms are blurred and failures, single quantal responses, doublets, etc., cannot be distinguished. Various fitting algorithms have been developed, with some success (reviewed in Korn and Faber 1987; see also Stricker et al. 1994), their limitations, however, leaving some questions unresolved. One is the size of the quantum, which is related to the number of channels opened by an exocytotic event, and to their unitary conductance, and can be quite small at central contacts (Finkel and Redman 1983, Edwards et al. 1990). Another is that at some junctions there may be a mismatch between the large number of transmitter molecules released and the relatively few receptors available postsynaptically, which led to the suggestion of a saturated response (Jack et al. 1981). If so, the principles of quantal analysis would no longer hold, as quantitization would be imposed post- rather than presynaptically.

A related issue is the difficulty in determining the pre- or postsynaptic locus of the increased synaptic weight that occurs during LTP, using quantal analysis alone. Raging controversies have not yet been entirely resolved, and mechanisms on both sides of the synapse have been invoked (see Stevens 1993, Liao et al. 1995, Isaac et al. 1996). One of the most intriguing proposals is that although the induction process is postsynaptic, its maintenance can be expressed as an increased release probability, which requires signaling in the reverse direction across the synapse, by a retrograde messenger (reviewed in Bliss and Collingridge 1993). This debate could be obscuring the essential notion of the unity of the synapse where pre- and postsynaptic regulatory factors could be implicated separately or in unison, depending upon functional requirements.

7. *Other Avenues for Synaptic Studies*

Like all scientific fields, synaptic studies cannot remain confined to their historical roots, such as statistics, and need to be enriched by other approaches. The most direct is imaging of dynamic changes at the synapse, associated with the ability to tag pre- and postsynaptic structural components of activated junctions with fluorophores (Malgaroli et al. 1995). In addition, computer-aided modeling of single synapses, or of populations, is necessary to understand biophysical properties of vesicular exocytosis, the fate of the released molecules in the cleft, and their interactions with the postsynaptic receptors, all of which govern the size and kinetics of the postsynaptic response (Bartol et al. 1991, Kruk et al. 1997). Together with

Figure 5
Modulation of gene expression during learning

anatomical correlates, these techniques should not only solve issues such as those related to single vs. multivesicular release and receptor saturation, but also deepen our understanding of brain development, and learning and memory, and how synapses are affected in pathological conditions. Along this line, it can already be envisioned how synapses contribute to genetic or acquired illnesses of behavior and cognition, including psychiatric disorders (Kandel 1998). Figure 5 illustrates the manner in which expression of a gene, leading to the production of a specific protein, could be altered following synaptic activation associated with learning. Conversely, genetic alterations can lead to significant psychiatric disorders, and it can be postulated that they do not leave synapses untouched. This example shows once more that synaptic studies represent a bridge between the neural sciences, cognitive psychology, and behavioral sciences.

Syncretism

The meaning of the term 'syncretism' has changed drastically over the course of time. Currently, the term refers to the mixing together of elements from different religions. This mixing is sometimes viewed with contempt, especially by the clergy of the religions concerned. Scholarly use of the term is more objective and does not entail this kind of value judgement. In this article we shall describe the history of the term. Special attention will be given to current debates on power mechanisms in syncretism. Lastly, syncretism will be compared with fundamentalism.

1. *History of the Term 'Syncretism'*

1.1 *Earliest Uses*
