Estimates of the absolute duration of short intervals are more accurate than of long intervals. But estimates of the relative duration of short and long intervals are about equally accurate. For example, the error in judgment of a 10-s interval and a 60-s interval is approximately the same if the error is calculated as a proportion of the interval. This is an example of Weber's law for timing (Gibbon 1977). In peak procedure, the bisection procedure, and many other procedures, both the mean and the standard deviation increase linearly with the temporal interval. Thus the ratio of the standard deviation to the mean, the coefficient of variation, remains constant. A more general principle has been called 'superposition.' This refers to the fact that the entire functions relating the behavioral measure to time in the peak procedure, the bisection procedure, and many other procedures are very similar if time, and the behavioral measure, are scaled in relative units (Gibbon 1991).

The ability of animals to time intervals in the range of seconds to minutes is now well established, and the quantitative effect of variations in the conditions on performance in different timing tasks is now well established. These results have provided a guide for the development of psychological explanations about the mechanism of timing. For the evaluation of quantitative psychological models of timing, it would be useful if archives of raw data from timing experiments were available. Such resources are becoming increasingly feasible to establish.

2. *Psychological Explanations*

A psychological process model of timing and time perception necessarily involves intervening variables.

These intervening variables can generally be classified as being related to perception, memory, and decision processes. A formal model of the process consists of rules connecting the input to one or more of the intervening variables, one or more of the intervening variables to the output, and, perhaps, the intervening variables to each other. In a quantitative model of the process, the rules are specified mathematically.

The input to a psychological process model of timing is a physical duration of time that begins with some event, such as the onset or termination of a stimulus, response or reinforcement. This event initiates some internal or behavioral process that changes in a regular way with time, a process that is often referred to as an 'internal clock.' Many types of internal representations of physical time have been proposed. One proposal is that a pacemaker emits pulses according to some distribution, the event that begins the timing process closes a switch that permits the pulses to enter an accumulator, and the psychological representation of time is the accumulation of pulses. This leads to an approximately linear relationship between psychological and physical time. Another proposal is that the event begins a continuous, nonlinear process, such as an exponentially decaying memory trace, and the magnitude of the trace provides a nonlinear relationship between psychological and physical time. Other functions to convert physical to psychological time have also been proposed.

The internal clock may consist of multiple processes that are initiated by an event. The multiple processes may be a several periodic or nonperiodic functions with different characteristics that are initiated at the same time, or several processes that are initiated serially. The representation of time with such clocks is usually a vector of heights of each of the functions. There has been no consensus regarding the nature of the internal clock. Any of them can account for the behavioral data qualitatively, and none of them can be ruled out as neurally implausible.

A psychological process model of timing also requires some memory of previously reinforced intervals. For example, the animal must remember that it was reinforced 20 s after the onset of a stimulus, or it must remember that a left lever response was followed by food after a 2-s stimulus. One proposal is that temporal memory consists of an unorganized collection of examples; another is that it consists of a continuum of strengths that correspond with particular times after an event. In addition to a structure, a psychological model of timing requires a rule for storage of new information and a rule for retrieval of information. There has been no consensus regarding the nature of temporal memory based upon either the behavioral or neural data.

Finally, a psychological process model of timing requires some decision about whether or not to respond, or, if multiple responses are available, which response to make. The response decision is based upon a comparison of perception of the current time with the memory of the reinforced time. If the perceived current time is near enough to the remembered time of reinforcement, a response will occur.

Many quantitative models of timing have been proposed that can be described in terms of the three processes of temporal perception, memory, and decision (Church and Kirkpatrick 2000). Some of them are mechanistic, but others consider the animal to be a computational device that operates on symbolic representations (Gallistel 1990). The models differ in their quantitative representation of each of the parts. Scalar timing theory (Gibbon et al. 1984) is based upon a perceptual representation of time that has a pacemaker that emits pulses that are switched into an accumulator, a memory representation of time that is based on an unorganized collection of examples, and a decision that is based on a ratio comparison of the perceptual representation with the a single sample from temporal memory. In contrast, the Behavioral theory of timing and related models (Killeen and Fetterman 1988, Machado 1997) are based upon a perceptual representation of time that is a cascade of functions, a memory representation of time that is based on the strength of each of the functions at the time of reinforcement, and a decision that is based on the product of the perceptual and memory representation. The various quantitative models of timing have been found to produce reasonable fits to the data in different timing procedures, but none of them make accurate quantitative predictions in all procedures. The development of a single quantitative model of timing that makes accurate quantitative predictions for a large number of behavioral measures in a wide range of procedures is essential. Such a model is likely to contain modules for temporal perception, memory, and decision processes that included parts of current theories.

3. *Neural Explanations*

The perception of time is quite different from the perception of physical stimuli such as lights, sounds, and chemicals. In the case of vision, audition, olfaction, taste, pain, and other sensory systems, there are physical stimuli that impinge upon receptors specialized for particular physical stimuli. But time, like location, is an attribute of any stimulus and there are no known specialized receptors. A perceived time refers to the time since the onset of a physical stimulus, the interval between two physical stimuli, or the duration of a physical stimulus. Thus, it is possible that the psychological explanations that propose general mechanisms for timing are incorrect. Instead, there are specialized mechanisms for the perception of the duration of visual stimuli, auditory stimuli, and others, based upon the unique properties of each modality. One argument in favor of some general

processes is based upon the success of the cross-modal transfer experiment. Rats trained to make a temporal discrimination in one modality (such as a 2-s noise vs. an 8-s noise) can be tested on a temporal discrimination in another modality (such as a 2-s light vs. an 8-s light). The test can either use the same response assignments for the short and long stimuli or use a reversed assignment. During testing the rats learned significantly more rapidly with the same assignment of responses to the short and long stimuli than with reversed assignments (Roberts 1982). This demonstrates that there is something general about a 2-s and an 8-s stimulus in different modalities.

Although it is clear that the brain is the biological mechanism responsible for interval timing, the specific neural processes involved are not well understood. To obtain a general understanding of the neurotransmitter mechanisms and their sites of action, the primary methods have been to study the effects of brain lesions and systemic drug administration on behavior in timing procedures. The goal is to obtain some degree of neural and behavioral selectivity. Neural selectivity refers to the specificity of the brain structure or receptors affected, and behavioral selectivity refers to the specificity of the observed effects. With the development of timing procedures with well-established quantitative functional relationships between independent and dependent variables, and quantitative psychological models of the timing process that consist of three or more separate modules, it has become possible to search for biological manipulations that affect one module but not others. On the basis of systemic injection of dopamine agonists and antagonists, the speed of the internal clock appears to be controlled by activity of D^2 dopamine receptors. Similar research with systemic injection of cholinergic agonists and antagonists produced results that suggested that the memory storage appears to be controlled by the level of activity of the cholinergic system (Meck 1996). Other research with neurotoxin lesions has identified the clock effects with structures in the basal ganglia, and the temporal memory and attentional effects with structures related to the frontal cortex.

Tip-of-the-tongue, Psychology of

The 'tip-of-the-tongue' (hereafter, TOT) phenomenon is an everyday, near-universal experience characterized by the inability to retrieve a word known to the speaker. Researchers have long been interested in this phenomenon, both in terms of understanding why it occurs and when it is more likely to occur, and because TOT provides a window into memory retrieval. In this article the main findings stemming from these different lines of research are summarized.

At a youth conference in London in 1998, the British Deputy Prime Minister John Prescott, when asked to justify the increasing costs of the Millenium Dome in Greenwich, said in front of thousands of attendees, 'The money came from the…you know…what do they call it…' and finally blurted out in desperation 'the raffles.' In response to laughter from the audience, Prescott tried to show he knew something about the word he could not produce: 'I don't do it myself.' At this point the conference chairperson whispered discreetly 'the lottery,' but it was too late to cover up the retrieval failure which was reported in the next day's *Times* (*Times*, January, 1998, from Schacter 2001).

Like John Prescott, seemingly all speakers occasionally experience the temporary inability of retrieving a word: a TOT. In a survey including 51 languages,

Schwartz (1999) reports not only that all informants across languages knew what a TOT was, but also that all the languages considered had a specific expression for it. Furthermore, in 45 of these languages, this expression includes the word 'tongue,' which may be related to our feeling of immanent retrieval of the word during a TOT.

This feeling was well described by William James (1890, pp. 251–252):

> Suppose we try to recall a forgotten name. The state of our consciousness is peculiar. There is a gap therein: but no mere gap. It is a gap that is intensely active. A sort of wraith of the name is in it, beckoning us in a given direction, making us at moments tingle with the sense of closeness, and then letting us sink back without the longed-for term. If wrong names are proposed to us, this singularly define gap acts immediately so as to negate them. They do not fit into its mold.

This description captures some of the basic facts about TOT. The longed-for word is known and on the verge of coming out. Furthermore, the word is not completely unavailable: its 'mold' is there.

1. *Methodologies Used to Investigate TOT*

Psychological studies investigating TOTs are based on introspection. Using either experimental methods to induce TOTs or naturalistic observations, researchers have capitalized on speakers' ability to identify their TOTs and their ability to reflect on their cognitive state during TOTs.

1.1 *Experimental Induction of TOTs*

Experimental studies started in 1966, with the work of Brown and McNeill (1966). They presented speakers with definitions of rare words such as 'a place where bees are raised for their honey' and then asked them to provide the name. When speakers could not say the name, they were first asked to indicate whether or not they were in a TOT state (unable to say the word but sure they knew it, and feeling that the word was on the verge of coming back). If in a TOT state, they were asked to provide information about the unavailable word (other words that came to mind, the initial letter of the word, etc.). Finally, speakers were provided with the target name (e.g., *apiary*) and were asked whether the word they were attempting to retrieve was the same as the experimenter's target. Cases in which speakers did not recognize the experimenter's target as their target were defined as *negative TOT states* and used as a baseline for guessing, which could be compared with the information reported for *positive TOT states* (i.e., cases in which the experimenter's target matched the speaker's target). This experimental methodology (and its variants) to induce TOT has since been used in a number of studies to investigate, for example, lexical retrieval during speaking.

1.2 *Diary Studies*

A second methodology that has been used is the recording of TOTs as they spontaneously occur during daily activities (see *Speech Errors, Psychology of*). For example, in a study by Burke et al. (1991), speakers of different age groups were asked both general questions about their retrieval failures (e.g., to estimate how often they experience TOTs), as well as specific questions concerning TOTs as they occurred over a four-week period. These specific questions (as for experimentally induced TOTs) included reporting partial information, but also strategies used to resolve TOT states. Such a methodology has provided important information regarding the incidence of TOTs for different verbal materials and for different populations (i.e., young and elderly speakers).

2. *Incidence of TOTs*

TOT incidence is influenced by a number of factors; some of the most important are reviewed below (see Brown 1991 for a comprehensive review).

2.1 *Speaker-related Factors*

In their diary study, Burke et al. (1991) found that TOT states are more common for older (1.65 TOTs per week) than younger (0.98 TOTs per week) speakers. Other studies have also found a higher incidence for older speakers (see also *Memory and Aging, Cognitive Psychology of*)

Dramatic differences in incidence rates are also related to brain damage. Anomia is defined as a language specific disturbance arising after brain damage whose main symptom is the inability of retrieving known words. In some anomic patients, these retrieval failures have the same features of TOTs occurring for nonlanguage-impaired speakers, but they are far more common. For example, patient MS (Vigliocco et al. 1999), failed to retrieve the target name for a picture 32 percent of the time (for the same pictures, 10 nonlanguage-impaired speakers performed 100 percent correct). On these occasions, MS could still provide partial information about the name, indicating that he was indeed in a TOT state.

2.2 *Word-related Factors*

Certain words are more susceptible to TOTs than others. In their naturalistic study Burke et al. (1991) found that 62 percent of the reported TOTs involved

proper names, 12 percent involved object names, and 23 percent involved abstract words. In her catalog of TOTs, Browman (cited in Brown 1991) found that 50 percent of the words inducing TOTs were proper names, 25 percent were concrete and abstract nouns, 14 percent were adjectives and 9 percent were verbs. The predominance of retrieval failures for proper names is also well established in other studies (see Brown 1991 and Schacter 2001). Why? One reason may be that proper names, relative to common names, are not so well integrated with related concepts: they denote individuals but they do not provide any further information about those individuals. This possibility is supported by experiments that suggest a higher incidence of TOTs for proper names which are nondescriptive (e.g., John Baker), than for proper names that are descriptive of some attribute of a character (e.g., John Baker who is a baker) (Schacter 2001). Another possible reason is that proper names cannot be replaced easily by another word, while this is often an option for common names. For instance, if I want to introduce Flavio Monti, I have no option but to say his name; if instead I want to talk about a sofa, if I am experiencing retrieval difficulties, I can use a synonym (couch).

Burke et al. (1991) further reported that the higher incidence of TOT for proper names was magnified by age differences. That is, although there was an overall increase in TOTs from younger to older adults, such an increase was particularly dramatic for proper names. Burke et al. (1991) discuss this result in the framework of a model of the TOT phenomenon in which the difference between proper names and common names is thought of as a difference in the convergence of activation from conceptual to lexical representations. For proper names, a single conceptual representation (denoting the individual) would activate the corresponding lexical representation; for common names multiple conceptual features would converge on a lexical representation. In this framework, the difference between younger and older adults is further accounted for by assuming an age-related weakening of the conceptual to lexical connections.

Differences in frequency and recency also contribute to words' differential susceptibility to TOTs. Low frequency words tend to induce TOTs more often than high frequency words. Rastle and Burke (1996) investigated whether differences in recency of use of a word may account for the different incidence of TOTs for proper names and within this class, for the different performance of younger and older adults. In their study, recency was manipulated by priming target words in an experiment inducing TOTs. They found that while recent use of a word, indeed, decreased the incidence of TOTs, it did not differentially affect proper names and common names and did not differentially affect younger and older adults, suggesting that recency has a global effect on the retrieval process.

3. *Information Available for Report during a TOT State*

Numerous studies have reported that speakers in a TOT state are able to report partial information about the word, which supports the interpretation of TOT as a memory retrieval failure rather than a memory encoding or storage problem (see also *Memory Retrieval*). In experimental studies, speakers' guesses when in a TOT state are compared to baseline guesses. Two types of baselines are usually used; (a) the speaker's rating of being in a 'don't know' (as opposed to a TOT) state; (b) negative (as defined above) TOTs. It has been shown that speakers in TOT states can report both lexicosyntactic and phonological information about the words above baseline.

Regarding syntactic information, researchers have shown that Italian speakers can report above chance whether a noun is masculine or feminine (i.e., a syntactic property that does not have conceptual connotates for nouns referring to objects and abstract entities); English language-impaired (e.g., patient MS) and unimpaired speakers can report whether a noun is countable (i.e., pluralizable, such as *opinion*) or mass (i.e., nonpluralizable, such as *knowledge*) (see Vigliocco et al. 1999) when such information is not semantically transparent. Regarding phonological information, many studies from the seminal work by Brown and McNeill (1966) have shown that speakers can report above chance information such as the number of syllables, the main stress, and the first phoneme or letter in the word.

Often, in both diary and experimental studies, words semantically and phonologically similar to the target are reported by the speakers. This fact has led some researchers to propose that TOTs are blockages caused by the intrusion of these unwanted words; however, this hypothesis has not received much experimental support (Meyer and Bock 1992).

4. *A Psycholinguistic Perspective on TOT*

TOT has been used as a tool to test hypotheses regarding lexical retrieval in production. Theories of speech production (see *Speech Production, Psychology of*) assume that lexical retrieval is achieved in two main steps. During a first step an abstract lexical representation that specifies the meaning and the syntactic properties of the intended word is retrieved; during a second step the phonological make-up of the word is retrieved. Within this framework, TOT states can be accounted for in terms of an inability to retrieve the phonological word form, despite successful retrieval of the abstract lexical representation. The fact that speakers in a TOT state can report information about the syntactic properties of a word is compatible with the specification of this information at the level of abstract representations; while the availability of

phonological information may be accounted for in terms of partial activation of word-forms.

5. Metacognition, Feeling of Knowing, and TOT

TOT is related to the 'feeling of knowing' (FOK), which is the ability to predict the likelihood of later recognition of a word presently unavailable. In both cases, speakers 'know that they know,' that is, they have knowledge about their memory state (see also *Metamemory, Psychology of*). Although related, note that the two differ because while TOTs occur spontaneously, FOK judgments are usually elicited. Furthermore, speakers in TOT states are confident they will eventually recall the word; FOK, instead, assesses recognition likelihood for a word. In TOT and FOK there is a discrepancy between the subjective conviction of knowing the word and the actual inability to produce it. This discrepancy has been taken by some authors to suggest a distinction between the ability to monitor the content of memory and the ability to retrieve from memory. Alternatively, it has been suggested that FOK and TOT arise as a consequence of the amount of accessible information pertaining to the unavailable word (see Koriat 1993 for an overview).

Tocqueville, Alexis de (1805–59)

1. The Unity of a Process

Born into a family of very old Norman nobility on July 29, 1805 in Paris, Tocqueville first studied philosophy and rhetoric at the Collège Royal in Metz, then law in Paris. In 1827, he was appointed to the judiciary and became a probationary judge at Versailles. Throughout the Restoration, he took part in the bitter struggle which set the old aristocracy, enclosed in its traditions, against the new France, led by the middle classes. After the Revolution of 1830, and having sworn—not without hesitation—the oath of allegiance to Louis-Philippe, he gave himself plenty of room as far as events were concerned by requesting a commission to conduct a survey into the American penitentiary system. This trip (April 1831 – February 1832), undertaken with his friend Gustave de Beaumont, resulted first in a report entitled *Du Système pénitentiaire aux Etats-Unis et de son application en France (On the penitentiary system in the United States and its application in France)* (1833), then the first two volumes of *De la Démocratie en Amérique (Democracy in America)* (1835), and finally what is known as the *Second Démocratie (Second Democracy)* (1840). The success of the first part of this work was enough to establish his reputation; in 1838 he was elected to the Academy of Moral and Political Sciences and, three years later, he entered the Académie française.

Tocqueville's liking for philosophical reflection did not cancel out his sense of political action. Elected to the Chamber of Deputies in 1839, and reelected several times in his Valognes constituency, he committed himself resolutely to the parliamentary path on the side of the constitutional opposition. On January 27, in a speech with a prophetic note, he announced the revolution which was to break out one month later. After the February Days, he was witness to the clashes of June 23 to 26, 1848 which put 'the haves' at odds with the 'have-nots.' His *Souvenirs (Recollections)* (1951–, Vol. XII) relate what this 'great battle waged in Paris' was like. A short-lived Minister for Foreign Affairs under the Prince President of the Second Republic, Tocqueville was returned to his studies for good with the coup d'État of December 2, 1851. *L'Ancien Régime et la Révolution (The Ancien Regime*

and the Revolution) appeared in 1856, the second great work which its author was anticipating expanding when tuberculosis cut short his life. He died on April 16, 1859 in Cannes.

Tocqueville's work—which comprises the two great texts of 1835/40 and 1856, the *Recollections*, various papers, speeches, and reports, as well as a vast correspondence—draws its unity from the constant questioning which inspired it: why since 1789, in 1830, and then in 1848, was it always the *same* revolution which starts up again? The unity of the work also stems from the method adopted in order to understand the repetition—in Europe, and in France in particular—of the revolutionary process. Its comparative method, not systematized, but rather applied spontaneously, allowed it to avoid the perils that Eurocentricity and sociocentricity are denounced for today. 'Whoever has only studied and seen France will understand nothing of the French Revolution.' (1951–, Vol. II, 1, p. 94) It was therefore without being obsessed with one singular case, and being free of all aristocratic prejudice, that Alexis de Tocqueville set about penetrating the essence of democratic society; by combining 'holism' and 'individualism,' he posited a diagnosis along with a prognosis on modern society whose value and validity were only recognized much later.

2. *In Search of Democracy*

'It is not only in order to satisfy curiosity—however legitimate—that I examined America,' Tocqueville wrote 'I wanted to find any lessons there from which we might profit […] I confess that in America I saw more than just America; I sought an image of democracy itself, its tendencies, its character, its prejudices, its passions. I wanted to become acquainted with it, if only at least to know what we should hope or fear from it.' (1951–, Vol. I, 1, p. 11) With this definition, the Tocquevillian project was set out as an effort to understand a 'social state' and, secondarily, a political regime. If the first readers of the 1835 work were attracted to the evocation of exotic locations, they were rather more invited to turn the American mirror upon themselves. Three years later, they were to see a different image of democracy which was less suited to charming them.

Tocqueville's confessed search was not, in fact, separable from the recognition of a tendency—considered from the outset irresistible and irreversible—which was specific to modern societies: the march towards the equalization of conditions. Behind the analyses which were put forward, the contrast between aristocratic society and democratic society operated in a virtually permanent state, and it was the transition from the traditional order to the new arrangements in human relations that Tocqueville undertook to study. He approached this by going back to the principles which govern social states and to the institutions which arise out of them. From an early stage, he realized that one principle had to dominate and that the government which was called mixed, that is, which united an aristocratic element with a democratic one, was merely an idle fantasy. The English monarchy, with its strongly dominant aristocratic character, was still able to pass for the model of government; but it was the American system which was called upon to become the model for modern nations. Equally, Tocqueville also developed an 'ideal type' for democratic society, based on the equality of conditions and set against an aristocratic society founded on the hierarchy of status.

If the paths leading to democracy are marked out in different ways, 'the great advantage of Americans is to have arrived [there] without having to undergo democratic revolutions, and to have been born equal rather than having to become it.' While examining the customs—defined as 'the moral and intellectual state of a people'—of Americans, Tocqueville assigned their foundation to a fully accepted equality of conditions. (1951–, Vol. 1, p. 300) In the USA, democracy was in some way 'natural'; its inhabitants had not had to struggle against privileged groups, such as the ones which had resisted in France; they made up an immense middle class within which there was active mobility. Whatever was set down in custom was fostered by institutions—the commune, the jury, and numerous associations. Decentralization and communal democracy allowed citizens to take part in public affairs, and allowed the body social to regulate itself. 'Each individual makes up an equal portion of the ruling body, and plays an equal part in the government of the State.' The close bond between the political and the social was actually realized in this society, a society which acted upon itself and through itself, since power only existed within it. In this way, the negative effects of individualism were limited. As for the ills which could arise out of equality, liberty provided the cure. In this society where one endeavored to bring people together rather than to set them against each other, and where the most serious social antagonisms were excluded (one found rich people, not a rich class), religion made a powerful contribution to social regulation. Tocqueville clearly highlighted the role of religious beliefs in the bolstering of customs and the upholding of Republican institutions. Religion prevented the American citizen 'from imagining everything and forbids him from daring to do everything.' It ordered him to confine himself to the representation of that which was real and to the conception of that which was useful. Through this, the American mentality took shape—pragmatic, not speculative; with a firm grasp of the facts, not prey to ideology.

The general characteristics of the American model are set out clearly in *Democracy in America II*, along with its potential variations such as liberal democracy and revolutionary or democratic despotism; it also

includes the amendment to the relationship between the passion for liberty and the passion for equality. Individualism—the childhood illness of democracy—is defined in this work as 'a deliberate and peaceful feeling which inclines each citizen to isolate himself from the mass of his fellow men and to withdraw from his family and friends. In this way, after having created for himself a small-scale society for his own benefit, he readily leaves wider society to itself.' (1951–, Vol. I, 2, p. 105) In *The Ancien Regime and the Revolution* one again finds the threat this represents illustrated in the case of France, and the dangers signaled in 1840 which were brought up to date by the comparative analysis of the passions of democracy and of revolution. Another model, this time continental, was in place at the time and was in a way the negative of the American model.

3. *The Analysis of Social Change*

'What strikes the European who travels through the United States,' Tocqueville noted in *Democracy in America I*, 'is the absence of what we call government or administration.' (1951–, Vol. I, 1, p. 69) In 1840, he further drew attention to his initial observation: 'Wherever, at the head of a new venture, you see the government in France and a nobleman in England, in America you can be sure to find an association.' (1951–, I, 2, p. 113) If it was true that a good government was one which taught its citizens to manage without it, this was not working in France. The backdrop to the 1856 work, which links the interpretation of an historical crisis with a theory of social change, was provided by feudalism and its networks of dependence and solidarity where masters and servants were united by reciprocal services. It was this system, social and political, with its intermediary groups, corporations, village communities, provincial assemblies, and so on, that the French monarchy had set about destroying by means of administrative centralization. No one benefited from it; neither the nobleman whose preeminence was affected, nor the bourgeois whose vanity was wounded, nor the ordinary man who still remained the underling. Discontent was universal.

By suppressing the intermediary bodies, by condemning the nobility—stripped of its function and devitalized—to appearing merely as the ornament of despotism, while at the same time encouraging the emergence of new elites but without satisfying their statutory ambitions, royalty had converted an organic whole where each individual was bound to a group into an homogenous mass oscillating between apathy and demand, submission and subversion. Such was the new social state: 'men, no longer being bound to each other by any bond of caste, class, corporation, or family, are only too inclined to concern themselves with their own individual interests and too prone to considering only themselves and to withdrawing into a state of narrow individualism where every political virtue is stifled.' Thus, centralization, the restriction of liberties, and the deterioration of public life combine forces. In this way, equality leads to despotism, since it is no longer built on liberty or on participation in communal affairs.

The explanatory variations which Tocqueville identifies therefore relate, as in the 1835/40 work, to characteristic customs, institutions, and circumstances. In the process which they deal with, the Revolution no longer appears as a rupture; the Terror had only prolonged the process of state centralization which had been initiated earlier. There was, in reality, a continuity between royal absolutism, revolutionary Jacobinism, and imperial politics. In the process in question, religion had also played an important role by virtue of the universalist dimension presented by Catholicism. At the same time, the Revolution—itself preaching the abolition of privilege and the equalization of conditions, had 'itself become a kind of new religion, an imperfect religion.' (1951–, Vol. II, 1, p. 89) As a result of this, Tocqueville was in no doubt that 'all the Revolution did would have been done without it; it was only a violent and hasty process with whose help the political state was adapted to the social state, the deeds to the ideas, and the laws to the customs.' (1951–, Vol. II, 1, p. 66)

One should take note of the manner in which Tocqueville analyzes the social conflicts and their origins and exacerbation. They were born in eighteenth century France in a short period of economic recession following a long phase of general prosperity. It was therefore not increased poverty which triggered off the conflicts, nor was it the weight of former coercive institutions which were the cause. The Revolution 'did not break out in the regions where these institutions were better preserved and their discomfort and rigour felt most acutely by the people, but on the contrary in those regions where they were felt the least, in such a way that their yoke had seemed all the more unbearable precisely where it was the least heavy.' (1951–, Vol. II, 1, p. 99) It is a question here of situations that one analyzes today in terms of relative frustrations. Tocqueville recognized them perfectly in the case of the emancipation of the peasantry, just as he had in the case of the ascendancy of the bourgeoisie. They made two strongly felt passions explosive: one was 'the violent and inextinguishable hatred of inequality'; the other 'more recent and less deep-rooted' led individuals 'to want to live not only equally, but also freely.'

These were the passions which the *philosophes* of the Enlightenment had stirred up. They provided a theoretical framework for social protest by showing the necessity of replacing traditional habits with new rules. Far removed from the affairs of state, with no practical experience and therefore inclined to conceive of 'general and abstract theories in government matters,'

men of letters undertook to found cloud cuckoo land. Vain debates of ideas took the place of public life: 'Political life was violently driven back into literature, and writers, taking the direction of public opinion in hand, found themselves from one moment to the next holding those positions which the leaders of political parties usually occupied in free countries.' (1951–, Vol. II, 1, p. 196) With this observation, Tocqueville paved the way to a sociology of intellectuals.

4. *The Originality of the Contribution*

The author of *Democracy in America* was hailed by his contemporaries as a new Montesquieu. The historians of the nineteenth century saw in *The Ancien Regime and the Revolution* a major contribution to historiography. If the glory of Tocqueville knew no eclipse in the USA, his work did in France, however, fall into a kind of oblivion from which it did not emerge until after World War II. It is to Raymond Aron (1967) and André Jardin (1984)—who actively worked on the publication of the *Oeuvres Complètes (Complete Works)*—as well as to Jean-Claude Lamberti (1970, 1983)—the author of the first state-commissioned thesis on Tocqueville—that one principally owes the renewal of interest in a work which from then on took its place among the classic works of sociology. There are many reasons for this long purgatory. Tocqueville was not a maker of systems as one so likes in France; he appeared as the champion of liberalism at a time when this current of thought was being strongly denounced; nor did his interpretation of the French Revolution seem ideologically sound; and then his way of thinking seemed to come under a mixed genre of headings—political philosophy, philosophy of history, and general sociology.

The reasons for Tocqueville's return are by no means separable from the turnaround in the intellectual climate which took effect in the last two decades of the twentieth century. The new tendencies are well known—the decline of hypersocialized conceptions of the individual; the freeing of collective memory previously marked by the rupture of revolution; and the loosening in particular of the vice of monocausal determinism. On the latter, the *Recollections* give this opinion which is consistent with the orientation of the social sciences at the beginning of the twenty-first century: 'I, for my part, hate these absolute systems, which make all the events of history dependent on great first causes, each one being linked to the other by a chain of inevitability, and which, as it were, remove men from the history of mankind.' (1951–, Vol. XII, p. 84) The social protagonists are restored with a power of deliberation and decision, the choice of strategies, and a certain amount of room for maneuver through methodological individualism. They have 'good reasons,' as Raymond Boudon (1977) definitively emphasized, to act as they do, and it was these reasons which, in concrete situations, Tocqueville attempted to bring to light.

This writer was original and modern first and foremost through his method of implementation; it brings together observations, comparisons in space and time, and generalizations; it retains the significant fact without losing sight of the point of view of the collective whole; and the investigation which it guides is situated both on the macrosociological as well as the microsociological level. The rational reconstruction of the significance, in the end ascribed to human actions and historical events, is carried out from objective and subjective elements. The protagonists' reasons are integrated into the explanatory schema along with their passions. Tocqueville, in fact, invites his reader to weigh up the importance of the passion factors; he urges him thus to 'imagine' through a sympathetic understanding the fate of the French peasant in the eighteenth century: 'Imagine this man's condition and calculate if you can the wealth of hatred and envy which has amassed in his heart.' (1951–, Vol. II, 1, p. 106)

Tocqueville's contribution to social science is also original in the way that it poses problems and formulates questions. Why, it is asked in the *Mémoire sur le pauperisme (On pauperism)* (1835), are the countries which appear to be the most poverty-stricken the ones which, in reality, have the lowest number of inhabitants? And why, inversely, is a section of the population of the opulent nations forced to have recourse to the help of other people in order to live? A comparison between Portugal—where poverty was hardly to be seen because the responsibility was assumed by the networks of traditional solidarity—and England—whose social regulations were broken by the Industrial Revolution which created its wealth—provided the answer. It is therefore not simply a question of observing and describing—*Democracy in America* is not a simple monograph resulting from banal field research—but of understanding the social processes arising from 'good questions.'

Tocqueville's way of thinking was modern, in particular because of the subject it was applied to—that is, democracy. A type of entirely new society was establishing itself in the nineteenth century. Emphasizing its principal traits—notably the reign of public opinion—and the dangers it comprised—in particular the tyranny of the majority—Tocqueville assigned its foundation to a dependent work force and the equality of conditions. The development of the egalitarian mentality which accompanies the establishment of democratic society is a source of dissatisfaction that the hope of mobility is not up to appeasing. Inequalities, reduced in one sphere, spring up again elsewhere—there will never be an end to them. Individualism which causes social completeness to disintegrate brings about a displacement of the boundary which separates public space from the

private sphere; the latter extends like a zone of retreat where one concern rules: that of material well-being. At the same time, the author of *Democracy in America* 'saw,' in a splendid passage where prophecy and prediction merge the 'type of despotism that democratic nations have to fear.' This was a vision of a 'vast mass of people all alike and all equal,' seeking trifling pleasures, all separated from each other, and above whom 'rises up an immense guardian power, absolute, intricate, regulated, provident, and gentle,' (1951–, Vol. I, 2, p. 324) which reduces men to the level of children by making them dependent—this tableau really is the Welfare State.

Tolerance

By 'tolerance,' most contemporary social scientists mean citizens' willingness to put up with others' efforts to participate in public life even if they personally dislike those others' views. In other words, 'One is tolerant to the extent one is prepared to extend freedoms to those whose ideas one rejects, whatever these might be' (Sullivan et al. 1979, p. 784). Tolerance among the mass public has been assumed to be a crucial psychological underpinning of democracy, a form of restraint that makes it possible for a wide range of groups and people to express their ideas and participate in public life (Almond and Verba 1963). It is an orientation toward political and social life that presumes agreement on certain basic procedural norms by which differences of opinion are negotiated. In the USA, this is usually interpreted as support for the basic civil rights of those with whom one disagrees, for example, their right to free speech, free assembly, due process, privacy, freedom to seek political office, and other similar liberties.

Tolerance suggests that despite (or perhaps because of) the diversity of opinion on matters of public interest, there needs to be general agreement on the 'rules of the game' (Neubauer 1967), the procedural norms by which substantive matters are negotiated, and these rules must then be applied equitably to all groups, regardless of how counternormative their views might be. The notion of political tolerance evolved from the idea of religious toleration (Sullivan et al. 1982); the former was a way to live with one's ideological enemies just as the latter was a way to live among those of different religions.

The body of social science research pertaining to political tolerance is closely related to research on support for civil liberties (see *Civil Liberties*) and studies of intergroup conflict, but the concept has evolved in such a way that it now carries a more specific meaning: In order to 'tolerate' another person or group, one must disagree with the views that the person or group represents or espouses (Sullivan et al. 1982). Thus a communist who supports the civil rights of other communists is not demonstrating tolerance because the element of disapproval and disagreement is missing. Only when the same level of support is extended to those with whom one disagrees can the label 'tolerance' be properly applied.

The many definitions of tolerance that have been offered and the corresponding measurement strategies

they have spawned are part of a lengthy progression in social scientific interest on this topic dating back to the McCarthy era in the USA. As Finkel et al. note (1999, p. 204), the key questions and controversies motivating research on tolerance to date have included:

To what extent are citizens willing to extend procedural democratic liberties (such as freedom of speech and association) to unpopular political groups? How widespread is political intolerance?

What are the cultural, demographic, social, psychological, economic, and political sources of political tolerance and intolerance? Are certain types of citizens (e.g., the less educated) more intolerant?

Is the mass public becoming more tolerant than it once was? If so, why?

Does intolerance tend to be concentrated on a few unpopular groups, or is it more widely dispersed? In other words, to what extent is intolerance 'pluralistic?'

Are elites more tolerant than the rank and file? If so, why? And is the elite-mass tolerance gap widening or narrowing?

Are there significant cross-national differences in tolerance, whether in the general public or among elites? How can such differences be explained?

What individual-level behaviors and system-level outcomes does tolerance or intolerance foreshadow?

In this article, I begin by providing a brief description of the seminal, early studies of political tolerance in the USA. Although an overview of all of the areas of subsequent research described above is beyond the scope of this article (see Sullivan and Transue 1999, and Finkel et al. 1999 for two recent and far more extensive literature reviews), this discussion highlights four of these important themes including (a) differences in levels of tolerance held by the mass public as opposed to more politically active segments of the population; (b) debates over the conceptualization and measurement of tolerance; (c) evidence pertaining to whether tolerance has increased in the USA; and (d) cross-national examinations of political tolerance. These four topics serve as a loose organizational scheme for the article, but because these debates are closely interconnected, these topics cannot be neatly divided into four separate discussions.

1. *Early Research on Tolerance*

In what is widely recognized as the first systematic national study of tolerance in the USA, Samuel Stouffer gathered information on the opinions of a large probability sample of Americans in 1954. They were asked a series of questions about support for the civil liberties of a variety of unpopular left-wing groups including socialists, atheists and Communists. His findings, published as *Communism*, *Conformity*, *and Civil Liberties* (1955) suggested that the majority of Americans did not think an admitted communist should be allowed to make speeches in public, to retain American citizenship, to teach in high schools or colleges, or even to work as a clerk in a store. Moreover, the majority felt that books by communists should be taken out of public libraries, that the government should have the authority to tap their personal phone conversations to acquire evidence against them, and that they should be thrown in jail. Although these same responses suggested somewhat greater tolerance when asked with reference to socialists, atheists, or 'suspected communists,' the reaction this study generated was still one of great surprise. Either the USA was not truly a democracy, or the assumption that widespread public commitment to these procedural norms was necessary to democracy was incorrect. The latter interpretation predominated, and subsequent studies seized upon two findings that seemed to explain how democracy could thrive without widespread political tolerance among members of the mass public.

1.1 *'Carriers of the Creed'*

Stouffer's work, along with two important studies published in the early 1960s (Prothro and Grigg 1960, McClosky 1964) illuminated patterns of findings that continue to be central in debates over tolerance today. One explanation that was offered for how democracy persisted without mass tolerance centered on mass-elite differences. Stouffer's original study included a sample of local community leaders, and this group proved to be much more supportive of the rights of left-wing groups than the mass sample. Likewise, in his study of political party activists in the late 1950s, McClosky (1964) found greater support for civil liberties among political activists. Consistent with this pattern, Prothro and Grigg (1960) found greater tolerance among the well-educated and well-to-do. Thus the dominant conclusion that was drawn was that the well-educated and politically active segments of the population were the 'carriers of the creed' who protected the democratic system from an intolerant majority (Prothro and Grigg 1960, p. 281). If the intolerant were inactive, they could do little damage; moreover, their apathy supposedly prevented them from acting on their political views.

1.2 *Principles versus Application*

A second prominent explanation for democratic stability in the face of apparently low levels of support for procedural norms emerged from Prothro and Grigg's (1960) study which asked respondents both about general principles of democracy and about some specific applications of those principles. They found widespread support for the principles but greatly diminished support when questions were posed so as

to apply those principles to specific controversial cases. So, they argued, to say that Americans did not support democratic principles was technically incorrect; they did so in theory but often did not apply those principles when faced with specific applications. Consistent with the elite model of democratic stability, McClosky's study (1964) further confirmed that political activists were more supportive of the rules of democracy both in principle and when they were applied to specific cases.

The general conclusion drawn from these early studies was that democracy could be sustained even with mass intolerance. This was possible because the intolerant were concentrated among the politically inactive segments of the population. The relatively tolerant attitudes of political elites were assumed to be due to their educational and socioeconomic backgrounds and a result of their exposure to democratic norms through actual involvement in the political process (Finkel et al. 1999, p. 208).

That the well-educated and politically-engaged tend to be more tolerant than ordinary citizens has now been widely documented over the years. Nonetheless, the underlying cause of mass-elite differences has not been fully resolved. Moreover, if one argues that tolerance demands support for freedom of expression and assembly, due process and privacy *even for those groups that promote intolerance*, then the thesis of democratic elitism itself can be questioned. As Sniderman et al. (1996) point out, although there is a consensus among elites in support of free expression and assembly for most unpopular groups, when racists are the target group, there is no elite consensus in defense of their rights.

2. *Changing Conceptualizations and Trends in Tolerance Over Time*

In the 1970s, Nunn et al. (1978) updated Stouffer's original work and found Americans far more supportive of the civil liberties of those same groups that had been the target of Stouffer's assessments 20 years earlier. Nunn et al. argued that although mass democracy in America may have been on shaky ground in the 1950s, improvements in education as well as other demographic changes had made it far more tenable by the 1970s. Perhaps political leaders were no longer so essential to sustaining democratic norms.

This optimistic conclusion was soon called into question. Sullivan et al. (1979) countered this assessment by pointing out that the target groups used by Stouffer as well as Nunn and his colleagues to assess levels of tolerance had been almost exclusively groups on the left. If tolerance is defined as putting up with those with whom one disagrees, then support for the rights of groups on the left alone should not be considered an adequate measure. For those who are on the left themselves, such questions do not require tolerance. Sullivan et al. proposed an alternative measurement technique that involved first asking individual respondents which groups they liked the least, and then asking them the standard items addressing support for civil liberties with respect to those specific groups. This two-step technique insured that respondents did, in fact, have negative feelings toward the groups they were asked about.

Based on results using this technique, Sullivan et al. argued that the American public was far less tolerant than Nunn et al. had indicated. Instead, they suggested that Americans were more tolerant only of groups on the left; other unpopular groups, primarily right-wing or racist groups, still elicited high levels of intolerance when people were asked about their rights to demonstrate, run for office, give public speeches, and so forth. Although there were no comparable data from earlier points in time using this same two-step technique, Sullivan et al. suggested that the improvements in levels of tolerance noted by Nunn et al. were 'illusory' at best. On the more optimistic side, however, they argued that intolerance that was focused on a multitude of targets—so called 'pluralistic into lerance'—was safer for democracy because large groups of people did not gang up on particular groups as targets. A multitude of targets was deemed preferable to intolerance focused on one or a very small number of groups.

2.1 *Critiques of the Least Liked Group Technique*

Following Sullivan et al.'s efforts at reconceptualizing tolerance, this two-step, 'content-free' technique has become increasingly popular. However, both the technique and the conclusions that have been based on it have not been accepted without question. In response to Sullivan et al.'s claim about the lack of an trend toward greater tolerance over time, both Abramson (1980) and Immerwahr (1980) pointed out that it is impossible to tell without comparable data from the 1950s whether the increases noted by Nunn et al. were truly 'illusory.' Mueller (1988) analyzed trends using a comparable content-controlled approach, and concluded that there had been a marked increase in tolerance since the early studies, but that this had occurred mainly because Americans had grown less concerned about threats from leftist groups as the communist threat dissipated, and their concern was not redirected toward similarly threatening rightist groups. Although incontrovertible evidence on the shape of the trend over time does not exist, it appears that tolerance in some forms has increased.

A second controversial aspect of the Sullivan approach is its effect-driven view of tolerance (see Finkel et al. 1999). Respondents are asked to name their most disliked group, and this becomes the basis for tolerance judgments, with the assumption that this

should serve as a critical test because it will be most difficult to extend these liberties to one's most disliked group. But surprisingly, intolerance of people's second most disliked group actually turns out to be higher than for the most disliked group (Sullivan et al. 1982), thus raising questions about whether negative effect is the best criterion for group selection.

In addition, as Sniderman et al. (1989) and Gibson (1989) point out, if Sullivan's conclusions about safety in the proliferation of groups that could serve as possible targets for intolerance were correct, then the levels of tolerance that individuals express should vary a lot based on which groups they are asked about, and conservatives and liberals should pick different groups, with liberals more intolerant of conservatives and conservatives more intolerant of liberals. But in their empirical analyses, Sniderman et al. found that neither the group nor the act made much difference to people's responses. And while conservatives are less tolerant than liberals, this did not much affect their choice of target groups; both liberals and conservatives were most likely to choose militarists and racists. Gibson (1989) concurred with findings showing that tolerance of communists and Ku Klux Klan members were highly correlated. Findings in this vein have led to the conclusion that tolerance is adhered to as a general principle rather than as a group-specific construct (see also Duckitt and Farre 1994):

> The person who does not honor and protect the rights of those whose point of view clashes with his own is … a bad bet to protect the rights even of those whose point of view supports his own … It is the racial bigot, not the person committed to racial tolerance, who is more likely to oppose free speech for racists (Sniderman et al. 1991, p. 135).

Although the shortcomings of the Stouffer-type approach to measuring tolerance are widely acknowledged, currently there is no consensus on an ideal measurement technique, and thus researchers continue to use variants of the Sullivan technique (for example, Barnum and Sullivan 1989) as well as Stouffer-like measures that are balanced across the ideological spectrum. Although these techniques result in different distributions of the proportion of the population that is tolerant and intolerant, Gibson's (1992) study suggests that the same set of independent variables predicts both kinds of tolerance measures equally well, thus the structure of relationships remains similar regardless of measurement technique.

2.2 *Further Conceptual Dilemmas*

The concept of tolerance may be religious in origin, but over the past century it has been explored primarily in terms of the tolerance of groups holding particular political viewpoints. Although the term racial tolerance was in general use in the latter half of the twentieth century, the term is now seldom used, at least in part due to the reconceptualization of the term by Sullivan et al.: If tolerance presumes dislike of the target group, then racial tolerance is not what most advocates of racial equality have in mind. Rather, the goal is a lack of discrimination on the basis of race and ethnicity so that these groups would not be disliked any more than any other and thus not need to be 'tolerated.' Instead of racial tolerance, terms such as prejudice, discrimination, or, more generally, racial attitudes are used in discussions of attitudes toward racial and ethnic minorities (see *Prejudice in Society* and *Discrimination, Racial*). Nonetheless, the distinction between attitudes toward racial as opposed to political groups have become increasingly important to understandings of tolerance in contemporary politics.

For example, in the many studies using the least liked group method, much of the intolerance observed in contemporary samples is what might be described as *intolerance of intolerance*. In other words, it involves people's objections to the exercising of these basic procedural rights by groups who themselves promote intolerance. The most commonly mentioned target groups of this kind are racists or Ku Klux Klan members.

Does tolerance require that one tolerate the intolerant? While there has been general agreement that citizens should be free to organize their lives around their own beliefs and values even if they are at odds with the majority, there has been no consensus as to whether people whose beliefs and values are at odds with the majority by virtue of being intolerant should be allowed the same rights of speech, assembly, and so forth (Sniderman et al. 1996). The current popularity of anti-hate legislation in the USA testifies to this important tension in current definitions of what tolerance means. Does tolerance demand that citizens support measures to restrict the rights of intolerant groups, or does it require that they support their rights despite their promotion of intolerant views?

Although this is an old quandary, it brings to the fore the often oversimplified perspective of research on tolerance where the 'correct,' politically enlightened answer was typically assumed to be straightforward and obvious (Sniderman et al. 1996). Discrepancies between belief in the principle of tolerance and willingness to support its application to certain cases typically have been ascribed to citizens' lack of ability to understand the connection between principle and practice. Instead, this discrepancy appears to be due to citizens' efforts to balance support for tolerance with other values, such as the desire to discourage negative racial attitudes.

3. *Cross-national Research*

These same kinds of core democratic values also have been studied in contexts outside of the USA, including established democracies such as Canada, Israel, and

New Zealand, and newly-emerging democracies such as post-World War Two Europe, the former USSR countries, and Latin America in the 1980s. Some of the measures used in these efforts are identical to or adapted from those already described, while others use entirely new measurement strategies tapping a far broader range of attitudes toward democratic norms and values than tolerance *per se*.

Of particular interest to understanding the origins of mass tolerance in democratic systems are studies of the attitudes of citizens in countries without established democracies. Kaase's (1971) study of postwar West Germans found that by 1968 their beliefs were similar to those of people in the USA in their high levels of support for principles involving free speech and assembly and the necessity of political opposition. Also like US citizens, levels of support were much lower when these principles conflicted with public order or other values. Kaase's study, along with others in Spain, Italy, and Japan, suggested that changes in attitudes toward democratic values can occur after a regime change (see, for example, Gunther et al. 1986).

To explain processes of 'democratic legitimation' after a regime change, Weil (1989) developed an influential model suggesting that the longer people live within a responsive, competitive, and democratic system, the more they will develop support for democratic values. Thus, in studies of democratization during the post-Cold War era, what was particularly surprising was the high levels of support for democratic principles found immediately after the demise of communism (see, for example, Klingemann and Hofferbert 1994 on the former DDR (East Germany); Seligson and Booth 1993 on Nicaragua and Costa Rica; Finifter and Mickiewicz 1992, Gibson et al. 1992, Reisinger et al. 1994, Rose and Mishler 1994, and Tedin 1994 on the former USSR and Eastern Europe). Since little time had elapsed for the gradual emergence of democratic values, and citizens had had little experience with a responsive political system, this rush to embrace democratic norms was unexpected.

Post-hoc explanations for high initial support for democratic values have led to caution in interpreting these prodemocracy, protolerance attitudes as indicative of a wholehearted embrace of democratic values. One interpretation suggests that what researchers are observing are sheer novelty effects based on citizens' initial attraction to and excitement about democracy. A second explanation for high initial levels of support suggests that through 'demonstration effects' from observing the West, democratic political values have actually already been exported to these countries (Dalton 1994, Gibson et al. 1992, Weil 1996).

However, it is worth noting that responses to questions asking about commitment to, or overall evaluations of, democracy are less supportive than those asking about specific values associated with democratic government (e.g., Whitefield and Evans 1996) and there is considerable variation from question to question, thus suggesting ambivalence at best in countries formerly within the USSR (see Dalton 1994, Miller et al. 1994).

One of the ongoing measurement problems in studies utilizing broader attitudes toward democratic government is the extent to which these measures are tapping attitudes toward current system performance as opposed to support for democratic values (see Finkel et al. 1999). Moreover, it has been difficult for researchers to discern the stability of these beliefs over time, especially in rapidly changing political circumstances. Still, these cross-national studies have tremendously improved the study of political tolerance and support for democratic norms, not only by providing contexts in which there is greater variance in levels of tolerance than in the USA, but also by providing insight into the process by which tolerant attitudes develop in the mass public.

Until relatively recently, claims about the causes and correlates of tolerant attitudes have been heavily dependent on American data, thus making generalizations about tolerance quite difficult. Levels of tolerance clearly vary by country. For example, Gibson et al.'s studies in the (now former) USSR suggested that even countries without strong democratic traditions may have high levels of support for democratic norms in the abstract, yet their levels of tolerance when applied to specific cases were extremely low, much more so than in the USA and other countries where democracy has had a longer time to take root. Sullivan et al.'s (1985) studies in Israel and New Zealand using the same least-liked group method also found substantial aggregate differences in levels of tolerance with New Zealanders much more tolerant than Americans and Israelis.

But aggregate differences aside, cross-national research suggests some degree of generalizability of findings from the USA. For example, Sullivan et al. found that although the *level* of threat perceived varied by country, its impact on tolerance judgments was roughly the same, and the same was true for the influence of personality characteristics. In their studies of tolerance among the Soviets, Gibson et al. (1992) likewise found that perceived threat was the strongest predictor of tolerance, and personality characteristics such as dogmatism were also influential in promoting intolerance. Commitment to abstract democratic norms decreased intolerance as it did in the USA and New Zealand. However, Sullivan et al. found that the impact of belief in democratic norms was quite different in Israel, and reflected cross-national differences in understandings of what constitutes democracy. Thus although the goal of tolerance may be the same in all places—finding a peaceful and noncoercive way to deal with inevitable political conflict—cross-national research on tolerance must take into account the fact that not all countries will define democracy to include the same norms for adjudicating its differences of political opinion.

Topographic Maps in the Brain

Topographic maps in the brain are organized collections of neurons, within subcortical nuclei or in cortical areas that isomorphically represent or map the

receptor sheet or muscles of the body. Topographic sensory representations reflect the arrangements of receptors on the receptor sheet, while topographic motor maps reflect the arrangement of the muscles. Maps might be of the mechanoreceptors of the skin or muscles, the photoreceptors of the retina, or the row of hair cells of the cochlea in the inner ear. In a topographic map of the receptors of the skin, touching a sequence of positions on the skin activates a comparable sequence of groups of neurons in the map. The order of representation reflects the order of activating afferents terminating in the map, although the map is rendered more precise by local circuits within the map that tend to inhibit less active and sparse inputs. Thus, neurons have smaller receptive fields, and there is less overlap of receptive fields for adjacent groups of neurons. All vertebrates have topographic maps in the brain. Many of these maps are in the brain stem. Mammals have a specialized part of the forebrain, the neocortex, which varies greatly in size and differentiation across taxanomic groups. All mammals have a few homologous topographic maps in neocortex, but mammals in which neocortex is greatly enlarged have additional maps that are not found in all mammals. Topographic maps appear to be fundamental to the processing of sensory information and motor control.

1. *The Discovery of Sensory and Motor Maps in the Brain*

One of the early advances in the field of neuroscience was the realization that the brain has functionally specialized subdivisions and does not act as a whole or single organ. Instead, the brain consists of a number of interacting and interconnected subdivisions, or organs of the brain, usually termed nuclei for subcortical or brain stem structures and areas or fields for neocortex. Some of the most convincing evidence for the view that functions are localized in specific parts of the brain came from early electrophysiological studies that demonstrated that neocortex has topographic maps of receptors and muscles.

The first signs of the existence of maps in the brain came from careful clinical observations of the impairments of patients with cortical lesions or focal epilepsy. Most notably, in the 1860s the neurologist, John Hughlings Jackson, reasoned that only the existence of orderly maps in the brain would explain the experiences of patients with epilepsy where a sensation or movement would start at some location on the body and then expand systematically to include successively more distant body parts. Compelling experimental evidence for such maps soon came from investigators that exposed the neocortex of dogs and monkeys, and directly stimulated the brain through small electrodes applied to the cortical surface. Remarkably, they found that small, brief currents often evoked movements of some part of the body, especially when the electrodes were placed in the frontal lobe of the brain. While movements could be evoked from many locations in the brain, it soon became obvious that movements could be evoked with the smallest currents in a strip of cortex in the back of the frontal lobe, and that the type of movement depended on the location of the electrode in this strip. In monkeys and in humans, movements of the foot, trunk, hand, and face could be evoked in sequence as the electrode was moved across the strip. Similar organizations were identified in the most posterior portion of frontal cortex in a range of mammalian species, and this cortex became known as primary motor cortex, or M1.

A second systematic representation of body movements was soon identified in cortex along the middle edge of the cerebral hemisphere just ahead of M1, first in human patients undergoing brain surgery and later in other mammals. This motor representation was termed the supplementary motor area, SMA, and it is also sometimes called the second motor area, M2. We now know that monkeys and other primates also have a number of additional motor representations.

The topographic organizations of motor maps were soon revealed in more detail when thin, penetrating microwires or microelectrodes were used instead of surface electrodes. The exposed tip of the microelectrodes could be placed in cortical layer 5, the layer projecting directly to motor neurons in the brain stem and spinal cord, and thus only a small number of the most relevant neurons could be activated. Because the corticospinal projections of the neurons in M1 on the right side of the brain predominantly cross in the lower brain stem to terminate on or near motor neurons projecting to muscles in the left side of the body, neurons in M1 mainly control contralateral body movements. The topographic maps in M1 and other motor areas are largely of contralateral body movements.

Generating small currents to stimulate neurons proved to be technically much easier than recording the small currents generated by neurons as they are activated by sensory stimuli or other neurons. Thus, topographic maps of sensory surfaces were demonstrated later than the first motor maps, initially in the 1930s when the oscilloscope for measuring small currents and good amplifiers came into general use. Clinton Woolsey was in the forefront of such recording, and he soon demonstrated maps of the skin, cochlea, and retina in the cortex of rabbits, cats, and monkeys. A strip of cortex just behind M1 was responsive to light touch and taps on the body surface, and as for M1, the sequence of representation across this strip of cortex was from foot, trunk, hand, and face. This first discovered somatosensory representation became known as S1, or primary somatosensory cortex. A second representation was soon discovered on the lateral margin of S1, and this representation became known as S2. The second representation is

activated by the face along its border with S1, while the foot and hand (forepaw) are more lateral. Presently, there is evidence that most mammals have two to three additional somatosensory representations, and monkeys and most likely humans have several more.

The same recording techniques allowed the discovery of topographic representations of the cochlea and retina. In initial studies, different parts of the cochlea were electrically stimulated while recording electrodes were variously placed in auditory cortex. Later brief tones of different frequencies were used selectively to activate receptors along the long, narrow, coiled row of receptors in the cochlea. Both methods revealed a primary auditory area, A1, where the cochlea is represented from base (low tones) to apex (high tones) in a sequential manner. Inputs from both ears activate auditory cortex, but the stronger input is from the contralateral cochlea. Soon, a second auditory area, A2, was proposed, but this second area, originally described in cats, was later found to include parts of other auditory areas. A redefined A2 was described with a crude representation of tones that parallels A1 in representation of tones. Possibly because of early confusion over the nature of A2, the term is not commonly applied to an auditory area except in cats. Gradually, more topographic maps of the cochlea have been described in cats and monkeys, and monkeys may have as many as 10 areas with at least a crude representation of tones.

The organizations of visual areas were first explored by positioning flashing lights in various parts of the visual field and later by presenting bars and spots of light on a screen in front of the eye. Most of visual cortex can be stimulated by either eye, because both eyes project to the lateral geniculate nucleus of the visual thalamus of each cerebral hemisphere. However, the inputs to each nucleus are only from the portions of retina that are devoted to the contralateral half of visual space, the contralateral half of the visual field. In the visual cortex of the right cerebral hemisphere, neurons are activated by stimuli in the left visual field via the nasal half, or more, of the retina of the left eye and the temporal half, or less, of the right eye. Recordings from visual cortex at the posterior end of the cerebral hemisphere revealed a systematic representation of the contralateral half of the visual field, that was termed primary visual cortex, V1.

In all mammals, V1 corresponds to the classically defined architectonic subdivision of cortex, striate cortex or area 17 of Brodmann. In V1 of cats and rabbits, stimuli along the vertical midline (the zero vertical meridian) of the visual field activate neurons along the lateral border; stimuli progressively further into the lower visual quadrant activate neurons located progressively further anterior, while upper quadrant stimuli activate more posterior neurons. Stimuli in peripheral temporal vision activate more medially located recording sites in V1. In monkeys, V1 is rotated so that the border representing the zero vertical meridian is mediolateral in orientation, and much of V1 is on medial and ventral surfaces of the posterior end of the cerebral hemisphere, as well as within a brain fissure of the midline surface, a fissure that is found in all primates. Soon after the discovery of V1, recordings in cortex lateral to V1 in cats and rabbits revealed a second representation of the visual field, V2. This representation occupied a narrow strip of cortex, sometimes identified as area 18. V2 parallels V1 in representations of lower and upper visual quadrants along a common representation of the zero vertical meridian, but the outer border of V2 corresponds to the zero horizontal meridian. Thus, V2 is a 'split' or second-order transformation of the visual field. More recently, a number of additional representations of the visual field have been discovered, especially in well-studied cats and monkeys.

2. *Brain Maps Today*

After many years of intense study, a number of conclusions about brain maps seem justified. First, brain maps are often associated with anatomically distinct subdivisions of the brain. Recently, a number of histochemical methods have been developed to help reveal these subdivisions. Furthermore, some of these procedures reveal internal patterns within some cortical areas and subcortical nuclei that precisely conform to the representational topography of these structures. Thus, some brain maps have visible morphological correlates of their physiological maps. Most notably, there are maps of skin receptors that have visible subdivisions for each digit, pads of the palm, and often separate parts of the body. The maps contain isomorphs of the receptor sheet.

Second, maps vary from fairly precisely reflecting the order of the receptor sheet or muscle arrangement, to only roughly doing so. Thus, maps range from being highly topographical to being only roughly topographic. In general, the more precise maps are found early in sensory processing hierarchies, and less precise maps occur later. Thus, the brain stem nuclei that directly receive peripheral nerve afferents have the most detailed maps, while subsequent relays of this information to higher brain stem and thalamic nuclei may degrade this order, with further changes occurring in primary sensory cortex and beyond. Most higher-order representations are only globally topographic.

Third, even the gross topography of brain maps may be arranged in various ways. While primary visual cortex topographically represents the contralateral half of the visual field, the superior colliculus of the midbrain represents both the contralateral half of the visual field and much of the ipsilateral half of the visual field, including all that is seen by the contralateral eye. Only primates appear to have a superior colliculus that represents only the contralateral half of the visual field. Another example is the split repre-

sentation of the visual hemifield along the zero horizontal meridian in V2. The reasons for the different types of topographic representations are not clear. However since there can be different types of representations of the same receptor surface in the same individual, the arrangement of the receptor sheet is not the sole factor in the formation of maps.

Fourth, topographic cortical maps are commonly and perhaps always modular in internal organization. Primary visual cortex of most primates segregates inputs related to the right or left eye with so-called ocular dominance columns or bands, separates neurons according to preference for stimulus orientation and direction of movement in so-called orientation columns, and isolates different classes of neurons within and without a dot-like honeycomb pattern of neuron groups that express high amounts of the oxidative enzyme, cytochrome oxidase. The second visual area, V2, of monkeys and other primates has three types of band-like modules that are arranged in repeating sets of three along the length of V2. Thus, V2 actually consists of three fragmented, interdigitated maps of the contralateral visual field. Locally, there are discontinuities and repetitions in the map, but globally a topographic pattern is maintained. Primary somatosensory cortex, area 3b, isolates small patches of cortex devoted to slowly adapting cutaneous afferents from patches activated by rapidly adapting afferents. Auditory maps are unusual in that the receptor array is a row rather than a sheet, and thus a representation of these receptors covers only one dimension of a two dimensional surface of a cortical area. Thus, one dimension is of tone frequencies and the other dimension consists of the same frequency contours. Nevertheless, bands of neurons with similar binaural response properties are segregated from bands of neurons with different binaural properties. Motor maps are also quite modular and fragmented, with variable adjacencies and arrangements of modules of neurons for given movements. Thus, each type of module may be adjacent to a number of different types of other modules, possibly allowing more types of interactions for cooperative movements.

Fifth, there are maps that do not reflect the order of the receptor sheets, but are orderly in some other way. As these maps appear to be derived or computed from topographic maps, they have been called computational maps. As an often given example, a map of auditory space for the systematic location of sounds in space exists in the midbrain of birds and probably other vertebrates. This map does not reflect any arrangement of auditory receptors, but it is constructed from information derived from the differences in how the same sound source in different locations stimulates the two ears. Most higher-order cortical maps appear to reflect both topographic and computational components.

Sixth, species of vertebrates and especially mammals vary in the number of brain maps that they have. Mammals are impressive in that many have greatly expanded sheets of neocortex, providing more space for cortical maps. Most mammals resemble the first mammals in having small brains with relatively little neocortex. These mammals only have a few maps in cortex, usually S1, S2, and two or three other somatosensory maps, V1, V2 and one or more other visual maps, A1 and perhaps a few other auditory maps, and possibly but not always M1 and M2. In contrast, monkeys have a lot of neocortex and they have over 30 visual representations, 12 or more auditory representations, 10 or more somatosensory representations, and six or more motor representations. Possibly humans, with vastly more neocortex, have even more cortical maps. More complex information processing seems to depend on having more maps.

3. *The Development of Maps*

Sensory inputs to brain stem nuclei form orderly arrangements during development, and these nuclei form orderly connections with other nuclei, which in turn project to cortical areas in an orderly fashion and so on. The rough order in at least the early stations of this sequential process seems to depend on intrinsic factors in the brain. More specifically, it has long been hypothesized that afferents are chemically labeled according to some gradient, and target neurons are also chemically labeled with a comparable gradient across the target structure. Thus, the neurons find chemical matches and a topographic map is created. However, chemical or molecular matching is not the only factor in the development of brain maps, since there is much evidence that the development of such maps can be altered by changes in the sensory environment that induce changes in neural activity patterns. The details of sensory maps appear to be fine tuned by an adjustment and sorting of local connections in largely adaptive ways in response to variations in patterns of sensory activation. The claim is that neurons that fire together wire together. Coactive neurons with overlapping connections maintain and strengthen their synapses on shared target neurons, while neurons that do not respond at the same time tend to weaken and lose synapses on their shared target neurons. Thus, neurons with uncorrelated activity patterns tend to segregate their terminations so as to activate separate groups of neurons in the next structure. This allows maps to adjust and compensate for losses or additions of inputs, and maps in a sequence to adjust to each other.

There are many types of evidence that maps adjust to sensory changes during development. Usually, this evidence comes from some sort of experiment where some sensory input is removed or altered. Normal inputs expand to activate neurons formerly devoted to the removed or weakened inputs. Other evidence comes from the variations observed in maps in nature.

Rats and mice have morphological maps of the whiskers of the face in S1. Each whisker activates neurons in a small oval of cortical tissue that resembles a barrel, and is commonly called a cortical barrel. Rats and mice usually have the same number of whiskers, and there is one barrel in S1 for each whisker. Likewise there is one barrel-like structure for each whisker for the termination of afferents from the face in the brain stem, and in the ventroposterior nucleus of the thalamus. Thus, maps at three levels of the somatosensory system precisely match the arrangement and number of whiskers on the side of the face. This match could be due to innate developmental mechanisms, such as the matching of connections between levels as a result of a chemical code, but this appears to be unlikely.

Mice have been found that differ in the number of whiskers by having one or two more or less than the normal number, and in these mice the maps at all three levels match exactly the increase or decrease in whiskers. Thus, somehow the receptors in the skin are informing the central maps about their organizational state. In a similar way, the star-nosed mole has 11 sensory rays or protrusions from each side of its nose, and processed sections of somatosensory cortex reveal 11 corresponding bands of tissue in S1, one for each ray. Eleven bands are also seen in S2, the ventroposterior nucleus, and the somatosensory brain stem. Moles with 10 or 12 rays have been found, and 10 or 12 bands are then seen in all four brain structures in these moles. This matching of maps from one level to the next and with the peripheral receptor sheet would be most easily accomplished by a system that uses natural activity patterns to fine-tune its maps.

4. *Why Have Topographic Maps?*

Much of the brain is devoted to topographic maps suggesting that they are a useful way of organizing brain tissue. One cannot argue that such maps are simply preserving the order of afferents from the periphery, since afferents become mixed and disorderly, but sort themselves out again as they terminate. Instead, topographic maps appear to be adaptive in that they provide a substrate for making the most common types of computations in the nervous system over short, local connections. Neurons in topographic representations are well arranged to make center-surround comparisons between stimuli anywhere on the receptive field sheet, and stimuli in the immediate surround. This type of comparison provides biologically useful information. Neurons rapidly determine if a stimulus at some location is brighter, greener, harder, louder, or moving differently than stimuli in the immediate surround. While it may be possible to make such computations in nontopographic structures and systems, neurons would need to be massively interconnected and over larger distances. This would add unreasonable bulk to the brain, and would be metabolically costly. In complex brains with large amounts of neocortex, it is probably more efficient to have multiple interconnected maps, rather than just making maps larger. Large maps are most suitable for extremely local comparisons of stimuli, while more global comparisons can be mediated over short connections in small maps. Thus, it seems to be more productive to subdivide tasks, and process information in parallel over sequences of interrelated small maps, and use long connections to coordinate the activities of maps within and across processing sequences. Maps vary in size in the same individual because large maps are better at fine-grain local comparisons while small maps are better at more global comparisons.

Torts, in Law

Tort law is a fascinating topic of research for legal sociology generally, when law is observed from the viewpoint of legal sociology, two aspects are involved. One is 'to make observations putting law within society': observing how law operates in fact, within society. Another is 'to make observations of society within law': observing how the imprint of society is found in the law. Both aspects develop a circular, reflexive relationship, whereby law incorporating society impacts on society, and society being affected by law affects law. By then observing a particular society's law from a distance, adopting a comparative

sociological viewprint, one law appreciate the distinctive features characterizing that society's law.

Reading with such awareness the sociological literature on both law, the literature can be understood either as dealing with processes for achieving desirable social consequences with tort law operating in society or as dealing with processes whereby various interests and conceptions within society are read into the law.

1. Functions of Tort Law

Generally, it is said tort law has three goals: compensating harm, preventing accidents, and achieving justice. Tort law adopts the structure of requiring a person to compensate for harm caused to another when the former has been negligent in some way, defined as a breach of a duty of care. This is expected to encourage people to avoid obligations to compensate others, making them more careful, thus reducing accidents. Further, under this structure compensating harm is seen of itself as a desirable objective to the benefit of the injured and imposing this obligation directly on negligent people, rather than on third parties for the state, accords with our feelings of justice.

However, these three functions cannot always be achieved purely by implementing tort law (Sugarman 1989). In fact, various mechanisms are interposed, resulting in the creation of complex systems.

1.1 Compensating Harm

First, concerning 'compensation of harm,' various schemes of the third party assumption of the duty to compensate the injured have been developed. The most familiar one is the liability insurance, which covers the risk of tortfeasors incurring huge debts to pay compensation. It is also beneficial for the injured to receive full compensation. So, quite often the state intervenes for the sake of the injured either to require the tortfeasors to carry liability insurance or to assume the duty to compensate the injured while levying some form of 'tax' on the potential tortfeasors. This scheme of compulsory liability insurance is seen in many countries, especially in the case of automobile accidents compensation. The state managed compensation, scheme is also used when it is judged too serious to leave the matter in the hands of private insurers, as in the case of accidents caused by nuclear power plants. The state takes such an initiative when it is both feasible (easy to calculate the loss and/or to identify and levy the tax on the potential tortfeasors), and politically wise to have such schemes (to show the concern over the plight of the victims, or to assuage the fear of the local residents surrounding the power plant).

The extent to which the state initiates this kind of compensation scheme is dependent upon the political culture of the respective countries, however. The most elaborate initiative along these lines is known as the New Zealand model in which compensation is paid out from the pool of dues collected mainly from the designated firms and drivers. The similar notion of paying out compensation with greater certainty and without costly legal battles is found in the United States as well. But the actual scheme is more fragmented, with legislative interventions mostly creating no-fault compensation for injuries from automobile accidents. In Japan, within the framework of general tort law, still in principle based on fault, compensation payments have been standardized and ever more detailed compensation structures have been elaborated. Especially in automobile accident compensation this system is so refined that adversarial confrontation is virtually eliminated from the majority of cases (Tanase 1990).

Policy intervention in law is, therefore, facilitated by the emergence of insurance. Spreading costs through insurance lessens the difficulties involved, and it becomes generally easier politically to adopt policies oriented towards compensating injured parties. This promotes reform of tort law involving more certain compensation of injured parties and higher duties of care approaching strict liability. Such reform also reflects a general normative consciousness that society should be made safer and less traumatic, just as we have used science to overcome nature and create more amenable environments. This consciousness, along with more mundane political considerations, leads to what have been termed 'liability explosions,' or what Friedman (1985) calls a vision of 'total justice.'

1.2 Struggles over the Meaning of Compensation

Nonetheless, even if a trend does develop towards greater protection of injured parties through compensation, such protection does not come about uniformly and without tensions. Changing the rules creates winners and losers, and political dissension inevitably arises regarding such changes. To counter 'liability explosions,' politics emerge regarding legislative initiatives, and at a more micro level tort law rules are reinterpreted through courts and litigations. Tort reforms specifically to cap compensation amounts and limit rights to bring suit, by legislation, have been an ongoing and vocal point of political debate in the United States. Such political dissension about access to the law is an important topic for sociolegal analysis. In particular, as the political attack on the expansion of tort liability often involves critiques of the 'litigious society' and 'society of lawyers' in the US, it leads to an examination of problems in legal order in a broader sense and of how people relate to law.

In this regard, commentators taking views of tort law reform as being played out on the people's fear of losing control to professionals, for instance, have gained much support. They argued that assertions like 'litigation explosions hurt the US economy,' or frightening reports of 'suits by children for malparenting,' used to criticize the legalization of society, are unfounded in reality and based on hidden political agendas such as curbing the exercise of rights by consumers and minorities vis-à-vis corporations have strong elements of a campaign (Galanter 1983). The reality, they claimed, is that litigation turned out not to have grown so explosively. In fact, compared to the large body of accidents, people mostly acquiesced without asserting legal rights, or if they tried to do so, they were hampered in their attempts.

However, it seems that the roots of the problem lie deeper than suggested by these arguments. The political campaign against tort litigation developed in an era in which the American economy was losing its international competitiveness. Understandably, in these circumstances, the culprit was sought in businesses and individuals engaging in unproductive litigation strategies, rather than seeking to expand the pie, for instance, through technological innovation. At the same time, in this self-criticism of a society relying on litigation there was a clear nostalgia for the vision of an American society which hitherto had not indulged in litigation. One can smile at such anachronistic attitudes, but the shift towards a society in which law formed a central element for social integration and a basic model for social relations, had proceeded in many stages even in the United States. It is understandable that Americans would have felt concern especially over one important period of rapid transition, the 20 years from the 1960s, when the numbers of lawyers tripled. Yet in due time, neighboring institutions were reshaped, and they learned to play the game under the new rules, finding themselves once again surrounded by now familiar environments.This is a reason why criticism of the legalization of society died out, especially as the American economy revived over the 1990s.

Underlying these concerns is an appreciation that society and law operate on different logics. As the roles of law expand and law penetrates society more deeply, tensions and frictions from the collision of these different logics mount, which are reflected in the reaction against law by citizens involved in social life. This is true especially in tort litigation, which derives from events involving traumatic incidents such as loss of life. Torn by anger and sadness, people try to find 'life-world' meaning in a search for justice, and the law played out fully by over-zealous lawyers is resented as neglecting this aspect and transforming grief into greed. Unlike parties to a contract who make explicit legal commitments beforehand, parties in tort actions forge legal remedies out of ordinary contacts. So tort litigation is put through more rigorous tests of community standards before being accepted by people. For example, in a traditional American community, while contract litigation is taken for granted because 'one should naturally return money borrowed,' tort litigation tends to involve the dubious morality of 'getting another to take responsibility, rather than admitting one's own' (Engel 1983). This consciousness may have dissolved now in the United States, as further time has elapsed since the study was conducted. But we should not forget that there are always communities, which resist the control of the law, or that there are everyday interactions in which individuals give their own meanings to accidents, disputes, and solutions, which are not exhausted by legal frameworks. This is particularly important in sociolegal analyses aimed at understanding how law works within society, drawing on areas of law such as tort litigation.

2. *Strains within Tort Law*

2.1 *Deterrence through Tort Litigation*

There are also major corrections to the central mechanism underlying the traditional tort function of 'deterring accidents,' namely that tort law obligations create an incentive for tortfeasors to avoid harm caused by negligent behavior. The most important reason is that deterrence through obligations to compensate is undermined by 'moral hazard' resulting from insurance. Returning to a world without insurance remains too risky for both tortfeasors and injured parties, however, and hence an unrealistic policy option. Thus, deterrence of accidents must be assigned to legal enforcement by criminal or administrative sanctions, rather than tort law.

Yet such enforcement by specialist institutions then involves the problem of tending to lack necessary incentives and information to enforce the law at optimal levels. A system of legal enforcement must incorporate action by those who have suffered the injury, after all, and it is this aspect that is most distinctive about the United States. Known as the 'private attorney general' model (Cappelletti 1978), rights are given to injured parties under specific legislation, and systems are developed to lessen the economic burden of bringing suit, such as class actions, triple damage awards, and award of legal fees to the prevailing party in suits against the government. The possibility of being awarded punitive damages also heightens the capacity of injured parties to bring suit and to penalize the tortfeasors' negligent acts harshly. Although there is criticism that this goes too far, and punitive damages have become the biggest issue in the tort law reform debate, Americans seem to believe in the wisdom of utilizing private pecuniary interests to

advance the public interest in achieving the rule of law.

With legal enforcement capacity heightened in these ways, mass litigation is now frequently brought. In litigation involving drugs, asbestos, and recently tobacco, large companies have been forced into the corner through the pressure of massive compensation obligations, after political action proved ineffective. Particularly in regard to compensation for injuries resulting from smoking, an interesting tension emerges vis-à-vis American consciousness of liberty and dislike of paternalism (Kagan and Vogel 1993). When plaintiffs who had continued smoking claimed damages against tobacco companies, they met resistance from many citizens who asked 'didn't you continue smoking of your own free will?' This not only creates more difficulty in winning against tobacco companies (Rabin 1992) but also strains smokers in assuming 'victim' status. For to call oneself a victim, one must assert either that one is seduced to smoke by tobacco companies' advertisements or that one is too weak to stop smoking once hooked by nicotine. In either case, a smoker-plaintiff presents oneself as a weak person, someone who cannot 'smoke by choice' despite being given the 'freedom to smoke.' In fact, this kind of twist is not peculiar to tobacco litigation. Indeed, it is widely seen in other claim-making situations, wherein one assumes a victim status, whereby one is susceptible of being victimized (Bumiller 1988).

At the same time, however, in the case of tobacco, citizens' anger was directed towards tobacco companies as the greater evil especially when the companies were found to have lied before the public. This sentiment reflected upon jury trials. In one judgment finding tobacco companies liable, the foreman was quoted of saying 'companies must not lie about their products, this is our message.' Especially in these days of 'jury activism,' tort litigation functions to send messages from citizens to firms.

2.2 Morality in Tort Law

Finally, regarding the function of 'achieving justice,' while justice defined as 'just deserts' by classical tort law is not losing its importance, it is no longer enough to appreciate the contours of justice in contemporary tort law. This is connected, first, to the fact that many of the accidents which become the subject of tort law nowadays either arise repeatedly and extensively (like automobile accidents), or relate to more sporadic accidents which nonetheless can have large effects on society (such as product liability cases). In dealing with such cases, it is possible, and necessary in view of its extent, to calculate cumulative damages, and to weigh them against the costs necessary for their prevention. In fact, this risk management is carried out by companies as well as by the government.

In this 'collective justice' approach—'collective' in the sense of taking accidents as an aggregate, and 'justice' in the sense of achieving the maximum safety given a set amount of available resources—to give priority to the standpoint of efficiency in deciding on whom to impose what obligations may sometimes come into conflict with the moral meaning attributed to accidents premised on traditional notions of 'individual justice.' The moral dubiousness of tort litigation in general in the eyes of the self-reliant traditional villagers, or in particular of smokers claiming victim status, is evidence of this.

Furthermore, related to such totalizing tendencies, there is a problem associated with the fact that tortfeasors come to lose a sense of pain in relation to making compensation, as liability insurance, both private and publicly managed, becomes pervasive. Particularly in automobile accident cases, insurance companies take over settlement negotiations in place of the insured, and the matter is resolved without the tortfeasor ever having to face the pain caused by his or her acts to the injured party. This may offend the sense of justice held by at least some people. Gilligan (1982) points out the existence of 'a different voice,' the morality of 'care and responsibility,' the core sensibility is to empathize with the pain of the other caused by his or her act and think through the way to minimize it. To the extent that this moral reasoning is foreclosed from the workings of tort law, the latter is judged to be morally deficient.

In fact, leaving matters to the insurance company in this way still arouses strong condemnation from injured parties in Japan. A tortfeasor is expected to visit the hospital or to join the funeral, enduring the baleful gaze of the injured party and his or her family, as a proper attitude of 'human sincerity.' It would be enough to pay compensation in the form of damages arising from a breach of one's legal obligations, but there is an important truth hidden in this seemingly irrational ceremonial apology on top of the legal duty. That is, the law defining the dispute and resolving it represents only one part of the whole dispute. For an injured party affected by an accident, someone able to empathize with his or her hurt is a necessary part of recovery so aside from monetary compensation, the matter must be viewed 'pre-legally' as involving relations between vulnerable human beings.

This much may be obvious. In the United States, too, this role for apology is presently being revisited. But in the legal world, to make an apology is not easy. For it is deemed admitting responsibility and conceding defeat from the outset. Although some states in the US have passed laws legally not to use an apology as evidence, the 'attribution of responsibility' gave, rejecting one's own responsibility and pushing responsibility onto others, is played out. In these adversarial circumstances, apology itself easily comes to be seen as a mere gesture (Taft 2000). More generally, the sense of liberty abhorring constraints

other than those expressly assumed, or mandated by law, is at the core of the law. So 'moral reductionism,' divorcing issues from nonlegal duties, and forcing them into the framework of legal duties, easily prevails.

The future is opaque. The trend towards 'legalization'—increasing resort to law—is generally proceeding irreversibly, and these 'pre-legal' negotiation processes are gradually being abbreviated. But the counter-ideal emanating from the direct experience of the ways people interact within community may put the validity of law in question. This 'law skepticism' comes to surface most acutely in the case of tort law as it directly touches the daily lives of the common people, and hence is affected by commonsense interpretations of justice. In this sense, 'communitarian justice' should inform the law along with the other two notions of justice.

Torture and its Consequences, Psychology of

1. Introduction

Torture remains a widespread problem despite numerous international conventions prohibiting its practice. There are no reliable estimates of the prevalence of torture in the world. The only data available are those published by human rights organizations such as Amnesty International (AI). The 1998 Report of AI listed over 150 countries known for some form of human rights violation in the previous year (Amnesty International 1998). According to an analysis (Başoğlu 1993) of the 1992 AI report, systematic torture was reported in 93 of the 204 countries in 1991. Although reports of torture were more common from countries affected by political unrest, the problem was not confined to these regions. Systematic torture and/or ill-treatment in police custody or prisons were also reported in 25 percent of the Western European and North American countries. Thus, although torture is more widespread in certain parts of the world, no society or ideological system enjoys complete freedom from gross human rights violations.

Little is known about the prevalence of torture among various at-risk populations. About 5–35 percent of the world's 14 million refugee population (0.7–4.9 million refugees) are estimated to have had at least one experience of torture (Baker 1992). These figures do not reflect the current extent of the problem after the recent developments in Eastern Europe, former Yugoslavia, Middle East, and other parts of the world torn by political turmoil, nationalistic movements, and regional wars.

In this article, the evidence on the long-term mental health effects of torture will be reviewed. Torture is a sociopolitical phenomenon with wide-ranging physical, psychological, social, economic, and political consequences. Our knowledge on these issues is limited owing to the scarcity of systematic research. This review will focus on the psychological effects of torture as relatively more work has been done in this area. Detailed information on the physical effects of torture can be found elsewhere (Skylv 1992). The reader is also referred two books (Başoğlu 1992, Jaranson and Popkin 1998) for more detailed information on other aspects of the problem.

The difficulties in defining torture have been widely recognized. Scientific study of this problem requires a clear definition. The definition adopted for the present review is the one that has been provided by the 1986 United Nations Declaration of Human Rights: 'any act by which severe pain or suffering, whether physical or mental, is intentionally inflicted on a person for such purposes as obtaining from him or a third person information or a confession, punishing him for an act he or a third person has committed or is suspected of

having committed, or intimidating or coercing him or a third person, or for any reason based on discrimination of any kind, when such pain of suffering is inflicted by or at the instigation of or with the consent or acquiescence of a public official or other person acting in an official capacity.'

2. *Psychological Effects of Torture*

Most studies of torture survivors have methodological limitations that preclude definitive conclusions on the psychological effects of torture. These include insufficient description of the interview procedures, assessment instruments, diagnostic criteria, and medical diagnoses. Few studies have examined the relationship between the symptoms and the diagnosis of post-traumatic stress disorder (PTSD) (see *Post-traumatic Stress Disorder*). Most studies used an uncontrolled design and thus did not control for other nontorture, potentially traumatic life events. Furthermore, most of these studies have been carried out on refugees so the additional effects of refugee trauma are not controlled for. In recent years, however, controlled studies have been carried out, attempting to overcome some of the methodological problems of the earlier studies. The evidence will be reviewed in two sections, uncontrolled and controlled studies, with greater emphasis on the latter.

2.1 *Uncontrolled Studies*

In a review of eight studies by Goldfeld et al. (1988), the most common problems in torture survivors were anxiety, depression, irritability/aggressiveness, emotional lability, social withdrawal, disorientation, memory and concentration impairment, impaired reading ability, lack of energy, insomnia, nightmares, and sexual dysfunction. Another review of the literature (Somnier et al. 1992) involving 46 studies, reported similar findings. Although cerebral atrophy, abnormal sleep patterns, somatization, and traumatic brain injury have also been reported (reviewed in Başoğlu 1997), the evidence on these findings is not conclusive.

Some of the evidence comes from studies of former prisoners-of-war (POWs) and concentration-camp survivors. In a review of the literature, Miller (1992) concluded that former POWs continue to have anxiety, depression, and PTSD 40 years postcaptivity and torture during captivity is related to more severe psychological problems in the long term. (Solkoff 1992), in his review of the literature on concentration-camp survivors, pointed to various methodological problems which characterize the research from which the 'survivors' syndrome' evolved. The author concluded that the effects of Holocaust-related trauma on survivors and the second generation have not been adequately investigated.

2.2 *Controlled Studies*

A Danish study (Hougen et al. 1988) compared 14 tortured refugees with 14 nontortured controls. The torture survivors had more psychological symptoms than did the controls. The sample size, however, was too small and matching of controls was not adequate. The measurement of symptoms was not sufficiently detailed. Another controlled study (Petersen and Jacobsen 1985) of Spanish torture survivors found that tortured individuals, relative to controls, had more symptoms of depression, anxiety, emotional lability, sleep disturbance, nightmares, and memory and concentration difficulties. However, the measures were not sufficiently detailed and standardized instruments based on established diagnostic criteria were not used. In addition, the sample size ($n = 10$) was too small for statistical analysis.

A more recent study in Turkey (Başoğlu et al. 1994a) used standardized assessment instruments in comparing 55 tortured political activists with 55 nontortured political activists and 55 nontortured, nonactivist controls, matched for age, sex, marital and socio-cultural status. The torture survivors had significantly more lifetime and current PTSD than did the controls (33 percent vs. 11 percent and 18 percent vs. 4 percent, respectively). Secondary impact of captivity/torture on family, family history of psychiatric illness, and post-torture psychosocial stressors related to long-term psychological status (Başoğlu et al. 1994b). Both torture and subsequent psychosocial stressors contributed to traumatic stress symptoms (Başoğlu and Paker 1995). In an attempt to explain the relatively low prevalence of PTSD in this sample, the investigators pointed to the possible protective role of a strong belief system, commitment to a cause, prior knowledge and expectations of torture, and prior immunization to traumatic stress (Başoğlu et al. 1994b). The majority of the survivors were highly committed political activists with prior expectations of and psychological preparedness for torture. They also had a negative appraisal of the state and had not maintained beliefs concerning a 'benevolent state' before the trauma, another factor that may have protected them against the traumatic effects of torture (Başoğlu et al. 1996).

The study by Başoğlu et al. (1994a), while pointing to the possible protective role of 'psychological preparedness for trauma,' could not test this hypothesis because most study participants were highly committed political activists. A further study (Başoğlu et al. 1997) was carried out to compare 34 less psychologically prepared, nonactivist torture survivors with the previous sample of 55 tortured political activists. Compared with the political activists, the nonactivists were relatively less severely tortured but had significantly more PTSD (58 percent vs. 18

percent) and major depression (24 percent vs. 4 percent). These findings supported the role of prior immunization in reducing the effects of traumatic stress, and of unpredictability and uncontrollability of stressors in exacerbating the effect of torture.

Another study (Maercker and Schutzwohl 1997), which investigated the long-term effects of political imprisonment in the former German Democratic Republic, compared 146 former political prisoners with 75 controls matched for age and sex. In comparison with controls, the former political prisoners had significantly higher rates of lifetime (59.6 percent) and current PTSD (30.1 percent), claustrophobia, social phobia, substance abuse, and higher scores on measures of anxiety, depression, general psychopathology, and dissociative symptoms.

A controlled study by Shrestha et al. (1998) involved 526 Bhutanese refugee survivors of torture in Nepal matched with 526 nontortured refugees on age and sex. The study group was selected randomly from the Bhutanese refugee community in the United Nations refugee camps in eastern Nepal. Compared with the control group, the torture survivors had more PTSD symptoms, higher anxiety and depression scores, and more musculoskeletal and respiratory system complaints. The authors concluded that torture may increase the risk of mental health problems among refugees and that PTSD symptoms appear to be part of a universal reaction to torture.

A further study (Mollica et al. 1998) in the USA involved 62 Vietnamese ex-political detainees and 22 controls. Compared with the controls, the ex-political detainees showed significantly higher scores on depression and PTSD symptoms but the prevalence rates of PTSD (77.3 percent vs. 88.2 percent, respectively) and major depression (36.4 percent vs. 56.9 percent, respectively) across the two groups did not reach statistical significance. Severity of torture was the most significant predictor of depression and PTSD symptoms, particularly of arousal symptoms among the latter. The authors suggested that a small sample size may have accounted for the lack of statistically significant differences in the prevalence of psychiatric diagnoses.

A controlled study (Holtz 1998) in India involved 35 tortured refugee Tibetan nuns and lay students and 35 nontortured controls matched for sex, age, lay status, and years in exile. Relative to the controls, the torture survivors had significantly higher scores on measures of anxiety but the two groups did not differ on ratings of depression. Lack of prior knowledge of and psychological preparedness for torture was a significant predictor of post-torture anxiety symptoms. Other predictors included male sex, longer duration of torture, exposure to solitary confinement, feelings of hopelessness in prison, and recent arrival in India. The author suggested that the survivors' Tibetan Buddhist training as nuns may have contributed to their resilience against the traumatic impact of torture.

In conclusion, there is clear evidence that in some individuals torture has psychological effects independently of other associated stressors such as harassment and persecution by the authorities, unlawful detentions, unfair trials, imprisonment, exposure to mass violence and life-threatening situations, threats of death to self and family, having to go into hiding, loss of employment or educational opportunities, bereavement, uprooting, and refugee status. The distinction between the effects of torture *per se* and those of other associated stressors is important for medical and legal reasons.

3. *Implications of Current Knowledge for Survivor Care Policies*

The research evidence reviewed so far may have important implications for legal and public health policies concerning torture survivors. Immigration, asylum, and refugee care policies need to take into account the fact that a significant proportion of asylum seekers and refugees may have a history of torture and be at risk of disabling psychological problems. Due attention to mental health issues may be as important as providing legal, social, and economic aid for refugees. Research findings (Başoğlu and Paker 1995) suggest that social support may not be sufficient for recovery unless it is complemented with effective psychological treatment. Greater funding needs to be allocated for mental health care services for tortured refugees and mental health professionals need to play a more central role in policy making in refugee care.

Given the prevalence of torture in the world and the mental health hazards posed by its chronic and disabling psychological consequences, there is an urgent need for psychological treatments with demonstrated efficacy. Survivor care policies need to place greater emphasis on developing effective treatments through systematic research and on training of mental health workers in treatment techniques.

Finally, there has been relatively little scientific interest in the study of torture and the treatment of its consequences, despite the serious mental health hazards posed by the problem. Much of the available resources for survivor care is often used for social, legal, and economic aid and for various rehabilitation programs, the efficacy of which has not yet been demonstrated. In policy making, research is either given low priority or sometimes even dismissed as unethical. Scientific research with due regard for ethical issues is possible and essential for effective survivor care. Study of torture survivors also has important implications for human rights, theory, assessment, classification, treatment of traumatic stress responses, and legal issues concerning torture survivors.

4. Directions for Future Research

Future research needs to focus on three main issues: psychobiological mechanisms of traumatization, factors related to long-term psychological functioning, and effective treatments for survivors of torture. Given the evidence on the role of psychological preparedness for trauma as a protective factor, further studies are needed to elucidate the behavioral and cognitive components of this construct. A better understanding of resilience factors is needed to develop more effective treatment programs.

More research is needed to clarify cognitive responses to torture and their bearing on long-term outcome. Among these cognitive responses, sense of injustice arising from impunity for perpetrators is of particular importance. Little is known how various forms of compensation and redress relate to survivors' psychological functioning. Studies of this issue would also be useful in clarifying the psychological effects of 'truth and reconciliation' processes, such as in South Africa, both on survivors and on the community. It could also provide insights into how such processes should be conducted to avoid further traumatization and maximize the psychological well-being of survivors and their community.

Further work is needed to examine how various stressors such as torture, uprooting, refugee trauma, and loss of social support relate to psychological problems in survivors of torture. International collaborative studies are needed to develop standardized and validated assessment instruments for refugee and nonrefugee torture survivors.

There is need for greater emphasis on research in developing effective treatments for torture survivors. Controlled treatment trials are needed to identify the most effective treatments and their mechanisms of action. Given the scarce resources available for the care of torture survivors, the efficacy of current rehabilitation models needs to be evaluated and their therapeutic ingredients clarified. For Western countries facing a serious refugee problem, epidemiological studies are needed to investigate the prevalence of past torture and associated psychosocial problems among refugee populations.

Torture: Legal Perspectives

Torture is regarded as an aggravated kind of criminal violence, mainly carried out by state agents, but occasionally by non-state actors or with the toleration of governments. It can be perceived as the strongest form of inhuman or degrading treatment in civil society. It has often been used as a tool in criminal proceedings to force confessions from a suspect. Since the time of the Enlightenment in eighteenth-century Europe, nations increasingly have disapproved of torture and, at least since World War II, have considered torture a serious violation of fundamental human rights. The Law of Nations has universally prohibited torture: In the Universal Declaration of Human Rights of 1948, Art. 5 states 'no one shall be subjected to torture or to cruel, inhuman or degrading treatment or punishment.' Nevertheless, some detainees and prisoners still suffer. Therefore, an urgent need exists for more effective prevention as well as for support and treatment of victim survivors.

1. *Defining Torture*

According to the United Nations Convention against Torture (UNCAT 1984, Art. 1 sect. 1), torture is defined as 'any act by which severe pain or suffering, whether physical or mental, is intentionally inflicted on a person for such purposes as obtaining from him or a third person information for a confession, punishing him for an act he or a third person has committed or is suspected of having committed, or intimidating or coercing him or a third person or for any reason based on discrimination of any kind, when such pain or suffering is inflicted by or at the instigation of or with consent or acquiescence of a public official or other person acting in an official capacity. It does not include pain or suffering arising only from, inherent in, or incidental or (*sic*) lawful sanctions.'

Although this notion is widely accepted, it is still a matter of controversy whether the concept of torture should be enlarged to incorporate similar patterns carried out by non-state actors or organizations, such as armed opposition groups. These groups have used torture as a weapon of war, to terrorize and thereby to control segments of the population. For example, mass rape of women as a tactic of 'ethnic cleansing' in the wars in the former Yugoslavia, combined with a feminist reconceptualization of human rights, made it impossible for the world community to continue to keep gender-based violence outside the circle of urgent anti-torture strategies (cf. Copelon 1993/4, pp. 293 and 367). Because the growing public sentiment could no longer be ignored, rape and sexual abuse of both females and males can now be considered a form of torture.

2. *Historical Development*

There is a long tradition of torture in various countries, although its objectives differ widely. It has accompanied mankind since approximately the beginning of the hierarchical organization of society. In the ancient city of Athens, torture was used to extort confessions from slaves. In the Roman Empire, free men as well as slaves were tortured for the purpose of obtaining or confirming evidence. Torture was also employed by government authorities against detained persons. In Europe, the use of torture as a means of directly extorting evidence dates back to at least the fourteenth century. Although early legal records demonstrate awareness of the dangers inherent in torture, its application was intensified in the so-called trials by inquisition. The developmental significance of these trials hence ought not to obscure the fact that the torture system authorized the commission of crimes far more serious than those for which the torture was imposed. Only sporadic attempts were made to stem these excesses.

The Age of Enlightenment initiated the modification and, sometimes, the abolition of torture and inhumane treatment by the state. This was no doubt due not only to the realization that such a line of action is inhumane, but also to the fact that trials by inquisition (prevailing at that time) were increasingly subject to criticism. As a consequence, the main goal of torture (to extort a confession at any price) lost importance.

Despite these advances, various codes of criminal procedure in the nineteenth century still stipulated that an accused who refused to disclose information or who denied facts was to be either caned or imprisoned in chains. Indeed, some of these codes or their relevant provisions remained in effect until almost the mid-twentieth century. The renaissance of torture and inhumane treatment of criminals under the auspices of authoritarian or totalitarian state systems, particularly under the national socialist regime during World War

II, shocked the entire international community and intensified efforts towards recognition of antitorture standards, protection of vulnerable people and rehabilitation of victim survivors.

3. International Conventions and Control Mechanisms

Although the prohibition of torture has been effective as imperative international customary law since about the end of World War II, and despite the fact that Art. 5 of the Declaration of Human Rights of December 10, 1948 explicitly includes this prohibition, torture and other kinds of serious ill-treatment of detainees are still rather common and, in some parts of the world, an everyday occurrence. Many victims are tortured with modern technology ('high-tech torture'), at times even under medical supervision, while some are subjected to 'isolation torture.' These modern methods of torture are unique because they do not leave visible marks. Torture has taken on a more psychological character, causing permanent mental disorder in the victim. Ill-treatment has therefore become rather difficult to ascertain and to verify. Thus, the need to advocate the prevention of torture and the protection of human rights remains acute.

The international community is developing control mechanisms and counter-measures against torture. The United Nations and the Council of Europe have increased their efforts to combat torture and other forms of ill-treatment by the introduction of special control mechanisms (cf. Bank 1996, pp. 9 et seq., 19 et seq., 381 et seq.). Art. 7 of the International Covenant on Civil and Political Rights of December 19, 1966 and Art. 3 of the European Convention for the Protection of Human Rights and Fundamental Freedoms of November 4, 1950 (European Human Rights Convention, EHRC), which have legal force at least in all European states. Both explicitly guarantee the protection of detainees from torture and from inhuman or degrading treatment or punishment. In order to assure the fundamental freedoms under the conditions of deprivation of liberty, the adoption of a supplementary protocol to the EHRC is currently being discussed. If adopted, this provision is intended to strengthen the legal position of detained persons.

In 1985, the UN Commission of Human Rights appointed a special rapporteur to prepare and submit an investigative report of torture (cf. e.g., Rodley 1994). In 1987, the Convention against Torture and other Cruel, Inhuman, or Degrading Treatment or Punishment (UNCAT) became effective, and was simultaneously backed up by the establishment of the Committee against Torture (CAT), a taskforce set up to oversee implementation of the Convention. The European Convention for the Prevention of Torture and Inhuman or Degrading Treatment or Punishment, and the European Committee for the Prevention of Torture (ECPT) came into being in 1989 (cf. Council of Europe 1989, pp. 2 et seq., Evans and Morgan 1998, p. 1 et seq.). Moreover, in 1987, the organization of American States enacted the Inter-American Convention to Prevent and Punish Torture, with the aim of imposing substantive obligations on member states very similar to those enshrined in the UNCAT. But as the American Convention neither provides for a specialized body to pursue implementation nor introduces any novel procedures, it has had only a small impact. Nevertheless, the Inter-American Court on Human Rights on December 2, 1999 condemned the State of Guatemala for the torture of five street youths in violation of the Inter-American Convention for the Prevention and Punishment of Torture.

To date, the most reliable information on torture, inhuman and degrading treatment is based on the reports of the coalition of International Nongovernmental Organizations (NGOs) against torture (CINUT) and the so-called fact-finding missions of the European Anti-Torture Committee (ECPT). The ECPT carried out more than 90 visits to nearly 40 European countries during the 1990s (cf. Council of Europe 1999, pp. 2 et seq., Kaiser 1995, pp. 2 et seq.), starting in Ireland and ending in Siberia at the Japanese Sea. On this solid basis, enriched by the worldwide reports of NGOs (e.g., Amnesty International 1997, pp. 3 et seq.), one can generalize the findings of present-day torture and ill-treatment practices.

4. Pressing Problems and 'Sensitive' Domains

In the 1990s, much of the 'torture' literature has focused on abuses by police officers and, through solitary confinement and overcrowding of prisons in general, on the totality of inhumane custodial conditions. Complaints of prisoners that came to ECPT's attention ranged from serious bodily torture (hanging up by the arms, electric shocks, contusion of testicles, caning of soles of the feet [*fallaka*], violent penetration of body orifices with truncheons) to considerable mental injuries resulting from solitary confinement in extremely small, unlit and unventilated cells. Many of the complaints were confirmed by further evidence; frequently the alleged acts of ill-treatment were verified medically. However, none of these acts was shown to be systematic. It is hence to be assumed that amendments to laws or even to constitutions are not alone sufficient to prevent the ill-treatment of prisoners. Rather, what is needed is a fundamental change of attitude throughout the entire system of criminal justice: we must refuse to accept that torturers are simply 'ordinary people' whose willingness to carry out acts of torture can be attributed to the brutal socialization techniques of totalitarian regimes.

Observations indicate that the risk of ill-treatment by prison personnel is considerably lower than the risk

posed by local police. At present, however, it seems that inhuman living conditions and a pattern of torturous behavior by the prison staff are not unheard of in some institutions in which prisoners are held prior to trial.

5. *People Particularly Vulnerable to Torture*

Certain categories of people are particularly vulnerable to torture: aliens, minorities, and apprehended persons from the moment of arrest throughout their imprisonment. Detention of asylum seekers and refugees, especially those likely to be expelled, presents considerable difficulties with respect to equal treatment and the prohibition of discrimination. Penitentiaries in European capitals or in large cities with an international airport frequently harbor detainees from more than 30 countries. All in all, native and foreign prisoners speak various languages, engage in a variety of eating habits and religious practices, and have diverging recreational needs. These circumstances render difficult communication, treatment, and assurance of basic rights such as visits, exchange of letters, and telephone contact. Restricted communication with the outside world, denial of education, and denial of privileges are often imposed by the prison administration for security reasons upon the foreign detainee. The dangers of tension in the institution, of interpersonal violence between detainees, and of ethnic conflicts between different groups of foreign inmates are additional aggravating circumstances. In this respect, the prison management must counteract possible conflicts by distributing the prison population sensitively and responsibly.

6. *Overcoming the Restricted Impact of Control Mechanisms*

All international organs and agencies acknowledge the limited impact of their activities. Because fewer than 120 state parties have ratified the UNCAT, it remains one of the least ratified human rights treaties at the level of UN. Additionally, the international organizations are sometimes confronted by obstructive government reactions; their recommendations for structural changes are not always met with positive responses. Of course, the most effective results could be produced with the help of an international control network representing the international bodies themselves. In particular, follow-up visits would constitute an effective monitoring tool. Nevertheless, none of the agencies—including the ECPT—are in a position to provide close and continuous monitoring of new developments. Careful observations by the NGOs might contribute and fill the gaps.

The future of torture control ought not to be confined to Europe. The establishment of a universal visitation system, based on the model of the European Convention, is as necessary as ever. Therefore, the prospects for effective protection against torture throughout the world will depend on the introduction of a global system of visits. Lasting control of torture and effective improvements in the conditions of detention presuppose international recognition of the preventive visitation system. The existence of international conventions and the criminalization of acts of torture do not always succeed in preventing ill-treatment and abuse. Thus, we must attach increasing importance to the training of police and prison officials in accordance with the relevant recommendations of the United Nations.

In addition to strong efforts to repress and prevent torture, the need to provide for the care and rehabilitation of torture survivors is urgent. This is regarded as a new field and is supported by the International Rehabilitation Council for Torture Victims.

Tory

The term Tory is colloquially used as a synonym for a British Conservative. However, it is best defined as a particular tendency within conservative thought that stresses order over liberty. Conservatism is marked by a tension between two of its fundamental principles, the necessity of order and the desirability of liberty (see *Conservatism: Historical Aspects*). The former is concerned with how government is conducted; the latter with the role and limits of government. For example, conservative communists can exist in Russia in the first sense, but not in the second. Often, perhaps usually, these two elements of conservatism are mutually reinforcing, but not always. In this tension, Tories emphasize order. This article will examine six issues: origins; principles; history; contemporary forms; relevance outside the United Kingdom; and future.

1. *Origins*

The origin of the word 'Tory' comes from the Irish *toraighe*, an Irish thief dispossessed of his lands and existing on raids on English settlers. It was used in British politics as a term of abuse during the debate on the succession to Charles II in 1679. His natural heir and brother, James, Duke of York, was a devout follower of the Catholic church, which made him unacceptable to a largely Protestant people. Those who insisted that he should become King, despite his religious views, were called by their opponents 'Tories.' In return they accused their opponents of being 'Whigs,' or Scottish bandits (see *Whig*).

For the seventeenth and eighteenth centuries 'party' is too formal to describe the loosely allied groups and factions based around particular individuals. The Tories were those who favored the Crown, the Church of England ('the Tory party at prayer'), and rural or 'Country' interests, and largely drawn from the local squirearchy of small landowners, in opposition to the aristocratic Whigs. The first identifiably Tory thinker was Henry Bolingbroke. In *The Idea of a Patriot King* (1738), he articulated several recurring Tory themes: a reliance on experience against abstract theory; the significance of social groups such as the family; a constitution based on historical liberties; a suspicion of power; and the need to abandon unsustainable positions that undermine stability, in this case sympathy for the Jacobite cause.

2. *Tory Principles Within Conservatism*

W. H. Greenleaf (1983), in his magisterial study of the British ideological tradition, identified a tension between libertarian and collectivist thinking within all parties. The collectivist element within conservatism is described as Tory paternalism, sympathetic to state intervention in the economy and the welfare state, and associated with humanitarianism, duty, piecemeal concessions, and social and economic reforms. His terminology of dualism exaggerates these differences into deep and irreconcilable divisions.

The most extensive attempt to distinguish between Tory and Whig within conservatism is to be found in Norton and Aughey (1981). They contrast Tory themes of traditionalism, original sin, order, and authority, with Whig themes of capitalism, rationalism, faith in human progress, and the creation of wealth. Toryism is associated with security and stability, concern for the moral and economic well-being of the people, trust, instinct, honor, loyalty, authority, discipline, prejudices, traditions, customs, and obligations. 'Toryism is sceptical, with a touch of fatalism' (Norton and Aughey 1981, pp. 64–5). The problem with this distinction is that Whiggery is given a solely economic orientation, which ignores its perspectives on other issues, while Toryism is left bereft of an economic position.

Norton and Aughey identify four subdivisions within Toryism. Pessimistic or fatalistic Tories accept change as inevitable though undesirable. Paternalists are motivated by a strong sense of *noblesse oblige*, of responsibilities and duties toward others. Progressives seek to update paternalism and demonstrate its contemporary relevance. Combative or reactionary Toryism is opposed to any attempt to undermine the values of society. These categories are primarily ones of style rather than substance.

3. *Toryism in the History of the Conservative Party*

When did the Tory party become Conservative? How has the Tory tendency expressed itself within Con-

servative party politics? The emergence of British parties is usually associated with the divisive reaction to the French Revolution, between those who feared and decried it around William Pitt the Younger, and those who hailed it around Charles Fox. The former were known as Tories, although Pitt always described himself as a Whig.

The founder of modern conservatism, Edmund Burke, was also a Whig, of the Rockingham persuasion. He was the chief critic of the French Revolution, and provided intellectual sustenance to the Pittites. Burke combined Tory and Whig elements into conservative philosophy, the scepticism of the Tory David Hume and the economic liberalism of the Whig Adam Smith. The chief Tory features of his thought were: the limits of reason, the inherent weakness of human nature, the wisdom of institutions, the defence of private property, the necessity of reform for stability, and the protection of the social order. The term Conservative was first used to describe the party in January 1830 by the *Quarterly Review*. The modern Conservative party is usually dated from the 1832 election and the Tamworth Manifesto written by Robert Peel.

Peel came under increasing criticism from a group within his party over his support for religious toleration for Catholics and free trade. While predominantly based on the landed aristocracy, its spokesman was Benjamin Disraeli, probably the first writer to identify distinctively Tory thinking within conservatism. In *Sybil* (1845), he declared 'Toryism will yet rise from the tomb … to bring back strength to the Crown, liberty to the subject, and to announce that power has only one duty—to secure the social welfare of the people' (Blake 1985, p.5). The Conservative party broke over free trade and the repeal of the Corn Laws in 1846, which Peel felt was essential to address the famine in Ireland. In conservative historiography, Peel is the epitome of the Whig tendency of economic rationality and Disraeli of romantic Toryism.

Disraeli proclaimed the principles of the Conservative party as the upholding of established institutions, the maintenance of the empire, and the elevation of the condition of the people. The emphasis on the latter, through social legislation aimed at benefiting the working class, absorbed the Tory Radicals, such as Robert Southey and the poet Samuel Coleridge, who favored an alliance of the aristocracy and the working class against the commercial middle class. This strand of social reform can be traced through Tory Democracy, led by Lord Randolph Churchill, to Prime Minister Stanley Baldwin, and to the contemporary One Nation Tories. In the 1940s, R. A. Butler and the One Nation Group articulated a progressive Toryism, accepting an extensive role for the state. This found expression during the premiership in the 1950s of Harold Macmillan, who earlier had advocated a Middle Way between capitalism and communism. Edward Heath belonged to this tradition of progressive Toryism. The reaction to it led to Margaret Thatcher, who combined Whig and High Tory elements together in the New Right, despite the tensions between them. Two groups of Tory critics, High and One Nation, emerged against the Whig dominance within the New Right, who represent the current state of Toryism.

4. *Contemporary Toryism*

The leading intellectual exponent of High Toryism is Roger Scruton, editor of the *Salisbury Review*. He identifies the features of High Toryism as: legitimacy based on custom, history, popular morality, religion, and patriotism; the value of a ruling class; the validity of private property; suspicion of unbridled capitalism; and a belief in one nation of different classes held together by mutual obligations. He protests that Toryism has been undermined by commitments to democracy, liberalism, and the market economy. He uses the unusual term 'low Toryism' of business and free enterprise, and deplores its influence over the Conservative party (*A Dictionary of Political Thought*, Macmillan, London, 1983, p. 466). Critics see a strong Hegelian and continental influence in his writing, in contrast to Burkean conservatism. The *Salisbury Review* is the main mouthpiece for High Tories, with its fascination with the Established Church, fox hunting, rural life, and the nation-state. With the exception of the issue of the European Union, their problem is the appearance of irrelevance to the concerns of the average person.

The other school is the One Nation Tories, consciously echoing Disraeli. They criticize Thatcherism for promoting economic reform at the expense of a divided nation, and surrendering the tradition of social legislation. They were dismissed by Mrs Thatcher as 'wets.' Their most prominent intellectual was Ian Gilmour who wrote a series of withering attacks on Thatcherism, which he portrayed as abandoning traditional Tory scepticism towards ideology. He became ever more virulent towards Thatcher for dancing with dogma and her successors for drifting with dogma. The weakness of One Nation Tories is the lack of a coherent program, with their most distinctive policy, European integration, clashing with their own terminology of One Nation.

5. *Toryism in the English-speaking Diaspora*

Those colonists who opposed the American Revolution against the Crown were known as Tories, and most were forced to migrate to English Canada. Toryism is associated in the USA with monarchy, aristocracy, class, and hostility to change, ideas incompatible with American values of individualism,

freedom, progress, and natural rights, embodied in the Declaration of Independence and the Constitution. It is viewed as fundamentally alien to the liberal society that is America. However, Russell Kirk provided numerous favorable references to the Tory tradition in *The Conservative Mind* (1952), which invigorated the conservative movement in the 1950s. He happily embraced the term Bohemian Tory. His description of conservatism has been attacked as more Anglo than American, and fails to convey the distinctive nature of American conservatism from its British cousin. George F. Will defends Tory notions of scepticism towards capitalism and an affirmative role for the state in promoting virtue. Beyond the UK, Tory can be found in extensive use only in Canada, as a synonym for the Progressive Conservative party, more collectivist than its British counterpart and close to One Nation Toryism. Historically Toryism was associated with strong links to Britain, Crown, and Empire.

6. *The Future of Toryism: Three Scenarios*

First, Toryism could disappear as an influential political voice. Outside of its use as a synonym, Tory has an old-fashioned flavor. Tory themes of hierarchy, elitism, authority, and deference appear out of step with the Zeitgeist of the twenty-first century. Toryism has always suffered from several weaknesses: uncertainty as to whether it is an ideology; problems in turning instincts into a political program; difficulty in clearly articulating its principles; a tendency to narrow nationalism; and a lack of appeal to the young who believe in the capacity to improve the world. Its deepest flaw, as Hayek (1962) notes, is its inability to provide an alternative direction; it can only slow the process of change, it cannot direct it. In this scenario, Toryism will be seen as an obsolete relic of the past.

A second scenario is that, as conservative parties surrender to neo-liberalism and neglect their concern for order, Tories will seek alliances with the left, especially the green movement, which opposes the destructive trends of capitalism, as the only genuinely conservative, if not reactionary, force in modern politics. This is the conclusion of John Gray in his numerous jeremiads against neo-liberalism. The third scenario is that Toryism will once again become the dominant thinking amongst conservatives and that Whiggery will be recognized as an alien import that should be expunged. This is the aspiration of both High and One Nation Tories, despite their distinctive political goals.

Totalitarianism

Totalitarianism was a major concept of the twentieth century. Yet both its meaning and its application were contested. While most political scientists believed that the concept summarised well the key features of both Fascism (inc. Nazism) and Communism, historians such as Alan Bullock argued that the difference between Nazi Germany and the Soviet Union (particularly under Stalin) were such that it was misleading to use a single term to describe both. While there unquestionably were important distinctions between Fascism and Communism, particularly in terms of the role played by ideology, the predominant view nowadays is that the term *is* a useful short-hand way of describing a range of systems that, on balance, had more commonalities than differences. As will be demonstrated, while having much in common with authoritarianism, totalitarianism is conceptually distinct.

This article begins by considering the defining features of totalitarianism, and then outlines the development of the concept in terms of its historical and intellectual contexts. Following this is a brief evaluation of the concept. The final section concerns its relevance today and into the future.

1. *Defining Features of Totalitarianism*

As suggested by the root of the word, totalitarianism refers to a system in which control of the population is greater—closer to 'total'—than in any other type of system. It is the most extreme version of the subordination of the individual to the state and to a questionable notion of the collective. Totalitarian and authoritarian dictatorships have much in common,

including a lack of respect for citizens' rights, for the public accountability of political elites, and for the rule of law. But a totalitarian dictatorship is distinguishable from an authoritarian one in several ways (see Linz 1975).

First, ideology plays a far more significant role in the former than in the latter, even though many observers agree that ideology was less important in Fascist Italy and Nazi Germany than in Stalin's USSR and other communist states. While totalitarian ideology often makes use of the past, particularly national traditions, it is basically radical and future-oriented ('chiliastic' or 'teleological'), whereas authoritarian regimes typically focus more on the past and continuity. It is also often overtly exclusionary, and arbitrarily identifies particular minority groups as 'enemies' of the state and/or the people (e.g., Jews and gays in Nazi Germany, or 'the bourgeoisie' or *kulaks* [rich peasants] in Stalin's USSR), for whom life could become literally unbearable.

Another difference is that, in theory at least, the single political party plays a more prominent role in a totalitarian regime than in an authoritarian one. Third, authoritarianism relates primarily to a political system, and there is no necessary implication that the state is involved heavily in the economy. In contrast, most theorists of totalitarianism maintain that, while communist states generally controlled the economy much more than did fascist states, the *overall* level of state interference was much higher in totalitarian states than in authoritarian. Finally but importantly, totalitarianism was seen as a peculiarly twentieth-century phenomenon. This was largely because it was not until then that the technological means for controlling and transporting populations existed. With the rapid development of the means of mass communication, notably the radio and cinema, citizens could be subject to a constant barrage of state propaganda in a manner that was not possible in earlier kinds of dictatorship. This, together with the much greater emphasis placed by totalitarian regimes on state-run education for all, meant that the state's capacity for indoctrination ('thought control') reached qualitatively new levels.

Although there have been several comparative analyses of totalitarianism, the most widely cited are those of Friedrich and Brzezinski (1956, 1965). In the earlier study, these authors identified what they considered to be the six salient features of totalitarian regimes. These were an official, all-embracing, and chiliastic ideology; a single mass party, typically led by one man (the dictator); a system of terroristic police control (high levels of apparently arbitrary coercion); a near-complete monopoly of the means of communication; a near-complete monopoly of the means of armed combat; and central control of the entire economy. In the second edition of their book, this list was supplemented to include a commitment to expansionism and the administrative control of justice. One other distinguishing feature, emphasised particularly by Arendt (1951), is a high level of citizen alienation.

2. *The Development of the Concept*

The concept of totalitarianism can be traced back to the 1920s; from 1925, Mussolini himself used it to describe the Italian fascist system, for instance. But the term was not in common usage in English until after the Second World War. As Brown (1999) points out, one of the first to alert the public to the differences between traditional authoritarian and the new totalitarian regimes was not a social scientist, but the novelist George Orwell. In *Animal Farm* (1945), Orwell focused on the hypocrisy and undemocratic nature of communism, while in *Nineteen Eight-Four* he highlighted the horrors of a society in which the notion of ends justifying means was taken to new extremes, and in which political elites could manipulate mass consciousness through high technology indoctrination. In this nightmare world, the goal of achieving a better society in the future was seen to override the concerns of ordinary individuals in the present.

Within the social sciences, it was primarily a number of scholars of German or East European origin who elaborated the concept and produced comparative analyses of its application in practice. While Arendt and Friedrich were of German origin, Brzezinski had Polish roots. These analysts, or members of their families, had often experienced the horrors of totalitarianism first hand. While fascism appeared to have been defeated by the end of the Second World War, Stalin's USSR became stronger, with much of Eastern Europe coming under direct Soviet influence for the first time. One of the objectives of many scholars of totalitarianism was thus a normative one. They wanted not only to explain what it was and how it had arisen, but also to demonstrate that it was inherently evil, and why the West should resist it. In the climate of the early Cold War between liberal democracy and communism, such normative analyses found considerable resonance and support, especially in the USA.

But the term began to lose some of its popularity by the 1960s, even in the USA (see Friedrich et al. 1969). Many now felt that it was inappropriate to use the same term to describe both Stalin's and Khrushchev's USSR, for instance, especially since the latter was by the early 1960s referring to his predecessor's crimes against the Soviet population. The term became even less fashionable in the early-1970s, when the relationship between the Soviet bloc and the West entered a more constructive phase, known as *détente* (lit. a reduction in tension). At about the same time, scholars such as Jerry Hough in the USA and Gordon Skilling in Canada began publishing articles and books, based on solid research, that suggested there might be a limited form of pluralism emerging in the Soviet Union.

But in the aftermath of the Warsaw Pact invasion of Czechoslovakia of 1968, according to Rupnik (1988), many intellectuals in what is nowadays known as Central and Eastern Europe began to use the term totalitarianism in a different way from that favored by Western (esp. American) observers. These East Europeans tended to focus less on political institutions, and more on the political use of language—not merely to indoctrinate citizens, but to limit the scope of discussion (discourse) and hence the parameters within which thought could roam. They also criticized the methods used by totalitarian—here, basically meaning communist—regimes for suppressing knowledge of the past that did not suit those regimes. Totalitarianism was, thus, seen to be intent on destroying historical memories, and hence culture, that did not suit the rulers.

3. *The Usefulness of the Concept*

As indicated, totalitarianism has been criticized for over-generalization about regimes that some analysts consider too diverse to be grouped together under one heading. To Italy and Germany, for instance, could be added several other countries that were fascist or quasi-fascist at some point during the 1930s and 1940s, including Croatia, Hungary, Japan, and Romania. Among communist states, there were substantial differences between, for instance, the *relatively* liberal and outward-looking Yugoslavia or Hungary and the far more orthodox and isolationist Albania or North Korea. The point also pertains in some cases to significant changes within one country over time. Is the concept, therefore, too broad to be useful?

There is considerable variety among systems usually labeled 'liberal democracies,' yet few would advocate abandoning the term; most accept that there is more in common between these systems than there are differences. Much the same can be said of totalitarian systems. The term is particularly useful if it is used as an ideal type, rather than as a model. The former is taken here to mean a pure form of an idea, against which actual regimes are measured. While the concept of a model has diverse meanings, it refers here to an attempt to encapsulate the salient features of a given system or type of system in a structured, schematic way. If totalitarianism is used as an ideal type, it is possible to say that a given country is more or less totalitarian than another, or more totalitarian at one time than at another. Using totalitarianism in this way overcomes one of the most frequent criticisms of the concept, namely that it is statically descriptive and lacks any internal dynamism.

4. *Totalitarianism Today and Tomorrow*

The concept of totalitarianism has experienced a limited resurgence of popularity since the collapse of communist power in 1989–91, especially among Central and East Europeans. When the communists were in power in that region, generally it was forbidden to suggest publicly that they were totalitarian dictatorships. Indeed, most of these countries officially claimed to be 'socialist' democracies. Since the early-1990s—and in some more liberal communist states even before that—many critics of the old regime regularly have referred to their countries' pasts (until the late-1980s) as totalitarian. Although this usage of the word is often loose and little more than a term of abuse, it has led some scholarly analysts to argue that the concept may have been abandoned prematurely during the Cold War (see Siegel 1998), and that, liberalization phases and certain changes notwithstanding, most communist states remained fundamentally totalitarian until their collapse.

While there are no overtly fascist regimes at present (2000), there remain five communist ones (PR China, Cuba, DPR Korea, Laos, Vietnam), and these are sometimes still described as totalitarian. Moreover, while it might be true that globalization and the Internet are rendering it ever more difficult for individual governments to control their populations in ways they sometimes did in the twentieth century, it is possible that governments will catch up with the technological revolution and harness it to new totalitarian objectives. The rise of the extreme right (neo-fascism) in several European countries—including Austria, France, and Germany—from the 1990s means that it would be ingenuous to consign totalitarianism to the rubbish bin of history. It may yet rear its ugly head again.

Totalitarianism: Impact on Social Thought

If it is right to say that the meaning of a concept is at least in part determined by its use, then we can find in the career of the concept of totalitarianism many distinct meanings. They include:

(a) its directly political use in the 1930s for or against the establishment of the Nazi and Stalinist regimes;

(b) its conventional use within postwar political science and political philosophy to define and denounce these regimes from the point of view of liberal democracy;

(c) its more radical use within critical theory to trace the linkages between what happened at Auschwitz and in the Gulag and the 'normal' forms of modern political life;

(d) its rejection, especially by Marxists, as an inherently ideological concept which falsely equates communism with fascism; and

(e) its reappropriation by postmodern social theorists as the prevailing potentiality of political modernity.

1. *Political Origins*

The Italian idealist philosopher, Giovanni Gentile, coined the term 'totalitarianism' in the 1920s to express what he saw as the actuality of 'total freedom' and 'total domination' in which the self-realization of the individual is identified with the universality of the state and when the state itself is 'comprehensive, all embracing, pervasive … total' (Bellamy 1988). Gentile (1961) presented his theory as 'Hegelian' but he criticized Hegel for having an *a priori* view of individual right and morality and argued that the rationalistic conception of atomized individuals still present in Hegel's philosophy of right had to be overcome. He insisted that *society* should be seen as the (one) true subject of right and that our obligation to the *state* is the product of our own will. He argued that for the individual the law is identified with the 'very act of his self-realization' and cannot therefore be opposed to force. When the law constrains us, we are 'forced to be free.' My will is subordinate to the state to the extent that it is identical to it: 'I want what the law wants me to want.'

In the 1930s the concept of totalitarianism was also used in a critical sense by political writers who sought to compare the regimes that ruled over Stalinist Russia and Nazi Germany or who believed that the whole world might be going down this same path. Leon Trotsky, for example, argued that Stalin's regime was like Hitler's except for the 'greater barbarism' of the former. He faced up to the conjunction of socialism *and* barbarism in a way that was largely absent in a Marxist tradition which either denied the barbarism of Soviet socialism or the socialism of Soviet barbarism (Trotsky 1937).

2. *Political Science and Political Philosophy*

After World War II the concept of totalitarianism was used in conventional political science to denote an antiliberal political system which annihilates all boundaries between the state, civil society and individual personality. Totalitarianism was meant to be a distinct type of modern dictatorship which manifests the following characteristics: state power is concentrated into a single party; control is exercised over all areas of social life; terror is employed by the secret police; the mass of the people are mobilized behind the regime; and an official and irrefutable ideology is disseminated which aims either at the construction of a new historical order or at the recovery of a lost order of nature. During the Cold War the concept was often used in an openly polemical sense to indict twentieth-century Marxism and to contrast 'authoritarian' regimes on the right with 'totalitarian' regimes on the left on the ground that only the former were open to democratization. Perhaps the key to the conventional use of the concept is that it leaves liberal ideas, practices, institutions and forms of government intact as the innocent, unfortunate victim of malevolent external forces. No *intrinsic* relation between liberal modernity and the origins of totalitarianism is posited or permitted. Among those political scientists who wrote more or less in this vein were Carl Friedrich and Zbigniew Brzezinski (1967) and Leonard Schapiro (1972).

Gentile's neo-Hegelian idealism misconstrued what Hegel was doing in the *Philosophy of Right*. Textual support for his reading of the text was found in its depiction of the state as 'the divine idea as it exists on earth' and its declaration that the existence of individuals is a 'matter of indifference' compared with the ethical life of the state. However, when Hegel characterized the concept of the state as the march of God on earth, it was in order to display the vanity of its concept and the untruth of 'conceptual thinking' which hives off the concept of the state from its actual social existence. While Hegel insisted that the idea of the state was the unity of its concept and existence, Gentile, by contrast, turned the concept of the state as

an ideal to be actualized. He was not alone in reading Hegel in this way, and from another point of view, this interpretation also encouraged many liberal political philosophers to depict Hegel as a key intellectual forerunner of totalitarianism.

After World War I, L. T. Hobhouse (1918) set the scene in his *Metaphysical Theory of the State* when he described Hegelianism as a 'false and wicked doctrine' which uses so-called 'dialectical logic' to convert the freedom of the individual into the freedom of the state against the individual. After World War II, with the experience of totalitarianism before its eyes, 'English' liberalism became ever more impassioned in its hostility to Hegel's 'doctrine of the state.' Bertrand Russell, Ernst Cassirer, John Plamenatz, Isaiah Berlin and most famously Karl Popper, wrote to the effect that Hegel's political philosophy not only justified every internal tyranny and external aggression, since 'the state is everything and the individual is nothing,' but was the crucial link between old Platonism and modern totalitarianism. It was Hegel's *inversion* of freedom into its opposite which appeared as his greatest offence. There was a *prima facie* case that Hegel's philosophy of right prepared the way for totalitarian movements, but this reading was one-sided and excluded Hegel's repeated insistence on the centrality of the right of subjective freedom in the modern age.

3. *Critical Theory*

A more critical appropriation of the concept of totalitarianism was defined first by its acknowledgement of the implication of liberalism in the origins of totalitarianism. The basic message was that when liberalism presents totalitarianism as the Other of itself, it can understand neither totalitarianism nor itself. Second, it was defined by its challenge to the empiricism of conventional political science. The argument was that 'totalitarianism' should be treated neither as a fixed analytical category nor as a *type* of political system which can be defined according to the presence of certain specifiable criteria, but more dynamically as a movement of thought and practice which has deep roots in the modern political age. Third, critical theories of totalitarianism dismissed the notion of any *direct* connection between the *event* of totalitarianism, that is, the fact that in the twentieth century totalitarian movements came into being and achieved power, and any of the great nineteenth-century thinkers (not just Hegel and Marx but also Kierkegaard and Nietzsche or more recently Weber and Durkheim) who were both heirs to and rebels against the tradition of 'Western' political thought. Among the social theorists who used the concept of totalitarianism in this way were the critical theorists of the Frankfurt School; former Trotskyists/left socialists like Cornelius Castoriadis, Claude Lefort and George Orwell; existentialists such as Albert Camus and Hannah Arendt; and individual thinkers such as J. L. Talmon who perhaps bridged the conventional and radical paradigms.

Against the charges leveled against Hegel and Marx by 'English' liberals, 'German' critical theory stressed the incompatibility of Hegelianism and totalitarianism. It was stressed that the aim of Hegel's political philosophy was not to subordinate the individual to the state but to harmonize the principles of political community derived from the ancient *polis* with principles of individual freedom derived from modern Christianity (Löwith 1967). Franz Neumann argued that Hegel and totalitarianism made impossible bedfellows and that this is why Hegel's doctrine of the state supremacy was abandoned in Germany: 'Today, the doctrines exalting the state, notably Hegelianism, have been thrown overboard ... Hegel's idea of the state is basically incompatible with the German racial myth ... Hegel's theory is rational; it stands also for the free individual.' (Neumann 1942). For the Nazis, by contrast, the state represented not an end in itself but a means for their movement and the idea of the state was subsumed to the authority of the 'true community' bound together by blood and soil and subject to no rational norms. Totalitarian ideologues attacked Hegel's philosophy of right, as Gentile had done, precisely because individual right remained the basis of his rational state.

Critical theory was united, however, in arguing that Hegel failed in his attempt to reconcile individual freedom and political community because of his incapacity to address the social questions that were determining the future of bourgeois society: how to control the poverty brought about by wealth, the increasing claims of the masses who sought to rule by force of numbers, the collision with liberalism (Löwith 1967, p. 241). Löwith concluded that Hegel was, like many philosophers, politically naive. Marcuse and Neumann argued that Hegel's philosophy contained an inexcusable paean to the Prussian state, 'the state of broken promises, of disappointed hopes, a state which cared nothing for free institutions,' and expressed the authoritarian inclinations of liberalism itself. In their eyes Hegel inadvertently revealed something fundamental about the origins of totalitarianism: namely that the only solution *within existing conditions* to the antagonisms of civil society was to turn the state into an ever more 'independent and autonomous power.' From this standpoint it seemed that liberalism was fully implicated in the origins of totalitarianism and that the only alternative was to foster new forms of individualism and political association which transcend this given historical reality. This meant facing up to the 'universal negativity' of bourgeois society and advancing an 'affirmative materialism' which privileges 'the idea of happiness and material satisfaction' over the system of right (Marcuse 1979).

The full force of critical theory's criticism of the totalitarian tendencies present within both Hegel's

philosophy of right and modern liberalism was to be found in the work of Theodor Adorno. In his *Negative Dialectics* (Adorno 1973) he writes of how Hegel turns the state into an object of worship, degrades individual subjects into its mere executors, dissolves the everyday experience of alien and oppressive power from an allegedly higher philosophical vantage point, associates 'fault-finding' with inferior consciousness, disguises decisions of state as democratic procedures emanating from the will of the people, identifies the rational individual with obedience to the state and holds the individual always in the wrong whenever he is 'too benighted to recognize his own interest in the objective legal norm.' According to Adorno, the world which the *Philosophy of Right* sanctified contains 'an endless procession of bent figures chained to each other, no longer able to raise their heads under the burden of what is.' It is a world which compresses the particular 'like a torture instrument.' It was not Hegel, however, who was 'responsible' for the rise of totalitarianism; he was rather the first to admit that the universal prevails over the particular in modern states, to repudiate the individualistic illusions of liberal thought and to demonstrate that liberalism itself possesses totalitarian potentialities.

4. *Hannah Arendt*

Hannah Arendt also counted the failure of liberalism to live up to its own ideals and its inability to resist the rise of totalitarian movements 'among the historical facts of our century' (*Essays in Understanding* 1998). She too insisted that to hold the thinkers of the modern age, especially the nineteenth-century rebels against tradition, responsible for the structure and conditions of the twentieth century is 'even more dangerous than it is unjust.' She argued that the implications apparent in the *event* of totalitarian domination went far beyond the most adventurous ideas of any of these thinkers and that their greatness lay in the fact that they perceived their world as one invaded by 'new problems and perplexities which our tradition of thought was unable to cope with' (*Between Past and Future* 1977). The more immediate culprits were imperialism, racism, anti-Semitism, inter-imperialist wars and the destructive nihilism of a front generation which celebrated violence and cruelty as supreme values. She praised these nineteenth-century rebels for being the first to think 'without the guidance of any authority whatsoever' and for retrieving the concept of political freedom from the buried treasures of ancient Greece, but she believed that they were still held by the categorical framework of the tradition against which they rebelled. In her view they ended up reducing 'divergent values, contradictory thoughts and conflicting authorities to a unilinear and dialectically consistent thread of historical continuity.'

Arendt was not consistent in her writings, but the main thrust of her work was not to treat totalitarianism as a *type* of political system but to understand it as a principle of movement: one that has perpetually to destroy in order to survive and offers an infinity of violence in place of any real power. The totalitarian mind dreams of the identity of total domination and total freedom but the obstacle that this modern megalomania encounters is that the world is not a nullity in relation to its own will. Arendt recognized that there is something profoundly inhuman about an idea which treats human beings *as if* their own self-consciousness was fully identified with that of the state, without conflict or contradiction, *as if* nothing is left over and there is no supplement, and *as if* the victims really are turned into mindless things and deprived of spontaneity, difference and plurality. To be sure, totalitarianism for Arendt was not 'merely an idea' but neither should it be confused with the actuality of social life. It is always an 'as if': an imaginary identity which is actualized in an unsatisfiable will to destroy.

5. *Marxist Criticism*

The use of the concept of totalitarianism was strongly criticized by Marxist scholars who refused to accept that the Soviet Union was ever 'like' Nazi Germany and objected to what they read as its confusion between two different systems of rule. They maintained that Communism held universal values, only denounced democracy because it is merely formal, endeavored at least in theory to establish a true or higher form of democracy, justified violence only if it served as a counter-violence, and had as its final aim the good of humanity. On the other hand, they held that Nazism glorified nationalist passions, sought only to realize the particular destiny of the *Volk*, attributed absolute superiority to a pure race summoned either to subjugate inferior races or to eliminate them, put anti-Semitism and hatred of others at the center of its political program, and treated violence as an expression of life itself. It was argued that Communism referred, in however distorted a fashion, to laws of history while Nazism referred only to illusory laws of nature. In the first case, we have a political order based on the overcoming of private property and capitalist exploitation; in the second, an ethnic order from which private property profited. Claude Lefort has convincingly argued, however, that these objections to the concept of totalitarianism remain on the surface of political life and fail to measure the difference between ideology and practice. They are especially vulnerable to the countercharge that what is as important as the manifest content of these rival ideologies is the comparable function they performed. Thus in both cases, the dominant ideas were tied to the existence of

a party movement whose organization and unity represented the untouchable ground on which 'the power of discourse and the discourse of power became indistinguishable' (Lefort 1998).

6. Totalitarianism and Modernity

In contemporary social theory, especially that which is sometimes dubbed 'postmodern,' the idea of totalitarianism has been expanded to refer to the tendencies within political modernity to elevate the idea of society over the individual, to subject all aspects of social life to surveillance and discipline, and to sacrifice moral choice at the altar of instrumental rationality. Modernist social theories are represented as having a mimetic relation to the society which they theorize. Marx is indicted for submitting subordinating human action to the laws of historical necessity; Durkheim for equating morality with conformity to social norms; Weber for idealizing a rational bureaucracy which limits itself to amoral choices based on criteria of efficiency. The idea that totalitarianism has roots in 'normal' society has been radicalized so that totalitarianism appears as an ever-present, ever-pressing product of 'modernity' or at least of 'high' or 'hard' modernity (Fine and Turner 2000). For Zygmunt Bauman (1990) the 'rationality' of the modern age, or at least the instrumental form of rationality which dominated both the conception and execution of the Holocaust, appears as the main connecting link between modernity and totalitarianism. He writes that this 'period' may be finished now that we have entered what he calls the age of 'liquid modernity,' and that the threat of totalitarianism has accordingly abated. There is, however, an instability in an approach which totalizes the specter of totalitarianism in one period and evaporates it in the next.

7. Conclusion

The event of totalitarianism, marked by Auschwitz and the Gulag, confronts social theory with the question of whether the phantasmagoria of a fascist consciousness should be imported into the conceptual arsenal of critical social theory. The totalitarian mind dreams of the conjunction of total domination and total freedom, but it is less the realization of this dream than its failure that draws it into mammoth displays of power (we may think of those represented cinematically by Leni Riefenstahl) and into what Arendt calls its 'escalating orgies of destruction.' In social theory we are accustomed to the argument that the way people present themselves should not be confused with who they are, but we are inclined to forget that this holds not only when people present themselves as all-good but also when they present themselves as all-powerful. An analogy might be drawn with Foucault's error when he turns the advertising slogans of Jeremy Bentham's *panopticon*—that it would be all-seeing, all-knowing, all-powerful, a perfect machine for 'grinding rogues honest,' etc.—into the actuality of disciplinary power. Foucault successfully used Bentham to devalue the claims of penal reformers who presented their innovations in the language of the 'rights of man' or as advances in humanitarian practice, but he did not apply the same skeptical consciousness to those, like Bentham himself, who claimed that they had finally discovered the means of achieving a rational, complete, pervasive, gapless and seamless power. Somehow, when it comes to power rather than to humanism, social theory is more inclined to miss the shadow that lies between the image and the act.

Totemism

There is patently a history of the study of totemism: the eminent French scholar Claude Lévi-Strauss provides good chunks of it in *Totemism* (Lévi-Strauss 1963). Considerably less clear is whether there is any one thing to study here, and in the present scholarly age of 'deconstruction' this is an especially salient issue. Lévi-Strauss says there is, most notably in his subsequent *The Savage Mind* (Lévi-Strauss 1966), but nowhere does he say how much his grapplings with the problem are indebted to those of Franz Boas and his early students, particularly Alexander Goldenweiser, in the second, third, and fourth decades of the twentieth century (Shapiro 1991). This article draws heavily on Goldenweiser's thinking, supplemented here and there by that of Lévi-Strauss. Hence the following definition: totemism is a scheme of thought in which some sort of relationship is posited between classes of people and classes of objectifications. This is deliberately vague, and inconsistent with textbook definitions in three ways: (a) it does not specify the nature of the relationship; (b) it does not insist that the classes of people be situated in spatially bounded 'groups'—the sorts of collectivities with which anthropologists have been most comfortable; and (c) it does not insist that the classes of objectifications be animals, plants, or other natural phenomena.

This last feature was crucial in early theories of totemism, and it nowadays feeds readily into the primitivist assertion of an alleged 'kinship with nature' in the Tribal World. The pervasiveness of this kinship has frequently been overstated, and its metaphorical character—where it *does* exist—unrecognized: e.g., it is neither flattering to some Aboriginal Australians, nor is it literally true, that they consider themselves to be descended from eaglehawks or crows. Moreover, such romantic interpretations of totemic systems are caught short when Aboriginal social classes claim mystic affiliation not only with segments of nature but also with Indonesian ship-masts, the Christian cross, and diarrhea (Keen 1994; Worsley 1967). Still further, recent work in Central Australia, the *locus classicus* of much theorizing on totemism, indicates that the archetypical Creative (Dreaming) beings, even when they do have animal features, blend them with human ones, or change from one to the other (Morton 1987). And finally, there is often a decided chasm posited between animal-like Dreaming beings and their current zoological manifestations. The conclusion here is that 'kinship with nature' and totemism have some overlap but do not co-occur with such frequency as to be considered aspects of the same phenomenon. It will be argued below that, quite to the contrary, they are more often antagonistic.

Similar qualifications apply to the alleged link between local groups and totemism. A clear example—and one much closer to home—is the system of Zodiac signs, which classifies people by 'location' in a calendrical scheme, i.e., in a system of temporal classification. What Aboriginal Australian totemism does, by contrast, is to classify people according to systems of *spatial* classification, and this has mistakenly been rendered by much of the anthropology of the last half-century as a form of residential grouping. Such iconic use of space is of course widespread, and it occurs in traditions which no one would wish to call 'totemic.' Pilgrimage sites in Christianity, Hinduism, and the other Great Religions are exemplary.

This leaves the relationship between classes of people and classes of objectifications. The key—and here the argument follows Lévi-Strauss following the Boasian scholars—is the relationship of analogy, such that

> people A: objectification A(1, 2, 3 …):: people B: objectification B(1, 2, 3 …):: people C: objectification C(1, 2, 3 …) …

Here a distinction can be drawn between those schemes in which the number of peopled segments is clearly subject to historical contingency, such as Aboriginal Australian clan systems or American sports leagues, and those which deny the contingency and keep constant the number of peopled segments, such as the Zodiac system, or the clan system of the Bororo of Central Brazil, wherein a division of the population into eight such units is desperately maintained (Crocker 1985).

Still, there is something lacking in this analysis, for none of the systems noted seems to be entirely satisfied with positing analogy between segments: however imperfectly, they all assert a relationship *within segments*—a bond of *consubstantiality*. But this bond, though like a kinship one, can also be an anti-kinship one, i.e., it can be derived from common participation, real or imagined, in an entity or activity other than sexual generation: location of conception, quickening, birth, or initiation in Aboriginal Australia (Tonkinson 1978), time of birth in the Zodiac system, naming among the Bororo, birth from hermaphroditic Creative Beings in the Northwest Amazon (Hugh-Jones 1979), and real or vicarious co-participation in controlled violence in sports. These are all forms of what has been called *pseudo-procreation* (Shapiro and Linke 1996), and they are by no means limited to totemic systems.

Hence a rethinking is called for of a subject once dear to the hearts of kinship theorists, viz. 'clan totemism.' Objectifications in such systems are not simply emblematic, as Lévi-Strauss would have it, nor is the 'common descent' of clan members even 'assumed,' in some sexual sense. If anything, it is *denied*, at least in the Bororo and some Aboriginal Australian cases (Shapiro and Linke 1996), where, as elsewhere, what *is* asserted is a 'mystical' bond between clanspeople. Thus the suggestion that these units be renamed 'pseudo-procreative corporations' (Shapiro 1988). They—at least many of them—are not 'descent

groups,' as received wisdom would have it, even where membership is based on the mother/child tie ('matrifiliation,' in anthropological parlance), or on the father/child bond ('patrifiliation'). The resultant 'descent' through 'lines' of women or of men, respectively, may prove to be more often in the heads of anthropologists than in those of the people they have worked with; and the key conceptualized common relationship among clanspeople may well turn out to be their shared consubstantial relationship with their totem or totems rather than their shared 'descent.' Christians who find this odd need to be reminded that a comparable relationship of asexual consubstantiality is the cornerstone of their faith, and that similar 'second-birth' ideologies pervade the world's religions (Bloch and Guggenheim 1981).

At stake here is another chunk of primitivist assertion whereby the Tribal World is a universe of libertines, which stands in stark contrast to Western puritanism. From this fresh perspective, totemism—particularly clan totemism—is a means by which human beings deny what Ernest Becker (1973) calls their 'creatureliness,' their embeddedness in sexualized nature. It thus points *not* to a link with nature, as was once thought, but in the opposite direction, i.e., it is an attempt to dissociate from it.

All this calls into question materialist theories of clanship and clan totemism, such as those put forward by Lowie (1920) and many other scholars. It is true, as these theories contend, that clanship tends to occur not among the simplest hunter–gatherer populations but among more sophisticated ones (Woodburn 1982), and those who have crossed the 'neolithic' threshold and taken up farming. But there are numerous instances, probably most common in Amazonia, of farmers without clans. Moreover, the (supposedly) technologically-generated residential alignments—men hunting or raising animals and related through male links, women cultivating gardens and related through female links—of incipient clanspeople are often absent, or as among the Bororo, part of the 'superstructure' of clanship. Correspondingly, the alleged 'corporate' character of clans in domains other than ritual has been shown to be illusory.

Finally, the time-honored theory that a certain kind of kin-classification system—the one, following Murdock (1949), introductory textbook writers label 'bifurcate merging'—is congruent with clanship is in fact nothing of the sort. Advocates of this theory like to point to certain restricted areas of genealogical space, e.g.,

$$F = FB \neq MB$$

To put this more prosaically: unlike English, which lumps both paternal and maternal uncles under a single term ('uncle') and separates out one's genitor ('father'), many languages in the Tribal World classify the paternal uncle (FB) with the genitor (F) and distinguish both from the maternal uncle (MB). Now this much is consistent with a clan system: with 'patrilineal' clans my genitor and his brother are members of my own unit, whereas—assuming, as is usually the case, clan outmarriage or 'exogamy'—my maternal uncle is a member of another unit. And with 'matrilineal' clans, the structure is the same but its composition is reversed: I am in the same unit as my mother and her brother, whereas my father and his brother are in another unit.

There are so many problems with this interpretation that the wonder is that it has survived for so long. For one thing, a very large number of bifurcate merging systems exist in the absence of clans. For another, in many such systems, kin-terms are extended beyond the sphere of close relatives—indeed, sometimes they are extended to anyone an individual may encounter—and the principles of extension, now well-known, usually have nothing at all to do with clan affiliation even where such units exist. But even in the sphere of close kin the 'clan theory' of bifurcate merging breaks down: as in English, a man's children are usually equated with a woman's, paternal grandparents with maternal grandparents, and other cross-clan equations exist. Finally, and with the greatest theoretical import, it has been repeatedly shown that, in bifurcate merging and other systems of kin-classification, the core or 'prototypical' members of such classes are the genealogically closest kin (Shapiro 1995). Hence the 'clanship' interpretation of bifurcate merging is without foundation, and the supposed causal chain—from farming (or 'advanced' hunting–gathering) to certain residential alignments of kin to clan totemism to bifurcate merging kin-classification—is called into serious question. Rather, genealogical space in 'clan' populations seems to have much the same structure as such space elsewhere. We are left with a theory which views clan organization not as the outcome of 'material conditions of existence' but as systems of existential categories. And this leads again to an emphasis on a consubstantiality which is asexual. Clan totemism, like other forms of totemism, is not an epiphenomenon to a way of making a living but a way of living which, in a manner typical of our species, grapples with our uncomfortable sense of ourselves as creatures of biology.

Tourism

1. The Subject of Tourism

Mankind has traveled since ancient times, but the phenomenon of tourism is a new kind of travel born of modernity. The word 'tourism' began to be used only in the nineteenth century due to the development of modern transportation technology on the one hand, and the socioeconomic changes caused by the industrial revolution on the other. Before that travel was hard and used to require patience and effort. In fact, the English word 'travel' is related to the French word 'travail', meaning 'labor.'

In the West in the second half of the twentieth century, the work ethic was transformed, and people's desires for making life worth living through leisure and enjoyment became increasingly evident. The length of the working week decreased and paid holidays were lengthened. As a result, tourism as a form of leisure activity became widespread in the developed countries of the North.

Tourism has, then, become a phenomenon of enormous importance in the contemporary world. Against this background of a massive expansion in tourism, many countries, both developed and developing, are now pouring resources into the industry, which they see as a possible option for economic development.

2. The Anthropology of Tourism

However, in the humanities and social sciences of the past, tourism was not taken seriously as a subject for research. Even among anthropologists it made its debut as a focus of research quite recently. The first academic symposium on tourism was held in conjunction with meetings of the American Anthropological Association in Mexico City in 1974. Up to then there had been a few pioneering efforts, but nothing systematic had been carried out. The results of the symposium were published in Smith's (1977) book, *Hosts and Guests*. Focusing on the relationships between the 'hosts' (the society receiving the tourists) and the 'guests' (the tourists themselves), this book was the first edited volume to deal with the anthropology of tourism. During the 1980s, tourism became established as an item on the menu of anthropology, both for research and teaching.

The central task of the anthropology of tourism is to investigate the sociocultural implications of tourism. In fact, in many parts of the world it has become obvious that tourism is playing a culturally dynamic role. Amidst the 'global cultural flows' (Appadurai 1996), social boundaries are weakening and people are enjoying the benefits of the culture which is crossing them. As this happens, expressions of traditional culture on the one hand are being progressively fragmented, while on the other culture is being reinvented, especially in the context of tourism. Therefore, MacCannell (1992) wrote that tourism was a primary ground for the production of new cultural forms on a global base.

These circumstances present a challenge to the student of culture. It is becoming impossible to treat culture in the way that it once was, as a closed system of meaning and symbols. It is also increasingly difficult to use the old-fashioned ethnographic method of recording coherent, patterned cultural systems enclosed within discrete territories and peoples. As Hannerz (1992) has suggested, one must investigate culture in relation to the macrolevel system and the 'global ecumene,' a region of persistent cultural interaction and exchange.

3. The Tourist

Smith (1977) defines a tourist in the following way: 'a temporarily leisured person who voluntarily visits a place away from home for the purpose of experiencing a change.' Here, 'work' is contrasted with 'leisure' and time is structured as follows: tourists are released from

work, this leisure time they devote to themselves, and they return to work refreshed once more. This structure of time is very similar to that of ritual as analyzed by Leach (1961) who suggested that ritual puts a stop to normal and profane time, and creates abnormal or sacred time. The end of the ritual signifies reintegration with normal and secular time. Based on this analogy with ritual, Graburn (1977) treats tourism as a 'sacred journey.' In fact, in Europe and many other parts of the world, pilgrimage, which provided the model for tourism, was simply a ritual journey.

Tourism, therefore, takes the place of ritual in the modern world. Just as rites of passage bring about a change in status or circumstances through the ritual experience, what the tourist is looking for is the experience of a change. The essence of tourism always consists of experiences that are different. As a result a trip is a success if a change can be seen in the self. People refresh themselves by traveling: they are 'reborn' with a new lease on life.

This difference in perception may also apply to tourist space in what Urry has called the 'tourist gaze.' Applying Michel Foucault's concept of the 'gaze,' Urry (1990) states that the tourist experience is 'to gaze upon or view a set of different scenes, of landscapes or townscapes which are out of the ordinary.' Just like tourist time, then, tourist space is marked and 'framed' as discussed by MacCannell. Tourism is, as MacCannell (1992) put it, an ideological framing of history, nature, and tradition; a framing that has the power to reshape culture and nature to its own needs.

4. *The Tourist Experience*

There are two important theories of the tourist experience. The first is the theory developed by MacCannell (1976) that tourism itself consists of the search for 'authenticity.' This starts from Marx's observation that living in the modern world produces a state of alienation in which we cannot realize our real selves. The reason why people travel is, therefore, to escape from the real world of the present day, to experience a different world, and to discover the 'authentic.'

On the other hand, Boorstin (1962), writing before MacCannell, observes that the authentic tourist experience is impossible in the contemporary world. Rather than being a journey in search of authenticity, travel is increasingly based on artificial images. Before setting out on a trip, tourists read the guidebook. They then go to the places written up in the guidebook, and take photographs similar to those in the guidebook. This is an experience that Boorstin has called a 'pseudo-event.' Thus, the tourist experience ends up oscillating between being a 'pursuit of authenticity' and a 'pseudo-event.' Cohen (1979), however, does not regard it as either of these two alternatives. He suggests instead that there are a number of different modes of tourist experience ranging from the recreational mode in search of mere pleasure to the existential mode in search of one's real self. Thus, there are many different types of tourism (e.g., 'historical tourism,' 'ethnic tourism,' 'recreational tourism,' and so forth), and many different types of tourists. Further, tourist experiences may vary with 'who travels, and where.'

Today, where the boundary between an original and a copy is becoming increasingly blurred in many areas, the very basis of the question of whether tourism is a search for authenticity or a pseudo-event has lost its meaning. *Cannibal Tours*, a film by O'Rourke (1987), illustrates this point. The film describes the 'ethnic tourism' to the villages on the Sepik River in Papua New Guinea. As Bruner (1989) says, the tourists already know that in New Guinea things like cannibalism no longer exist. If cannibalism did exist, or if there was no air-conditioned cruiser, they would probably not go to New Guinea. What they really want is to experience going from a safe, 'civilized' place to one that is 'primitive.' What they experience here is not something which is really primitive, but a reconstructed primitiveness. The substance of this 'postmodern tourism' is, then, the experience of a copy or *simulacrum*, and the copy becomes more important than the real thing.

Cannibal Tours also poses the critical question of how this type of tourism is based upon the issue of relations between the North and the South or 'neocolonialism.' In fact, the majority of the world's tourists are from the 'northern' countries: 57 percent from Europe and 16 percent from North America. Eighty percent of all international travelers are nationals of just 20 countries. In terms of expenditure on tourism, the world's top five spending tourist countries in 1995—Germany, the United States, Japan, the United Kingdom, and France—were responsible for 48.6 percent of the total (Mowforth and Munt 1998).

5. *The Host Society*

The anthropology of tourism investigates the interaction between hosts and guests. The central issue here has been the question of how the development of tourism influences the culture of the host society. Much of the debate along these lines has focused especially on whether its effects are beneficial or not.

On the relationship between tourism and culture, tourism has been often seen in a negative light, the general tenor of discussions being that it contributes to the destruction of traditional culture. For example, Greenwood (1977) described the case in Spain of a traditional Basque public ritual, *Alarde*, and discussed how it was commoditized and packaged for sale with

the introduction of tourism, resulting in the destruction of the irreplaceable historical heritage of the Basques.

However, this line of reasoning is not necessarily correct. First of all, tourism is not the only influence on these societies. It is just one of many ways in which the contemporary world system brings about change in the societies within it. Local cultures are also transformed by other factors, including industrialization, urbanization, migration, the mass media, pollution, poverty, and civil war, as Greenwood (1989) himself admitted in his revised version.

It is useful on this point to recall Clifford's distinction between two ways of narrating culture: metanarratives of homogenization and loss on the one hand, and of emergence and invention on the other (Clifford 1988). A narrative of homogenization becomes an 'entropic' narrative or one of loss, because modernization or Westernization means a loss of indigenous tradition. But such an analysis as the disappearance of an 'innocent' tradition that is not affected by modern Western civilization is often incorrect, because it presupposes the idea that a cultural tradition dates back to primordial times, which is actually seldom the case (cf. Hobsbawm and Ranger 1983).

In relation to the theme of creation of culture in tourist contexts, therefore, special attention should be paid to Clifford's narrative of emergence and invention. Culture in this perspective is observed as something emerging: it is not something static but a dynamic, evolving process. An example may be taken from Bali, Indonesia. In Bali, traditional culture, and particularly the traditional dances such as the famous *kecak* dance, have been elaborated and refined since the 1930s under the 'tourist gaze.' 'Traditional culture' reconstructed in this way not only has become 'symbolic capital' for developing tourism but also has been appropriated by the local people to assert their own identity. As Picard (1996) puts it, tourism has neither 'polluted' Balinese culture, nor kindled its 'renaissance,' but made the Balinese self-conscious about their culture.

Therefore, it is simplistic to consider only the 'impact' of tourism as an exogenous force, assessing its effects as either 'good' or 'bad' (Lanfant et al. 1995; Yamashita et al. 1997). What is at stake is not simply the impact of tourism on local cultures, but rather how the local cultures develop during the dynamic process of making use of tourism to redefine their own identities.

6. *Touristic Culture*

Culture in this context is not the unconscious custom with which conventional anthropology has been concerned. Rather it is an object of conscious manipulation within a broader social, economic, and political context. In other words, in the context of tourism, what is involved is not an 'authentic culture' but a newly created 'staged culture.'

Staged culture in the tourist context, or what Picard (1996) calls 'touristic culture,' including examples such as dance performances, cultural exhibitions, or souvenir production for tourists, is usually disparaged, because it is not 'authentic.' However, in the case of Bali, as was seen, it is rather the 'tourist gaze' that has stimulated creativity in their arts. What, then, is the mechanism for the emergence of touristic culture, particularly tourist art?

As an example, *Sepik* carvings, the souvenirs of *Cannibal Tours*, originally were used in ritual contexts. At the end of the nineteenth century, however, they were designated 'primitive art' by western explorers, and were seen as having objective, 'authentic' value by western scholars. Now they have been transformed into 'touristic art,' by being taken up by the tourist guidebooks to be sold to tourists. This kind of transformation occurs in the scheme of what Clifford (1988) called the 'modern art-culture system.' The *Sepik* carvings have, in this way, been transformed from cultural (ritual) to artistic objects, and then to tourist (commercialized) objects (see also Graburn 1976).

What is necessary for describing these phenomena is not an 'entropic narrative' of traditional cultures which are vanishing. Rather, it is a narrative of new cultures emerging in the context of tourism. It is in this point that tourism has become a catalyst for contemporary cultural production.

7. *Tourism and Sustainability*

The notion of sustainability became something of a buzzword from the 1980s, with the increased awareness of environmental and other problems to which particular kinds of tourism could lead. In 1989 in Zakopane, Poland, the theme of the first general meeting of the International Academy for the Study of Tourism was 'alternative forms of tourism' such as 'appropriate tourism,' 'responsible tourism,' and 'ecotourism.'

Sustainable tourism can be defined as development which will benefit the people of today without harming the resources to be shared by future generations and their prosperity. It is promotion of development which maintains a balance between the ecosystem and the society and culture concerned. According to de Kadt (1992), the sustainable development involves the following traits: ecological soundness; small-scale production; recognition of needs other than those of material consumption; equal consideration of the needs of all (including future generations); and political involvement from below.

However, human societies at present are experiencing problems that they are unable to cope with only through local knowledge. What matters most is the way in which the local people handle the process of adapting themselves to the macrosystem surrounding their own region, under the name of development.

8. *The Lesson of the Study of Tourism: Anthropology on the Move*

In reviewing research in the anthropology of tourism, Crick (1989) argues: 'Anthropology has often been defined as the study of human beings in culture and society. Tourism is thus an odd anthropological object, because international tourists are people *out* of culture in at least two senses. First, they do not belong to the culture of the destination country, and second, they have stepped beyond the bounds of ordinary social reality into what has sometimes been referred to as a 'ludic' or 'liminoid' realm.' The lifestyle of international tourists that involves living a double existence, inside and outside culture and society, as well as work and leisure, means that people are separated from their home areas, and move across international boundaries in the transnational age.

Following this, rather than tourism being an eccentric object of study for anthropologists, it is on the contrary an essential object of study if anthropologists are to change the object of their research. Anthropologists formerly used to assume that, in a given area, a given people lived with a given culture. This kind of static anthropological viewpoint cannot deal with the 'realm in between.' A new kind of anthropology that extends to lifestyles on the move must be shaped in the gaps between cultures and between societies. The anthropology of tourism presents one challenging attempt to do just this.

Tourism, Geography of

Tourism geography is concerned with the place, space, and environmental aspects of tourism. While there is a distinctive field of tourism geography studies, with its own specialist journal, *Tourism Geographies: An International Journal of Tourism Space, Place and the Environment* (first published by Routledge in 1999), there are considerable overlaps with the interests of economic and cultural geographers. These have infused tourism geography with greater theoretical content in recent years, counter-balancing a more traditional emphasis on the empirical, allied to a concern for applied research. Tourism geography contributes to, as well as being influenced by, discourses on subjects such as globalization, representation, and sustainability. A review of the contribution

of tourism geography and of its links with neighboring disciplines can be found in a special theme issue of *Tourism Geographies* (2000, Vol. 2, no. 3).

1. *Definition*

An early issue in tourism geography has been the generic definition of tourism. Most definitions emphasize that tourism is characterized by nonpermanent moves, an intention to return home within a relatively short time period, and a purpose other than taking up permanent residence or employment. This gives rise to two main difficulties. First, there is no clear conceptualization of 'permanence,' and instead the pragmatic device of absence from home for at least one night but for less than 12 months is adopted both by academics and by the leading international tourism body, the World Tourism Organization. Second, the definition is chaotic in the way it bundles together diverse motivations and practices, ranging from business tourism, to education to pleasure. The relationship between tourism and recreation constitutes another problem area (Shaw and Williams 1994), for some forms of tourism activities are virtually impossible to differentiate from recreational activities undertaken by excursionists (or day visitors). In this instance, the case for a distinctive tourism geography lies not so much in differences in the content of the recreational practices but in the *implications* which follow from tourism involving overnight stays away from home.

It is the latter concern which, potentially, places tourism geography at the heart of tourism studies. While, technically, overnight stays could involve staying at a nearby hotel for a conference or a training event, or children 'sleeping over' at the homes of friends within the same town, there is an in implicit assumption that tourism involves more profound interactions between the destination and host areas. There are three main dimensions to this. First, there is an economic dimension arising from the expenditures related to the overnight stay (long distance travel, accommodation, meals, and other services) so that there are significant inter-regional transfers of income, and tourism becomes a potential economic development instrument. Second, travel brings individuals into contact with the 'other,' in the form of different cultures, with implications for both the tourists and for the receiving communities; there is a strong overlap here with the work of social anthropologists on host-guest relationships (Smith 1977). Third, tourism brings an additional dimension to the environmental impacts of human activity, resulting from the scale and intensity of travel, the redistribution of human activity across space, and a hypothesized change in attitudes to the environment amongst tourists when freed from the cultural constraints of 'home.'

2. *Changing Perspectives in Tourism Geography*

In the twentieth century, the changing approaches to tourism geography research have broadly mirrored wider shifts in other social sciences, although the applied interests of many researchers has meant that these changes have attracted relatively little methodological debate. Nevertheless, there has been a shift from a largely inductive positivist framework to approaches grounded in political economy or cultural interpretation, although tourism geography remains methodologically diverse.

2.1 *Spatial Models*

Positivist approaches have mostly been inductive, but there are some notable deductive contributions. Foremost amongst these is a relatively neglected early paper by Christaller (1963), who is otherwise best known for his work on central place theory. This paper sought to conceptualize tourism flows from 'central' to 'peripheral' locations in Europe in terms of basic principles of accessibility, and—at least indirectly—was the forerunner of an array of models concerned with the spatial interactions between areas of tourist origin and destination. Pearce (1995) has developed a fourfold typology of such models. Models of tourist travel analyze the alternative routes which link places, and the volume and character of tourist flows along these; they are often informed by a distance decay assumption. Origin-destination models are more sophisticated in that they examine the flows to and from a multiple set of areas, and identify spatial hierarchies of tourist destinations. Structural models are concerned with the evolution of distinctive spatial structures in destination areas, reflecting the asymmetrical power relationships between tourists, the tourist industry, and the destination society. These relationships are often epitomized by the development of resort enclaves which are spatially, culturally, and economically isolated from their local milieu. Finally, evolutionary models—reflecting geographers' time-space concerns—have examined the development of tourism spaces, especially resorts.

The most widely known evolutionary model is Butler's (1980) resort life cycle model, which contends that resorts pass through a series of stages: exploration, involvement, development, consolidation, and stagnation, culminating in a number of alternative trajectories, ranging from immediate decline to rejuvenation. The key factors shaping the evolution of individual resorts are visitor numbers, the roles of local/external entrepreneurs, competition, and the pressures on carrying capacity. The model is largely deterministic, but does acknowledge the role of human agency in the latter stages when alternative futures are possible, depending on the responses of the tourism industry complex. Although the model is more de-

scriptive than explanatory, it has spawned a considerable debate as to the shape of the curve, the determinants of change, and the criteria for identifying turning points between stages.

2.2 The Political Economy of Tourism

Since the 1970s, there has been a more critical approach to tourism geography which, initially at least, drew on the experiences of the less developed countries and on the political economy of development. De Kadt's (1979) '*Tourism: Passport to Development?*' argued for a more critical approach to understanding tourism impacts, but failed to offer a coherent alternative conceptual framework for this. Britton (1991), however, did set out such a framework, based on theories of capital accumulation, cultural capital, and the representation of place. This key paper developed two main streams of analysis—the commodification of culture and of place, and the particularities of tourism production within capitalist systems. These were explored through a number of case studies, such as spectacles and urban regeneration.

Britton's work did inspire a more critical approach in tourism geography, although there has been relatively limited further development of a political economy framework. One major exception to this has been the work of Ioannides and Debbage (1998), whose book sought to integrate studies of tourism production with economic geography. Their own contribution to this volume analyzed changes in tourism production in terms of a shift from Fordism to post Fordism, drawing on regulation theory. Inevitably, they conclude that there are sectoral differences between, for example: airlines and tourism retailing, and that different forms of tourism production coexist at any one time. The underlying concern of this and other research on the tourism industry has been the requirement for flexible accumulation in the face of variable demand and labor intensive production (Shaw and Williams 1994).

2.3 Cultural Interpretations

Tourism geographers have a long-standing interest in the notion of place, and in the way in which tourism behavior is both shaped by and shapes places. They have drawn extensively on the work of sociologists, such as Cohen (1984), who emphasized that all tourists are seeking some degree of novelty and difference, whilst at the same time wanting to retain an element of familiarity. The way in which tourists balance these differing needs was used by Cohen to construct a typology of tourists ranging from mass to more individualistic travelers. This, and other, typologies have been important because of the way they highlight the relationship between the different forms of tourism consumption and their impact on destination areas.

The representation of place is also of central importance in tourism behavior. The search process before booking a holiday is strongly influenced by the media and other sources of images of the destinations, both formal and informal. These are important as they condition expectations, and therefore affect the actual holiday experience and the way in which this is evaluated. The notion of the tourist gaze, which has been developed by Urry (1990, p. 2), 'presupposes a system of social activities and signs which locate the particular tourist practices.' In terms of image, the tourist gaze is constructed through signs and signifiers in the landscape, with tourists being collectors of such signs. Tourist practices do not simply entail the purchase of specific goods and services but their practices involve the consumption of signs, which are constructed around and help to define notions of place.

One of the most interesting aspects of Urry's thesis is that, in the late twentieth century, there was a change in the values held by tourists, and in the signposting of the objects to be gazed upon. The contrast between tourism as a separate sphere of social activity and the practices of every day life has greatly diminished. Tourism has become de-differentiated or merged with other activities, and this has contributed—at least in the UK—to a shift in interest from traditional seaside resorts to urban/industrial heritage sites along with valued rural landscapes and cultures. More recent cultural interpretations have been characterized by broader concerns with the embodiment of tourism experiences (Crouch 1999).

3. Tourism Geography and the Challenges of a Changing World

Tourism geographers are increasingly contributing to debates about the role of tourism in a changing world. Two themes are of particular note: the environment and economic restructuring.

In recent decades (i.e., the last decades of the twentieth century) there has been considerable research on the environmental effects of tourism, and geographers have played a key role in this. Mathieson and Wall (1982) provided an early and enduring review of the impacts of tourism. Most research, subsequently, has involved a refinement of the measurement of these impacts, through such techniques as carrying capacity, rather than advances in conceptualization *per se*. Most of the research has been in wilderness or other protected areas and there has been surprisingly little work on mass tourist environments. In the 1990s tourism geography engaged enthusiastically with the notion of sustainability, and a specialist literature has developed around

sustainable tourism. Much of the geographical contribution has been at the level of advocacy, but a more critical stance is emerging (Hall and Lew 1998). Tourism geographers have argued for a more holistic approach to sustainability, which recognizes the links between the economic, social, and environmental dimensions. They have also become more critical of idealistic attempts to build partnerships of stakeholders, as evidence emerges of unequal power relationships within these.

Tourism geography is also engaging with economic restructuring, and this is particularly evident in urban areas. In the face of major declines in their traditional economies, many urban localities have looked to tourism as one, and often the leading, component in their regeneration strategies. Tourism has the advantages of being labor intensive, requiring relatively limited investment, and having the capacity to refashion place images so as to reposition localities in the wider map of economic opportunities. Tourism geographers have played a role in analyzing the social and spatial impacts of such strategies, whilst demonstrating that their success is in part contingent on place characteristics. Similar research also exists on the role of tourism in other types of place environments, including the rural and the coastal resort.

Trade and Exchange, Archaeology of

The term 'trade' can invoke images of professionals making profits in marketplaces, while 'exchange' implies the reciprocity of goods, such as food, between nonkin, or the movement of valuables within a social group itself. In this article trade and exchange will be treated equally and defined as the movement of materials or goods between individuals, social groups, or organizations. Ancient trade and exchange are often associated with rare and exotic valuable materials known to have restricted distributions, such as lapis lazuli, ostrich egg shell (Africa), amber, spondylus shell, jade, obsidian, copper, and other precious material items. Yet most past trade and exchange would have involved materials or goods used for daily existence, such as food. These, however, would be rarely seen in the archaeological record, being perishable. Thus the archaeology of trade and exchange deals mostly in those resilient artifacts hardy enough to be left in the archaeological record, such as obsidian, stone, pottery, or jade. Even then, these goods are residues 'resulting from a succession of repeated exchange transactions' (Kirch 1997). How and why an archaeologist identifies prehistoric trade and exchange is the subject of this article.

1. The Development of Trade and Exchange in Archaeology

Since the 1980s there has been an upsurge in studies on the archaeology of trade and exchange. The reasons for this are twofold. First, advances in science and technology have allowed and made easily available the sourcing and characterization of many materials. This provides evidence for the physical identification of their movement. Second, archaeologists began to see the usefulness in using trade and exchange in modeling the distribution of materials over space, and in explaining changes in societies over time.

1.1 Technological Developments

Developments in technology since the 1960s have led to an upsurge in chemical 'sourcing' or characterization studies. Yet the identification of traded archaeological material is not a recent phenomenon. Perhaps

the most famous early study was by Anna Shepard, who in the 1930s and 1940s postulated the exchange of pottery over wide areas of the Southwest USA by analyzing mineral inclusions in thin sections to pinpoint the origins of the minerals (Shepard 1965). Chemical techniques to identify the elemental composition of archaeological materials as a means of characterization are also not new. Neutron activation analysis was applied on coins from the Louvre in 1952, while in 1957 oriental ceramics were analyzed using nondestructive methods of x-ray fluorescence spectrometry (XRF) and x-ray diffraction (XRD) analysis (Young and Whitmore 1957). However, access to these techniques was restricted and costly.

A major advance in the chemical analysis of archaeological material came from the initiative of Dr. R. Oppenheimer. On March 8, 1956 he assembled a group of archaeologists and chemists at the Institute of Advanced Studies, Princeton, to discuss the possibility of applying methods of nuclear research to the study of archaeology (Sayre and Dodson 1957). As a result of this meeting, work was undertaken at two laboratories—the Brookhaven National Laboratory in the USA and the Research Laboratory for Archaeology and the History of Art at Oxford, UK. Techniques used included neutron activation analysis (NAA) and spectrographic methods. These early studies were reasonably successful, being able to separate pottery wares from Asia Minor, Greece, and Italy, and different factories of Samian ware. These studies laid the foundations for chemical analyses for the next three decades, in which thousands of analyses using varying techniques were carried out on many types of object including pottery, stone (obsidian, marble, chert, volcanic rocks), amber, and metals including coins. Apart from NAA, XRF, XRD, and spectrographic methods, techniques currently in use include proton induced x-ray emission and proton induced gamma ray emission (PIXE-PIGME), inductively coupled plasma emission spectrometry (ICP), lead isotope analysis, and electron microscopy, to mention a few. Major changes in the instrumentation of these techniques since the 1970s have meant that more elements can be analyzed with a higher precision. The choice of technique depends on availability to the archaeologist and cost. See Harbottle (1982) for a list of materials that can be characterized.

1.2 Theoretical Developments

The importance of trade and exchange in archaeology is the result of a reorientation in the ways archaeologists have perceived trade/exchange operating in the past. The realization that migrationist/invasion models could not adequately explain the distribution of material across the landscape, nor change in societies over time, led archaeologists to look at other mechanisms. Inspired by the works of economic anthropologists such as Polanyi (1957), who defined three types of trade and exchange (reciprocity, redistribution, and market exchange), and anthropologists such as Malinowski (1922), who studied trade and exchange in a Melanesian society, archaeologists realized that trade and exchange were embedded within the social and economic structures of society. By studying trade and exchange, the intention was to reconstruct the economies and organizations of past societies and their changes over time. The access to and control over prestige goods through trade and exchange were seen as prime movers for change leading to ranked societies.

A major proponent for the study of ancient trade and exchange was Colin Renfrew. In a classic paper on trade and culture process in European prehistory, Renfrew (1969) argued that trade was a causal factor for cultural change leading to the beginning of urbanization in the Aegean. An increase in trade with new wealth, craft specialization, and communication, led to change from a 'village subsistence economy into an urban society.' This was a marked shift away from inferring invasions or diffusion from a 'higher culture' to account for the Aegean Early Bronze Age. See Rathje (1971) for a similar case study involving the Maya.

2. Current Theory and Research

From these earlier studies a number of influential edited volumes on the archaeology of trade and exchange appeared: Sabloff and Lamberg-Karlovsky (1975), Ericson and Earle (1982), Earle and Ericson (1977), Renfrew and Shennan (1982), and Renfrew and Cherry (1986). These proceedings covered an eclectic array of topics from the Old and New Worlds, and provided the benchmark for trade and exchange studies for the next decade. These studies were important not only in identifying the movement of materials in the past, but also in cementing links with the chemists, geologists, or physicists who undertook the physicochemical analyses which demonstrated that trade and exchange took place. These studies are also important in initiating innovative research into the archaeology of trade and exchange, such as correlating the distribution of materials with modes of exchange and types of social organization, or exploring the relationship between trade and exchange with production and consumption patterns. These innovations will be discussed below.

Within this research a distinction has been made between two schools of thought about the way in which trade and exchange should be modeled: formalist and substantivist. The formalist approach works within the paradigm of market economics. Here, all exchange transactions can be viewed by economic rationalism, based on cost efficiency. Fall-off models presented in Sect. 2.2 below are based on

cost efficiencies. The substantivist school, on the other hand, views exchange as being embedded in social and economic processes. This approach allows an investigation into social groups, and social change. In reality, archaeologists draw from both approaches to model ancient trade and exchange.

Research mostly followed the following steps:

(a) identifying that exchange/trade took place;

(b) modeling the distribution patterns of the exchanged/traded material.

2.1 Identifying What is Moving and What is Not

Trade or exchange *must be demonstrated* rather than assumed. Archaeologists often view stylistic similarities over large distances as a consequence of exchange. Stylistic similarities in pottery, for instance, have been equated with the trade or exchange of pots from one or a restricted number of centers. Yet, in many instances this is not the case. One pottery tradition, Lapita, for instance, is spread from Papua New Guinea to Tonga, a distance of over 4,000 km. It is stylistically homogeneous, having a suite of shared decorated motifs made by a dentate stamping technique. Before the 1970s it was thought that this pottery was made in one or a handful of manufacturing centers and then exchanged to other communities, thus accounting for its spread within Melanesia. Yet, after extensive petrographic and chemical analysis, it was established that with the exception of a couple of assemblages, most Lapita pottery is locally made. It was people and ideas that were exchanged, not the pots. Thus, if local production of an object is demonstrated then models other than the trade/exchange of the object must be developed to account for stylistic similarity.

Identifying the source of an object and studying the context of production is not easy. The use of a 'resource zone concept of source' is useful here in defining a geographical region from which the object was produced (Clark et al. 1992). For instance, the exact spot where the firing of a pot took place, or where obsidian was extracted is not crucial here, only whether the pottery is of local origin or not, or whether the obsidian originated from a defined area. Attributing an object to a general regional zone (or procurement zone) is often more important than trying to identify a precise spot for manufacture.

The aim of many physicochemical analyses is to discern the geographical origin of the object under study. Ideally, the sources of material with restricted distribution could be characterized and 'fingerprinted' chemically or petrographically. Obsidian, for instance, is chemically homogeneous, and its sources can be chemically fingerprinted. Obsidian found in archaeological contexts can be analyzed and related back to the source. Identifying the potential source areas of a material requires an intensive search within a known region. For instance, in a recent study on obsidian exchange within the western Pacific over a 20,000 year time span, archaeologists have concentrated on the source areas within West New Britain, Papua New Guinea. Over a number of years, obsidian flows were mapped and samples taken for characterization, with the result that a finer discrimination of sources was possible with five source localities chemically defined (Summerhayes et al. 1998). By analyzing obsidian found in archaeological sites (some up to 3,700 km distant), it was possible not only to trace obsidian to its source localities, but also to define changes in the selection of different sources over time. For an overview of archaeological approaches to obsidian studies, see Shackley (1998).

Pottery, on the other hand, is more difficult to characterize or fingerprint (see *Ceramics in Archaeology*). Often archaeologists use what is called a 'criterion of relative abundance,' which infers that most pottery from a production center is to be found locally. Yet if pottery was produced for exchange only, then little would be found locally, thus limiting the application of this concept. The 'criterion of relative abundance' is useful, however, when used with a physicochemical analysis for provenance studies; that is, relating the pottery under study back to its raw materials: non-plastic inclusions (minerals, sands, etc.) and clay. Mineral inclusions found within pottery can be related to local geology and both river and beach sands. Clays, on the other hand, vary greatly in respect of the underlying geology, and a study of the elemental composition of pottery may give a clue to its origin. The chemical analysis of clay is complex. Bishop et al. (1982) note that clay minerals not only depend on their parent material, but are also affected by weathering or hydrothermal activity, climate, and geomorphology. They state that 'even if a region is considered to be homogeneous in its gross geologic characteristics, significant mineralogical and chemical differences may be discerned between clay deposits' (Bishop et al. 1982).

In any provenance study of archaeological objects a few words of caution from Garman Harbottle, a nuclear physicist, should best be heeded:

> archaeologists love the term sourcing, with its upbeat, positive thrust—that you analyze or examine an artifact and, by comparison with the material of known origin, 'source' it. In point of fact, with very few exceptions, you cannot unequivocally source anything. What you can do is characterize the object, or better, groups of similar objects found in a site or archaeological zone by mineralogical, thermoluminescent, density, hardness, chemical and other tests, and also characterize the equivalent source materials, if they are available, and look for the similarities to generate attributions. A careful job of chemical characterization, plus a little numerical taxonomy and some auxiliary archaeological and/or stylistic information, will often do something as useful: It will produce groupings of artifacts that make archaeological sense. This, rather than absolute proof of origin, will often necessarily be the goal. (Harbottle 1982)

For an overview of archaeological approaches to pottery characterization studies, see Neff (1992).

2.2 Distribution Patterns

Archaeologists analyze the distribution of an object from its source or production area to its consumption site in order model the type of trade/exchange that took place. In some instances the nature of the society participating in the trade/exchange system is inferred, such as egalitarian versus chiefly, or nonhierarchical versus hierarchical.

Popular among archaeologists is the use of fall-off curves and modes of trade/exchange. By plotting the frequency of an item against distance from its source (fall-off curve), Renfrew (1975) observed different distribution patterns which he attempted to relate to modes of exchange or access. Some of these modes included reciprocity, down-the-line, and central-place exchange.

How were fall-off curves and modes of exchange related? Down-the-line exchange and reciprocity led to an exponential fall-off in abundance away from the source or production center. The term 'law of monotonic decrement' was coined to account for this fall-off in the frequency of an item away from the source (Renfrew 1977). Attempts were also made to define an object's value by the slope of the curve. A small slope equates with high-value goods, such as spondylus shells in Europe, Maya jade, and Oaxaca iron-ore mirrors. These modes were equated with an egalitarian society (semisedentary agriculturalists and hunter-gatherers; nonranked; nonhierarchical).

Central-place exchange, on the other hand, was seen as directional (no exponential linear fall-off), should lead to multinodal fall-off curves, and is indicative of redistribution. Central place relates to the movement of goods toward one place or center, from which they are then distributed. Redistribution has been related to complex chiefly societies (hierarchical, ranked and/or stratified societies). Examples of such societies given by archaeologists include early states such as the Maya, Egypt, the Near East, or chiefdoms such as Hawaii.

Although problems occur with equifinality—that is, different modes of exchange produce similar distributions—this approach is important as it relates the measurement of archaeological material away from the source to trade and exchange modes and the structures of societies.

3. Future Directions

Approaches to the archaeology of trade and exchange will continue to change on three fronts. First, change will occur in tune with developments in archaeological theory. As archaeologists will be asking different questions about the roles of trade and exchange and society, changes in approaches and methodologies will take place. Second, at the same time, it is reasonable to expect advances in characterizing techniques, making them yet more accessible and cheaper to use. Lastly, archaeologists will consolidate knowledge on the sources and distribution of a variety of goods, giving a more complete perspective on the roles of trade and exchange within a society. As an example, attention is drawn to the Pacific where the production and distribution of a number of materials, such as pottery, obsidian, chert, volcanic adzes, and shell artifacts, are used to show that each class of material has different production and distribution patterns. If any class of artifact were taken by itself, a 'myopic' view would be seen of the roles of trade and exchange within societies. Only by comparing the production and distribution patterns of the complete range of material available can a proper picture of trade and exchange be given.

Trade Unions, Economic Behavior of

1. Trade Unions

A trade union is an organized association of workers formed for the protection and promotion of their common interests. The standard view of trade unions is that they are monopoly organizations that improve the welfare of members, principally by raising wages above the competitive level. This article investigates the conditions under which a union can increase wages, and explores ways of modeling the competing preferences of unions and management.

2. Conditions Under Which a Union can Improve Workers' Welfare

For a trade union to be able to increase wage rates above the competitive level, there must be some surplus that can be shared between the firm and the union, and the union must have some bargaining power to induce the firm to share this surplus. How can a union achieve such power? It may be able to organize all workers in an industry, thereby acting as a monopolist over the supply of labor. The earliest successful unions were craft unions, which became established because of a combination of high demand for skilled labor during industrialization, and the control of trained labor by skilled workers through the apprenticeship system. The emergence of general or industrial unions followed a different path. During industrialization, the huge surplus of unskilled displaced agricultural labor made manipulation of labor supply impossible. A depression, coupled with a readily available pool of substitute workers, could destroy a union. To ensure survival, a general union needed political support or very high levels of membership. Obtaining the latter was difficult in the early stages of unionization, when there were no immediately obvious wages benefits because the union had not yet obtained any power.

Union bargaining power derives from the ability of the union to inflict damage on the firm by withdrawing labor. This works when there is no substitute pool of nonunion workers, for example, if there are high labor turnover costs or if the union controls labor supply through entry restrictions or through having high levels of membership relative to the size of the sector. The view that workers have to battle to acquire sufficient power to induce the firm to concede any surplus accords with the Marxist analysis of the capitalist means of production (see, for example, Bowles 1985). Union membership density may play a part in determining the power of the union to extract from the firm a share of any rents. As membership density increases, there is a shrinking pool of workers available to the firm should it choose not to employ union labor. Thus one would expect to find a minimum critical level of membership below which firms would refuse to recognise and bargain with the union (Osborne 1984). Where membership density is crucial to the union's monopoly power as, for example, with the emergence of the general unions, the union must consider how to attract workers at the margin. The basic problem for economists in explaining why workers join a union relates to the free-rider problem, arising because of the collective nature of many of the goods provided by the union (Olson 1965, Booth 1985). Why join the union when union dues are costly, and when the benefits are not immediately available or apply to all workers regardless of their union status? Of course established unions may also provide incentive private goods that encourage workers to unionize. Indeed, a union can act as the workers' agent, since it can reduce the costs of negotiation and processing of grievances, a role which may also be useful to employers (Faith and Reid 1987).

Even if a union controls labor supply, it will not necessarily be able to negotiate a large wage increase relative to the competitive level. The magnitude of the union wage depends crucially on the elasticity of labor demand in that sector. There can be little doubt that, if unions emerge in competitive markets, high union

wages introduce allocative inefficiencies into the economy through the distortion of factor prices. Without unions, allocative efficiency is associated with the equalization of the marginal products of identical factor inputs across sectors. With higher wages in the union sector, union firms employ fewer workers. Displaced union workers crowd into the nonunion sector, lowering wages there. As a result, too few workers are employed in the union sector where output falls, while too many workers are employed, and too many goods produced, in the nonunion sector. There is a deadweight efficiency loss, because the value of marginal products in the two sectors are not identical. In addition, there are distributional issues to consider, and longer run effects due to substitution of capital for labor. Furthermore, in unionized sectors there may be under-investment in capital through the hold-up problem (see, for example, Grout 1984).

This discussion of allocative inefficiency assumes that the union has emerged in an economy characterized by competitive product and labor markets. But there is considerable evidence that, in modern industrialized countries, many product markets are characterized by imperfect competition. Moreover, nonunion firms may also face an incumbent workforce with a degree of bargaining power (Lindbeck and Snower 1988). Thus, even in the absence of unionization, management and workers may be in a situation of bilateral monopoly. An important question (little addressed in the literature) arises as to whether or not the replacement of individual bargaining by collective bargaining generates additional inefficiencies and misallocation of resources in situations where markets were previously not functioning in accordance with the textbook model of perfect competition. The majority of formal trade union models in the literature assume a perfectly competitive product market to allow the models to focus on wage and employment determination in the simplest environment (Dowrick 1989 *inter alia* is an exception). Nonetheless, it is an empirical regularity that imperfections in product and labor markets are correlated (Stewart 1990).

Even within the competitive model, there are arguments suggesting that, in the presence of imperfect information and uncertainty, unions may enhance efficiency. To the extent that unions reduce labor turnover and negotiating costs, they may increase the available surplus to be shared between parties (Freeman and Medoff 1984). Of course, there may be interdependence between the monopoly and efficiency roles of trade unions: unless the union has some bargaining power, it may be unable to increase efficiency.

3. *Formal Modeling of Union Behavior*

To investigate union behavior, the economist needs to model the objectives of the relevant actors involved in wage setting, as well as the means of resolving their potentially conflicting objectives. Most union models consider the objectives of two agents—the union and management. Typically, the government's behavior is assumed exogenous. Because the objectives of union and management may be conflicting, models need to consider how conflicts might be resolved within the constraints provided by the institutional environment. The range of issues covered by collective bargaining in Europe is narrower than in the USA, which probably reflects a relative lack of US social welfare legislation. (In Europe, legislation typically covers issues such as health insurance, pensions, redundancy pay, and unfair dismissal that are often covered by collective agreements in the US.)

While bargaining may take place over a number of issues, for tractability researchers typically concatenate wages and other forms of compensation, such as fringe benefits, under the single heading of wages. Union preferences appear to include employment as well as wages, but it is rare to find instances of the union and the firm bargaining over both wages and employment. Of course, unions affect employment indirectly, not only through increasing wages but also through negotiation over staffing levels, recruitment, and redeployment.

While unions typically have a number of goals (from increasing remuneration to broad political aims concerning the labor movement as a whole), the orthodox union model assumes unions are concerned only with the unionized sector. But a union typically comprises heterogeneous individuals with varying and possibly conflicting preferences as to the union's strategy. For example, there may be principal–agent problems arising because union leaders (agents) have objectives that may conflict with the membership (the principal). The leadership may be better informed than its membership, or perhaps interested in self-aggrandizement or in wider labor goals. Unions are usually large, with complex organizational structures concerned with representation of members' interests and with administration. Because the internal organization of the union is typically hierarchical in structure, the question arises as to how well members' preferences are transmitted through the various levels, each of which may have conflicting aims. Moreover, there is heterogeneity across unions in terms of their structure and constitution (ranging from the democratic through to the totalitarian) that may determine a union's maximizing strategy.

While there is a small literature allowing for union objectives to be affected by membership heterogeneity or a conflict of interests between leaders and members (Farber 1978, Blair and Crawford 1984), the widely used models of union behavior side-step these problems by supposing that all workers in the union sector are identical and are union members. They also assume that the union cares only about the economic welfare of the union sector. For simplicity, union-negotiated

Figure 1
The isoprofit curve

benefits are assumed to be encapsulated in the wages variable. Because the union is also hypothesized to care about the employment of union workers, union objectives can be specified as an increasing function of wages w and employment n.

In most recent union literature, the union is assumed to maximize either a utilitarian objective function, or an expected utility objective function. The utilitarian objective function assumes that the union maximizes the sum of the individuals' utilities. The union comprises identical members treated identically by the union, and therefore in this context no distributional or normative judgments are being made by the utilitarian objective. However, if workers were assumed heterogeneous, the use of this as the union objective would introduce normative judgments (since if individuals were not identical, it would be necessary to consider why the utilitarian social welfare should be adopted instead of some alternatives such as the Rawlsian or Maxi–min criterion, or a more egalitarian approach). If the union's wage-setting behavior results in some union members being unemployed, the utilitarian objective function is:

$$U = nu(w) + (t-n)u(b) \quad w > b;\ 0 < n \leqslant t \qquad (1)$$

where $u(.)$ is a concave (indirect) utility function, w denotes wages, n denotes employment in the union sector, t is the total number of union workers in the sector (and membership by assumption), and b is the alternative sector wage or the unemployment benefit.

The second popular union objective function is the expected utility function. If membership is fixed, Eqn. (1) can be written equivalently in terms of expected utility. Since the union raises wages above the competitive level, each member faces some probability $(1-n/t)$ of being unemployed. If unemployed, a worker receives the alternative sector wage or the unemployment benefit. The expected utility of a representative union member is given by:

$$E(U) = \frac{n}{t}u(w) + \left(1 - \frac{n}{t}\right)u(b) \quad u'(w) > 0;\ u''(w) \leqslant 0 \qquad (2)$$

where $u'(w) = \mathrm{d}u/\mathrm{d}w$. The slope of the union indifference curve in (w, n) space is found by totally differentiating either Eqns. (2) or (3) with respect to w and n, holding (expected) utility fixed, yielding $\mathrm{d}w/\mathrm{d}n = -[u(w) - u(b)]/nu'(w)$

Both the utilitarian and the expected utility objective functions have the implication that identical workers receive different outcomes *ex post*. Employed members receive the union wage, while the unemployed workers receive b. However, if unemployed members effectively leave the union, the leadership will be concerned about future union viability, since there will be a larger pool of nonunion labor that might undercut the union wage, and union income from dues would fall. This is likely to affect union outcomes, and is an argument for inclusion of the level of membership in the union objective function as an endogenous variable. Moreover, b may not be exogenous—the union may affect remuneration for unemployed members through redistribution by benefits or redundancy pay, suitably adjusted for the disutility of work for those in employment. Indeed, historically, many unions paid unemployment benefits to out-of-work members, and some commentators argue that this was important for union growth and survival.

Now consider the behavior of the firm. The necessary conditions for a union to be able to appropriate any surplus in a competitive product market, without driving the firm out of existence, are: very high levels of unionization in a competitive industry, no nonunion foreign competition, entry barriers, and inelastic product demand. Without the first three conditions, domestic firms, or foreign firms, or new firms entering the industry could simply hire nonunion labor and produce at a lower cost than unionized competitors, thereby driving them out of business. Assuming the firm maximizes profits and has no power in the labor market (which means it will take wages as given), it has just one choice variable—employment. The optimization problem facing the firm is therefore:

$$\max_n \pi = pq(n) - wn \quad q'(n) > 0;\ q''(n) < 0;$$
$$q(0) = 0 \qquad (3)$$

where π denotes profits, p denotes product price, and $q(n)$ is the production function characterized by diminishing returns to labor. The firm's wage bill is wn

Figure 2
Inefficiency of the Monopoly Union Model

and capital is held fixed. The slope of the firm's isoprofit curve in (w, n) space is found by totally differentiating Eqn. (3) with respect to wages and employment keeping profits fixed, to obtain $\mathrm{d}w/\mathrm{d}n = [pq'(n) - w]n$. The locus of the turning point of each isoprofit curve traces out the labor demand curve where $pq'(n) = w$, as illustrated in Fig. 1. Two isoprofit curves IP_0 and IP_1 are illustrated in Fig. 2, together with two union indifference curves IC_0 and IC_1.

4. *The Monopoly Union Model*

In the monopoly union model, there is no bargaining between the two parties. Instead, the union acts as a monopolist in the supply of labor and imposes a wage rate on the firm. The firm, however, retains its managerial prerogative to determine the number of workers employed at the union wage. Once the union sets the wage, the firm reads off from the labor demand curve the number of workers to hire at that wage. Thus, a union maximizing the expected utility of its representative worker sets wages as follows:

$$\max_{w} E(U) = \frac{n}{t}u(w) + \left(1 - \frac{n}{t}\right)u(b) \quad \text{subject to} \quad pq'(n) = w \tag{4}$$

The first-order condition can be found directly by equating the slopes of the union indifference curve (giving the union's marginal rate of substitution of employment for wages) with the slope of the labor demand curve, illustrated as point A in Fig. 2. The monopoly union seeks its highest level of utility, subject to the constraint of the firm's labor demand curve, where w^* and n^* are the optimal wage and employment levels. It can be seen, from the first order condition in Eqn. (5), that wages will be set by the union such that the percentage increase in a member's utility due to a percentage increase in wages is exactly equal to the wage elasticity of labor demand ε. Intuitively, this result arises because an increase in wages reduces union employment, and thus each worker faces a greater probability of being unemployed. On the other hand, any member lucky enough to be employed receives a higher wage. Thus, in equilibrium, the percentage marginal benefit is equal to the percentage marginal cost:

$$\varepsilon \equiv -\frac{n'(w)w}{n} = \frac{wu'(w)}{[u(w) - u(b)]} \tag{5}$$

This equation simply characterizes the equilibrium situation. To obtain a specific value for wages, it is necessary to choose explicit functional forms for the utility function and the labor demand function that can then be inserted into the generalized characterization and solved for the wage rate. For evaluation of empirical work attempting to test this model, see Pencavel (1991) and Booth (1995).

Using this model, it is straightforward to show how the wage set by the monopoly union alters due to a change in each of the explanatory variables. An isoelastic increase in labor demand has no effect on wages, but employment increases. An improvement in alternative opportunities increases the union wage, but employment is reduced as we move up the labor demand curve. An increase in membership has no effect on wages or the numbers employed. The empirically testable predictions of the monopoly union model are first that the alternative wage and unemployment benefit should affect wages directly. But employment should be determined by the wage rate, and unaffected by variables measuring alternative opportunities. Second, membership changes should have no impact on the union wage.

5. *The Bargaining Approach*

Next consider more sophisticated methods of reconciling the different preferences of union and management, using a bargaining approach. It turns out that the monopoly union model is nested as a special case within a simple bargaining framework. While some researchers argue that the monopoly union model is a reasonable approximation for particular industries at particular times, observation suggests that wages are more often bargained over by unions and firms. When union and firm bargain over wages, they are in a bilateral monopoly situation, in which a single seller confronts a single buyer of labor. A vital element in this bargaining is the ability of each agent to impose costs on the other agent if it refuses to bargain and engages in a strike or lockout. Although strikes are relatively infrequent, this does not mean that the strike or lockout is unimportant. It is the threat to

withdraw that counts. What induces the two parties to bargain is the threat of facing costs imposed by the other party.

Since the union and the firm are in a situation of bilateral monopoly, additional structure must be imposed on the model to generate a determinate solution of the division of the available surplus between the two parties. There are two broad approaches to modeling bargaining behavior—the axiomatic or Nash bargaining approach, and the more recent game theoretical approach (Nash 1950). Under certain conditions, these generate identical predictions in spite of the fact that they proceed from very different assumptions (Binmore et al. 1986).

The solution concept widely used in the union literature is the generalized Nash bargaining solution, according to which wages are determined by maximization of the product of each agent's gains from reaching a bargain, weighted by their respective bargaining strengths. Since management is assumed to retain the right to determine employment unilaterally, this is referred to frequently as the 'right-to-manage' model. Define a status quo or fall-back point for each party as its position if no bargain is reached. For the firm, the status quo is zero, because if it does not reach a bargain with the union workforce, it cannot obtain any other workers since there are no nonunion workers in the sector. So the firm's net gain is simply its profits function. For the union, its status quo for a representative member is $u(b)$, since that is what a member will receive if no bargain is reached. Thus, the net gain to the union is simply the expected utility of a representative member (see Eqn. (2)) less fall-back utility, given by $[u(w)-u(b)]n/t$.

The generalized Nash bargaining solution (the product of the weighted net gains to each party) can be written as:

$$\max_{w} B = \left\{ \frac{n}{t}[u(w)-u(b)] \right\}^{\beta} \{pq(n)-wn\}^{1-\beta} \quad (6)$$

where β measures the bargaining strength of the union and $(1-\beta)$ is the bargaining strength of the firm. The solution to this bargaining problem is obtained from the first order condition of Eqn. (6), and is given by:

$$\frac{\beta w u'(w)}{u(w)-u(b)} = \beta\varepsilon + \frac{(1-\beta)wn}{pq(n)-wn} \quad (7)$$

where ε is the wage elasticity of labor demand. The left-hand side of Eqn. (7) represents the proportional marginal benefit to the bargain from a proportional increase in the wage. Since only the union receives this benefit, it is weighted by the union's bargaining power β. The first term on the right-hand side is the union's proportional marginal cost (the percentage reduction in employment due to the proportionate wage increase) weighted by union power β. The second term on the right-hand side represents the firm's proportional marginal cost, weighted by the firm's power $(1-\beta)$. If the union has all the power, $\beta = 1$ and the union extracts the entire surplus—the right to manage model collapses to the monopoly union model. For $0 < \beta < 1$, the employment and wage outcome will lie on the labor demand curve anywhere between the monopoly union extreme and the competitive outcome. If the firm has all the power, $\beta = 0$ and the wage is then simply the alternative wage b.

The empirically testable predictions of the right-to-manage model are the same as a monopoly union model with the addition of the prediction that variables proxying union strength will affect wages directly.

Is the right-to-manage model Pareto-efficient? (Pareto efficiency is defined by economists as a situation where no one can be made better off without making someone else worse off.) Or can at least one party be made better off by shifting to some other (w, n) pair? In Fig. 2, the isoprofit curves IP represent different levels of profits for the firm, with higher curves denoting lower profits since they are associated with higher wages. IC denotes the union indifference curves, with expected utility increasing as the union moves northeast. Suppose the equilibrium of the right-to-manage model is at point A. The union could be made better off while keeping the firm on the same isoprofit curve, by shifting to point B. Alternatively, the firm could shift to a higher isoprofit curve, while keeping the union on the original indifference curve, by moving to point C. Both parties could be made better off by shifting from A to any point in the shaded area. Positions on the labor demand curve are thus Pareto-inefficient. Either the union or the firm could be made better off by bargaining over employment as well as wages, allowing them to shift from a point such as A to B or C or anywhere in the shaded area. Efficiency in the context of this model is where the marginal rates of substitution of employment for wages, for both union and firm, are equal.

6. *The Efficient Bargaining Model*

Now suppose the union and firm simultaneously determine wages and employment. While evidence suggests that unions and firms do typically not bargain over wages and employment, this approach has been important in the union literature because of its efficiency property beloved by economists. But the fact that this does not appear to happen in practice suggests that there may be something economists are missing in their modeling. (Of course the wage and employment outcome predicted by the efficient bargaining model is inefficient from the viewpoint of society as a whole.)

Efficiency requires only that one party's welfare be maximized subject to an arbitrarily fixed level of welfare of the other. This makes it possible to characterize an efficient outcome simply by consider-

ing union and firm preferences, without imposing a particular bargaining structure. While this does not yield a unique outcome, it illustrates the necessary conditions for efficiency. An efficient bargain over (w, n) solves:

$$\max_{w,n} pq(n) - wn \quad n \geqslant 0; \; w \geqslant b$$

$$\text{subject to} \quad \frac{n}{t}[u(w) - u(b)] + u(b) = \bar{U} \qquad (8)$$

From the first-order conditions is obtained the result that an efficient (w, n) pair is given by equating the marginal rates of substitution of employment and wages for the union and the firm. This means equating the slopes of the isoprofit and union indifference curves, as illustrated as point C in Fig. 2, and shown below:

$$pq'(n) - w = -\frac{[u(w) - u(b)]}{u'(w)} \qquad (9)$$

The contract curve is defined as the locus of all points satisfying Eqn. (9). Two points on the contract curve are B and C in Fig. 2. The contract curve is positively sloped for risk-averse workers (but vertical if workers are risk-neutral). From Eqn. (9), note that the value of the marginal product of labor $pq'(n)$ is less than the wage rate, by an amount that is equal to the marginal rate of substitution of employment for wages. Hence, the contract curve lies to the right of the labor demand curve for $w > b$. If $w = b$, then from Eqn. (9) $pq'(n) = w$, the perfectly competitive result. Thus, the contract curve and the labor demand curve coincide where $w = b$. Since for efficiency we only require that one party's welfare be maximized subject to any arbitrarily fixed level of welfare of the other, any point on the contract curve represents an efficient outcome for a particular arbitrarily fixed level of welfare of one agent.

To determine a unique (w, n) pair, a means of obtaining a particular solution to the bargaining procedure must be added to the model. A common approach is to use the generalized Nash bargaining model of Eqn. (6) modified to allow for bargaining over both w and n. The solution to this maximization problem generates a determinate outcome for wages and employment, which lies somewhere on the contract curve (Leontief 1946, McDonald and Solow 1981). In the 1980s considerable attention was devoted to devising ways of testing which model was appropriate for the union sector (Pencavel 1991).

Many unions are unable to bargain over employment directly, and thus the relevance of this fully efficient model might be questioned. However, unions can often affect employment indirectly, for example, through bargaining over the labor-to-capital ratio, work intensity, or redundancy payments. Johnson (1990) find that, in models in which there is bargaining over wages and the labor-to-capital ratio or work intensity, the wage-employment outcome lies somewhere between the fully efficient and the right-to-manage model.

7. *Conclusions*

This article can only give a flavor of the economics behavior of the trade union, and many important topics have been omitted, for example, the impact of unionization on the macroeconomy (Layard et al. 1991). Other important topics omitted (but covered in Booth 1995) include the economics of strikes (see *Dispute Resolution in Economics*), the relationship between unions and hours of work, and the modeling of endogenous union membership, an important topic in countries such as the UK, in which compulsory union membership is illegal. There is also a vast empirical literature estimating the impact of unions on economic performance (see *Trade Unions: Empirical Analyses*).

What areas are currently being investigated by economists working on unions? Some recent developments include combining ideas about oligopolistic firm behavior with a unionized labor market in a dynamic framework. While it is too early to see where this literature is heading, this approach might possibly be instructive about appropriate forms of collective bargaining structure. Some countries (such as many European economies) have centralized wage bargaining arrangements, while others such as the US are decentralized. It is important that these institutional differences are incorporated into the modeling framework. Calmfors and Driffill (1988) model the impact of collective bargaining structure on economic performance, while Horn and Wolinsky (1988) model choice of collective bargaining structure. These approaches could in principle provide pointers as to what an 'ideal' collective bargaining structure might be.

While union membership and power have declined in many industrialized countries in the 1980s and 1990s (for example, Britain and the US), it is unlikely that unions will vanish all together. Indeed, in the future unions may well become stronger in Eastern European, Asian, and African countries. It is therefore important for researchers working on the economics of trade unions to consider what form of unionism might be least distortionary in a modern economy. Moreover, while many models of union behavior refer to explicit labor contracts between a union and management, the models are also relevant to a wider class of situations than those in which a union explicitly represents workers. The models are potentially applicable, with only a few minor modifications, to nonunion labor markets where incumbent workers have some market power and where the firm has economic rents that might be shared.

Trade Unions: Empirical Analyses

A common definition of a trade union is that it is an association of workers who bargain collectively with their employer regarding the terms and conditions of employment. Empirical analysis of trade unions falls largely into four related categories:

(a) Unions as maximizing agents.

(b) The bargaining process: strikes and labor disputes.

(c) The effect of unions on wages.

(d) The determination of union membership.

Category (a) is covered in *Trade Unions, Economic Behavior of*, and category (b) in *Dispute Resolution in Economics*. This article is organized around discussions of categories (c) and (d), the effect of unions on wages and the determination of union membership, respectively. The discussion will rely on the (admittedly atypical) institutional arrangements that exist in the United States, but the key points are applicable more generally to unions in market economies. The discussion is necessarily selective, and it is meant to give an overview of a very substantial literature.

1. The Effect of Unions on Wages

1.1 Unions and Wages: What is Measurable?

Lewis's (1963) classic monograph set the standard for empirical analysis of the effect of unions on wages using aggregate (e.g., industry-level) data. As individual level data became available beginning in the late 1960s, a substantial literature, surveyed comprehensively by Lewis (1986), developed, addressing this same question using the new data. Other useful surveys of this literature are continued in Freeman and Medoff (1984), Hirsch and Addison (1986), and Booth (1995).

There are at least two levels on which unions can affect wages in an economy. The first is the direct effect of unions on the wages of workers in jobs where wages are set through collective bargaining (for nonmembers as well as members). The second, and less well understood, level is that the presence of unions in an economy can change the level and distribution of wages generally. For example, unions can raise the wages of their members, but the wages of nonunion workers can fall or rise as well. A standard competitive market model would imply a fall in the wage of nonunion workers. The mechanism is that unions, in raising wages of their members, cause a decline in employment in the union sector. The result is an increase in the supply of workers to the nonunion sector as displaced union workers move to that sector, implying a drop in the nonunion wage rate, called the 'spillover effect' of unions. A force working to raise

nonunion wages is the so-called 'threat-effect' of unions. The threat effect results from nonunion employers raising the wages of their workers in order to avoid becoming unionized (Rosen 1969, Freeman and Medoff 1981). Thus, based on theoretical considerations, the effects of unions on aggregate wages in an economy are not clear.

In order to be more precise, define the effect of unions on the wages of union and nonunion workers respectively as:

$$\Delta_u = \frac{W_u - W_0}{W_0} \tag{1}$$

and

$$\Delta_n = \frac{W_n - W_0}{W_0} \tag{2}$$

where W_u and W_n represent the union and nonunion wage, respectively, and W_0 represents the wage that would have prevailed in the absence of unions in the economy. It is not possible to estimate either of these wage effects because W_0 is not observable.

The union–nonunion wage differential, called the union wage gap, and defined as:

$$\Delta = \frac{W_u - W_n}{W_n} \tag{3}$$

is estimable and is related to the underlying union and nonunion wage effects by:

$$1 + \Delta = \frac{1 + \Delta_u}{1 + \Delta_n}. \tag{4}$$

As long as all differentials are small (less than 0.25 or so), this expression is usefully approximated by

$$\Delta \approx \Delta_u - \Delta_n. \tag{5}$$

This relationship states that the measured union wage gap is approximately equal to the difference in the proportional effects of unions on the union and nonunion wage.

The union wage gap, defined in Eqn. (3), can be approximated usefully by the difference in log wages. This implies that:

$$\Delta \approx \ln(W_n) - \ln(W_n) \tag{6}$$

and estimation of this quantity is the goal of much of the empirical literature on the effects of labor unions.

The union wage gap reflects a combination of effects. Clearly, it includes the direct effect of unions on the wage of unionized workers, and it includes the offsetting effects, described above, of unions on the wage of nonunion workers. It is not possible to parse estimates of the union wage gap into its component effects, and estimates of Δ have been interpreted broadly as the effect of unions on wages.

A further complication is that workers are heterogeneous and only a single wage is observed for each worker: the union wage for union workers, and the nonunion wage for nonunion workers. If both wages were observed for workers, then calculation of Δ would be straightforward. But workers make choices regarding whether to seek union or nonunion employment, based in part on the wage they would receive in each sector. Thus, union status is endogenous to wages, and the result is a classic selection bias problem that has been treated extensively in the literature. In the presence of this selection bias, the value of Δ estimated from a standard cross-section of workers can be interpreted as the average difference in wages between union and nonunion workers, but it cannot be interpreted as the effect of union membership on the wage of a particular worker.

1.2 Estimating the Union Wage Gap

Trade unions have been characterized variously as organizations whose operational goals have been to 'take wages out of competition,' to impose a 'standard rate,' and to attach wages to jobs rather than to workers. This characterization has important implications for who will be union members and, hence, for the estimation of the effect of union membership on wages.

The standard approach to estimation of the union–nonunion wage gap using individual-level data is to estimate by OLS:

$$\ln W_i = X_i\beta + \delta U_i + \varepsilon_i \tag{7}$$

where i indexes individuals, X_i is a vector of worker characteristics including such skill measures as education and labor market experience, U_i is a dummy variable indicating union membership, and ε_i is a random component. The parameter δ represents the average proportional difference in wages between union and nonunion workers adjusted for measured differences in worker characteristics, and it is the regression adjusted analogue of Δ. Most estimates of δ are in the 0.1–0.25 range.

A central problem with this approach is that it constrains the marginal effect of skill on earnings to be the same in both union and nonunion jobs. Given that unions tend to 'standardize wages' and 'attach wages to jobs,' it is likely that the function characterizing the earnings of union workers will be flatter in skill dimensions than the function for nonunion workers. Specifying separate earnings functions for the two sectors yields:

$$\ln W_{ni} = X_i\beta_n + \varepsilon_{ni} \tag{8}$$

for nonunion workers, and:

$$\ln W_{ui} = X_i \beta_u + \varepsilon_{ui} \tag{9}$$

for union workers. The usual modus operandi of unions implies that $\beta_u < \beta_n$ in skill dimensions such as education and experience. Since wages are tied less closely to individual characteristics in the union sector, and since the X_i vector consists largely of individual characteristics, the R^2 from cross-sectional estimation is generally smaller for the union earnings function than for the nonunion earnings function. It is also the case that the residual variation in earnings is smaller in the union sector than in the nonunion sector, again likely the result of standardization. Bloch and Kuskin (1978) were among the first to estimate separate union and nonunion earnings functions, and to note the systematic differences. Separate earnings functions imply that the estimated union–nonunion wage gap varies with worker characteristics such that the estimated union wage gap is declining in skill.

Ordinary least squares estimates of nonunion and union earnings functions, such as Eqns. (8) and (9) provide evidence consistent with the standardization-of-rates view of union wage setting. Table 1 contains estimates of nonunion and union log-earnings functions based on data from the outgoing rotation groups of the 1999 US Current Population Survey. These regressions control for age, education, sex, marital status, the interaction of sex and marital status, and sector of employment (private vs. public). The general character of these estimates is consistent with the large number of similar estimates that have appeared in the literature since the 1970s.

With respect to education, the most important skill measure, the college–high school wage differential is 22 log points (25 percentage points) larger in the nonunion sector than in the union sector. Thus, skill is rewarded more in the nonunion sector, and the union wage gap is considerably larger for less-skilled workers. This is a consistent finding in the literature on the union wage gap.

Additionally, other personal characteristics are of lesser importance in the union sector. Nonwhites in nonunion jobs earn about 8.2 percent less than whites, while nonwhites in union jobs earn about 6.1 percent less than whites. This confirms the earlier work of Ashenfelter (1972, 1978) that the union wage gap is larger for nonwhites than for whites. Married males in the nonunion sector earn 21 log points (23.5 percent) more than single males, while the marital status differential is only 9.5 log points (9.9 percent) in the union sector.

One apparently anomalous result is that the sex differential in wages is *larger* in the union sector than in the nonunion sector. This is due to the fact that females are substantially segregated in particular occupations, both within and outside the union sector.

The union wage gap varies with other measures of job and worker characteristics that are not included in the estimates in Table 1. The union wage gap differs substantially across occupations, with relatively large wage gaps in the less-skilled occupations. This is a manifestation of the organization of unions in the United States along industrial lines, and the standardization of wage rates in the union sector. It also appears that the union wage gap varies inversely with firm size. Workers in small firms receive a large wage advantage from unionization, while workers in larger firms receive a much smaller advantage. Given that unions are more common in large firms than in small firms, this might reflect the well-known firm-size wage differential where large firms pay higher wages than small firms (Brown and Medoff 1989).

Overall, existing estimates suggest a substantial positive union wage gap for most workers. The raw (not regression adjusted) union wage gap in the data used in Table 1 is 28.5 log points (33 percentage points). The wage gap for a single 40-year-old white male high school graduate predicted by the estimates in Table 1 is 38.6 log points (47 percentage points). This declines sharply as education increases, falling to 16.4 log points (17.8 percentage points) for an otherwise-similar college graduate, but it remains

substantial and positive. The wage gaps are smaller for otherwise-similar married males, falling to 27 log points (31 percentage points) for married high-school graduates, and to 4.8 log points (4.9 percentage points) for married college graduates.

Other evidence consistent with the standardization-of-rates view is that regression mean squared error is larger in the nonunion sector than in the union sector. This suggests that unobservable characteristics of workers are more important in wage determination in the nonunion sector than in the union sector. It is also the case that the R^2 of the estimated earnings function is considerably larger in the nonunion sector than in the union sector, which is also consistent with the view that observable individual characteristics are a relatively more important determinant of wages in the nonunion sector than in the union sector.

The standardization of wages in the union sector, and the concomitant lower variation in wages in the union sector implies that unions reduce the overall dispersion of wages. A force for increased dispersion as a result of unions is the potential decline in the nonunion wage as the union wage increases and the supply of labor to nonunion jobs increases. Freeman (1980a) analyzed the effect of unions on the dispersion of wages, and he concluded that, on balance, unions reduce the aggregate level of wage dispersion. Card (2001) finds that 15 to 20 percent of the increase in male wage inequality in the United States between 1973 and 1993 can be accounted for by the decline in union membership.

The substantial variation in the union wage gap, particularly by worker skill level, has important implications for worker preferences for union representation, and for employer hiring decisions. A reasonable inference, made explicit in the next section, is that the union status of workers is related to skill, both observable and unobservable. This implies that union status is endogenous to the determination of wages, so that OLS estimates of the union wage gap are likely to suffer from selection bias.

1.3 The Non-wage Effects of Unions

In addition to the work of the effect of unions on wages, there has also been substantial research on the effect of unions on non-wage aspects of employment. This literature is surveyed by Freeman and Medoff (1984), and by Hirsch and Addison (1986). Some of the findings are:

(a) union members receive a larger fraction of their compensation in the form of fringe benefits such as health insurance and pensions (Freeman 1981);

(b) workers in union jobs are less likely to quit, reflecting the higher level of wages and benefits. Freeman (1980b) suggests that this is due to union provision of a mechanism for 'voice' as an alternative to 'exit' in addressing workplace concerns; and

(c) workers in union jobs are more likely to be laid off, reflecting the fact that union employers cannot adjust wages in the short run in response to demand shocks (Medoff 1979).

2. The Determination of Union Status of Workers

There are two components to the determination of union status of workers. First, workplaces must become organized by trade unions. In the United States, the presumption is that workplaces are not unionized, and it generally takes a substantial effort on the part of workers and unions to organize the workplace. However, once the workplace is organized and a contract is negotiated, the terms and conditions of employment of all workers, present and future, are determined through negotiation between the union and the employer. This organization process effectively sets the stock of union jobs in the economy, and it is largely determined by past organization activities.

The second component of the determination of a worker's union status is the individual decision regarding whether to seek a job in a union or nonunion workplace. Taking a job in a unionized workplace is essentially costless (other than the payment of a modest initiation fee and the regular payment of dues), and does not involve any investment in organization.

2.1 The Worker-choice Model

Early empirical analyses of the union status of individual workers (e.g., Lee 1978) relied on a model (the worker-choice model) where the stock of union jobs was not taken as a binding constraint, and where individual workers compared their utilities in union and nonunion employment and selected the sector that yielded the highest utility. In order to focus the discussion, consider a worker-choice model where unions affect only the wage received by workers but where the effect on the wage can differ across workers. Let each worker i have a nonunion wage of W_{ni}, and a union wage of W_{ui}, so that the wage advantage to workers i of being in the union is $V_i = W_{ui} - W_{ni}$. Given a cost of union membership of C_i, worker i is unionized if $V_i > C_i$, and is nonunion otherwise.

This simple model has direct implications for the composition of the union sector. Abstracting from differences across workers other than in skill, suppose that the earnings of worker i in a nonunion job are defined by:

$$\ln W_{ni} = \beta_0 + \beta_1 S_i + \beta_2 \mu_i + \varepsilon_{ni} \qquad (10)$$

and that the earnings of worker i in a union job are defined by:

$$\ln W_{ui} = \gamma_0 + \gamma_1 S_i + \gamma_2 \mu_i + \varepsilon_{ui} \tag{11}$$

where S_i is an observable measure of skill, μ_i is an unobservable measure of skill with mean zero, and the εs are random components. The βs and γs are parameters. The worker-choice model of union status determination implies, using Eqns. (10) and (11), that workers are unionized if, and only if,

$$V_i = (\gamma_0 - \beta_0) + (\gamma_1 - \beta_1) S_i + (\gamma_2 - \beta_2)\mu_i + (\varepsilon_{ui} - \varepsilon_{ni}) > C_i. \tag{12}$$

To the extent that unions raise the wages of at least low-skilled workers, it is the case that $\gamma_0 > \beta_0$. The characterization of unions as standardizing pay implies that the marginal effect of both observed and unobserved skill on wages is likely to be greater in the nonunion sector than in the union sector ($\beta_1 > \gamma_1$ and $\beta_2 > \gamma_2$). The clear implication of the worker-choice model is that the union sector will be composed disproportionately of less-skilled workers. Consistent with this, Farber and Saks (1980) find that the likelihood that a nonunion worker will desire union representation is related inversely to the worker's position in the earnings distribution of the potential bargaining unit being organized.

The worker-choice model of union status determination implies a standard binomial discrete choice specification, such as a linear probability, probit, or logit model. While Lee (1978) made the structural formulation explicit, most others who have estimated binomial discrete choice models of union status determination are not clear about the foundations and consider the specification a reduced form. Hirsch and Addison (1986) attempt to interpret a variety of estimates of models such as this in the context of the worker-choice model.

2.2 The Queuing Model

A more realistic model of the determination of the union status of workers takes account of the fact that not all workers who desire union employment can find union jobs. This is because, as noted above, workplaces are costly to organize, but, once organized, remain so into the indefinite future. The result is that there will be workers who would desire employment in an already-unionized workplace but who would not be interested in undertaking organization themselves.

Denote the cost of organizing an unorganized workplace by C_o and the cost of taking a job in a existing unionized establishment by C_e so that $C_o > C_e$. Then a worker will desire a job in a unionized establishment when $V_i > C_e$, but a worker will be willing to invest in organization activity only when $V_i > C_o$. Since the organization decision is what determines the stock of union jobs, there will be workers who would like an existing union job but who are unwilling to invest in organization themselves. These are the workers for whom $C_e < V_i < C_o$. The result is that there will be more workers who desire an existing union job than there are union jobs available. Thus, there is likely to be excess demand by workers for existing union jobs, resulting in an implicit queue. Aside from some unions of skilled trades workers, union employers in the United States are free to hire workers of their choosing to fill vacancies. Thus, the union status of a given worker is the result of decisions by both the worker and union employers (Abowd and Farber 1982, Farber 1983a).

The queuing model also has important implications for estimating models of the union status of workers. A worker will be in a union job only if the worker prefers union employment to nonunion employment *and* a union employer hires the worker. As in the worker-choice model, the most skilled workers are less likely to want a union job. But the standardization of wages reduces the marginal cost of skill to employers, so that union employers will want to hire the most skilled workers from among those workers who desire a union job. Thus, union workers will be those in the middle of the skill distribution. The most skilled will not want union jobs, and the least skilled will not be hired by union employers. This selection process could account for at least part of Freeman's (1980a) finding that there is less dispersion of earnings in the union sector.

Empirical implementation of the queuing model requires a bivariate discrete choice model in order to capture both employer and worker decisions. Identification is a potential problem because it is not known *a priori* whether nonunion workers are nonunion because they did not desire a union job, or because they were not hired by a union employer. Farber (1983a), Farber (1990), and Farber and Krueger (1993) use several US surveys on preferences of nonunion workers for union representation to provide this information.

2.3 Implications for Estimation of the Union Wage Gap

Regardless of which model of union status determination is appropriate, applying standard OLS techniques to the estimation of the union wage gap using either Eqn. (7) or Eqns. (8) and (9) will yield biased estimates of the key parameters. Both models imply that workers' union status is determined at least partly on the basis of unobservable skills (μ_i), so that there will be classic 'selection bias.'

In the context of the worker-choice model, less-skilled workers are more likely to be union members, so that workers in union jobs are more likely to be those with low values of μ_i relative to workers in

nonunion jobs. The result is that OLS will yield a downward-biased estimate of the effect of unions on the wage of a particular worker.

The effects of the double selection implied by the queuing model on OLS estimates of the union wage gap is not clear. The two selection processes appear to have offsetting effects on the estimated wage gap, with the worker selection implying a negative bias, and the employer selection implying a positive bias.

Two general approaches have been used to address the problem of selection bias in estimating the union wage gap. The first approach is to model union status determination simultaneously with earnings, and to estimate an econometric model that takes account of the simultaneity. However, this requires strong assumptions regarding functional form of the distribution of the errors in the earnings and union status determination functions. Virtually all existing work proceeds using a two-step estimator where the earnings functions and the union status determination function are assumed to have errors that are jointly normal. Lewis (1986) surveyed most of the studies that used this general approach, and he concluded that the specific results are unreliable and depend heavily on arbitrary assumptions regarding functional form and untestable exclusion restrictions (variables assumed to affect union status but having no direct effect on earnings).

The second approach relies on repeated observations on wages for individuals who change union status (Freeman 1984). Thus, both union and nonunion wages are observed for these workers, and the difference in wages for these individuals can be thought of as their union wage gap. However, this approach relies on the strong assumption that the probability of switching sectors is not related to unobservable skill.

Another problem with the use of longitudinal data in the context of difference or fixed effects models is that there is error in the classification of workers as union or nonunion. Card (1996), based on data from the January 1977 Current Population Survey (Mellow and Sider 1983) estimates that the misclassification rate of union status in the CPS is approximately 2.7 percent. Even this relatively low rate of misclassification implies that the number of changes in union status will be overstated substantially. It is well known that measurement error is a more serious problem in estimating fixed effect or difference models than in estimating standard levels models. The result is that estimates derived using longitudinal data can be subject to substantial attenuation bias (bias toward zero). Even relatively low rates of misclassification of the key union status change variable imply that estimates of the union wage gap derived using fixed effect or difference models are likely to be biased downward substantially. Lewis (1986) presents a full discussion and analysis of this problem. He finds that the estimates derived using these techniques are substantially smaller than those derived using cross-section data, and he attributes this to measurement error bias.

H. S. Farber

Tradition, Anthropology of

Few concepts have played a more central role in the development and practice of anthropology than tradition. We will first outline the principal senses in which tradition figures in anthropological thought, then trace the historical foundations of these contemporary usages, and conclude with the major lines of inquiry centering on tradition in contemporary anthropology.

1. *Tradition as Substance, Process, Practice*

In its most general usage, tradition may be defined as the element of historical continuity or social inheritance in culture, or the social process by which such continuity is achieved. More substantively, tradition refers to the collective social inheritance of particular people, culture, society, group, or collectivity, and as such, stands as the referent of its collective identity. In this sense, tradition is generally conceived of as the aggregate mass of cultural forms—cast as knowledge, beliefs, practical routines, or texts—that are the constituent elements of a culture, handed down from one generation to the next. One may speak also of 'a tradition' as any discrete element or trait within the general mass. Here, tradition takes on the sense of an inherent quality of the past which is diagnostic of traditionality; hence, 'a traditional practice,' 'a traditional belief,' 'a traditional tale,' and so on. So conceived, a tradition assumes the guise of a durable natural object, passed down through time by successive generations of 'culture bearers.'

A more concrete and practice-centered understanding of tradition recognizes that the temporal continuity of tradition is instantiated in successive enactments of cultural forms that are guided by precedent and convention and construed as replicating, in some essential sense, what has been done before. When the focus is on the dynamics of tradition, the process of handing down, or intergenerational transmission, the element of social learning is often emphasized, whether under the rubric of enculturation, which foregrounds the acquisition of cultural knowledge, or the now preferred socialization, which foregrounds the social matrix of the acquisition process.

The conjoint consideration of socialization and tradition tends to foster a conception of intergenerational transmission as the replication of uniformity, in Anthony F. C. Wallace's (1970) apt phrase. This orientation points to what is perhaps the most common theme in anthropological considerations of tradition, that is, its normative force, the notion that tradition enjoins conformity. The binding force of tradition is variously attributed to the force of precedent or habit inherent in the routinized quality of replicated practice, the psychological pressure attendant upon deviating from accustomed modes of thought and action, the moral weight of public opinion, and—most strongly—the power of a coercive apparatus of external sanctions sustained by sacred mandate (as from the ancestors) and intensified by ritual enactment. Where such discriminations are made systematically, they are generally marked by terminological distinctions, as between custom and tradition, with tradition reserved for the most strongly sanctioned and ritualized elements of the social inheritance. In general, however, there is little definitional rigor or regularity of terminological usage in the field; as often as not, terms such as tradition, custom, or folkways are employed as loosely equivalent. In such systematization, again, tradition may be distinguished from law, the former deriving its force from 'the sanctity of immemorial traditions,' the latter from 'the legality of enacted rules,' in Max Weber's classic formulation. Others, however, such as Bronislaw Malinowski, take custom and tradition as more or less equivalent, but argue that certain traditions, those surrounded by supernatural sanctions and sustained by coercive machinery, are the functional equivalent of law in 'primitive' societies.

Perspectives also vary in regard to how they frame the locus of traditional authority. One line of inquiry focuses on epistemological issues, emphasizing the binding force of traditional modes of thought, characterized by a purported resistance to or incapacity for rational, reflective, critical, or skeptical stances toward knowledge and belief. In a related vein, the emphasis may fall on the behavioral correlates of such epis-

temological conservatism, manifested in traditional patterns of 'tried and true,' naturalized modes of action and in ritual. A third line maintains a discursive focus, concentrating on authoritative discourse; here, authority is vested in the weight of ancestral and collective truth expressed in oft-repeated, socially resonant texts, such as proverbs, myths, or legends. Finally, we may identify a sociopolitical frame of reference, which is primarily concerned with traditional authority as vested in particular statuses or roles, such as elders (by virtue of their accumulated knowledge and the historical reach of their experience into the past) or ritual specialists (who control the coercive machinery of supernatural sanctions), whose claims to authority rest upon their connection to an authorizing past. These distinctions are analytical; much work, both theoretical and substantive, explores dimensions of inter-relationship among these loci of traditional authority.

2. *Tradition and the Construction of Modernity*

The roots of the anthropological preoccupation with tradition lie in the seventeenth and eighteenth centuries, in the epistemological challenges of enlightenment empiricism, the religious overturning of the Protestant Reformation, and the interpretive explorations of classical and biblical philology. Enlightenment philosophers, such as Bacon and Locke in the UK and Condorcet in France, insisted that the rational, empirical pursuit of true knowledge required a throwing off of traditional authority, which demands the surrender of one's capacity for independent thought and renders one incapable of making new contributions to knowledge.

Baconian natural philosophy and the concomitant enlightenment ideology of progress were foundational to the development of antiquarianism in the late seventeenth and eighteenth centuries. Antiquities were the etiolated remnants of past ways of thinking, acting, and conveying knowledge that were 'derived down' uncritically into the present, shorn of their original meaning and functional coherence. In this sense, the notion of antiquities anticipates E. B. Tylor's concept of survivals. Only by rigorous historical investigation of their origins could they be fully revealed as irrational survivals of 'old customs' and expunged from modern life. For Protestant reformers, the remnants of old 'heathen' and 'Romish' 'superstitions,' handed down to the credulous members of the populace by 'custom,' 'tradition,' and 'hearsay,' were likewise to be revealed by historical investigation and extirpated from modern life. There was a clear sociological component to the antiquaries' and reformers' antiquarian programs as well, identifying the 'vulgar' classes, country people, the elderly, the uneducated, and women (as in 'old wives' tales') as the segments of the population among whom the survivals of past error were most likely to persist, thus, in effect, constructing a set of social 'Others' within contemporary society who were to be the special targets of tradition-oriented antiquarian investigation.

The development of eighteenth-century classical and biblical philology was stimulated by the literary battles of the Ancients and the Moderns, contesting the proper basis of contemporary literary production. This line of inquiry had a textual and interpretive focus: to render ancient and exotic texts, like the Homeric epics and the Hebrew Old Testament, intelligible, coherent, and meaningful to contemporary readers and to secure their canonical status and value. This interpretive approach combined a kind of proto-relativism, reading the texts as shaped by the social, cultural, and linguistic milieu of ancient Greece or Israel—that is, as the inspired expressions of a nation—with a species of conjectural history, in terms of which the ancient texts were characteristic expressions of an early stage in the development of human society. One of the most significant methodological consequences of this approach was to motivate the use of data from living cultures—chiefly peoples of 'the Orient,' such as Arabs, Turks, East Indians—viewed as developmentally behind their modern European contemporaries, to illuminate the archaic cultures reflected in the Homeric epics and the Old Testament. These peoples of the East, then, took on the guise of exotic 'Others,' living exemplars of a 'rude' and 'primeval' age, bound by tradition rather than by an ideology of progress, reliant on oral communication rather than literacy, credulous and emotional rather than rational, and so on.

In a sweeping synthesis and extension of the philologists' program and a critical counterstatement to the social contract theories of enlightenment political philosophers, the German political philosopher, Johann Gottfried Herder argued that the authentic foundation of a viable polity is the poetic tradition of its people, made up of the inspired expressions of its poets—who are also its 'lawgivers'—who give voice to the spirit of the Volk, rooted in its particular time and place. This intertextually constituted tradition became 'the archive of the people,' the principal expression of national identity, the mechanism of its cultural cohesion and continuity, and the charter for its social and political life. In the most general sense of the term, Volk designates a nation, a people in its organic wholeness, but it may also designate that portion of a more complex, stratified society that remains grounded in its inherited language and traditions and still open to poetic feeling, as distinct from those who have been distanced from their traditions and feelings by over-rational refinement, the alienation of writing, or the adoption of foreign languages and alien ways. In Herder's (see Bauman and Briggs 2000) intellectual synthesis, then, a precursor to Boasian anthropology, tradition is most powerfully operative in simpler, premodern, community-based societies and in those

sectors of complex modern society in which a sense of community cohesion, the emotionally resonant ties of locality, kinship, and attunement to the national spirit still prevail.

Herder's thought was influential in the emergence of Romanticism, which was also inflected by the violent upheavals of the French Revolution. One response to the Revolution took the form of a conservative reaction, in which the sanctity of tradition and the cohesive force of kinship, religion, customary law, rootedness in place, and traditionally founded hierarchy were valorized as the essence of an authentic national character and a viable and moral polity. What is noteworthy, however, is that traditionalist conservatives tended to see the trajectory of change in the same terms as the rational reformers, framing an oppositional contrast between tradition and modernity. This contrast, convergent with jurisprudential investigations and symbolic constructions of 'customary law,' became the core of the classic typological tradition in social thought out of which emerged the modern social disciplines, including anthropology, in which the force of tradition served as a defining criterion of social types.

By the latter half of the nineteenth century, the foundational ideas we have summarized coalesced in a series of typological syntheses aimed at comprehending the broad historical trajectory of human social and cultural development and at providing a classificatory framework of social formations based upon stages of evolutionary progress. Whether framed in terms of ideal types, developmental continua, or evolutionary stages, these magisterial syntheses all accorded a defining or diagnostic role to tradition in the construction of contrastive social types. E. B. Tylor (1960 [1881]), for example, in contrasting 'savage' and 'civilized' man, ascribes the former's intellectual conservatism and aversion to change to his 'tendency … to consider his ancestors as having handed down to him the perfection of wisdom.' Ferdinand Tönnies (1988 [1887]), in basing his classic distinction between Gemeinschaft and Gesellschaft on contrastive forms of common will, characterizes the 'natural will' that predominates in Gemeinschaft societies as becoming naturalized 'through practice and tradition.' Emile Durkheim, in outlining the contrast between mechanical and organic solidarity, attributes the authority of the collective conscience in mechanically solidarity societies to 'the authority of tradition.' Max Weber, in constructing his three pure types of legitimate domination, maintains that 'the validity of a social order by virtue of the sacredness of tradition is the oldest and most universal type of legitimacy.' These and related formulations served to crystallize the notion of 'traditional society' as a typological category, intellectually and behaviorally conservative, bound by an unreflective and unquestioning adherence to traditional ways and submission to traditional authority, and slow to change, in contrast to 'modern society,' dynamic, impelled by the exercise of reason and rationally motivated innovation, and open to change. This typological contrast has proven remarkably durable, persisting to the present day as an orienting framework in the social disciplines, not least in anthropology. *Mutatis mutandis*, it underlies Robert Redfield's folk-urban continuum, Karl Popper's closed versus open society, Talcott Parsons' pattern variables, Lévi-Strauss' cold vs. hot society, and a host of other variations on the theme, persisting in the face of trenchant criticisms of its resistance to operational specificity, its lack of analytical utility in the investigation of empirical cases, its masking of the dynamics of tradition in so-called 'modern' society, and its role in sustaining structures of social inequality and policies of domination.

3. *Tradition in Contemporary Anthropology*

The conceptual and critical reach of tradition in contemporary anthropology is pervasive, especially as it implicates the element of continuity in culture. We may, however, outline several foci of empirical, conceptual, and critical interest in which the notion of tradition figures relatively explicitly.

3.1 *The Social Organization of Tradition*

One prominent line of inquiry concentrates on what we might call the social organization of tradition, addressing those aspects of the typological model that cast traditional societies as homogeneous or undifferentiated, with the implication that tradition is collectively shared within the group. This understanding may be called into question in several ways, most directly by the recognition within the group of cultural specialists, who are charged with or have an individual bent toward the cultivation, formulation, or communication of tradition, as ritual specialists, elders, reciters, or other custodians of expert or esoteric knowledge. The foci of investigation here include the definition and organization of specialist roles; the recruitment, socialization and careers of cultural specialists; and the institutional and situational context in which cultural specialists act in their expert capacities.

This latter focus may direct attention to cultural performances or display events, such as rituals, festivals, contests, or dramatic performances in which the knowledge, symbols, and values of the group are embodied, enacted, and placed on public display. The production of such events typically requires the efforts of specialists in various capacities, and an organization of production by which the performance is accomplished. These lines of inquiry have been especially prominent in studies framed in terms of the distinction between the Great Tradition (cf. 'high,' 'classic,'

'cultivated') and the Little Tradition (cf. 'low,' 'folk,' 'popular') developed by Robert Redfield.

Investigation of the social organization of tradition may converge as well with the study of socialization and enculturation: the roles, contexts, and practices by which knowledge and behavioral patterns are conveyed to, and acquired by, succeeding generations. Finally, it is worth noting that the social organization of tradition has critical implications for anthropological method, insofar as cultural specialists figure prominently in ethnographic work as favored sources of data, and that ethnographic encounters, organized around the getting and giving of knowledge, are frequently framed as pedagogical events.

3.2 Tradition and Creativity

A further variation on the categorical opposition between tradition and modernity is the contrast between tradition and creativity, especially prominent in the anthropology of the arts. Classic work in this area, such as Franz Boas's *Primitive Art* (1955 [1927]), tended to view tradition as a constraint on the 'primitive' artist, consistent with the typological conception of traditional society as inherently conservative and Herderian notions of artistic forms as the collective expression of a national spirit. Thus the convention of collective attribution that has dominated the presentation (with a few notable exceptions) of verbal and material art forms from 'primitive' or 'traditional', or 'folk' societies (a Navajo chant, a French folktale, a Yoruba staff).

Since the 1960s, however, there has been an accelerating shift in the anthropology of the arts toward greater attention to the role of the individual artist/performer, and more nuanced investigation of the interplay between convention and creativity in artistic practice. In the anthropological study of the material arts, the distinctive styles and virtuosic achievements of individual artists and the situated practice of artistic production, use, and evaluation have aided significantly in the recalibration of the balance between tradition and creativity, and even further to a re-evaluation of what constitutes creativity, no longer restricted to novelty but understood to include the use of conventional forms in new ways.

There has been a parallel development in the study of the verbal arts, stimulated by Milman Parry and Albert Lord's pioneering studies of the composition in performance of Serbo-Croatian oral epic and by the correlative turn to the ethnography of performance by linguistic anthropologists and folklorists. Central to these investigations is a focus on the situated nature of performance as a mode of communicative practice and recognition of the emergent quality of performance. In linguistic anthropology especially, the ethnography of performance has incorporated the close analysis of formal, functional, and intertextual relationships as a vantage point on the calibration in performance of conventional, 'traditional' orienting frameworks for the production and interpretation of discourse on the one hand, and the exigent and emergent 'creative' qualities of situated performance on the other. Both qualities are always present, and the task becomes one of determining the relative weight and the dynamics of interplay of the two in particular social and historical circumstances.

3.3 Tradition and Communicative Technologies

Closely related to the typological contrast between traditional and modern societies is the distinction between oral and literate societies, which foregrounds specific technologies of communication as diagnostic—even determinative—of the contrastive types. The typological uses of orality and literacy have their roots in eighteenth-century philology, which in turn had a shaping influence on anthropology. The twentieth century revival of this framework by classical scholars has once again infiltrated anthropology and re-energized debates concerning the validity of 'Great Divide' typologies. Stated in very general terms, the 'literacy hypothesis' attributes to the advent of writing, the invention of print technologies, and the associated spread of literacy, a concomitant transformation of modes of thought, specifically the objectification and decontextualization of knowledge, and the encouragement of a critical or skeptical orientation toward received truth. These intellectual (or cognitive) orientations, according to proponents of the literacy hypothesis, had a transformative influence on society and culture, effecting an epochal shift from a blind and unreflective adherence to traditional modes of thought and practice to the rational, scientific openness to change that is diagnostic of modernity.

While some anthropologists have endeavored to find ethnographic corroboration of the typological contrast between traditional and modern modes of thought, the weight of ethnographic evidence has tended to call the literacy hypothesis into question. The most effective and persuasive critiques have come from linguistic anthropology and related work in the anthropology of teaching and learning. A large and growing body of ethnographic studies, focusing on speaking, writing, reading, and the acquisition of communicative competence as social practices embedded in situational and institutional contexts of use, has provided a range of critical correctives to unitary conceptions of orality and literacy studied in relation to abstract systems of thought. These lines of research, illuminating the role of communicative technologies, forms, and practices in the production and reproduction of social life, offer as well an increasingly ramified and nuance understanding of the dynamics of

continuity and change in human society, to supplant the classic categorical distinction between tradition and modernity.

3.4 The Politics of Tradition

The political force of tradition has been a consistent theme in anthropology, built into the very foundations of the discipline and epitomized in Weber's identification of traditional authority as one of the three pure types of legitimate domination. Oriented by classic conceptions of traditional authority and 'traditional' society more generally, foundational studies of traditional authority in anthropology have tended largely to view it as a unifying force in the service of social system maintenance, sustained by the mechanisms of socialization, the mythological charter of institutions, and the rigid formalization of ritual and traditional oratory.

Here again, however, the ethnographic turn to situated practice, and especially to discursive interaction and performance, has led to recognition of the ways that traditional tales, for example, may be instruments of divisiveness rather than unity, insofar as they may be performed in defense of competing claims to status, or that the formal regimentation that marks the performance of oratory as 'the words of the ancestors' may serve to enhance the rhetorical power of disputants in political conflict. That is to say that rhetorical appeals to tradition and the public ideologies of traditional authority that motivate them do not necessarily have the binding force in practice that participants and observers alike may claim for them. Ideologies of traditional authority—like all ideologies—are positioned, interested, and strategically invoked, and tradition as a rhetorical resource may serve as well for conflict as for the 'binding force' of acquiescence.

The ideology and rhetoric of tradition are understandably more apparent under conditions of marked social and cultural change; indeed, the capacity of 'traditional' peoples consciously to intervene in the management of tradition was recognized earliest in anthropology in the study of nativistic movements, 'any conscious, organized attempt on the part of a society's members to revive or perpetuate selected aspects of its culture.' (see Linton 1943) This work anticipated a vigorous line of anthropological inquiry that has burgeoned since the 1980s, devoted to the investigation of tradition and related notions of authenticity as symbolic, interpretive constructions in and of the present through the invocation of links to a meaningful past.

The process of traditionalization—under the rubric of tradition, heritage, patrimony, custom, or the like—is a prominent resource in the service of nationalism, whether cultural nationalism or nation-state formation, and it is a conspicuous aspect of the politics of culture in many parts of the world in which there is an extended history of anthropological research but which are now increasingly determined to shed the vestiges of a colonial past and assert the integrity and authenticity of their own 'cultural traditions.' The readiness of anthropologists to identify the tradition or custom, or patrimony on which such claims stand as selective, strategic, symbolic constructions is a source of tension both within the discipline and between anthropologists and their ethnographic interlocutors: whose interpretations and constructions are to be accepted as authoritative?

This question and the further problems it raises afford an illuminating critical vantagepoint on the historical formation of anthropological theory and practice. The modern conception of tradition was shaped in an intellectual arena that was defined largely in political terms. What are the foundations of a viable polity? A legitimate authority? A national culture? What are the bases of social inequality? Who is authorized to intervene in the management of these formations? Tradition and allied conceptions of culture proved to be foundational to the emergent discipline of anthropology and the definition of its purview. A measure of the success of anthropology may be strength with which its core concepts have come to be accepted by the formerly 'traditional' peoples who have been its central objects of study. One of the challenges that now confronts anthropology is that in asserting their own subjectivity, these peoples should base their claims on those foundational concepts just as anthropologists themselves are increasingly inclined to deconstruct them, to recognize traditionalization as an interpretive process, to challenge the reification of tradition, or to unmask primordial traditions as recent inventions.

Traditions in Sociology

Traditions are broadly a form of received authority giving weight to the past in how social actors in the present orient themselves and act upon their situation. They are ways of acting upon the world transmitted from one generation or cohort to the succeeding one. All societies, all institutions except for some brief charismatic moments when 'all things are born new' are marked to some extent by tradition. Adherence to a tradition provides group awareness and identity; this includes sociology as a general discipline as well as its more differentiated units imparting sociological training to students at different levels.

In the late twentieth century there has been increased recognition of traditions as framing the development of sociology. Indeed, one can speak of an emergent sociological historiography which takes 'tradition' as the central focus for providing accounts of the genealogy of the discipline in terms of, following Anderson (1991), 'imagined communities' of scholars. Representing the development of sociology in terms of one or a few major traditions has become a more analytically challenging approach than earlier listings of names, single topics, or philosophical orientations. Yet, while the invoking of traditions may seem to be the present's salute to the past, the past does not speak for itself 'as it really happened.' Traditions, like ceremonials, rituals, and even like nations are not handed down as inert 'rocks of the ages'; they are activated and reactivated by contemporaries, even 'invented' on occasions for quite novel purposes (Hobsbawm and Ranger 1992). Essentially, then, the topic of sociological traditions interweaves objective referents of the past with subjective constructions or perceptions of these referents.

1. Traditions and Modernity

Without discussing sociological traditions specifically, Shils (1973, 1981) has provided an extensive analysis of tradition in the modern setting, including the tradition of intellectuals. This may be seen in the form of a paradox. On the one hand, social scientists are attached to the concepts and figures that are rooted in the past; on the other hand, they are negligent if not outright unsympathetic to traditionality; major traditions recognized as authentic by the great majority are 'antitraditional intellectual traditions (Shils 1981). This paradox may be traced to the 'enlightenment philosophy' that made change and progress new basic values of modernity. Rational, scientific knowledge, promulgated above all by intellectuals, would replace irrational authority bound by the chains maintained by traditional institutions. This modernist orientation is a constitutive element of a bundle of traditions in sociology deriving from the 'enlightenment's' project of human capability to reconstruct or 'reinvent' the individual, society, and social institutions. Shils also points out that 'no tradition begins *ab novo*.Every tradition grows out of another'; moreover, intellectual traditions though continuous are also replete with innovations, though 'at different rates in the different parts of the same traditions and in different traditions' (Shils 1973).

These observations are well exemplified in the development or evolution of '*Critical Theory*' over the course of several generations (Calhoun 1995). Emerging in late Weimar Germany as the *Frankfurt School* at the Institute for Social Research around such figures as Horkheimer, Adorno, and Marcuse, its chrysalis was in Marxist social thought enriched with cultural and historical materials (partly influenced by Weber) and supplemented by perspectives from psychoanalysis and phenomenology. Further, a major work by a central figure, Adorno's *Negative Dialectics*, likens the Marxist origins to their philosophical grounding in Hegel's dialectical method which Marx modified to dialectical materialism. But even this may be traced back to an older Western esoteric tradition of 'negative theology' and 'negative mysticism' transmitted from Denis the Areopagite through Meister Eckart and Jacob Böhme, a tradition that stretches over a dozen centuries. Although a German component has always been part of this 'critical tradition,' a certain Americanization was introduced, first during the period of exile in America of the Frankfurt School group (some staying permanently, some returning after the war),

and second by the serious reading of Parsons in Habermas's theory of communicative action.

As noted, the tradition of the Enlightenment has been a major pillar of the social sciences. Until the 1970s or so, the *paradigm of progress* formulated in an earlier era, though shaken by two world wars, still carried sufficient weight that the study of development tended to dichotomize between societies weighted down by 'tradition' and those fortunate few (Western) who had emancipated themselves in favor of a 'modern' social order. A more balanced perspective then emerged, viewing tradition and modernity as not so much zero-sum opposites as complementary forces and orientations in the structure and dynamics of societies (Eisenstadt 1973). In fact, to void a Western-centric bias, more recent conceptualization even favors the notion of multiple historical modernities (Daedalus 1998).

2. Traditions as Interpretations

For the most part it is sociologists offering a brush-stroke of the development of the discipline as a whole, and particularly of its general theoretical framework, who have been most articulate in providing accounts of the sociological tradition. Despite overlap, there is no standardized account of traditions, including their principal figures and elements. The accounts, though varying in how traditions are categorized, themselves are constitutive of the traditions since they entail an active and critical interpretation by present authors of the legacy of previous generations of sociologists.

Moreover, unlike the Weberian ideal-type image of 'traditionalist authority (Weber 1958), there is nothing sacrosanct about how sociologists treat their traditions (save Marxists hallowing the writings of Marx but not of themselves). An author who writes about sociological traditions can make substantive changes in depiction. Thus, in one edition of his popular text of readings, Farganis credits Comte with the origins of the 'classic tradition' in sociology but in the following edition he credits Marx with beginning the tradition, and there is no reference to Comte at all (Farganis 2000). Similarly, in 1985 another equally widely adopted text posited three main ongoing core traditions: the *conflict tradition* (in which is grouped Marx, Engels, and Weber), the *Durkheimian tradition* (that includes as primary figures Comte, Spencer, Merton, and Parsons), and the *microinteractionist tradition* embracing the pragmatist orientation of Peirce, Mead, and Dewey, the symbolic interactionist line of Cooley, W. I. Thomas, and Blumer, and the phenomenological derivative of Schutz, Garfinkel, and the later Goffman; in his conclusion, Collins (1985) noted that not all the history of the field can be fitted in one of these three principal traditions, such as the utilitarian tradition, sociobiology or structuralist network theory. However, the follow-up edition elevates the *utilitarian tradition* as a tradition in its own right, acknowledging that in the previous edition, the utilitarians 'figured largely as a foil for the other traditions (Collins 1994).

What is to be retained from these two instances is that *sociological traditions are always (re)interpreted by present authors* (just as all societal traditions are always interpreted by contemporaries).

Related to this, figures from the past may be left out in present accounts or conversely, some figures from the past who were not viewed as belonging to a sociological tradition may come by later sociologists to be so regarded. Thus, Marx in the United States has only in the past 40 years or so become taken as a sociological progenitor of 'conflict theory.' On the other hand, mention rarely is made of the sociologist Ludwig Gumplowicz (1838–1909) as a figure worthy of inclusion in conflict theory, although this *fin-de-siècle* Austrian sociologist gave centrality to ethnic and race conflict, which have been much more salient in recent decades in the West and elsewhere than the class conflict paradigm of Marx. By the same token, most anglophone accounts of the development of sociology in discussing 'classical' formulators of conflict theory leave out Pierre-Joseph Proudhon (1809–65), whose influence was very extensive well into the twentieth century.

A contrary instance of a figure 'moving into' the sociological tradition after his lifetime is Tocqueville, widely accepted in the late twentieth century as a major contributor to the comparative study of institutions and revolutions in the context of modernity. Yet, as Bondon et al. (1997) have indicated, it was not until after World War II and because of the intellectual effort of Raymond Aron that Tocqueville became recognized as a core figure in the sociological tradition.

3. Sociological Traditions: One or Many?

It is particularly in the teaching of theory courses that students are made explicitly aware of sociological traditions, usually in terms of models of social reality that provide normative and cognitive orientations having heuristic significance in the devising of research and the interpretation of established data. This is often in the context of presentations of the 'sociological classics,' including debates as to whether there is merit in discussing the framers and societal context of major classics. Much of the debate hinges around whether sociology at its core (or its major subfields) is (a) a series of discrete *paradigms* around which are organized multiple and discrete communities (as understood by Kuhn 1970), or (b) a *scientific research program* in the positivist tradition, displaying an 'intermittently progressive empirical shift,' which though maintaining a hard core of irrefutable assumptions permits verification of theories, predictions of new facts, and a general increase in empirical content (Lakatos 1970). A 'humanist' perspective of sociology would favor multiple paradigms or a pluralist view of traditions;

a 'positivist' perspective would favor a cumulative tradition.

Most professional sociologists would accept Marx, Weber, Durkheim, and Mead as having provided one or more key ingress to critical sociological aspects of modernity, and traditions of theorizing and research have developed from these early foundations. But whether these are discrete or interactive, and whether they are sufficient today as main frames of inquiry or need recasting with other, perhaps newer, traditions, are matters of controversy.

3.1 Great Traditions

Despite significant variation as to what figures are included (or omitted) from certain traditions, there is a widely-shared sentiment among sociologists of different orientations that there is a common core which provides continuity and identity, a unity in diversity. Derived from the comparative study of civilizations advanced by the anthropologist Robert Redfield and the sociologist S. N. Eisenstadt, sociology in its historical development may be said to be structured by a 'Great Tradition' that endures along with 'Little Traditions.' The former frames the basic identity of the discipline, its core problem areas and assumptions, its major endeavors, and in general what might be taken as a 'mission statement' for the discipline as a whole; the Great Tradition would include exemplars in succeeding generations who have been instrumental in giving viability to the discipline. The notion of Little Traditions pertains either to subfields (e.g., social stratification, demography, sociology of religion, comparative development) or to radical traditions (in effect, sociological heterodoxies) which reject the basic normative and/or methodological structures of sociology: phenomenological sociology, some derivatives of Marxist sociology, 'Christian sociology,' and 'humanistic sociology,' as instances.

An early and influential instance of conjuring a 'Great Tradition' perspective on the development of sociology was provided by Nisbet (1966) writing in a decade of change and acrimony in the discipline itself. He distanced himself from mere historical accounts of the discipline by arguing for a nucleus of five key unit ideas—*community, authority, status, the sacred, and alienation*—which crystallized in the formative period of sociology, 1830–1900. This set of 'unit-ideas' generated poles of antithetical values: on the one hand, *community, moral authority, hierarchy*, and *the sacred*; on the other, *individualism, equality, moral release*, and *rationalist techniques of organization and power*. As underlying the fundamental structural processes of modernization (industrialization and democratization), these antitheses of modernity have given continuity to the sociological tradition. Yet Nisbet (1966) in his epilogue acknowledged that the core ideas may have exhausted their vitality, rendering problematic the 'continuing viability of a tradition, or rather, the concepts which form it.'

A newer version of the Great Tradition of sociology is provided in the account of Levine, who seeks to establish a continuity in sociological thought that can repudiate prevalent intellectual nihilism which 'relativizes truth to matters of gender, race, ethnicity, class or narrow ideology' (Levine 1995). The continuity amidst diversity is located in the 'moral dilemmas of industrial civilization voiced early in the nineteenth century,' whence 'the quest for a rational ethic was the booster that launched the social scientific disciplines into orbit'(Levine 1995). The inspiration for this Great Tradition is a vision of a *secular ethic* that undergirds both different narratives of the history of sociology seeking to lay-out *the* tradition of sociology and national traditions in search of 'the good society dialogue.'

A third approach invoking a Great Tradition theme also seeks to combine analytical thematic materials with a broad geographical differentiation between the 'American' tradition and the 'European' tradition (Alexander et al. 1997, Boudon et al. 1997). Each complementary set of volumes is a congeries of readings integrated by an editor's introduction. In his, Alexander proposes that the American tradition, with a preoccupation on the individual self, has as a paramount orientation as the 'secularization' into scientific language of two utopian movements of reform seeking social salvation: Protestantism and anti-authoritarian democracy (Alexander et al. 1997). Unlike European sociology, American sociology is preoccupied with the motives ('action' in sociological terms) and mutual relations ('interaction') of individuals. Polar orientations of optimism and pessimism are traced to foundational documents in Jefferson and Madison, respectively.

While this volume is an imaginative construction or invention of a Great American Tradition, many of the authors in the selected readings are not sociologists (Madison, Gay, Emerson, Dewey); the 'native' antebellum first generation American Comtean sociologists (Henry Hughes, George Fitzhugh, and George Holmes) are ignored; and there is no reflection on the many sociologists (McIver, Sorokin, Coser, Bendix, Etzioni, etc.) who have come as immigrants, exiles, or refugees imbued or exposed to other traditions and who have thereby modified significantly what was identified as *the* indigenous microtradition. Moreover, sociology as the secularization of utopian movements of salvation based in the Enlightenment is arguably as much an ultimate goal of continental sociology.

Rejecting that there has occurred an 'epistemological break' between our era and the Enlightenment, Cherkaoui in presenting the European classical tradition proposes two paradigms that provide continuity: *holism* and *methodological individualism*. The core identity of the European tradition, he argues, was produced between 1890 and 1914 with the tutelary

figures of that generation providing the themes and theories for subsequent generations (Bondon et al. 1997). Within this Great Tradition umbrella, Cherkaoui gives particular attention to the postwar internal development of sociology in England, Italy, Germany, and especially France. If the last named was imprinted heavily by the dominant paradigm of *structuralism* (drawing from both Marxism and Durkheimian sociology as well as other sources), an important opposition deserves to be noted in figures like Boudon, Crozier, and Touraine who in different respects have an actor-oriented sociology, viewing the actor (either as an individual or as a collective subject) with 'greater or lesser autonomy, rationality, and ability to construct strategies,' (Bondon et al. 1997). Cherkaoui leaves out of his account an important cluster of postwar French sociologists who drew from the Durkheim–Mauss tradition a dynamic, non-structuralist orientation to problems of modernity: Gurvitch, Balandier, Dumazdier, and Duvignaud, among others.

Considering that postwar American sociology has had important structuralist orientations (e.g., from Goffman and arguably from ethnomethodology at the microlevel, and from world-system analysis at the macrolevel) and that recent European sociology has had important action or subject-oriented components (e.g., Boudon and Touraine in France, Joas in Germany), it would appear as if the sharp differentiation of 'American' and 'European' tradition is becoming less tenable.

3.2 An Overlooked Great Tradition

Since the *historiography of sociology* tends to be written by those most familiar and most likely to be specialists in sociological theory, most of the accounts of sociological traditions dispense with what is, in fact, an integral aspect of the discipline's identity: the tradition of *empirical research*. It is this tradition which is the backbone of graduate training. How it developed (or failed to develop) in different settings has to date been documented only fragmentarily.

Yet empirical and quantitative research has had from the beginning of the nineteenth century a parallel but neglected development with sociological theory (Lécuyer and Oberschall, 1968, Oberschall 1972). As part of the forgotten history of this Great Tradition, Lazarsfeld (who at Columbia stimulated research on the research tradition) pointed out that Weber contributed with his research associates, 'at least 1000 pages of research findings which, in style and format, would not be easily distinguished from the pages of our contemporary sociological journals,' (Lazarsfeld in Oberschall, 1965). Oberschall presents in detail why Weber's persistent efforts at establishing a tradition of collaborative empirical research failed to become institutionalized in Wilhelmine Germany (Oberschall 1965).

In contrast to Germany's failure, a research tradition flourished almost from the start in the United States. The evolution of that tradition is documented in the important account of the Chicago School by Bulmer (1984). Bulmer points out that almost forgotten in previous accounts is the quantitative aspect of research at Chicago in the interwar period of its great flourishing, with such figures as Burgess, Ogburn, Thurstone, and Stouffer; equally important, Chicago sociology had a major impact on the profession world-wide by institutionalizing *collaborative* sociological research that stimulated theory and research interacting in the same university department (Bulmer 1984).

3.3 Schools as Strong Traditions

Attempts at categorization in terms of 'schools' were pioneered by Sorokin (1928), who proposed about 11 broad orientations (e.g., the 'mechanistic school,' the 'geographical school,' varieties of the 'sociologistic school,' etc.). Expanding on the concept of school, a *strong tradition* may be established where actual members of a school in or more institutional setting transmit a core set of beliefs and methodological approaches to a new generations of recruits, which in turn will add content and modify some features of the orientation of its predecessor, though retaining the core presuppositions. In this vein, Tiryakian (1979, 1986) has suggested that major advances in the social sciences stem from the collaborative efforts of 'great schools' founded by a charismatic intellectual leader (such as Durkheim, Park, Parsons, Horkheimer, Malinowski, Evans-Pritchard, and Freud) who in fact frames a research program. While schools are not as comprehensive as 'great traditions' in the number of sociologists identifying with them, the density of interaction and the network of associates provide them with a concentrated impact on the development of their respective discipline.

3.4 Little Traditions

3.4.1 National traditions. There are many axes on which traditions of lesser magnitude than those embracing the entire profession may be drawn. One axis frequently used, explicitly or implicitly, is the national context of the development of sociology. Sociology's unstated assumption as the science of society favors a universalistic claim for the conceptual framework of its theories; yet, sociology for the most part develops in a national context in which graduate training is offered.

This is recognized in a volume edited by Genov under auspices of the International Sociological Association, stimulated in the 1980s by growing awareness that the question of national tradition becomes

salient in an era of *internationalization* (or *globalization*) and of the renaissance of social sciences in regions where they have not been in continuous contact with the mainstream (e.g., in countries blocked off from free and easy access to the West during the Cold War). The consequences of internationalization (or globalization) and/or of having been in the periphery raises the problematic of *indigenization* (Genov 1989). Genov's formulation of the question is the extent to which sociological 'newcomers,' those national settings which have only recently begun to participate freely in the development of sociology (including Eastern Europe and Russia), can achieve a balance between being responsive to their local problems and traditions and to the international aspect of sociology as a universalistic science. Stated otherwise, how much autonomy and originality can a national tradition retain with the internationalization of sociology? (Genov 1989). This may not be perceived as a problem for American sociology because of American hegemony in world affairs, including the linguistic hegemony of English, but it is a realized challenge for even established sociological centers like the French- and German-speaking countries.

While a national tradition is a major factor in the institutionalization and reproduction of the sociological enterprise from generation to generation, there are limitations to giving it undue weight. First, a national tradition may obscure significant variation in theoretical and methodological orientations within a national setting, from one sociological center to another. Second, national traditions, even where well-established, may become transformed due to factors exogenous to the sociological enterprise, such as political transformations. This happened (in the 1930s in Western and Central European countries, and in the 1950s and 1960s in various Eastern European ones) by regimes becoming authoritarian or totalitarian.

3.4.2 Other little traditions. Miscellaneous traditions of lesser scope than national ones or general paradigms continually are evoked, invoked, and invented in the course of providing accounts and legitimization to certain orientations. A few illustrations will indicate the range of these traditions.

In their overview of *the sociology of development* Evans and Stephens (1988) observe that:

> 'While Cardoso and Faletto's model (first published in 1969) was primarily concerned with internal dynamics, other work *in the dependency tradition* was much more preoccupied with tracing the connections between the evolution of core countries and developmental sequences on the periphery.'

Since Cardoso and Faletto are credited as having produced the 'founding statement of the dependency approach,' it would indicate that this tradition is of very recent origin.

Similarly, Giele in discussing pioneers in the gender field contrasts among orientations '*liberal feminist theory* (that) drew on Enlightenment ideas of individual rights, justice and freedom,' and '*traditional Marxist feminist theory*' (Giele 1988). Both of these recent cited traditions invoke older established 'great traditions' of liberalism and Marxism, not too dissimilar from new sects seeking legitimization by invoking very established older religious traditions. Also, Olick and Robbins (1998) in their overview of sociological approaches to collective memory and tradition make reference to 'the Mannheimian tradition in the sociology of knowledge and the Mertonian tradition in the sociology of science.' In this instance, a 'little tradition' is that of a specialized field of sociology—the sociology of knowledge and the sociology of science—whose foundation is identified with a recognizable person; presumably, even specialty areas within broad fields may also take on the aura of a tradition, whether the designation is given by the name of a figure or an institutional setting where a certain approach is handed down from generation to generation. Lastly in this vein, a 'little tradition' may be invoked tacitly by former students adducing the contributions of their illustrious teachers, as, for example, the volume of Merton and Riley (1980) dedicated to their teacher Talcott Parsons and having contributors testifying to such mentors as Weber, Mead, Park, Sorokin, Frazier, Lazarsfeld, MacIver, and Stouffer.

4. *The Future of Traditions*

Significant changes in the bearing of tradition(s) to sociology are likely to emerge in the twenty-first century, even if the changes that can provoke new images of tradition can only be partly anticipated.

Although some retention of the Great Tradition(s) is likely, structural, political, and technological transformations already underway will give only vestigial importance to much of the conceptual legacy of a past that was grounded in the dynamics of industrializing and late industrial society. While boundaries between national traditions may become increasingly blurred stemming from globalization and hybridization, emergent regional linkages (e.g., the European Union, NAFTA) will also prod sociologists to acknowledge established neighboring traditions. New subfields and new fields linking sociologists to other disciplines (in the humanities, social sciences, and natural sciences) will emerge and in becoming institutionalized, new traditions will appear evoking *their* founding figures and documents. Already, a new historiography reconstructing the tradition of women in the development of sociology is well under way (Lengermann and Niebrugge-Brantley 1998); it is likely that what had been the covert gender side of the Great Tradition will become recognized in terms of the contributions of

women to both social theory and social research, and in the process, recasting the image of the Great Tradition. By the same token, dramatic breakthroughs in knowledge of the biological bases of social behavior could also well lead to reconceptualizing the Great Tradition.

Traditions: Social

The concept of tradition has been important in the history of sociology in the twentieth century, but its signification has completely changed in contemporary works. At the turn of the century, sociologists and anthropologists utilized this concept to outline a type of society defined by traits placed in opposition to other traits characterizing industrial society, and in a well-known work Max Weber has distinguished three types of authority: legal-rational, charismatic, and traditional. One hundred years later, sociology considers tradition as an invented reference developed by societies in function of the demands of the present (Hobsbawm) and as a form of rationality among others that orients action (Boudon).

The tradition–modernity dichotomy dates back to Saint-Simon who compared the characteristics of the emerging industrial society to those of the *Ancien régime*. This dichotomy became a key element in explaining the social transformations that were oc-

curring in modernizing societies during the first part of the twentieth century. The defining traits of the traditional society are well known: the fusion of family and business, the division of labor dictated by social structure (age, gender, relatives), reference to custom as the dominant value, the privileged attention accorded to saving and accumulation to the detriment of productive investment, the importance of the local community, relative autarky, and self-sufficiency. The American anthropologist Horace Miner (1939) found in Saint-Denis-de-Kamouraska in Quebec a kind of archetype of the preindustrial traditional rural society depicted in a work that remains a classic in social sciences read by generations of American students. At the opposite end of the spectrum, the industrial society described by Raymond Aron, Georges Friedmann, Daniel Bell, and others is marked by the importance of technique, economic growth, calculation and management, productive investment, and the accumulation of capital, separation of family and business, establishment of a labor market, urbanization.

The transition from traditional to industrial society paradigm and the folk–urban continuum formalized by R. Redfield (1956) were criticized sometimes as descriptive approaches of social change and as paradigms with limited explanatory power. Henri Mendras (1976) underlined the fact that this vision of things denied the proper originality of nonindustrial societies and their diversity and he recalled that the concept of the traditional society often embraces different types of societies that are in fact very different (e.g., from primitive societies to peasant societies). He argued that one must not confuse traditional societies and peasant societies. If hunter-gatherer societies are totally independent, peasant societies are relatively autonomous but are embedded in larger, global societies having diverse characteristics. The paradigm of the transition from traditional to industrial society is based on an evolutionist postulate, that has been placed in question, that makes the developed societies the norm to be obtained. In the same vein, we can criticize the thesis of the resistance to social change by tradition because it supposes clear, obtainable goals and also the existence of bad faith on the part of traditional individuals attached to the past and incapable of recognizing the merits of anything new (Boudon 1984).

Consider another manner of conceiving the tradition–modernization opposition. Lévi-Strauss (1962) compares the knowledge and technique of the handyman, traits of a traditional society, with the knowledge and technique of the engineer, attributes of the industrial society. The first type represents empirical and inductive knowledge. It depends on a long tradition of precision which can be complex and efficient but it is also filled with errors, notably as to the explanation of its efficiency. The knowledge of the engineer is of another order. It is based upon experimental science, accumulation of scientific knowledge, verification, technique, manipulation of objects, operationalization, and organization. The classical opposition in economics between protectionism and free-trade also illustrates the opposition between the ancestral or traditional ways of doing business and the modern methods. The authorities in the Republic of Venice jealously protected the ancestral traditions of their glass-makers, sources of important benefits. Contemporary entrepreneurs count on innovation, discovery, free circulation, investment and strategic alliances to support the growth of their activities and their profits.

The examples of the engineer and the entrepreneur clearly demonstrates that tradition and modernization are differentiated in two respects. First, the relationship to time is different. Tradition is oriented towards a legitimate reference to the past, while modernization is oriented towards the mastery of the future, the discovery of the new. Second, tradition and modernization are marked by a strongly different manner of intervening in the world, of producing goods and services; an empirical manner of learning over time and transmission across social relations that are embedded within the family or small communities, and a scientific manner that asserts itself as the result of research and calculation, embedded within complex social networks and formal organizations.

E. Shils (1981) proposed a definition of the concept of tradition which was largely accepted. He defined tradition as anything which is transmitted or handed down from the past to the present. According to Shils, traditions include beliefs, norms, institutions, as well as material objects which all individuals will find when they grow up; traditions refer to transmitted things, ideas, and values. It is now generally accepted that the scope of tradition should be narrowed down. We will retain two aspects—which are hidden in the folk–urban continuum or in the community-society ideal type of Tonnies—which contribute to define tradition in contemporary analyses.

First, to be part of a tradition, objects, norms, or ideas have to be well alive, and never having been destroyed, abandoned, or forgotten. Specifically qualified fragments of the heritage should retain a strong intimate link with the present to be a tradition.

Second, it is generally accepted that traditions change with the passage of time. Traditions are not immutable and they are re-examined and questioned. Tradition is a transmitted heritage which survives and orients contemporary actions, but this heritage is often transformed (Halbwachs 1935/1994), Eisenstadt 1973). Sztompka (1994) stated that a special part from the whole of the historical heritage is elevated to the category of tradition by contemporary people for their own usage. In the United States, national history is being rewritten to take into account the role of Amerindians, women, and ethnic minorities.

Canada delimited the frontiers of a new territory that contains an Inuit majority in the North in

1998—Nunavut—that took into account the testimonies of the oral traditions of the elders. Scientific cartography and satellite images were the privileged work instruments but the life histories and experiences of those who inhabited the land were taken into account, especially to establish its Eastern frontier. Similarly, the oral traditions of Canadian Amerindians and the *wampums* of their material culture were also taken into account as elements of proof in the Canadian system of justice that examined their grievances and ancestral rights. Canadian judges are now obliged to interpret the rights of Amerindians in light of ancestral traditions and the orientations of modern ways of living (equality between men and women, for example). There is no doubt that the resort to tradition will inspire other courts of justice throughout the world where we find indigenous cultures, in Latin America or in Oceania, for example. Here tradition also appears as a legitimate form of knowledge—but different—than the scientific knowledge and cartographic techniques of historians or jurists and it is susceptible to applications in the same way as the latter. Tradition no longer appears as the only or principle source that orients behavior and decisions but as one element among others that is susceptible to being criticized.

Hobsbawm (1983) has contributed to the new examinations of tradition by stressing its *invented* character. He has distinguished three groups of invented traditions. First, there are traditions that express the social cohesion of nations and communities. Second, traditions can legitimize an existing order, status, institutions, or authority. Third, traditions which socialize certain values or rules of behavior into individuals. The traditions of the British crown, for example, leaves the impression that they are rooted deep into the past. Now the work of historians has demonstrated that these traditions are of more recent origins and were invented recently (in fact in the nineteenth century) in order to give greater legitimacy to the institution of the monarchy. Closer to us, the celebration of the new Beaujolais in France is a recent creation, the fruit of a new approach in the marketing of the wine of this region that has been successful in countries where they appreciate French wines. Another example, Australia. At the moment, the Australians are questioning whether or not they should abandon the royal symbols from their colonial period. If they decide to abandon those traditions and symbols, they will probably give themselves another symbolic tradition to mark the birth of their society peopled in large part by immigrants. A new tradition will therefore be created for use in the present.

The protection of the environment, fauna, and flora, has become a daily theme at the end of the twentieth century. In North America, the Amerindians have been characterized as environmentalists before the advent of an environmental movement. Research by anthropologists and historians has demonstrated that the picture is much more complex. Krech (1999) recalls that the Amerindians had overexploited the beaver in the St. Lawrence Valley after the arrival of Europeans in New France in the sixteenth century to the point of extinction. The notions of environmental protection and endangered animals were foreign to the traditional culture of the aborigines, because the way of life of hunter-gatherers is based on maximal exploitation of the immediate environment. On the other hand, the Amerindians have an animist conception of the animal world. Thus, the Plains Indians believed that they could not allow an animal to escape under the pretext that it would warn the others to not venture in that area, they therefore killed all the animals they saw. Because they believed in reincarnation, the majority of Amerindians thought that the dead animals would, at any rate, return the following season. For Krech, the myth of the ecologist Indian essentially reflects contemporary preoccupations for the environment rather than the traditional and historical culture of the Amerindians.

This analysis led us to the following conclusion: contemporary sociology has abandoned the transition paradigm (from traditional to industrial societies) and now integrates tradition into analyses of ongoing social change. In recent works, tradition is used to define a type of society (be it theoretical or empirical), and it also defines a subjective orientation toward action. These different approaches will be developed here.

In his general theory of action, Freitag (1986) defines three types of societies based on three forms of definition of the norms of social action. The first form he proposes—culture—defines mythic and archaic societies. The second one—power—defines two other types: traditional societies and modern societies, the later ones built against tradition. The third form of regulation—control—characterizes postmodern society, in which a large number of organizations contribute to the structuration of society.

Tradition is also used to describe empirically different societies. Following Max Weber's arguments, Huntington (1996) argued that the world is divided into eight major cultural zones which revealed persistent cultural differences caused by different religious traditions which are still powerful despite industrialization and the same forces of economic development. Inglehart and Baker (2000) have studied values in surveys made in 65 countries which cover more than 75 percent of the world population and they observed the persistence of distinctive traditional values.

Tradition is also considered as a normative orientation toward action, a perspective underlying Tocqueville's works (1856/1986, for example). In his works, Raymond Boudon formulates a general theory of action based on the actor's search for meaning. He proposes to enlarge the concept of the rationality of the actor by distinguishing five types of rationality:

utilitarian, teleological, axiological, cognitive, and traditional. All of these types of rationality describe the good reasons why the actor is driven to act in a certain way. Economists and rational choice theorists privilege the utilitarian rationality based on the pursuit of self-interest. However, for Boudon, there are other kinds of reasons/motives that can also influence the way that individuals act, and to limit the content of rationality to the single dimension of utility is an exercise in reductionism. Custom and habit can also incite individuals to act in a certain way. Therefore, when one speaks of traditional rationality—'it has always been that way'—he is speaking of one type of rationality among others.

For Boudon, sociological analysis has to define the context and circumstances in which one type of rationality or another is at work, keeping in mind that one type is no more important than another. This approach permits us to understand the role of tradition in sociological explanations. In peasant societies, the rhythm of the seasons is of major importance and the technologies are not very developed (Weber 1976). Here, the reference to custom and tradition is strong and the individuals do not have good reasons to question that which already works. They are led to value the stability and the family that provides the necessary labor to exploit the land. However, when technological inventions appear to menace the traditional ways of life, tradition remains important for understanding the implantation of these transformations or the difficulties in accepting them. Mendras (1967) has demonstrated that the introduction of inventions in peasant societies cannot be understood independently of the welcoming culture because these innovations have to be first integrated into the traditional culture before being fully accepted.

Boudon (1992) gives a good example that demonstrates the role of tradition in ongoing social change in restating the observations contained in the celebrated monograph by Thomas and Znaniecki (1927/1984) on immigrant Polish peasants in Chicago at the turn of the twentieth century. The immigrants that adapted the most rapidly to the welcoming society were those that manifested the highest degree of traditionalism and attachment to their original milieu. This integration in a familiar milieu gave them support and a frame of reference that slowed down the process of social disorganization that was typical of immigrant communities when faced with a radical rupture with their traditional original community. The Polish immigrants adopted a rational action that permitted them to integrate themselves in the welcoming society, the traditional collectivity serving as a relay.

To illustrate the richness of this approach, here is an example taken this time from French sociology. In his studies of religious sociology, Le Bras (1955) observed a paradox. The Bretons who migrated to Paris during the 1950s rapidly abandoned religious practice. A superficial analysis gave the impression that they practiced a strict conformist religion that they abandoned once they were beyond the traditional way of life structured by family and village. Le Bras proposed another explanation by demonstrating that the logic of behavior was the same in the village and in the city. In the village, behavior was regulated by the social group. Going to mass was not only a way of confirming one's Catholicism, it was also participating in a valued social activity which strongly rhythmed life. In the city, in a pluralist environment, going to mass was seen as expressing an opinion and a behavior that did not attract the adherence of all, and in a way, that was contrary to majority opinion. Thus, it was difficult for the newcomers, who wished to integrate in their new environment, to oppose something which was the norm in their original milieu. In this case, one could say that going to mass in the village and not going once in the city follow the same social logic.

All of these examples demonstrate different ways to refer to the concept of tradition. Tradition describes a type of society, but it also defines an orientation of action. This perspective can be found in numerous works of contemporary sociology and demonstrates how different types of rational behavior can mix together. To illustrate this perspective, we will recall how the reference to tradition is posed in three fields of empirical studies of major importance at the end of the twentieth century.

The market consumption society in the developed world proposed standardized products—fast-food, coca-cola, computers, cars, jeans, CDs, films—and globalization tends to homogenize commercial practices and modes of production. However, sociologists have started to discover the multitude of innovative responses in the national cultures of consumption, as Miller (1995) has illustrated in his research. He argues that local contexts remain extremely diversified and, in each case, outside material influences are reinterpreted. Cultural diversity continues to be reaffirmed and supported by living national and cultural traditions. Coca-cola does not occupy the same place in the dietary culture of the French and the connoisseurs state that American pizza is quite distant from its Italian cousin.

New technologies have a great impact on the character of work, but work is also embedded in culture and traditions. People work, and supervise other's work, within stringent institutional limits marked both by national traditions and organizational innovation.

The empirical work on the integration of immigrants in developed societies demonstrates that they do not form totalities with contours that are well defined by their original traditions. In fact, they are quite diverse and in reconstructing their traditions in the new country, they combine innovative elements with the adopted elements of their new home. Tradition and modernity combine to produce new cosmopolitan identities that can be different from one

country to another as Kymlicka (1995) has suggested. The reference to tradition, therefore, remains quite alive in present sociological analyses.

Training in Clinical Psychology in the United States: Practitioner Model

The practitioner model of training in clinical psychology focuses on preparing students to become highly skilled professional psychologists. A professional clinical psychologist is part of the organized community of scientific psychology; his or her professional efforts focus on helping individuals, couples, or families with the prevention and remediation of psychological problems in human behavior. This work may be with individuals, in families, or in group settings. Although some clinical psychologists who are trained as practitioners work in research or academic settings, most devote themselves to applied work.

Clinical psychologists have traditionally worked in a variety of settings including mental health centers, private practices, prisons, day care centers, psychiatric hospitals, substance abuse programs, and programs for persons with developmental disorders. They serve children, adolescents, adults, and the elderly with a full range of diagnostic labels.

1. A Brief History of the Development of the Practitioner Model

Several streams have fed the development of clinical psychology as a profession. These included the creation of a body of knowledge relevant to practice, the demonstration of the value of psychological treatments to ameliorate human suffering, and conferences that gradually shaped the standards and curriculum for educating clinical psychologists. We can date the establishment of clinical psychology as practice to the spring of 1896 when a psychologist at the University of Pennsylvania, Lightner Witmer, opened the first psychological clinic. Many of his early clients were children with intellectual and academic problems. After completing their education, a number of Witmer's graduate students went on to provide psychological services, establish treatment programs, and do research on clinical problems.

1.1 A Body of Knowledge

As Routh (1994) and others have noted, the science and practice of psychology should be tightly linked to one another. An effective profession requires effective skills. For clinical psychology the initial creation of this scientific knowledge base included such things as the development of tools for cognitive and personality assessment including the Binet and Wechsler tests of intelligence as well as the development of projective and objective tests of personality. Another aspect of the early growth of the profession came from the

establishment of outpatient psychotherapy centers. Many of these early clinics were psychodynamic in orientation. Later clinics offered services from the client centered, family systems, and behavioral approaches. It was important for the growth of the profession of clinical psychology to develop a body of research examining the process and outcome of these various therapies. Much of the knowledge base for clinical psychology was highly international in origin with creative work flowing to the USA from Europe. The creation of professional journals devoted to the publication of research on topics of relevance to clinical practice, including the *Journal of Abnormal Psychology* and the *Journal of Consulting Psychology*, also served to bring together in a focused way the base of scientific knowledge upon which practice could be founded. That initial knowledge base has changed greatly over the years as our understanding of scientific psychology has evolved.

1.2 Tensions Within the Field

Initially, the American Psychological Association (APA) was founded to support the advancement of psychology as a science, not psychology as a profession (Peterson 1997). Another group, the American Association of Clinical Psychologists, first met in 1917 to organize the clinical profession. Their action was highly controversial at the time (Wallin 1961) with considerable opposition within the APA to the creation of a new psychological organization. Although this group only lasted two years, out of it grew a clinical psychology section of the APA and the increasing recognition that clinical practice was a distinctive and legitimate aspect of psychology.

Creating a division within the APA to recognize applied psychology helped to advance the recognition of clinical psychology as a profession, but there remained tensions within the APA about the legitimacy of professional practice. Routh (1994) notes that one consequence of this continuing tension between practitioners and academics was the development of state psychological associations and of the American Association of Applied Psychology. The role of clinical psychologists during World War II brought recognition of the value of clinical services, and had a major impact on the growth of clinical psychology as a profession of practice as well as research. By 1945 there was a reorganization of the APA and the by-laws of that organization were expanded formally to include psychology as a profession as well as a science and to value the promotion of human welfare.

1.3 The Boulder Conference

The first major conference on the training of clinical psychologists was held in 1949 in Boulder, Colorado. This conference, sponsored by the National Institute of Mental Health, had a profound impact on the development of university programs to educate clinical psychologists. It was the Boulder Conference that defined the 'scientist–practitioner' model of professional training that for many years was the dominant model of clinical training in the USA. The goal of this model was to ensure that students were well grounded in research methods but also given applied training through their practicum and internship experiences. Although students felt pulled between these two sometime competing demands for research and practice, the Boulder scientist–practitioner model remained essentially the sole approach to clinical training for several decades (Routh 1994).

Routh (1994) points out that from early in its inception there were challenges to the Boulder model. The majority of clinical psychologists did not enter research careers after training and questions were raised about the value of the time spent teaching in-depth research skills to clinicians who would never use them beyond graduate school. Additionally, many practitioners argued that the Boulder model training programs did not devote sufficient time to teaching applied skills. Given the dissatisfaction with the Boulder model on the part of many practitioners, it is not surprising that an alternative model developed to training clinical psychologists for professional practice.

In 1964, an APA Committee on the Scientific and Professional Aims of Psychology, chaired by Kenneth E. Clark, recommended that clinical psychologists be trained in two tracks. One track would be for those persons who intended to focus on research careers and the other track would be for those who wished primarily to be practitioners. In spite of the Clark Committee recommendation, the growth of programs with primary emphasis on practitioner training proceeded slowly (Peterson 1985). The year Clark's APA committee issued its recommendations for two tracks of training, the only clinical training program focused mainly on professional practice was at Adelphi University. The Fuller Graduate School of Psychology was started in 1965. In 1968, the University of Illinois, which had a respected scientist–practitioner program in clinical psychology, added a professional practice program and granted a Doctor of Psychology (PsyD) degree to those who completed the training. The California School of Professional Psychology, a free-standing school, was established in 1982 and a number of other schools not affiliated with a college or university followed in the next decade.

1.4 Mission Bay Conference and Beyond

As practitioner programs became more prominent for clinical training in the USA, several national conferences on standards of training for practice were

sponsored by the National Council of Schools of Professional Psychology (NCSPP), a group representing the professional schools and programs. From a conference at Mission Bay California this group published *Standards and Evaluation in the Education and Training of Professional Psychologists: Knowledge, Attitudes and Skills* (Bourg et al. 1987). In successive conferences, the NCSPP has focused on such topics as ethnic diversity, curriculum, women's issues, and the role of evaluation in professional education (Peterson 1997)

2. Competencies for the Practitioner of Clinical Psychology

Modern practice in clinical psychology requires a broad base of knowledge in general psychology as well as specialized professional skills. The general base includes a background in biological functioning, cognitive processing, and human learning. The practitioner must understand the overt and covert functions of individuals, and the functioning of groups. A well-trained clinical practitioner is knowledgeable about how to assess and manage individual behavior, and he or she understands interpersonal relationships and group dynamics as well as the regulation of psychobiological factors in human functioning.

Along with their broadly based understanding of human behavior, the practitioner develops expertise in one or more approaches to the assessment and treatment of psychological problems. This expertise often reflects a specific theoretical orientation for understanding behavior, such as a psychodynamic, behavioral, humanistic, or family systems framework for approaching treatment. In addition, the professional will often have special expertise with one or more populations of clients including children, adolescents, adults, people with developmental disorders, individuals with addictive behavior, patients with serious mental illness such as schizophrenia or depression, or persons dealing with post-traumatic stress disorders. Each of these areas has an assessment and treatment literature that must be mastered by the competent practitioner.

Although the practice of psychotherapy is often through of as the core activity of the clinical psychologist, these practitioners do many other things as well. They must be able to do an assessment of an individual, family, or group, identify the best intervention methods to fit the needs of the situation, and then apply those techniques and make modifications in treatment based on feedback from the process of change. Empirically supported treatment techniques have been developed to intervene with some psychological problems and the clinical psychologist must be able to apply these as appropriate. He or she must also now how to modify or extend these treatment methods for patients who do not respond to the treatment procedures as they may be defined in a treatment manual.

Peterson (1997) employs the concept of 'disciplined inquiry' to describe the role of the practitioner in bringing intellectual rigor and a systematic approach to the evaluation of his or her work and decision making. One brings scientific knowledge to bear in solving the problems of one's client, but always with the needs of the client and his or her response to treatment as the guiding principle in choosing interventions.

3. Curriculum

Doctoral education to prepare a student to work as a practicing clinical psychologist combines academic instruction with practicum placements in settings where students apply the skills they learn in the

Table 1
A sample practitioner training curriculum

Year One
Theoretical foundations of intervention—behavioral
Theoretical foundations of intervention—psychodynamic
Theoretical foundations of intervention—organizational
Interviewing skills
Child psychopathology
Adult psychopathology
Individual cognitive assessment
Behavioral assessment
Psychodynamic assessment
Foundations of cognitive/affective psychology
Foundations of social psychology
Year Two
Philosophy and systems of professional psychology
Statistics and experimental design
Community psychology
Professional issues and ethics
A Course in intervention methods, e.g., family therapy, short term dynamic therapy, cognitive behavior therapy
Clinical psychopharmacology
Year Three
Intervention techniques with ethnic and racial minority clients and families
Courses in intervention methods
Begin dissertation research
Year Four
Elective courses
Dissertation
Year Five
Full time internship in clinical psychology

classroom. As shown in Table 1, the first year of such a doctoral training program typically provides foundation courses in such topics as the social, cognitive, and affective bases of behavior, descriptive adult and child psychopathology, basic interviewing techniques for gathering diagnostic and treatment data, and an introduction to the theories that underlie assessment and treatment modalities. Most commonly these theoretical approaches are behavioral, cognitive behavioral, family systems, humanistic, or psychodynamic in nature.

As students progress in training, their courses become focused on specific patient populations and treatment modalities. For example, a student may study family therapy treatment methods, psychoanalytic psychotherapy, or the use of cognitive behavior therapy in the treatment of children or adults. The typical program also requires students to learn basic research methodology and statistics in order to ensure that the practitioner is a sophisticated consumer of the research literature. To permit the systematic evaluation of specific efforts to deal with clinical problems, most programs require the student to do a professional dissertation. These projects often draw upon a broader methodology than the typical dissertation of a student who intends to pursue a career as a research psychologist. Examples of these research methodologies include a sophisticated set of case studies used to develop a theoretical concept, a program evaluation, or a qualitative analysis of interview data. Some practitioner dissertations may also employ a traditional empirical design.

Throughout their training, students will be exposed to various professional practice settings where they can apply their new knowledge under the close supervision of senior psychologists. One year of this training is a full-time internship that is typically done after the student has completed his or her course work and in many cases has also completed a dissertation project. Many newly graduated clinical psychologists will also spend one or two years in postdoctoral training further to develop special expertise under advanced supervision.

4. *The Practitioner Model vs. the Scientist Model*

Two major models have developed to educate doctoral students in the practice and study of clinical psychology. These are the 'scientist–practitioner' and the 'practitioner–researcher' (or practitioner–scholar) models. Table 2 summarizes some of the differences between these models. The differences in practice are sometimes less sharp than the models suggest. Some people trained as scientists are engaged in full-time practice of clinical psychology and some people trained as practitioners work in universities or research settings.

The scientist–practitioner model almost exclusively involves a Ph.D. degree at the completion of training, which is the degree held by most clinical psychologists who work in academic or research settings. These training programs typically provide more research training and less applied training than do practitioner programs. By contrast, the graduate of a practitioner–research or practitioner–scholar program is typically preparing for a career in practice. A few practitioner programs may grant a Ph.D. degree in psychology but most now grant the PsyD degree.

Training in Clinical Psychology in the United States: Scientist–Practitioner Model

Although some argue that the science and practice of psychology is as old as recorded history, contemporary psychology, as an evolving discipline, emerged at the end of the nineteenth century. From the beginning, the science and practice (or application) of psychology were inextricably woven together although few early psychologists embraced this model. Experimental psychology was born in 1879 in Willhelm Wundt's laboratory in Leipzig, Germany and brought to the USA by numerous students who worked with him. They pursued rigorous scientific investigations of animal and human subjects specifically around learning, memory, and sensory processes. At about the

same time in Vienna, Austria, Sigmund Freud was developing his 'talking cure' psychoanalysis, a clinical approach to the influence of trauma or past events on disruptive emotional symptoms often having to do with cognitive processes such as 'repression' or 'transference' (see *Psychoanalysis, History of*). But whatever the overlapping interest in learning, memory, and relearning, proponents of these two approaches had little to do with each other and a reapproachment between the scientific investigations of behavior and the clinical techniques of psychoanalysis was not offered until some fifty years later (Dollard and Miller 1950).

The late nineteenth century was also a time of considerable debate about the etiology of mental illness. Physicians, such as Emil Kraeplin who had also studied with Wundt, embraced an organic model which proposed that manic-depressive psychosis and dementia-praecox (schizophrenia) would be found to have a biological basis similar to syphilis, for which the spirochetes causing the brain degeneration had just been found. Others assumed that psychological processes composed the underlying etiology of emotional and mental disorders. These debates were further couched within discussions about whether investigations of general behavior or a concern with individual differences would lead to new understandings about the nature of human behavior.

Lightner Witmer, the father of clinical psychology, was an extraordinary exemplar of a scientist–practitioner. In his attempts to use psychology to help children who were having difficulty in school, Witmer was the first to write about the need to integrate the basic science of psychology and its application. In fact, he believed that there was no valid distinction between a pure science and an applied science.

Witmer founded the first Psychological Clinic at the University of Pennsylvania in 1896 and the first clinical journal, *The Psychological Clinic*, in 1907 (see *Clinical Psychology in North America, History of*). In the opening article of the journal, Witmer writes movingly of the difficulties he had finding ways to make psychology useful in his treatment of clients. One of his first cases was a fourteen year old boy referred by his teacher because he could not seem to learn to spell. Witmer (1996) looked to basic psychology but could not find 'that the science of psychology had ever addressed itself to the ascertainment of the causes and treatment of a deficiency in spelling. Yet, here was a simple developmental defect of memory; and memory is a mental process of which the science of psychology is supposed to furnish the only authoritative knowledge. It appeared to me that if psychology was worth anything to me or to others it should be able to assist the efforts of a teacher in a retarded case of this kind' (p. 2). Witmer goes on to quote the President of the American Association for the Advancement of Science noting that 'the final test of the value of what is called science is in its applicability … the pure and the applied sciences advance in a single front. What retards the progress of one, retards the progress of the other; what fosters one fosters the other' (Witmer 1996, p. 2).

In an effort to bridge the science and practice of psychology, Witmer linked his psychological clinic to the psychology laboratory at the University of Pennsylvania. His clinical cases also comprised part of the curriculum for the child development courses. Witmer proposed a 'scheme of practical work in psychology' that laid the foundation of clinical, counseling, and school psychology. This consisted of the investigation of the phenomena of mental development by means of statistical and clinical methods, a clinic, supplemented by a training school, practical experience for those working with children, and the training of students for a new profession—the psychological expert. Forty years later these guidelines were adopted almost in their entirety by the Boulder Conference on education and training in clinical psychology.

Numerous other children's psychological clinics were developed during the first few decades of the twentieth century. Usually these were associated with

universities but some were established to provide clinical intervention for juvenile delinquents. Clinical psychologists were also working in facilities for the mentally retarded and became heavily involved in intelligence testing. Both basic and applied psychologists extended psychology's expertise in 'mental' testing to the assessment of recruits into the military during World War I. Unfortunately, this began one of the most tragic episodes in psychology's history—the use of intelligence testing to keep thousands upon thousands of immigrants from relocating in the USA.

Debates about appropriate educational and training models for the proper roles and functions of psychology began in the earliest days. Most psychologists, especially those who had trained with Wundt, envisioned psychology as an evolving science which would explore the intricate processes of consciousness and memory, unlock the mysteries of sensory processes, and answer questions about how people perceive and make sense of the world. Psychological findings would be based on the most rigorous of experimental methods. Other psychologists, faced with practical and poignant human problems, such as a child's failure to learn, believed that psychology could advance knowledge through a consideration of practical issues and problems and be immediately applied to help people in need.

While the parallels are not perfect, these differences in epistemological styles reflect a philosophical conflict of some 2,500 years. A Socratic view of education places emphasis on curiosity and the accumulation of knowledge for its own sake while the Sophists emphasize human welfare and believe 'man is the measure of all things' (Kimble 1984). Within early psychology, William James (1907) described the history of philosophy as a constant battle between these two sharply contradictory intellectual styles. He described the 'tough-minded' skeptical, empirical scientific psychologists who depend only on facts vs. the 'tender-minded' rational and idealistic sort who base their efforts on principles. James commented on the antagonisms between the 'unrefined, callous, or brutal' tough-minded and the 'sentimental, soft-headed,' tender-minded (James 1907). Later, Snow (1964) wrote extensively about the clash of the 'two cultures' of science and humanism and Kimble (1984) extended this observation into psychology. Kimble suggests that contemporary psychology continues to have an identity problem in that the two cultures of the scientist and practitioner cannot agree on a coherent set of values.

This clash of cultures, as exemplified by the different values embraced by the scientific vs. the practitioner psychologist has always been with us. As early as the turn of the twentieth century, applied and clinical psychologists were complaining that the newly formed American Psychological Association (APA) was not meeting their needs. Practicing psychologists were particularly concerned that they be recognized through some formal mechanism as having been trained in psychology. In 1917, an American Association of Clinical Psychology was proposed as a vehicle whereby psychologists who were qualified to perform psychological testing could be identified. With some reluctance, APA agreed to certify some members as 'consulting psychologists' and formed a Clinical Section. The primary mission of APA, however, was to promote psychology as a science.

As practitioners involved themselves in psychological testing, child guidance, and helping individuals with 'adjustment' problems, issues of ethics, licensing, and standardization of training became paramount. In the early 1930s, the New York Psychological Association in an effort to meet practitioner needs at a national level became the Association of Counseling Psychologists. They became so strong that in 1937 the Clinical Section of APA disbanded to join them in the new American Association for Applied Psychology (AAAP).

AAAP began to move across the national scene to meet the needs of practitioners and state affiliates in regard to uniform training, certification, public relations, and ethical conduct. The group proposed a model certification act to gain licensure or registration for qualified psychologists and published a membership directory to identify such practitioners for the public. They proposed an ethical code and pushed for a curriculum, both undergraduate and graduate, that would include applied and clinical psychology. Further, Carl Rodgers (1939) proposed a supervised, one year internship training for clinical psychology graduate students and discussed the idea of a doctor of psychology degree, rather than the Ph.D. (Napoli 1981).

The advent of World War II had a powerful influence on organized psychology. In an effort to present a unified front for responding to the war efforts and the needs of the military, an Emergency Committee in Psychology was established that included representatives from all of the national psychology organizations (now up to six). A subcommittee on Survey and Planning for Psychology, chaired by Robert Yerkes, was formed to begin making long-range plans for psychology's future. Their first report deplored the splintering of psychology into various groups and proposed an increased emphasis on professional activities within the APA. They further proposed a new national organization that would serve both science and practice. When the war was over, the stage was set for the APA to reorganize to serve the needs of psychologists, whether their interests be basic or applied psychology. The two cultures of science and practice in psychology would be subsumed, once again, within one organization.

Psychologists had served in a number of capacities during World War II, ranging from the regular duties of the infantry to preparing propaganda and disseminating disinformation. Basic psychological scientists

became involved in human factors designing user-friendly instruments for vehicles and planes. Clinical psychologists found themselves providing counseling and psychotherapy for soldiers and by the end of the war, some 450 clinical psychologists were serving in the US Army.

At the urging of the National Research Council, the disparate national groups of psychologists began to meet together at the end of the war. Acting on recommendations from the Yerkes committee, the APA revised its by-laws to 'advance psychology as science, a profession, and a means of promoting human welfare' and incorporate other groups and representatives from state associations. The AAAP became the Clinical Division of APA and professional psychologists began to feel more at home in the then 4,000 member organization.

The National Institute of Mental Health and the Veteran's Administration were eager for clinical psychologists to continue to provide services for veterans who were suffering psychological and emotional problems. In fact, they began to subsidize training to increase the numbers of psychiatrists and social workers. They were willing to do the same for clinical psychology if appropriate training programs could be identified. APA provided the names of 22 such university programs and appointed a Committee of Training in Clinical Psychology to determine how best clinical psychologists might be trained (American Psychological Association 1947). The report of this Committee became the basis for a 1949 conference held in Boulder, Colorado which would recommend a revolutionary program of education and training. Clinical psychologists would be trained as both scientists and practitioners. Such an integrative model, unique among the major sciences and professions, would bridge scientific and humanistic traditions.

The Boulder conference was supported by the National Institute of Mental Health and the United States Public Health Service. Seventy-one representatives from universities, mental health service agencies, and allied professions met daily for two weeks to define clinical psychology and develop consensual standards for education and training. A 252 page book, *Training in Clinical Psychology*, reported the recommendations of the conference which were both comprehensive and specific (Raimy 1950). Clinical students' attributes were enumerated, faculty described, and curriculum proposed. Clinical psychologists were to be trained in general psychology and demonstrate research competence culminating in a doctoral (Ph.D.) dissertation. Further, students would engage in field training and a predoctoral internship so that they would be skilled in clinical assessment, diagnosis, and treatment. Such education and training was to take place in universities and internship facilities accredited under the auspices of the APA.

During the second half of the twentieth century, the Boulder or scientist–practitioner model became the preeminent mode of education and training in clinical psychology. Admissions to university-based, Ph.D.-granting programs were, and continue to be, highly selective. Academic requirements include general areas of psychology such as history and systems and psychopathology as well as cognitive, developmental, experimental, personality, physiological, and social psychology. Students are expected to learn to conduct research and be familiar with the various statistical methods necessary to evaluate results. Further requirements include practical training in assessment and intervention under close supervision including a one year predoctoral internship. The scientist–practitioner model has been reaffirmed at each major graduate educational conference held since Boulder although a professional model was also recommended at a 1973 conference held in Vail, Colorado (Strickland 1985, 1987, 1998).

The scientist–practitioner model is not reserved solely for clinical psychology. Other applied areas in psychology such as counseling and industrial-organizational psychology also embrace this paradigm as do the specialty areas of aging and health. For those who believe that psychology is a continually evolving discipline and field, basic training in science would seem essential in producing new knowledge. Further, practical training within such a model should lead to state-of-the-art applications. An integration of science and practice allows the continued interplay between scientific knowledge and clinical application where each informs the other.

Many would maintain that the development of the scientist–practitioner model has been one of psychology's finest achievements. Certainly for a newly evolving science which has clear implications for application this novel educational and training approach gives the field vitality and direction. Embracing the two cultures of science and humanism, the scientist–practitioner model has not been an easy one for individual psychologists to achieve. But, scientist–practitioners have served psychology and society well both through advancing knowledge and applying that knowledge for the greater good.

Transaction Costs and Property Rights

Transaction costs and property rights are related, important, and expansive concepts. Both move beyond technology to introduce law and organization. Both deal with issues of first-order economic importance (as against nuances). Because both have been difficult to operationalize, both have been used expansively and tautologically.

Property rights is the older concept, going back to antiquity. The use of transaction cost reasoning in the 1960s brought new life to the property rights movement. Not only is the economics of property rights basic, enduring, and important in its own right, but it also helped to usher in and remains an important part of the new institutional economics: 'Modern institutional economics focuses on the institution of property and on the systems of norms governing the acquisition or transfer of property rights' (Furubotn and Richter 1991, p. 7). Of the various categories of property rights, the right of ownership—which consists of the right to use an asset, the right to appropriate the returns from an asset, and the right to change its form, substance, or location (Furubotn and Richter 1991, p. 6)—is the most important.

The article begins with a sketch of the antecedents, then some of the leading property rights successes are examined, followed by the limitations and the conclusion.

1. Antecedents

Frank Michelman (1967) traces property rights concepts and thinking from Aristotle through the Christian Fathers, John Locke, David Hume, Jeremy Bentham, and Oliver Wendell Holmes. Despite this early and continuing interest, the economics of property rights 'has not been discussed analytically until very recently' (Demsetz 1998, p. 144). The introduction of transaction cost reasoning into the study of property rights in the 1960s is responsible for much of the analytical advance.

2. Modern Property Rights

2.1 Externalities

Work on the economics for property rights flourished in the 1960s. Leading contributors included Ronald Coase (1959, 1960), Armen Alchian (1961, 1965), and Harold Demsetz (1967). Much of this work contested the orthodox interpretation of externalities as 'market failures' for which government intervention 'in the form of taxes, or subsidies, or regulation' was presumptively warranted. Rather than take property rights assignments as given, Coase moved the analysis back a step to examine the ramifications of reassigning property rights. His treatment brought out 'the reciprocal nature of the relationship which tends to be ignored by economists who, following Pigou, approach the problem in terms of a difference between private and social producers but fail to make clear that the suppression of the harm which A inflicts on B inevitably inflicts harm on A. The problem is to avoid the more serious harm' (Coase 1959, p. 24). Assessing the more serious harm entailed introducing transaction costs.

Coase proceeded in a two-part way. Starting with the assumption of zero transaction costs, Coase advanced the (then) revolutionary proposition that 'the delimitation of rights is an essential prelude to market transactions; but the ultimate result (which maximizes the value of production) is independent of the legal [award of property rights to one party rather than the other]' (Coase 1959, p. 25). This is because, distributional considerations aside, the parties will bargain to the same efficient result whichever way property rights are awarded.

For Coase, however, this was an expositional device. The real world is one of positive transaction costs, whereupon the assignment of property rights one way or another does matter. Efficiency now turns on the differential transaction costs of assigning property rights one way rather than another. Coase furthermore contested the idea that a 'benign government' could be used to correct market failures, it being the case that all feasible forms of organization are flawed (Coase 1964). He also advised that total as well as marginal conditions needed to be included in a comparative assessment: there is a need to 'compare the total product yielded by alternative social arrangements' (Coase 1960, p. 42). This comparative approach in which transaction costs are featured reshaped the

study of property rights, market failures, and economic organization in the ensuing years, up to and including the present.

2.2 Common Pool Problems

Common pool problems arise in a variety of contexts, of which common grazing land (Hardin 1968), fisheries (Turvey 1964), petroleum extraction (Libecap and Wiggins 1985), and water and air pollution are familiar examples. Whereas the externalities examined by Coase were predominantly of a bilateral kind, the common pool problem poses the need to coordinate many actors. Additional problems arise because (a) different actors are differently situated, (b) the relevant information is dispersed and costly to verify, (c) strategizing and politicking often arise, and consent is needed to, (d) agree on an overarching plan, and (e) craft an organization to implement whatever plan is agreed to. The need for political action and regulation often arises in efforts to reach and enforce collective agreements in the multiactor context.

Recourse to public ordering, is not, however, the only or always the best response. Private ordering can and has successfully mitigated many common pool problems (Furubotn and Richter 1997, p. 102). Government assistance— for unitizing common pools (such as oil) or for creating markets (as in the creation of tradeable property rights for air pollution)—is often the cost-effective way to proceed.

2.3 Variable Access

The simplest transaction is an outright sale. But even that is complicated by the question of how the property right is defined. As Demsetz observes, 'To have the right to till a parcel of land is not equivalent to having all the rights to the land. Others may have rights both to minerals contained in the land and to trespass across the parcel. The identification of the owner of the asset is made more difficult by the virtually infinite number of different rights that can be associated with use of a given asset' (1998, p.145).

Access arrangements other than sale include leasing, tenant farming, inside contracting, and franchising. These can vary in length and protections. Incentives for due care (where the concern is over negligence by the lessee) and assured compensation for unexpired improvements (where the lessor stands to gain by refusing compensation for improvements made by the lessee that extend beyond the length of the lease) are common concerns. Access terms is also an area where the risk of changes in the political rules of the game is a chronic concern, the imposition of rent control being one example and the arbitrary exercise of imminent domain and 'takings' by the state being another (Michelman 1967).

2.4 Theory of the Firm

The theory of the firm poses numerous property rights issues, of which the most famous is the separation of ownership from control to which Adolf Berle and Gardiner Means (1932) made early reference in the context of the large corporation where shareholding is widely dispersed. Thus although shareholders remain *de jure* owners in the large corporation, effective or *de facto* ownership purportedly passes to the management. Berle and Means thereupon questioned the presumption that firms are reliably given to profit maximization.

Analytical reactions to this condition of separation have varied. One response has been to dismiss the issue by assuming that competition in product and capital markets is relentlessly taut. As Tjalling Koopmans has observed, however, 'if this is the basis of our belief in profit maximization, then we should postulate that basis itself and not the profit maximization which it implies in certain circumstances .... It would lead us to expect profit maximization to be most clearly exhibited in industries where entry is easiest and where the struggle for survival is keenest, and would present us with the further challenge to analyze what circumstances give to an industry that character' (1957, pp. 140–1).

Another response to the separation of ownership from control is to reformulate the objective function to reflect *de facto* control rights. The sales maximization hypothesis (Baume 1959), growth maximization hypothesis (Marris 1964), and managerial discretion hypothesis (Williamson 1964) are in this spirit. Still another response is to reconceptualize the problem of organization in contracting terms. The 'nexus of contract' approach (Jensen and Meckling 1976) brings out agency cost features to which monitoring is a response, while the governance structure approach (Williamson 1975, 1985) treats organization form as a decision variable. According to the latter, hierarchical decomposition principles—especially between centralized and decentralized modes of organization—matter. Organization is thus viewed both as a source of the managerial discretion problem and a partial solution, in that the large corporation can be reconfigured to mitigate some of its own failures.

A 'modern' property rights theory of the firm, of which Oliver Hart (1995) is the principal architect, has taken shape more recently. This theory works out of an incomplete contracting setup. The central issue with which this theory is concerned is that of vertical integration: who should own the assets of two related stages of production? This theory illustrates both the strengths and limitations of property rights reasoning. To its credit, the analysis makes clear how the ownership of property rights influences *ex ante* investments. But this exclusive focus on property rights comes at a cost, in that problems of *ex post* mal-

adaptation are suppressed (by assuming that the parties will costly bargain to an efficient result, whatever the assignment of property rights). The idea that organization matters—that the management of some transactions is better done by markets and of others by hierarchy—is sacrificed in the process.

2.5 Rent Seeking

The *de facto* ownership of property rights poses numerous intertemporal issues, of which rent seeking is one. The basic rent seeking proposition is this: the creation of 'rights' to which supernormal returns potentially accrue invites *ex ante* prepositioning, thereby to better qualify the applicant/bidder for the job or contract in question. For example, the award of a natural monopoly franchise or of a favored class of employment (Civil Service) invites parties to politick to receive the award and to make other efforts to improve their eligibility. Rent protective efforts also ensue (Tollison 1998).

In the degree to which such responses went unnoticed or were ignored by economists, such costs were mistakenly omitted from the original calculus. Upon 'discovering' such costs, most economists declared them to be wasteful. That, however, assumes that economics trumps politics (Stigler 1992). If political choices are to be respected, then the best course of action is to recognize that prepositioning is a predictable consequence of efforts to create new classes of rights, whereupon prepositioning effects are folded into the project design calculus. In that event, rent seeking, and its attenuation, are included in the 'approved plan.' Those who condemn rent seeking are loathe to come to terms with this proposition.

2.6 Economic Development and Reform

Early development theory emphasized 'macroeconomic accounting aggregates such as savings and the balance of payments, and the relative balance between broadly defined "sectors" such as "industry" and "agriculture"' (Lal 1983, p. 5). When that prescription proved disappointing, the pendulum swung in the opposite direction. The new imperative was to activate the market and 'get the prices right' (Lal 1983, p. 107), but that too was overly simple.

'Getting the property rights right' seemed more responsive to the pressing needs for reform in Eastern Europe and the former Soviet Union. But while 'an essential part of development policy is the creation of polities that will create and enforce efficient property rights, … we know very little about how to create such polities' (North 1994, p. 366). As discussed in Sect. 3.2.2, privatization is important but is not a panacea.

2.7 De Facto *Property Rights*

Just as the study of contract has benefited by going beyond a legal rules concept of contract to make prominent provision for private ordering (Llewellyn 1931, Galanter 1981), so too does the study of property rights benefit by going beyond *de jure* property rights to consider *de facto*. The recent application of *de facto* reasoning to explain economic development and reform in China (Qian and Weingast 1996) is illustrative. The dilemma was this: *de jure* privatization was politically unacceptable, yet the state-owned enterprises in China had weak incentives and poor performance. What to do?

Decentralization, by creating local township and village enterprises in which local government remained prominent, turned out to be a productive move. As Qian and Weingast put it (1996, pp. 87–8):

> These local government-owned enterprises have remarkably different governance structures from (central) state-owned enterprises and thus face better positive and negative incentives.… Politicians in every political system tend to bail out inefficient firms or spend on wasteful consumption. In a federal system, however, the mobility of resources across regions raises the opportunity costs to local governments of bailing out inefficient firms or wasteful public expenditures.

Not only do local governments share the successes of local enterprises, but they incur the risk that investments will relocate if governments interfere. Federalism is thus an instrument for realizing quasi-privatization and the incentive benefits that accrue thereto. *De facto* property rights thus vary with the political environment, *de jure* property rights unchanged.

There are nevertheless limits to the risks that parties will incur in a regime where *de jure* credibility is lacking. I conjecture that China will experience serious incentive obstacles in its attempts to develop leading edge technologies unless it provides more secure *de jure* supports for intellectual property rights.

3. Limitations

Although property rights concepts and property rights reasoning have gone a long way to reshape our understanding of economic institutions and effect public policy reform, the early ambitions of the economics of property rights have been incompletely realized. Here, as elsewhere, there can be too much of a good thing.

3.1 Oversimplification

According to Coase, 'a private-enterprise system cannot function properly unless property rights are

created in resources, and, when this is done, someone wishing to use a resource has to pay the owner to obtain it. Chaos disappears; and so does the government, except that a legal system to define property rights and to arbitrate disputes is, of course, necessary' (Coase 1959, p. 12).

This property rights solution applied not merely in general but even to such apparently intractable problems as allocating electromagnetic spectrum to radio broadcasters: 'there can be little doubt that, left to themselves, the courts would have solved the problems of the radio industry in much the same way [by defining and enforcing property rights] as they had solved similar problems in other industries' (Coase 1959, p. 30). Other interested parties were less sanguine. Chief Justice Taft, for example, resolutely 'dodged the radio question. I have refused to grant writs and have told the other justices that I hope to avoid passing on this subject as long as possible' (Coase 1959, p. 30).

Indeed, what would the courts, left to themselves, have done? Taft was baffled by the radio question because property rights were ill-defined and the courts did not know how to define them. Awaiting a workable definition of property rights in electromagnetic spectrum—with the help of economists, lawyers, engineers, or managers—a property rights 'solution' remained elusive.

As Arthur DeVany put it, 'the real stumbling-block to a market system of spectrum allocation is the interference problem. The spectrum is a multi-dimensional space; signals propagate indefinitely in the frequency, spatial, and time domain' (1998, p. 169). The team of DeVany, Ross Eckhart, Dan O'Hara, Charles Meyers, and Richard Scott (three economists, a lawyer, and a physicist) turned their attention to this matter in 1969. Their best efforts to define property rights that would be 'exclusive, predictable, capable of subdivision, enforceable and flexible' (1998, p. 169) notwithstanding, DeVany now concedes that their 1969 definition was merely a template and needed further refinements (1998, p. 169).

Indeed, going beyond the definition of property rights, there is a further problem: how to devise an auction? Although DeVany avers 'that our model has been used to privatize the spectrum in New Zealand, Australia, and Latin America' (1998, p. 168), Preston McAfee and John McMillan maintain that 'simultaneous single-round, sealed-bid auctions were used in New Zealand for spectrum licenses and in Australia for satellite-television licenses with disappointing results: low revenues and inefficient license allocations' (1996, p. 162). New developments in auction theory, which did not take shape until the 1980s and 1990s, were also needed. The simultaneously ascending auction was adopted by the FCC in the 1990s to auction spectrum for personal communications services: mobile telephones, two-way paging, portable fax machines, and wireless computer networks. Some judge that auction to be a 'success' (McAfee and McMillan 1996, p. 163), but the actual sale of spectrum turned out to be 'more complicated that anything in auction theory' (McAfee and McMillan 1996, p. 171).

Merely to conduct an auction ought not to be confused, moreover, with full privatization. In the US the FCC remains an active player in the management of spectrum. The upshot is that defining and enforcing property rights for some resources is a daunting exercise. Politics often continue, usually with the active participation of the key players. Realpolitik and partial privatization are evidently bedfellows.

3.2 Overreaching

3.2.1 The modern corporation. Might the salient features of the modern corporation be explained in property rights terms? Harold Demsetz took this position. Upon observing that there are 'significant economies of scale in the operation of large corporations … [and] that large requirements for equity capital can be satisfied more cheaply by acquiring the capital from many purchasers of equity shares' (1967, p. 358), Demsetz described the modern corporation in the following property rights terms: (a) efficiency is realized by delegating effective ownership to the management; (b) shareholders are essentially lenders of equity capital; and (c) limited liability relieves shareholders of the need to carefully examine corporate liabilities and the assets of other shareholders (as they would need to under partnership law).

This property rights interpretation of the modern corporation over-reaches in the first two respects. First, to suggest that diffuse ownership is responsible for delegation, whereupon the 'management group becomes the *de facto* owners' and that ownership is 'legally concentrated in management's hands' (Demsetz 1967, p. 358) is incorrect. For one thing, delegation is observed in large corporations whether there are many or few owners of equity shares. For that matter, delegation is observed in every large organization—public, private, nonprofit. Well-known limits on the span of control (from organization theory) rather than the economics of property rights are responsible for that result. Additionally, of the three rights of ownership—the right to use, transform, and appropriate the income from an asset—the management is never delegated this last. Equity is the residual claimant.

Second, to describe shareholders as 'lenders' of equity capital is misleading. Debt and equity are not merely instruments of finance; they are also instruments of governance. If shareholders are merely lenders, why not just sell collateralized bonds? Or why not loans from the banks? It is not for naught that equity investors, who invest for the life of the firm and are residual claimants, are awarded control of the board of directors (Fama and Michael 1983). The

efficiency logic of debt and equity is usefully viewed as a governance issue (Williamson 1988).

3.2.2 Russian privatization. The architects of privatizing Russian industry in the early 1990s appealed to the modern property rights theory of Sanford Grossman and Oliver Hart (1986) to urge mass and rapid privatization of all sectors of Russian industry (Boycko et al. 1995). The overarching theory was this: 'When property rights over a productive asset are clearly specified, and the person who decides how to employ his asset bears full costs and enjoys the full benefits of employment, he puts the asset to its most productive use' (Boycko et al. 1995, p. 19). Upon privatizing two-thirds of Russian industry in June 1994, Boycko et al. boldly declared that privatization had been brought to a 'triumphant completion' (1995, p. 8).

Subsequent events have been unkind. Although it may be unduly pessimistic to view Russian privatization as a failure (Braguinsky 1999, Black et al. 1999), it is undisputed that Russian privatization has not been a triumphant success.

Errors of two kinds explain the premature pronouncement of success. First, the property rights theory of the firm suppresses problems of *ex post* governance by assuming costless renegotiation. That has analytical advantages, but it is also disconnected from reality. Had Boycko et al. inquired into contract implementation, they would have discovered that the efficacy of privatization varies, working much better in some industries than others (Williamson 1976, Goldberg 1976, Priest 1993). Second, Boycko et al. never faced up to lapses in the laws and, even more, their efficacious enforcement in Russia. Failures to look beyond the immediate award of property rights and examine the needs for *ex post* governance support and effective legal recourse turned out to be fateful.

As with the allocation of electromagnetic spectrum and interpreting the modern corporation, so too with Russian privatization. Thus although property rights reasoning is pertinent to all, the economics of property rights is a self-limiting perspective. Awaiting a unified theory of economic organization, which is not in prospect, the application of several lenses—to include an examination of hazards that beset *ex post* governance and the condition of the institutional environment—has a lot to recommend it.

4. Conclusions

The economics of property rights is unarguably important. Were it that the Socialist Controversy in the 1930s was less preoccupied with technicalities (such as marginal cost pricing) but addressed itself more to an assessment of the property rights differences between capitalism and socialism, the field of comparative economic systems would have developed very differently (Demsetz 1998). But while property rights are crucial, they are not fully determinative of economic organization. To claim that efficiency will be realized upon defining and enforcing property rights simply over-reaches. Not only can property rights be difficult to define, but best efforts at court enforcement can be costly. Also, property operates in combination with contract and organization.

Kenneth Arrow's remarks about externalities, market failures, and transaction costs help to restore perspectives: 'I contend that market failure is a more general category than externality [and, because] market failure is not absolute … , it is better to consider a [still] broader category, that of transaction costs, which in general impede and in particular cases completely block the formation of markets' (1969, p. 48). Transaction cost is an inclusive concept that applies to property, contract, and governance.

Transfer of Learning, Cognitive Psychology of

1. *Scope of the Phenomenon and Definition of 'Transfer'*

Imagine someone handling a new text processing program on a PC, driving a car in Australia instead of in the USA, playing the counter-back role instead of the one used to, placing a bond portfolio under changed economic conditions, or meeting the new boss for the first time. In all these cases people are learning some specific new behavior using previously acquired knowledge and skills. For this phenomenon the term 'transfer of learning' was coined. The knowledge used may be of different kinds: (a) conceptual (known facts), (b) procedural (skills), or (c) metacognitive (evaluating or regulating one's own cognitive activities). The corresponding research has always focused on understanding and predicting extent, direction, and 'locus' of transferred knowledge (for overviews, see Cormier and Hagman 1987 and Detterman and Sternberg 1993).

2. *The Quest for a General Perspective of Learning and Transfer*

In order to give an overview, a general perspective for learning and transfer is outlined here. Learning, on the one hand, is thought (a) to occur within an immense body of prior knowledge, and (b) to be a process of continual integration of knowledge by constructions or reconstructions. Such (re-)constructions include:

(a) relating meaningful units of different conceptual levels that represent objects and their features,

(b) organizing these related elements into larger units according to the constraints imposed by the content structure of its concepts (e.g., money and goods have to be related first in order to become organized further to explain the higher-order concept of 'inflation'), and

(c) chunking: the process of *condensing* built-up structures for both memory capacity reasons and ease of subsequent use. The chunks may be related further

to other units of different conceptual levels, organized, and chunked anew. Chunks are indexed for retrieval and further processing, highlighting the top-level or goal concept: 'and all this is called inflation'; or 'and this is how acceleration is calculated in mechanics'; or 'this protection by the bird's color almost guarantees survival.'

Transfer, on the other hand, is thought of as a ubiquitous, continuous, systematic use of selected parts of the immense body of prior knowledge. It starts from a cognitive need for information that has to be (a) retrieved from memory, (b) selected for tentative application, and (c) mapped on a corresponding subprocess of learning as described above.

3. *Transfer of Skills: The 'Common Element' Theory of Transfer—An Old and a Modern Version*

Experimenters in cognitive psychology look for learning or, preferably, problem-solving tasks that can be constructed such that identities or similarities between two tasks (a source and target task) can be controlled. Some of the favorite research domains include learning programming languages, use of text processing programs, solving algebra word problems mainly from physics, and motor ability training.

3.1 *Playing the Violin—An Example*

One of the most obvious transfer situations can be illustrated by the use of common elements in playing a musical instrument, e.g., the violin. When practicing, a sequence of several notes and accordingly a sequence of finger movements of the left hand are learned. Once mastery has been achieved, the required skill can be applied to the whole range of the violin's touch board. This is the violinist's economy to use the practiced motor sequences to generate the very same melody in different pitches. This 'very same melody' was the kind of holistic unit or 'totality' Christian von Ehrenfels (Ehrenfels 1890) was working on, calling it a 'Gestalt,' a term used for a whole movement early in this century: the Gestalt psychology. The underlying common elements in violin playing that are transferred from string to string or from one hand shift to another are complete knowledge structures (chunks) containing the condensed motor program or action plan for performing that invariant melody. The specific parameters of the respective program or plan may be adapted if necessary, e.g., the higher the shift position of the left hand the shorter the absolute distances between the set fingers will be. However, the proportions of the distances between the fingers and the single movements within the sequence remain the same. Motor programs do transfer if the relative timing of a motor sequence is not violated. The music pattern can be speeded up without too high a risk of a loss of transfer.

3.2 *Common Elements—An Early Approach*

A first version of a 'common element' theory of transfer was developed early in the twentieth century by Thorndike. He showed how difficult it is to transfer general abilities from one academic domain to another (Thorndike and Woodworth 1901), except in cases where both share common elements: stimulus–response associations, typical for the explanation of behavior at that time. Transfer increased proportionally with the number of such overlapping associations in the learning and the test tasks (Thorndike 1913).

3.3 *Production Systems—A Modern Approach*

The common element theory of transfer has made considerable progress during the twentieth century. One of the well-known contemporary theoretical approaches for explaining what kinds of common elements are transferred in mastered skills comes from Anderson's ACT theory in its several versions (Singley and Anderson 1989) (the acronym ACT stands for adaptive control of thought). In the beginning of the violin play, each of the single knowledge elements (the printed notes to be transformed into movements) are elements of declarative knowledge (facts), each having both a certain single and a relational musical meaning (regarding rhythm and harmony). Repeating the sequence leads to what Anderson calls knowledge compilation: Some tones get closer to each other, are 'heard together' as a subpart within the sequence until, finally, larger and larger subparts are experienced as forming a totality. With practice, procedural knowledge is gradually built up. It is composed of specific conditions followed by actions (IF … THEN associations, so-called productions). In our example the condition (the IF part of the production) can be defined by the set of notes; it is followed by the corresponding action (the THEN part), namely the finger movements. If learned and practiced in a violin sonata by Händel, the production would transfer to a Mozart sonata if the same class of conditions were met again. Productions are, thus, the common elements that can explain transfer of skills. The progress in transfer theory in the twentieth century consists of (a) the elaboration of the former stimulus and the response side of knowledge use by introducing the production concept and (b) the integration of productions into compound production systems for knowledge acquisition and use.

4. *Analogical Transfer*

The most extensive transfer research since the mid-1980s has focused on so-called analogical transfer whereby true analogies are found in those problems that share a similar deep structure but not necessarily specific content (e.g., the analogy of the atom and the solar system). According to current research, an adequate theory of analogical transfer would have to account for how analogical transfer develops over the processing time span, and for the role that surface and schematic knowledge play. The process would have to follow several stages as the following 'green walnut' example illustrates (Fig. 1).

4.1 *The Green Walnut—Another Example*

Assume that a young girl has acquired the skill to handle several kinds of fruit properly: small apples, bananas, and even a coconut with the help of her father. She is now holding a green walnut in her hand (some time before harvest, as it is still covered by its soft green skin that later dries out), an object she has never seen before.

If we look at the process of analogical transfer the following four stages can be distinguished:

(a) Stage 1 refers to encoding some elements of the target problem. Our young girl encodes her object as something small, round, and green (top right in Fig. 1) which reminds her of some other object with which she is familiar: small, green apples (top left). The corresponding REMINDING 1 subprocess is based on surface similarities between a visible object and an imagined apple (as an exemplar of the class of small apples).

(b) Stage 2: retrieval of one or more source analogues (i.e., elements from specific prior knowledge) when presented with the target problem. The retrieval process can result in a variety of working memory activities: spontaneous spreading-out, systematic decomposing of chunks, or inferencing, leading to a list of features such as … is juicy, … has skin, … is biteable, that are candidate analogs to some corresponding characteristics of the target task.

(c) Stage 3: selection and mapping of the source analogue to the target task. The crucial question is which one of the retrieved items will be adequate for use. There are constraints determined by the target task limiting the selection of candidates to be used for attaining the goal of the target task. To identify the object, the selection will be an action schema or an assimilatory schema (Piaget 1952). Thus, the 'bite' schema is selected (subprocess SELECTION 1) for mapping (subprocess MAPPING 1). The corresponding schema use is an application of abstract schematic knowledge, the schema being a generalized unit of the prior knowledge repertoire of the child. Mapping is the subprocess of establishing a contact with the main learning process where still further processing will take place: the schema application as an operation on that green object to be identified.

(d) Stage 4: knowledge integration. The green object is now assimilated by the 'bite' schema: The object is indeed biteable. This knowledge is easily integrated into the child's knowledge, but this is not necessarily the case, as will be shown below. Although the taste while biting is terribly bitter, there is the important additional recognition that the object has a removable skin. (Status and 'locus' of stage 4 subprocesses will be discussed in detail.)

From here it becomes obvious that transfer is an oscillating process with recurrent subprocesses: The removable skin is encoded (a recurring stage 1 subprocess) and reminds (REMINDING 2) the child of another object with removable skin, a banana. It is certainly a very fast retrieval process followed by a similarly fast selection (since the task's constraints do not leave a great choice) of the 'peel' schema (recurring stage 3 subprocesses SELECTION 2 and MAPPING 2). These are, again, followed by knowledge integration in the form of the application of the 'peel' schema. This 'peel' schema is successful with the recognition of a hard shell covering the object. In a next step the hard shell is encoded (another stage 1 subprocess), leading to REMINDING 3, which, in turn, lets the child recall another object with a hard shell, a coconut. Here, stage 2 subprocesses will recur: memories about opening that coconut when the saw from her father's toolbox had to be used. The list of features of the retrieved coconut is relatively long (… is brown, … has fibers around, … is shakable, etc.) but the 'open-it' schema prevails according to the constraints of the task at hand (SELECTION 3 as another recurrent stage 3 subprocess). The 'open-it' schema will be mapped (MAPPING 3) for tentative use. But the assimilation by the 'open-it' schema will not be realized. Before looking for the saw that was adequate for opening the coconut, her father will explain the inadequacy of the old 'open-it' schema and suggest the use of the nutcracker. This is, in Piaget's terms, an accommodation of the assimilatory schema that would otherwise not satisfy the constraints of the task. So, knowledge integration adopts a specific form in the last phase of the learning process: The 'open-it' schema is accommodated and adapted into a 'crack-open' schema which, then, serves for assimilation. This is, of course, a specific stage, *not* of transfer subprocesses but of the main learning process: the accommodation of a schema enabling it for final assimilation in a whole series of accumulating assimilations (notice the embedded rectangles labeled L_1 through L_3 in Fig. 1), leading finally to the identification of the once unknown object as a 'walnut.' The crucial point of this final knowledge integration stage is that important processes take place: triggering further constructions after the arrival of a mapped element, partially reorganizing knowledge leading to new structures, chunks or insights. These processes certainly do not

Figure 1
The oscillating process of transfer—an analysis of the subprocesses involved

belong to the set of transfer subprocesses. However, several authors plead explicitly for a fourth stage in analogical transfer focusing on schema induction and structural abstraction (Gentner 1989, Holyoak 1985, Gruber et al. 1995).

4.2 Theoretical Conclusions from the Green Walnut Example

The following conclusions can be drawn.

(a) The interesting part of transfer research is to be found in the subprocesses and not so much in the outcome or the problem solution.

(b) Transfer (and mapping as part of it) has a definite serial time structure. It should be kept in mind that the need for knowledge stemming from a target task depends on the actual stage of the ongoing learning or problem solving process. This fact dictates the time sequence of mapping activities.

(c) Mapping is in itself not a unitary subprocess. Its components are selection for mapping, tentative matching (i.e., looking for fit), evaluation of fit (including feedback), and either return to a next selection or else finishing the mapping process and giving the information over to the ongoing learning process (knowledge integration).

(d) Mapping is an ancillary process in favor of the ongoing learning or problem-solving process. All subprocesses *after* a fit are part of knowledge integration, which is part of the main learning process, in our example the accommodation of the inadequate assimilatory schema.

(e) The transfer subprocesses are oscillating processes. They follow the constraints of the ongoing learning or problem solving process, including possible feedbacks from nonfit situations of some mappings (not exemplified in Fig. 1).

4.3 Analogical Transfer Research

There is a huge research literature on specific details while transferring source knowledge on to target knowledge: (a) the structure-mapping approach stresses the fact that 'analogy is a way of focusing on relational commonalties' (Gentner 1989, p. 201), (b) the pragmatic schemata approach emphasizes the construction of pragmatic schemata by comparing and abstracting the analogues of the two tasks (Holyoak 1985), and (c) the exemplar approach holds that concrete exemplars instead of abstract structures play the dominant role in analogical transfer. All three approaches agree on the above-mentioned stages of transfer but differ in attributing relative importance to content-specific surface analogues on the one hand and abstract schemata on the other across the stages of transfer. No single theory can explain all available data concerning the effects of source analogues on retrieval and application; there is a plea for a hybrid of the structural, pragmatic, and exemplar views for that purpose.

5. Enhancing Transfer Effects: Knowledge Constructions Need Consolidation

Lack of transfer is the rule rather than the exception—at least in every-day learning. It seems that the primary reason for this is the fact that basic learning processes have not been led up to a level of sufficient understanding, the students often remaining on a level of surface processing or mere symbol manipulation (especially in mathematics and physics). Conceptual and procedural constructions (including problem solutions) in the main learning process need consolidation, as follows.

5.1 Strengthening Knowledge Structures and Making them Transparent

Consolidation for strengthening cognitive structures involves modified reconstructions of previous constructions: Basically the same conceptual elements are connected again with each other

(a) in a different sequence (sometimes a backward reconstruction),

(b) under different conditions (e.g., time),

(c) from different perspectives, or

(d) with a different goal (e.g., for a different audience),

providing transparency and coherence to the structure. Much of this kind of consolidation can be implemented by means of self-explanations (Chi et al. 1994, Renkl et al. 1998).

5.2 Flexibilizing Knowledge Structures

Several approaches focus on flexibilizing knowledge structures, one stemming from Spiro et al.'s cognitive flexibility theory (Spiro et al. 1991). Another is the progressive transformation procedure (Steiner and Stoecklin 1997), aiming at structural flexibility by systematically transforming the original construction (mainly mathematical problem solving) forcing the learner to define similarities as well as differences by intensive comparisons. To secure flexibility of structures, it is important that knowledge is abstracted by the learners themselves (e.g., from examples) during the learning process instead of being taught as abstract units by some teacher or tutor.

One specific point refers to retrieval flexibility. In order to optimize stage 1 transfer subprocesses (encoding elements of the target task or problem), it is necessary that chunks formed during the previous construction process are decomposed in due time to keep the elements accessible for further processing (relating). Such decomposing activities can be seen as a specific form of retrieval practice that, at times, come close to self-explanations as mentioned above. In order to speed up retrieval of subroutines for learning and problem solving (e.g., conceptual knowledge in addition to algorithms for mathematical transforma-

tions), 'proceduralized' knowledge (after knowledge compilation; Anderson 1983) may yield an important contribution to transfer. However, the automatic use of proceduralized knowledge may include task-inappropriate effects if disconnected from the original declarative knowledge from which it is built up.

5.3 Transforming the Representational Format—Multiple Knowledge Representations

A specific kind of flexibilizing knowledge structures is transforming one representational format into another: a symbolic representation (e.g., an algebraic equation) into an iconic (pictorial) or an enactive (i.e., action-related) format and vice versa (Bruner 1966). The ability to transform representational formats and to keep knowledge structures accessible in several different formats renders parts of knowledge highly flexible and apt to play a role in several subprocesses in transfer.

5.4 Decontextualizing the Structures

Transfer often fails because knowledge is strongly caught in the training context, so that the common elements of source and target tasks cannot be found. Therefore, an important goal for learning for transfer is decontextualization. This means changing the content of the chosen examples, and thereby replacing contextual facts such as the agents of a problem situation (soldiers attacking a fortress from different directions instead of X-rays attacking a tumor in the same way), the concrete material (sand instead of water) or cultural circumstances (rural instead of urban) in order to have the learners recognize the invariant structural aspects or the abstracted schemata, respectively (Renkl et al. 1998).

5.5 Reviewing—Focusing on One's Own Processes, Not on Outcomes

There is one severe lack in today's teaching of learning for transfer, namely reviewing one's own learning processes: 'How did I acquire this wonderful problem-solving procedure, this marvelous proof in geometry, or this striking insight into a network of economic relations?' Reviewing one's own learning processes means mentally unpacking some of the chunks formed, recalling the relations established during listening to the teacher's explanations or the student-centered discussion; in short, reactivating the *how* of that multistep process of relating and condensing (chunking).

To sum up: the emphasis on consolidation is not an emphasis on automating (and thus not on knowledge compilation; Anderson 1983), but rather on making structures transparent, enhancing the coherence of relations and chunks, but also flexibilizing the elements, relations and larger units of a total knowledge representation including decomposing chunks. Consolidation contributes to the comprehension or understanding of the built-up structures (Kintsch 1998, Steiner 1999).

The crucial point for transfer is not whether or not chunks, productions, schemata, scripts, or mental models are constructed, nor is it their very nature that counts. It is *how* all these knowledge representations were dealt with in the original learning process to fight from the outset against structural deficits. There is a long-term aspect involved in transfer with accumulating learning effects that does not seem to be reflected sufficiently in current research.

6. Social, Emotional, and Motivational Aspects of Transfer

In the 'situated' learning approach (Gruber et al. 1995), the social context plays a significant role; it is encoded and stored as part of episodic memory. Indeed, actual features of target task elements or requirements may remind someone of episodic information that, in turn, may activate some conceptual source task information either to trigger a transfer process or to keep it going. Furthermore, learning, whether individual or social, is permanently accompanied by individual evaluations of both the potentially emotional aspects of the content and some individual aspects of learning such as goal attainment, success, or failure. It is therefore not surprising that emotional effects are encoded along with cognitive contents and activities that may be retrieved later in transfer situations when the target task itself evokes emotional or mood memories (Bower 1981). Moreover, there are motivational and personality-related aspects that contribute to the overall quality of the learning and transfer process and outcome: volitional self-regulations (Kuhl 1985) along with high personal involvement and mental effort.

6.1 External Support or the 'Proximal Zone of Development'

Experimental work and educational field studies suggest that transfer is usually not performed without external support, be it by hints with regard to similarities or analogues in two tasks, tutoring, or other sociocognitive guidance. All these measures correspond to the 'proximal zone of development', a concept introduced by Vygotsky (1978): the psychological space where individuals are able to develop cognitive achievements not by themselves but through the support of a tutor.

6.2 About Future Transfer Research

A lot of admirable experimental work has been done within transfer research but there is a strong bias toward artificial microworlds in the tasks to be learned

that diminishes the usefulness of the results with regard to broader, less experimental settings. As far as the 'analogues' are concerned, the nonexperimental reality often looks different: at the beginning of many problem-solving processes there are no analogues whatsoever in the learner's mind. It would be promising for future transfer research to focus on the subprocesses at the outset of transfer when individuals try to find and define the mental gaps to be filled in their learning or problem-solving tasks or when the retrieval subprocesses are set in motion. There is, furthermore, a definite need for more research focusing on both metacognitive and noncognitive aspects for explaining the lack of transfer so often observed.

Transference in Psychoanalysis

1. Definition

Transference, and its counterpart, countertransference, have been recognized as among the most fundamental organizing concepts of the psychoanalysis created by Freud. Basically, transference is the conception that our past, our lifetime of experience, lives on in us and plays a formative role in our interpersonal behaviors in the present. Transference was discovered by Freud quite inadvertently. In accord with his original conception that neurotic symptoms and behaviors were representations of earlier mental conflicts that patients had been impelled to repress from conscious memory, Freud devised the method of 'free association,' requiring that the patient try to verbalize every thought as it arose, without regard to usual considerations of logical and tactful expression, i.e., no matter how seemingly nonsensical, offensive, embarrassing, or shameful. To his dismay, he found that, no matter what the patient's conscious intent, this process of sequential narration would on occasion be blocked, with the patient lapsing into embarrassed silence or claiming that simply nothing came to mind. When pressed, the patient could often acknowledge that unbidden and unwanted thoughts or feelings about the analyst had come to mind, displacing the historical recounting.

Freud at first saw this as an unwelcome intrusion upon, and an impediment to, the joint therapeutic task of uncovering the originating traumatogenic events, and tried therefore to disengage the patient from such distracting impingements. He soon, however, realized

the regularity of this occurrence, that it was not an accidental or inadvertent happenstance, but rather a regular 'transferring' onto the person of the analyst of reactions to the earlier major figures in the patient's life, primarily parental and other family figures, but even more widely, any significant figures from the past who had played formative roles in the past experiences that were under present therapeutic scrutiny. In Freud's words, 'They (transferences) are new editions or facsimiles of the impulses and phantasies which are aroused and made conscious during the progress of the analysis; but they have this peculiarity … that they replace some earlier person by the person of the physician. To put it another way: a whole series of psychological experiences are revived, not as belonging to the past, but as applying to the person of the physician at the present moment' (Freud 1905). To state it simply: a feeling of anger welling up towards the analyst, perceived at the moment as an overbearing and arbitrary authority, would be a re-presentation of a sequence of childhood interactions with the patient's father, experienced often in just that light. Within this line of thinking, Freud designated transference reactions as father or mother transferences (or sibling, or mentor, or whomever), and as positive or negative transferences, depending on their emotional valences, whether affectionate, hateful, or some intermediate admixture.

Conceptualizing this way, Freud reversed his reaction to transference manifestations, from seeing them as impediments to analysis, to rather viewing them as essential vehicles for the analytic work. By 'analyzing' the transferences, i.e., unraveling their meanings in the interactions within the analytic session, and tracing them back, as representations in the present of pathogenic interpersonal interactions from the past, the patient's repressed traumatic past experiences would inevitably be brought to light, and their continuing formative role in the maintenance of neurotic behaviors in the present would be progressively dissipated. To revert to the example already given, the patient's chronic damaging interactions with his work superior, perceived as overbearing and arbitrary, that impeded his job satisfaction and could threaten job promotion or perhaps even the job itself, would be progressively eased, and even eliminated entirely, the more the patient could come to see them as unwitting re-enactments of his earlier experiences with his father (and to see concomitantly his own provocative role in eliciting those repetitive interactions).

Freud shortly came to feel in fact that just because of the emotional intensity experienced in the transference interaction in the immediate therapeutic situation, as compared with the remoteness of describing historical interactions in the long ago past, that the patient was most susceptible in the transference to the jarring emotional impact that could disrupt established, automatized behavior patterns, and lead to the shifts that we call insight and therapeutic change. This effect is described in one of Freud's most famous sentences as, 'For when all is said and done, it is impossible to destroy anyone *in absentia* or *in effigie*' (Freud 1912). In a well-known paper by Strachey, one of Freud's early adherents, interpretation of the transference was described as the only truly 'mutative' interpretation, all other interpretive efforts only leading up to, and supportive of, interpretation in and of the transference (Strachey 1934).

Freud's technical advice from the start was to allow the analytic transferences to unfold gradually, as they inevitably would, and only to interpret them as they clearly crystallized in the analytic situation as resistances to the ongoing work, either as negative transferences of hateful feelings directed at the analyst, or as erotized positive transferences of loving feelings. Freud did make an exception for what he called 'unobjectionable positive transferences,' the benign feelings that led the patient to the best possible conscious cooperation in the analytic work with the analyst, experienced by the patient as expert, helpful, and interested in effecting therapeutic change and cure.

In more modern times, some analysts have split off this so-called 'unobjectionable positive transference' into a separable conception alongside the transference, called the 'therapeutic alliance' (Zetzel 1956) or the 'working alliance' (Greenson 1965), usually operating automatically as a protective framework within which the transference vicissitudes—all of the complicated ambivalent relationships that characterize the human experience as it is lived out over a lifetime with all those who have played significant roles in each of our lives—could safely unfold, but at times, or regularly with some sicker patients, itself needing specific attention and nurture. Other analytic authors have, however, been dubious about this unobjectionable transference, seeing it as a defensive cover, hiding other much more objectionable transference manifestations, that would ultimately themselves need to be interpretively undone in the interest of the completeness of the psychoanalytic work.

As the transference unfolded over the course of the analysis, Freud further conceived of the evolution of what he called the 'regressive transference neurosis,' in which the presenting neurotic symptoms and behaviors dropped away in the patients' outside life, as their psychic life, with all of its neurotic components, came to full expression in the transference interplay within the analytic situation. To Freud, such a fully evolved transference neurosis, focused completely on the person of the analyst, recapitulated what he came to call the 'infantile neurosis,' the set of childhood maladaptive interactions that established the template for the later evolved neurotic illness that was to bring the patient to psychoanalytic treatment. It was the interpretive resolution of this fully-fledged regressive transference neurosis that Freud, and for long, most of

his followers, regarded as the central task of the analytic treatment, which could only be declared properly successful when the transference neurosis was fully resolved, and the various transference distortions were transformed into an objectively realistic relationship of the patient with the analyst.

2. *Transference Psychosis*

A related, and subsidiary, concept to that of the transference neurosis developed a good deal later, in the 1950s (but with roots back to Freud's close collaborator, Ferenczi, in the teens of the twentieth century), that of the transference psychosis. This conception developed along two distinct lines. The one was a precise analogue of the concept of the transference neurosis, i.e., that just as neurotic patients taken into psychoanalytic treatment display 'neurotic' transference reactions to the analyst, culminating in the full-fledged transference neurosis, so do psychotic patients taken into psychoanalytic treatment display 'psychotic' transference reactions which can coalesce into a fully formed transference psychosis. The other conception was that of a neurotic patient, seemingly well-suited for a classical psychoanalytic treatment, who under the regressive pressures of psychoanalysis could erupt (in an unforeseen way) into a psychotic transference response with loss of the usual reality moorings that maintain the transference as an 'as-if' phenomenon. I have reviewed this particular literature in detail elsewhere (Wallerstein 1967).

3. *Understanding of Transference at the End of the Twentieth Century*

Since Freud's day, our understanding of the transference has been altered and transformed significantly. A signal figure in this effort was Gill and Hoffman (1982) who, in a series of papers and a major monograph, squarely challenged the notion that transference manifestations consist just of the projections of the patient's past relationship patterns upon the neutral objective analyst who could be the epistemic arbiter of reality, clearly separating transference distortion from objective perception, and doing this from a position outside the transference display, as neither a participant in it nor a contributor to it. Given the inherent ambiguity in all human relationships, Gill saw the transference as the patient's plausible construction of his or her experience of the analyst and of the analytic interaction, with the analytic task then, the construction between analyst and patient of how they each differently perceive the same interaction, each perception being the product of the individual life experience of the perceiver, with the individually different predispositions then towards preferred ways of endowing meaning to the encounter.

The therapeutic focus would of course be on the psychology of the patient, what in the patient's life experience disposed him or her to construe the therapeutic situation and interaction in the manner manifested, and in that way to link the lived past to the present transference manifestations. Thus, the past is still present in the transference as a formative underlying template of interpersonal expectations, but the focus has shifted to a present-day interaction in the here-and-now of the therapeutic encounter as immediately experienced by the two participants, with again, the stated focus on the light that could be thrown thereby on the patient's prior life experience and the enlarged meanings that could now be ascribed to the life development. The focus has thus been shifted from the discovery of the past emergent in the present (in the transference), a focus on the there-and-then, to the new focus on the interaction in the present, in the here-and-now, as framed and colored by the past.

Along with that has been the concomitant shift from the transference as a purely intrapsychic phenomenon within the patient, projected onto the reflecting and assessing screen of the neutral, objective, and uninvolved analyst (what is now called the embodiment of a one-person psychology), to the transference as an interaction of two subjectivities, each bringing their own built-in predispositions to that interaction, with the focus again of course on the patient's characteristic construal of the situation, embedded in the life experience and consequent neurotic structuring of the patient, whose neurotic difficulties in living are, after all, the *raison d'être* of the therapeutic undertaking. This is called now a two-person psychology, the intersubjective interaction of two participants, albeit focused primarily on the difficulties of the one, the patient. These altered conceptions of the transference have been developed further as a fundament of what is called the object-relational perspective in psychoanalysis as distinct from Freud's perspective, called now drive/structural, or put differently, two-person vs. one-person psychologies. (For a full development of these distinctions, see the volume by Greenberg and Mitchell 1983.)

4. *Analytical Techniques*

These modern alterations in the conception of the transference have led to many consequent alterations in the technique of analysis. The focus is now more on the early interpretation of the transference, and on seeking out implicit allusions to the transference, and rendering them explicit, again, as early as feasible. The conception of the unfolding of the full-fledged transference neurosis as a necessary recapitulation of the infantile neurotic experience has given way to the experience of a great variety of transference mani-

festations in the present, more or less intense, more or less covert or manifest, of great range in emotional valence, and each embedded in uniquely characteristic relationship patterns, with past and present relationship experiences in constant dialectical interplay.

This entire history of transference development has been well summarized in an article by Cooper (1987) in which he contrasted what he called the 'historical' and the 'modernist' models of the transference. In Cooper's words, 'The first idea, close to Freud, is that the transference is an enactment of an earlier relationship, and the task of transference interpretation is to gain insight into the ways that the early infantile relationships are distorting and disturbing the relationship to the analyst, a relationship which is, in turn, a model for the patient's life relationships. I shall refer to this as the *historical* model of transference, implying both that it is older and that it is based on an idea of the centrality of history. The second view regards the transference as a new experience rather than as an enactment of an old one. The purpose of transference interpretation is to bring to consciousness all aspects of this new experience including its colorings from the past. I shall refer to this as the *modernist* model of the transference, implying both that it is newer, in fact still at an early stage of evolution, and that it is based on an idea of the immediacy of experience.' Implicit of course, though not directly stated, is that in the historical concept, transference is an intrapsychic phenomenon in one person, the patient, and in the modernist concept, it is an interpersonal phenomenon, involving two people.

5. *Countertransference*

One cannot talk about transference of course without considering countertransference. Originally, countertransference was conceived by Freud as the analyst's inappropriate and nonobjective responses to the patient's transferences, stemming from unresolved issues in the psychology of the analyst that were stirred up by the patient's transferences. This would necessarily cloud the analyst's proper evaluation of the transference, and was a conception therefore quite parallel to Freud's original viewing of the transference as an impediment to the analytic work. In this conception the recommended remedy was constant watchfulness by the analyst, to monitor such inadvertent and inappropriate responses, and to control as fully as possible their expression, in order to keep them from contaminating the transference display. If such monitoring and control to keep the countertransference from impinging on the transference proved ineffective, the further remedy would be rigorous self-analysis or a return by the analyst for more personal analysis of his or her own—in order to overcome these interfering neurotic residues. This view later came to be called the 'narrow' conception of the countertransference. Later, others, especially analysts working with sicker-than-neurotic patients, came to a wider conception of the countertransference, as the totality of the analyst's emotional responses to the patient, including countertransference proper (the specific neurotic response to the patient's transference), as well as emotional reactions by the analyst to the patient as a whole and to the activity of analyzing itself. This wider conception was called 'totalistic'; some analysts (Winnicott 1949) divided this overall countertransference into 'neurotic' and 'objective' components.

Though Freud came to see the transference, which he first felt to be an impediment to the analytic work, as, rather, the essential vehicle of the analytic therapy, with success hinging upon the successful recognition and interpretation of the transference, he failed to take the same step in his consideration of the countertransference. It was only about a dozen years after his death, in the early 1950s, that psychoanalysts, first in the UK, began to view the countertransference not as an occasional inadvertent and inappropriate intrusion upon the psychoanalytic process that needed to be guarded against, and only dealt with when it nonetheless manifested itself, but rather to the countertransference being an inevitable and constant expression of the analyst's involvement with the patient in the two-person, mutually interactive, treatment process. This was a reflection of the, by that time, almost universal shift to the totalistic conception of the countertransference as the totality of the analyst's emotional responses to the patient, whether in specific reaction to the patient's transferences, or whether stemming from the analysts' own developmental history and their overall (emotional) responses to the patient and to the situation between them.

It was further developed that through careful monitoring of their countertransference thoughts and feelings, the analyst could obtain useful insights into what the patient was trying to get the analyst to think or feel, and thus to obtain a wider knowledge of the patient's psychology and developmental history. This process of the arousal by the patient of emotional responses within the analyst has been variously called 'projective identification' (by the Kleinian school of psychoanalysis) or 'role responsiveness' (by the classical Freudian school; cf. Sandler 1976). Conceived and utilized in this way, the perception of the countertransference has likewise shifted from the initial view of it as an occasional and inappropriate intrusion upon the work of analysis (to be mastered and overcome by the analyst), to an inevitable and vitally necessary vehicle to the enlarged understanding of the patient, in this way, and many years later, following the same path as our understanding of the transference, seen first by Freud as an unhappy impediment to the analytic work, and seen only later as an essential conceptual and technical vehicle for that work.

In this sense, transference and countertransference are completely equivalent, neither being just a re-

sponse to the other, but each stemming from the psychological development of the respective parties to the psychoanalytic process. Some analysts (cf. McLaughlin 1981) have therefore even called for the elimination of the word countertransference, calling both sides of the responsive interaction transference, and privileging neither as just a response to the other.

Countertransference evocations tend to be more subtle and more contained with psychologically well-functioning analysts, and with classically typical neurotic patients, and more severe and difficult to contain with those sicker patients, called narcissistic or borderline in their character organization, seen nowadays with increasing frequency in psychoanalytic and psychotherapeutic practice. In this mutually interactive psychoanalytic situation, the intense transference-countertransference interplay results often in what are called 'role enactments' in which the analyst feels impelled to take on the role (punitive authority, benign rescuer, neglectful parent, or whatever) that the patient, through speech and behavior, is working, more or less unconsciously (usually more) to elicit from the analyst. And it is through the dawning awareness of having inadvertently taken on, or fallen into, the assigned role in the psychological interplay between them, that the analyst often becomes first aware of his or her countertransference involvement, and can then use this to trace out the psychic pressures from the patient that, when identified, become insights into the patient's character predispositions, with their linkages back into the patient's developmental history.

A major issue in this regard that is at present a matter of much professional controversy, is that of the circumstances in which it may be useful for the analyst to communicate to the patient aspects of understanding of the countertransference, when arrived at by the analyst. There are some who, while fully utilizing countertransference as additional avenues of access to the understanding of the patient, would avoid completely any countertransference 'confession' to the patient, as only an unnecessary, and varyingly troubling, burden for the patient to bear. Others advocate, at least at some times, or under certain circumstances, sharing their countertransference responses with the patient, as useful avenues towards the patient's understanding of what kind of reaction they were working to evoke in the analyst (and of course therefore with others in their daily life outside of the analysis), and the kinds of responses (so often consciously not desired by the patient) that are elicited in the other. And of course there are other instances where the patient detects the countertransference response before the analyst is aware of it ('You're angry at me and taking it out on me'), and at such times the analyst does need to deal with this truthfully, albeit tactfully, rather than to try to deny or avoid it.

A last and very important point about transference and countertransference: The psychoanalytic situation is a highly contrived arena in which these phenomena—emotional reactions to each other when individuals are engaged in an intimate and intensely personally meaningful dialogue—are highlighted and can be subjected to mutual scrutiny for the enhancement of the psychological understanding of the neurotic issues (and their developmental history) in the patient seeking relief from mental and emotional difficulties in life. But it is implicit in everything said to this point, and should be made explicit now, that we all live, all our lives, by transferences, in all of our human relationships. We always bring ourselves, our personalities or characters, as shaped and colored by our pasts, into all of our interpersonal encounters, and see our relationships and expectations in the present in very significant part through the dispositions built into us by the whole lifetime of our past experiences. In fact, it can be said that our entire capacity for relationships, for empathy with others, even for creative endeavor in any arena, rests on the transferences that we bring and live by (cf. Loewald 1980).

6. *Summary*

All of the issues covered in this article are explored at great length in Section III (more than 100 pages) in a book by Wallerstein (1995), *The Talking Cures: The Psychoanalyses and the Psychotherapies*, a volume that traces the historical development and unfolding of psychoanalysis and the derived psychoanalytic psychotherapies.

Transition, Economics of

The economics of transition is a relatively new field of scientific inquiry dealing with economic phenomena that arise as countries move from a communist system of central planning (also known as a command economy) to a decentralized market system. Transition economics uses as its laboratory the one-third of the world's population that left the market system for central planning in the first half of the twentieth century, and then launched an attempt to return to a market system toward the century's end. Since transition is one of the most important political-economic phenomena of the late twentieth and early twenty-first centuries, transition economics as a field has grown rapidly since 1990 and contains important theoretical, empirical, and policy components.

From an academic standpoint, the field of transition economics is unique because it permits researchers to examine how economies behave when markets are just being created and established phenomena of advanced economies, such as unemployment, are just starting to appear. Analysts of the transition economies are hence able to provide valuable information about the functioning of market economies, as well as to analyze the transition process itself. From a policy standpoint, understanding the transition process is important for the formulation of public policy in and towards these economies. Finally, the transition economies constitute an important part of the world market and an understanding of their problems and performance is essential for the formulation of an effective business strategy in these economies.

The performance of the transition economies to date has been uneven, providing variation that analysts need in order to draw significant conclusions and showing the sensitivity of outcomes to variations in initial conditions, government policies, and exogenous shocks. In particular, the fall of the Berlin Wall in 1989 has led to a rapid demise of the Soviet system of central planning and the launch of a relatively rapid transformation of the Soviet bloc economies into ones that would be based on free prices and newly created markets. Yet, while all the former Soviet bloc countries suffered an unprecedented decline in output at the start of the transition, their subsequent economic performance diverged considerably. The Central European and Baltic countries have performed relatively well, while countries further east, including Russia and the Ukraine, suffered further decline in output and achieved only limited structural transformation. In contrast, China's gradual reforms since 1978 have led to a remarkable transformation of the Chinese (more decentralized) version of the centrally planned system and generated a long-term period of rapid economic growth. These varied outcomes have naturally given rise to a debate as to which types of initial conditions and reforms are more conducive to a successful transition.

The principal theoretical models in transition economics focus on (a) the strategy of transition in light of various political constraints and uncertainty in the determination of optimal sequencing and speed of reforms, (b) the political economy of mass privatization (focusing on issues of possible privatization reversals, giveaway of shares of state-owned firms to the population at large versus managers and workers in these firms), (c) sectoral shifts, labor reallocation, labor market frictions, and capital accumulation, (d) speed and methods of price liberalization (including the Chinese dual-track approach), (e) the large output fall at the start of the transition (including explanation such as disruptions of supplies, inefficiencies of bargaining and search frictions), (f) the effect of weakness or collapse of government on economic performance (covering issues related to the switch from a strong communist government to a weak government plagued by corruption and the inability to collect taxes, enforce laws and prevent the rise of Mafia-type groups and an underground economy), (g) corporate governance, as well as governance at the level of a country, and the related issues of incentives, development of the banking sector, and large-scale bailouts of banks and firms.

The basic models of the economics of transition are similar in nature to the dualistic models of economic development that were developed in the 1950s and 1960s. The latter models describe development as a process of reallocation of labor from the low marginal productivity (traditional) sector to the high productivity (modern) sector. The modern sector generates surplus that is reinvested and leads to the expansion of employment in the modern sector. The traditional sector shrinks over time as its surplus labor is absorbed into the modern sector and the remaining workers adopt productivity-enhancing technology. The development process is finished when the marginal product of the traditional sector rises to the level of the modern sector and the dual economy becomes a single-

sector economy. In the transition models, transition consists of a reallocation of labor from the 'inefficient' state sector, where there is redundant labor, to the 'efficient' private sector that is assumed to pay labor its marginal product. Transition is a process in which these dualistic economies move toward a single-sector economy characterized by the equality of labor's marginal product across uses.

A prototypical model of transition is that of Aghion and Blanchard (1994). The authors assume that the marginal product of labor is higher in the private than in the state sector and that the government maximizes the net present value of output, which is equivalent to maximizing the rate of growth of private sector employment. The government engineers the downsizing of the state sector through the reduction of subsidies to state-owned firms and the creation of unemployment benefits for the released workers. Market forces determine employment in the private sector. The level of wages is a negative function of the unemployment rate and the creation of jobs in the private sector hence positively depends on the speed of downsizing of the state sector. Slow downsizing leads to low unemployment, which in turn puts upward pressure on wages and slows down the growth of the private sector. If the government downsizes the old sector too quickly, it will create high unemployment, which will reduce wage increases. However, the model assumes that private firms pay wage taxes that are used to finance unemployment benefits, and an excessive rate of closure of state firms, which leads to excessive increases in unemployment, and reduces the expansion of the private sector because of an excessive wage tax levied to finance unemployment benefits.

As was the case with the early development models, the question arises as to whether the first generation transition models provide a sufficiently useful approximation of the transition process. A number of features of the transition indicate that they may not be, and one may hence expect that further theoretical work, based on empirical evidence, will yield the next generation of theoretical models. The following two empirical patterns have been documented in empirical studies and are likely to be incorporated into future theoretical models.

First, while the private sector has emerged on a large scale in most transition economies, empirical evidence does not support the assumption that the private firms are more efficient than the state-owned ones. Ownership is also found not to be systematically related to employment and wage setting. Moreover, there are many different combinations of private ownership and corporate governance and they generate different levels of efficiency. In addition, while most theoretical models assume that private firms are newly created, a large number of private firms are privatized state-owned firms or spun-off subsidiaries. The phenomenon of breakups and spin-offs of firms appears to have increased the efficiency of both the spun-off and the remaining 'master' firms. Second, the flows of workers are more complicated than those captured in the first generation theoretical models. There are important job-to-job flows that do not entail unemployment and many workers move from one state firm to another, rather than from state to private firms only. Moreover, private as well as state firms are important in both job creation and job destruction.

The transition process is hence more complex than a shift of labor and other resources from inefficient state-owned firms to more efficient private firms. Existing evidence suggests that various types of firms coexist, compete for resources and markets, and through various forms of restructuring they improve their efficiency over time.

Since the literature on transition is relatively young and yet covers many traditional fields of economic inquiry, there are no large-scale, comprehensive surveys. The best overview of the theoretical literature may be found in Roland (2000), while a recent survey of the empirical literature related to the labor markets is in Svejnar (1999).

Transnational Citizenship: Cultural Concerns

Me velle civis totius mundi non civis oppidi. When Swiss Reformation leader Ulrich Zwingli offered Erasmus of Rotterdam citizenship in Zurich, the humanist philosopher is said to have replied that he did not want to become a citizen of this single city, but of the 'entire world.' World citizenship was always one of human-

ity's dreams, one considered as honorable as it is unfulfillable. Now globalization has not only razed the fortress of the nation-state (as progress in ballistics did to the fortified walls of medieval city-states), it has also created opportunity for what is called *transnational citizenship*. In historical perspective, nations provided the framework of modern community and society; they limited the space of communication where political parties and interest groups of all kinds acted, thus creating the prerequisites for equal representation and civic participation. In the welfare state, too, who should be included and who excluded from solidarity, was defined within this framework. But the universalistic principle of inclusion itself helped migrants gain a high-value status as residents, without being formal citizens. A person's national citizenship thus uncoupled from his or her right to have rights, insofar as international laws, for example to protect migrant labor, and human rights conventions became plausible as independent sources of individual and collective rights. The question at hand is: Between local patriotism and global markets, where can *homo politicus* be found?

1. The Term 'Transnational'

The *Oxford Dictionary* dates the emergence of the term to about 1920, documented with a quotation from an economic text that saw Europe after World War I characterized by its 'international or more correctly transnational economy'; interestingly, it added another source that identified the Christian Church as the sole power that could create the conditions for a 'transnational, non-racial democratic polity.' One author, who had 'transnational America' in view as early as 1916, is not even mentioned: Randolph S. Bourne. While the nations of Europe hit out at each other in enmity, this literary critic and pacifist from New York emphasized a special potential of the USA, one he thought represented the core and seed of future world society. The USA, as the 'first new nation' of immigrants, clearly did not have recourse to the European bases of nation-building and collective identity, either ethnic-cultural or state-bureaucratic. On the other hand, Bourne rejected the then-current idea of a 'melting pot': 'We are all foreign-born abroad or the descendants of foreign-born, and if distinctions are to be made between us they should rightly be on some other ground than indigenousness.' One should not seek the foundations of American collective identity in a mystified past, as was the case with the European nationalism, instead '… we must perpetrate the paradox that our American cultural tradition lies in the future.' From this, Bourne drew the conclusion: 'America is coming to be, not a nationality but a transnationality, a weaving back and forth with other lands, of many threads of all sizes and colors' (Bourne 1916, pp. 87, 92, 96).

At the beginning of the twenty-first century, 'transnational' has become a technical, but also a fashionable term, though one seeks it in vain in dictionaries and most social science lexicons. It is used especially in connection with international organizations and the 'multis' (transnational corporations, or TNCs). According to the original meaning of the Latin prefix 'trans,' it points beyond the usual diplomatic dealings among sovereign nation-states and the customary division of labor among 'national economies'; the unit of analysis, not only in international relations, has become *Weltgesellschaft* (world society, see Luhmann 2000). This does not intend to announce an 'end of nation-states'; but state sovereignty as we knew it has become 'anachronistic' (Czempiel 1969). From the accustomed macroperspective or bird's-eye view of the world economy, the glance drifts to the microlevel of *Lebenswelt* (life world), where we can trace the cross-boundary paths on which people and objects, metaphors and symbols, individual life histories and collective biographies are transferred. It is time for social science and political actors to acknowledge this 'paradigm shift' from international relations to transnational that also allows that a new form of world politics is arising: governance and citizenship beyond the nation-state.

2. Economic and Cultural Preconditions of Transnationality

2.1 Global Economy

From the beginning, the most powerful and conspicuous relativizers of the nation-state were the transnational corporations with their world-spanning trade and finance transactions. There has been a world market since sailing and techniques of navigation first permitted intercontinental trade, currency exchange, and investment; the Hanseatic League and the spread of Chinese family households throughout the Pacific demonstrate that the postmodern subversion of national borders has its premodern precursors. Yet, capital's inherent 'lack of patriotism' (Karl Marx) has meanwhile developed beyond the accustomed relations between parent companies and foreign subsidiaries; economic and financial conglomerates have merged so that, aside from having a legal seat, they are no longer anchored in one particular nation. E-commerce, including business-to-business deals, will further radicalize this despatialization.

Certainly, the prospects of the new economy must be viewed with caution, but state and cultural boundaries already play hardly any role anymore in its leading branches, telecommunications and biotechnology. Elimination of boundaries through 'digital capitalism' already have dramatic consequences for taxes and customs—which, after all, are the primary

sources of revenue for nation-states and even supranational economic communities like the European Union. Global standards of management and services are joined by the harmonization of trade and economic law through legal firms, auditing companies, and consultancies. These need not really have global reaches; what we observe is rather a regionalization (in the sense of 'continentalization') of economic domains (North American Free Trade Association, European Union) or a geographic subdivision, as with the executive board of ICANN (Internet Corporation for Assigned Names and Numbers) and other transnational private–public institutions.

2.2 Migrant Communities

These examples show that transnational spaces have arisen between nations. Moving in the interstices is a 'business class,' a loose conglomerate of managers, consultants, and service providers more closely associated with companies and concepts (e.g., the 'Apple culture' and, more recently, the 'Linux movement') than with native countries and native tongues. Border-crossing mobility is not limited to the upper levels of the labor market; even unskilled workers with precarious residence status have meanwhile become highly mobile and multicultural. This *Völkerwanderung* (mass migration), joined by masses of foreign travelers, commuters, and retirees in the sunny South, has especially stimulated thought about 'transnational social spaces' (Faist 2000). Today's nomads differ from their long-familiar precursors, especially the streams of immigration to the USA, Canada, Australia, and France in the nineteenth and early twentieth centuries. Today, 'homeland' and 'host country' are more closely connected and networks between them are much denser. With cheap transportation and easy communication, not to mention the worldwide reception of 'home' television and radio broadcasts via cable and satellite, permanent settlement no longer seems necessary. Bags were always packed and ready in the Diaspora, but usually they remained in the attic; and the back and forth of those times—for example between New York's Lower East Side and southern Italy or between Chicago and Warsaw—also lacked the emotional routine that now characterizes transnational mobility, and above all it did not have the effects on the structure of entire societies that transnational communities are likely to have today (Ong 1999, Leggewie 1999).

We can now define more precisely as transnational a social field, transcending national affiliation, in which a growing number of people lead a kind of double life. The expropriation of farmers, which tore the agrarian population from the 'soil' and drove them into the industrial cities, now finds its counterpart in a kind of 'expropriation of borders.' This casts doubt on sociology's 'container vision'; its spatial metaphors referring to closed national societies now seem exhausted. For transmigrants live in the long term in two or more places, constantly speak two or more languages, possess *en masse* two or more passports, and pass continually in both directions through makeshift households, networks of relationships, and spaces of communication. From this perspective, migration 'routes' count more for cultural studies than the migrants's 'roots' of personal identity in national collectivities (Clifford 1997, Hannertz 1996). All this together, perhaps combined with and crowned by the World Wide Web, a medium of transnationalization *par excellence*, leads to a despatialization that, unlike classic emigration, permits 'virtual proximity' and merely temporary absence. This allows communities to maintain themselves even without constant face-to-face encounters; and with successive long-term presence 'at home' and 'abroad,' both poles of such transitory existence finally become almost interchangeable.

2.3 Religious Pluralism

Wanderers between the worlds generally bring their native gods and rites in their bags, for people who are supposed to have lost their ties are especially likely to seek 'ties back' (Latin *re-ligere*), which is the literal translation of religion. Religious communities have always transcended national borders; spiritual belief is especially suitable for 'stretching' and reconstructing in what was originally called 'the Diaspora' since the scattering of Jewish and early Christian congregations. The supralocal spread of religious ideas and communities is not new in principle (the Catholic Church can be seen as the first-ever agent of globalization), but the transnationalization of religion is no longer identical to Christianization; nor has secularization, which became typical for the Christian societies of Europe, prevailed as a model for the world.

Though religious life (and dominant cultures based on it) are relativized by transnational migration, emigration can thus revive religious feelings of belonging. In regard to world society, religion pushes globalization forward precisely by resisting the profane effects of economic globalization inasmuch as it forms particularist congregations. Diaspora, once experienced as catastrophic, is no longer an exception in the religious pluralism of our time; and at the same time, protection of religious freedom has improved all over the world, so that imported religious symbols are becoming visible again in the public space of secularized societies. Globalization is thus not limited to corporate mergers, Internet communication, and financial transactions. Religious communities, too, travel around the globe, and not only in the organizationally and functionally supported manner of

world churches, but also and especially as decentralized grass-roots movements, as an unofficial, heterodox, self-founding, religious civil society.

2.4 Hybrid Cultures

What can be said about religious coexistence is also true for the diffusion and mixing of multicultural societies in general; a characteristic of this world of hyphens is provided by 'world music' (e.g., in the style of Peter Gabriel or Putumayo)—a collage of disparate materials often fusing completely contrary styles. In such mixtures, called 'hybrid' in allusion to biological crosses, things grow together that would not sound compatible to any purist's ear. But proponents of musical and other mixtures point to quite successful combinations since the earliest origins of the fine arts; and in general we can note that the creativity of cultures is never based on keeping the foreign at a distance, but to 'extraordinary' borrowings, i.e., to mimetic appropriation and the constant exchange of inventions, to innovation from the margins and the acquisition of the seemingly unassimilable. Seen in this way, phenomena of 'world culture' are merely a further stage of the hybridization of hybrid cultures, and all efforts toward canonical restoration are futile while the barriers between high and low culture have been razed, too (Appadurai 1996, Tomlinson 1999).

The 'wild' combining of artifacts, symbols, and identities began with the primary means of expression and communication, language itself, where it 'creolized' at the points of contact between two or more groups of speakers. The process of assimilation was usually asymmetrical and often violent, but, at the same time, hybrid constellations mirror the growing interdependence of world society, which of course excludes as often as it includes. In this process, components of all cultures are uncoupled from local roots and contexts; this has often been interpreted as 'standardization' and, since the origins of hegemonial popular culture can be traced to the USA, as Americanization. Much speaks for this assumption, if we observe the selectivity and modes of influence of the culture industry, whose effects sometimes amount to a kind of cultural extinction; on the other hand, the conformation of the world society's structural prerequisites does not lead to complete cultural uniformity.

In the terminology of cultural anthropology, culture must be conceived as bounded and embedded, and thus as a field that can be cultivated only in a particular time and place. The global economy and technology require and produce universal media like money and standardized systems of experts, which must ignore local origins, because this abstraction is the only thing that permits communication and creates trust; but cultural enclaves resist standardization. It is now rare for this aloofness to achieve the power of a fundamentalist resistance aimed at preserving one's own culture. For however much the desires for distinctions can be agitated and politicized against each other in this 'culture war,' in the end they remain oriented toward a structure of common differences. Popular mass culture permits travels through time and space without requiring viewers and listeners to leave their homes. For the first time, electronic mass media like CNN and MTV can reach overarching audiences with 'major events,' including warlike conflicts, athletic competitions, and appearances by entertainment stars. There are topics that enthrall literally the entire world, and there are growing audiences for global stagings. But this thematic concentration is accompanied by a fragmentation of local audiences, which again can illustrate the dialectics of globalization and localization.

3. Arenas of Transnational Citizenship

If the nation, in combination with government by bureaucratic agencies and popular representation, has been the fulcrum of personal identity and the condition of social affiliation since the nineteenth century, at the beginning of the twenty-first century, flexible forms of belonging and community transcending the nation-state challenge the representivity and legitimation of democratic rule. Again, the question is: Between local cultures and global markets, has the *homo politicus* become a dying species?

3.1 Transnational Governance

Governance without government, i.e., collective binding decisions outside the familiar arena of the nation-state (Rosenau and Czempiel 1992), is increasing, as evidenced by the multilateral regimes of the World Bank, the International Monetary Fund (IMF), and the World Trade Organization (WTO), as well of course as of the 'multilevel politics' of the European Union. These decisions are also effective, often to the dismay of national governments and populations, and they are no longer made solely unanimously, but increasingly also by majority votes. But the chains of legitimation for these supranational and transnational institutions are too long, and supranational and international regimes are suspected of disrespecting essential democratic prerequisites, namely the accountability of representatives and the congruence between those who make decisions and those who are affected by them. Attempts to ameliorate these defects, for example, by parliamentarizing the European Union, only underscore the difficulties of transnational citizen participation; the worldwide elections of the executive board of ICANN (fall 2000) show that there is a certain desire for worldwide participation and codecision, but also how difficult it is to organize such a process outside the nation-state. Only a few thousand out of millions of Internet users took part;

we can speak at best of 'successful failure,' from which conclusions should be drawn for the status of the world citizen in the age of global markets and information (Held 1995).

3.2 Complex Multilateralism

Up to now, participation in the transnational sphere has been mostly informal and unconventional. Analogously to the transition from medieval municipal citizenship to modern national citizenship, a space of communication has grown that transcends the nation-state's sphere. Here, individuals not only engage in economic and scientific exchange or unite culturally and religiously, but can also engage in political activity. One should mention more than 5,000 international nongovernmental organizations (INGOs) and, recently, social protest movements of global reach that articulate political will at conference tables, on the streets, and sometimes in both arenas. Both meanwhile fill the entire political space by devoting themselves to such topics as environmental protection and sustainable development, human rights, and equal rights for women. They can mobilize substantial resources and organize worldwide campaigns, with which they have attained the respect of and, if not a seat, at least a voice among representatives of states and international organizations. Such transnational activities can at least provide an impetus of agenda-setting, but they also extend as far as the sphere of problem solving and decision making. Here, in a broad and still undefined field, where the 'boundaries of the political' are still unstable, transnational citizenship is crystallizing; as a rule, formulation of political demands and decision making in these organizations and social movements are, alas, just as lacking in democratic legitimation and control. Nation-states are still the most effective accumulations of political power. Nevertheless, violations of human rights by dictators and ruling by force are generally made widely public and effectively condemned, ignoring claims to political or cultural autonomy. Basic rights have been bindingly codified in international conventions to the degree that this has resulted in an international jurisdiction, albeit in embryo form and without any means of enforcement.

In particular, the USA blocks any form of 'complex multilateralism' as soon as it relativizes US hegemony. Viewed in this way, it is a pretty irony but no coincidence that, once again a movement that intensely criticizes the lack of democratic citizen participation in international regimes spread from the US West Coast to circle the globe, this time under the slogan 'Seattle.' In December 1999, the WTO met there for a conference to address routine questions of the further liberalization of world trade. The meeting was poorly prepared, but this caused less trouble for all the government representatives than did the surprising fact that thousands of determined demonstrators blocked the entrance to the conference building and that the sometimes violent protests precluded any normal course of conferring. The wisps of tear gas have moved on, and, in response to other summits, the baton of similar protest has passed to other summits in Davos, Washington, Prague, and Seoul.

'Seattle' has meanwhile become the mantra of a new transnational social protest that makes use of the latest communications technology and may thus be regarded as the first virtual protest movement of its kind (O'Brien et al. 2000). Economic globalization from the top has found its counterpart in this movement, an opposition from below that is equally despatialized and that, where it is not protectionist and nationalist-populist, calls for an alternative, and more inclusive, form of globalization and, under the honorable slogan 'No globalization without representation,' sets out to battle the autocracy of international organizations. The movement is very heterogeneous and runs all the risks of short-livedness and fragmentation that social movements have always incurred. It includes environmental protectionists and trade unionists, Christians and secular human rights advocates, workers and academics, reformers and revolutionaries, libertarians and anticapitalists; and these groups find only small areas ideologically and organizationally in common.

Environmental protectionists lambast the destructive effects of industrial methods of production; the religious people denounce its materialistic disposition and indifference to human dignity; socialists of every stripe are bothered by exploitation and private property; others reject the consumerism of McDonald's and Coca-Cola. Ultimately, these groups contrast with each other as sharply as they do with their common enemy, the international organizations: Ecology and the economy can be arch-enemies; protectionist unionists want to close borders that dyed-in-the-wool cosmopolitans want to eliminate; development aid workers in the South attack the environmental protection regulations of the North as ecoimperialism, and so forth.

Here one can not predict whether such fronts will resolve into an opposition inspired by anticapitalism (like that at the end of the nineteenth century) against globalism or, more probably, into another reform movement from within globalism. But the logic of inclusion seems inescapable. In transnational spaces, 'internal affairs' no longer exist. What the humanist thinker Erasmus anticipated, is common sense now: one cannot be a citizen of a city without becoming a citizen of the world.

Transnational Religious Identities (Islam, Catholicism, and Judaism): Cultural Concerns

The subject of 'transnational religious identity' is unexpectedly complex. It refers to personal or collective religious identities that transcend enclaves, localities, regions, nations, and states to attain a wider unity of belief, practice, or community. Transnational religious identities also imply an inherent tension between claims to universality and the specifics of language, ethnicity, place of origin, locally shared culture, values, and history. The term also implies the existence of the nation-state system—with its own competing claims for personal and collective identity—as the principal worldwide form of political sovereignty. Transnational religious identities are continuously reconstructed in different contexts and ongoing struggles over ideology and authority in which shifting coalitions of elites, counter elites, ethnic groups, or those excluded from local authority structures compete for voice and recognition.

1. Constructing Religious Identities

Transnational religious identities, like other personal and collective identities, are socially constructed. They are not given or 'natural,' although the advocates of some religious identities, like secular nationalists, often make such claims. William Robertson Smith's influential *Lectures on the Religion of the Semites* (Smith 1956) traced the development of Semitic religious practices and institutions, stressing how a people's social and political institutions, and the shifting boundaries between their own and 'other' communities, contributed to shaping their religious and ethical conceptions. Thus the prophecies of Ezekiel and Samuel differed not because of a contradiction in the Bible, but because each prophet addressed himself to different groups and historical contexts.

For Smith and his successors, a key element in the growth and development of religions was the growing awareness that ideas and practices of community are socially constructed even if they are firmly rooted in divine revelation. In this view, a more 'modern' understanding of religious belief and practice implies a self-consciousness of ritual and tradition, places a high value on individual responsibility and commitment, and recognizes the existence of other religions and accords them some measure of legitimacy. In this respect, such Quranic verses as the following, revealed in seventh century Arabia, are distinctly modern: 'To each among you, we have ordained a law and assigned a path for each of you. Had God pleased, he could have made you one nation, but His will is to test you by what He has given you; so compete in goodness' (Quran 5: 48). From its beginnings in seventh century Arabia, Islam as religious tradition and practice has been remarkably open to the outside world. The vast expanse of the Muslim majority world, ranging from Morocco to Indonesia, inevitably meant that it came to encompass a variety of civilizational and cultural forms. In Arabic, the Quran exhorted its initial seventh century audience to break through parochial identities of tribe and kinship and aspire to a wider, more inclusive community of belief and practice.

Other religious traditions, including Judaism and Christianity, show similar diversity of form, commingling local and universal elements. Pilgrimages in all faiths serve to project believers across lines of immediate locality or group. Pilgrims set off from home in the hope of reaffirming contact with a spiritual center, encountering 'others' and returning home with a sharpened awareness of difference and similarity.

Whether to Mecca, Jerusalem, Ayodhya, Rome, the holy places of Shi'a Muslims or to the shrines of Sephardic saints (*zaddiqim*) in North Africa and Israel, pilgrimage creates unity as it highlights differences of locality.

Catholic missionaries and the adepts of Sufi religious brotherhoods also carried the word and practice of their respective faiths across vast spaces before they became nation-states (Rudolph and Piscatori 1997). The missionary activities of the Catholic Church in Latin America date from the Spanish conquests of the sixteenth century. Missionary orders such as the Jesuits and Franciscans implanted complex networks of churches, missions, and schools, transferring people and resources between Spain and the colonies. In the Middle East in the nineteenth century, French Catholic and American Protestant missionaries opened religious schools in the Levant, and, from the 1880s onward, the Alliance Israélite Universelle sent emissaries throughout North Africa and the Ottoman Empire. Although not primarily religious in orientation, Alliance missionaries had a profound impact on the self-perception of the Jewish communities where they worked. The work of these missionary enterprises was aimed, respectively, at Christians and Jews. These activities occurred within a framework of economic hegemony and political domination in which foreign powers actively sought to protect the interests of Middle Eastern Jews and Christians. However, these 'minority' communities were widely distributed geographically throughout the Middle East in the nineteenth century, so that missionary activities aimed at them had a significant indirect impact on the region's Muslim majority.

Sufi orders had a major role in propagating Islam, both in the Islamization of North Africa and in the subsequent consolidation of Islamic domination. Some orders, such as the Bektashiya, attracted as adepts the political elite of the Ottoman Empire. Other orders, such as the Tijaniyya, had a major role in the spread of Islam to West Africa. Some orders were highly structured, but most were only loosely linked through informal but pervasive networks of affinity and trust. Their forms of association were widely understood and respected throughout the Muslim world, and their organizational forms continue to serve as a template for many contemporary religious movements.

2. *Religious Identity and Nationalism in the Nineteenth Century*

In nineteenth century Europe, the idea took hold that peoples could be divided into nations sharing a common language, religion, ethnicity, and culture, and therefore should form separate political units. This notion was complemented by a heightened self-consciousness, systematization, and explicitness of religious traditions. By the 1830s, the plural 'religions' came into common currency, with a similar development in Arabic, to signify the idea of 'religion' as a system of beliefs and practices that could be set alongside nonreligious elements of the human condition and apart from other religions (Smith 1963).

The linkage between nationalism and religion was implicit and the boundaries of religious and national identities rarely coincided. Partially in response to political and ideological developments in nineteenth-century Europe, a pan-Islamic movement developed in the late nineteenth century. It continues in modified form to the present. Although the pan-Islamic movements of the 1880s bore similarities to the pan-Hellenic and pan-German movements of the time, only pan-Islam was based formally on a religious commonality. The pan-Islamic movements were initially confined to the educated elite, although this elite claimed to speak for all Muslims. The combined French and Spanish effort to crush the rebellion of Abd al-Karim al-Khattabi in 1927 generated protests throughout the Muslim world and appeals for pan-Islamic unity, but the results were transient and minimal.

3. *The Re-emergence of Religion in Public Life*

Prevailing theories of modernity and modernization in the mid-twentieth century assumed that religious movements, identities, and practice had become increasingly marginal to modern or modernizing societies, and that only those religious intellectuals and leaders who attached themselves to the nation-state would continue to play a significant role in public life. As Casanova (1994) notes, by the late 1970s this prevalent view rapidly eroded through the impact of several nearly simultaneous developments: the Iranian revolution, the rise of the Solidarity movement in Poland, the role of liberation theology in political movements throughout Latin America, and the return of Protestant fundamentalism as a force in American politics. Religion continues to play a significant role in politics and society worldwide. Even locally rooted movements benefit significantly with transnational sponsors or supporters, whether emigrants, states, or others sharing a group's objectives. Opposition to the Shah's regime was firmly rooted in Iran, but the safe haven provided for opposition leaders in exile and their transnational ties and freedom of movement and action were integral to the revolution's success.

Contemporary religious transnationalism and the identities it supports take many forms. Some are highly structured, while others are only informally organized and related primarily by affinity of goals. Informality and the lack of formal structure can be a strength in contexts of political and religious oppression.

At one end of the spectrum of organizational structure is the vertical transnationalism of the Roman

Catholic Church. In its encounter with the emerging system of sovereign nation-states in Europe, the Church incrementally reached an accommodation with nation states so that the Church hierarchy, although transcending the boundaries of nation-states, also worked within them. The close ties often formed with sovereign states often preserved a large measure of local freedom of action for the Church, but it also checked its ability to serve as a voice for social and political reform and for human rights.

The Second Vatican Council (1962–65) significantly altered the nature of Catholic transnationalism. With the Vatican's Declaration of Religious Freedom, *Dignitatis Humanae*, it unambiguously supported the doctrine of universal human rights and used its voice internationally to secure these rights for all peoples and not just Catholics. Vatican II also intensified interfaith dialog and formally recognized the diversity of Catholic belief and practice. It spurred the translation of liturgies into local languages and promoted lay participation in Church activities, further adapting the Church to local political and social circumstances.

The Church's overall hierarchical structure remained intact after Vatican II, but it was complemented and sometimes overshadowed in importance by decentralized grass roots networks and organizations created for purposes as diverse as Bible study, evangelism, and social and political action. Many organizations and networks had direct ties to the Church hierarchy, while others operated autonomously. In Latin America, as elsewhere, both types of networks benefited from transnational support. Dutch, Italian, French, Swiss, US, Spanish and other organizations acting transnationally contribute funds and personnel to sustain local developmental programs and action networks. Church-related human rights networks (along with groups with no religious affiliation, such as Amnesty International and Human Rights Watch) have played a significant role in sustaining resistance to authoritarianism and repression, giving concrete form to the idea and practice of transnational civil society.

Protestant transnationalism lacks the time depth of the Catholic presence in Latin America, Africa, and elsewhere, but missionaries from mainline Protestant denominations established a stronghold in Africa by the last part of the nineteenth century, often informally dividing spheres of influence with competing Catholic and Protestant groups, establishing schools and hospitals that often had no state counterparts. Schools have been especially important, and often formed the cadres of early nationalist movements (Beidelman 1982). Education, intended to inculcate Christian identity and practice, ironically undermined colonial authority and provided the cadres for African independence movements.

The first Protestant churches in Latin America were established primarily for European immigrants. By the 1960s, however, the mainline denominations were increasingly displaced by evangelical, Pentecostal, and fundamentalist churches and missionaries, trained and supported primarily from North America. Levine and Stoll (1997, p. 71) describe the growth of these groups, especially the 'Religious Right,' mixing evangelism with nationalism and anticommunism, as 'spectacular.' They suggest that these groups, in addition to providing needed community services, hospitals, and schools in areas where state facilities are minimal, appeal primarily to people experiencing intense social change and aspiring to improve their status and lives.

The ease of travel and the greatly enhanced role of the mass media have also enhanced the scope and ability of nongovernmental associations and networks to infuse an inherent transnational dimension to contemporary religious identity and practice. For both Catholic and Protestant groups, the 'horizontal' networks of civic and religious engagement, once established, become durable and self-sustaining. The transnational ties engendered through travel for labor migration, missionary activity, civic action, and human rights work sustains both institutional ties and a sense of moral community for all participants, not just for the elite. Unlike the hierarchical transnationalism of the Church in earlier periods, the loose network organization that characterizes many contemporary groups is more difficult for states to regulate or control. Moreover, the ease with which participants in such networks can spread information across state boundaries and secure external support serves as a brake on the state abuse of authority. This is as much the case for Latin America as elsewhere. Della Cava (1993), for example, notes the influential role of Catholic nongovernmental philanthropic and service organizations in Central and Eastern Europe as a catalyst for change and an alternative, although not a replacement, for attachment to the nation-state.

4. *Transnational Islamic Identities*

Islamic transnational movements occur in a significantly different context than Christian ones because Islam lacks a central organizational hierarchy. Although some Muslim intellectuals call for a spiritual or political unity, the Muslim world has almost always been characterized by a *de facto* pluralism of belief and practice. Even radical Islamic groups use the universal language of Islam but in practice seek only to establish an Islamic state or an Islamic order within their respective national borders even if they secure external support.

Some Islamic transnationalism is formal, organized, and linked to state organizations. After an arsonist's attack on the al-Aqsa mosque in Jerusalem in 1969, Muslim majority states founded the Organization of the Islamic Conference (OIC), which by the end of the twentieth century consisted of 52 member states.

However, this group has never advocated political unity and some member states, such as Nigeria, are anxious not to appear too closely identified with the organization. Nor has the OIC proved effective in the Iran–Iraq war (1980–1988), in defusing the Iraqi–Kuwaiti tension that led to the 1990 to 1991 Gulf War, or other conflict among Muslim majority states. However, its Islamic Development Bank, established in Saudi Arabia in 1974, has become one of the most effective aid agencies in the developing world, and various charitable funds associated with it have had a significant impact in its regions of activity.

Unlike Catholicism, in which vertical and horizontal transnationalism coexist, Islamic transnationalism is thus entirely horizontal. In addition to such formal organizations as the OIC, some clandestine or 'deniable' transnationalism is state-supported. After the Soviet invasion of Afghanistan in 1979, for example, the USA, with the cooperation of Pakistani and Saudi Arabian security services, supported the recruitment and training of mercenaries from other countries, including Egypt, Algeria, the Yemen, and Sudan to operate alongside Afghan refugees from bases in Pakistan. This 'joint venture' subsequently turned against its initial sponsors.

Islamic transnationalism is also manifested in nongovernmental movements such as the Muslim World League (*Rabitat al-'Alam al Islami*). It sponsors educational programs, religious scholarships for students to study at Saudi and Muslim world universities, and a vigorous publication program throughout the world. Such nonstate organizations, particularly through their formal presentation of Islamic issues and standardization of language and approach, help create common ideological communities that transcend state and national frontiers. Such organizations also show an increasing concern over the situation of Muslim minorities throughout the world, bringing their plight to the wider Islamic community worldwide. The concern of these groups with Muslims living in North America, Europe, and Australia is reci-procated by the Muslims', active concern with the situation of Muslims in their countries of origin or heritage and with the situation of Muslims in general. Other movements, such as those associated with the Turkish religious leader, Fetullah Gülen, are based on loosely connected clusters of supporters who lack formal central direction. Gülen's movement sponsors schools throughout Turkey, Central Asia, and Eastern Europe, as well as radio, newspaper, and television stations, notwithstanding the lack of central organization, the movement's educational and media programs have emerged as one of the most enduring forms of Turkish presence in Central Asia.

An even less formal and structured form of transnationalism is represented by *da'wa* (call to Islam) movements such as the Tablighi Jama'at (Masud 2000). Founded in India in 1927, the movement expanded worldwide after 1947 and currently operates in 80 countries. One principle of the movement is that the practice of Islam does not depend on educated elites alone. The movement's main efforts are directed at deepening the faith of other Muslims and, to promote unity, it avoids theological controversies and politics. South Asian in origin, the Tablighi Jama'at is also active in Europe, North America, and the Arab world. The movement offers no formal training institutes, although some institutions of religious learning are attached to Tablighi centers. Unlike other Muslim organizations, the Tablighi Jama'at lacks welfare or educational programs. Since the movement eschews the broadcast and print media as a matter of doctrine, its spread is entirely through personal contact. With its emphasis on strict adherence to rituals and a concern with the development of individual morality and renewal of personal faith rather than collective action and community change, the Tablighi movement has limited appeal to educated Muslims.

5. *Religious Identity and Globalization*

In the last third of the twentieth century, modern forms of travel and communication and mass education have accelerated religious transnationalism—the flow of ideologies, access to information on organizational forms and tactics, and the transformation of formerly elite movements to mass ones—rendering obsolete earlier notions of frontier as defined primarily by geographical boundaries and accelerating in pace the earlier spread of ideas already speeded through the introduction of print technologies. Thus the devotees of the North African Jewish saint, Baba Sali (Rabbi Israel Abouhatzeira) meet not only in Israel and Morocco, but also in New York and Europe.

Especially in the Muslim majority world, the advent of mass higher education since the mid-twentieth century, combined with the proliferation of mass media and the greater ease of communication and travel, has led to a significant reimagining of religious and political identities. One change is that patterns of authority have become more diffuse and open. Religiously committed activists increasingly replace traditionally educated scholars as sources of authority. Second, religion has implicitly been systematized and objectified in the popular imagination, making it self-contained and facilitating innovation. Questions such as 'What is my religion?' 'Why is it important to my life?' and 'How do my beliefs guide my conduct?' have become foregrounded in the lives of large numbers of believers, facilitating individual questioning and encouraging individuals to assume responsibility for their conduct and to participate in movements of social and political action. These transformations also mean that 'authentic' religious tradition and identity must be foregrounded and constructed rather than taken for granted. Finally, the greater access to

education, like access to the mass media, has broadened senses of language and community. Just as the rise of written vernacular languages in Europe since the sixteenth century and the spread of print technology created language communities wider than those of face-to-face interactions, mass education and mass communications play such a role in the contemporary world, transcending the narrow bases of local communities and dialects and creating new bases of religious identity.

Transportation Geography

Transportation geography describes, explains, and predicts flows of people, goods, and information across space. Flows occur as a result of some form of exchange: people offer their services to employers in exchange for wages, friends exchange information about husbands and children, manufacturers produce and sell consumer goods to wholesalers and retailers. Flows occur within a network: the journey to work in vehicles on roads or rail, information via telephone lines or the Internet, and goods across roads, rail, shipping lanes, or air route. Other subfields of geography are concerned with places and their spatial organization. Places and flows are interdependent, hence the boundaries of transportation geography are quite fluid. This article describes the major concepts of transportation geography and discusses some theories and issues.

1. Understanding Flows

Transportation is critical to contemporary society. In the USA, the transportation sector represents 11 percent of gross domestic product (GDP), and transportation is the second largest expenditure category for households. Economic growth is closely linked with transportation: movement of people and goods is positively associated with GDP. Why is transportation so critical, and what motivates these flows? Transport is costly, both in terms of time and money. Hence there must be some benefit to justify incurring these costs. Flows occur when the benefits derived from transport exceed transport costs. Flows can be understood in terms of a few basic principles.

1.1 Flow Depends on Transport Costs and Gains from Trade

The first principle of flows can be illustrated with the journey to work. Consider a worker: the cost of commuting is incurred in order to remain employed. How much is a worker willing to pay in order to receive a given wage rate? The average US commute is about 23 minutes (based on 1995 national survey data); and just 4 percent are longer than 1 hour. Since commute costs reduce the effective wage (wages net of commute costs), it follows that as commute costs increase, fewer people will be willing to accept employment at a given wage level. The converse also holds: as commute costs decrease, more workers will be willing to accept employment at a given wage level. The likelihood of flow taking place is a function of transport costs and benefits from trade. This principle applies to goods and information as well as people.

1.2 Declining Transport Costs are Associated with Increased Flows

Transport cost includes both time and money costs. Technological change and infrastructure investment have increased travel speeds and reduced unit costs.

Figure 1
Time/space convergence: (a) map of Europe, constant travel speed; (b) map of Europe, 1993 rail transport network

Figure 2
US passenger-miles of travel, air, and POV

The late nineteenth century transcontinental railroad offered trips from New York to San Francisco in 6 days; the trip by air today takes about 5 hours. Similarly, France's high-speed train offers service from Paris to Lyon in 2 hours. Around 1900 the same trip would have taken 6 or 7 days. These improvements also apply to intrametropolitan travel, but to a lesser extent, since intrametropolitan travel has so far been limited to surface transport modes. Transport cost has also greatly declined. For example, it is estimated that the average cost of commuting by streetcar in the USA at the turn of the twentieth century was about 20 percent of the average daily wage. Today the average cost for auto commuters is about 7 percent (Giuliano 1989).

Increases in speed result in 'time/space convergence,' a reduction in friction of both distance and time (Janelle 1995). Time/space convergence is illustrated in Fig. 1(a) and Fig. 1(b) for all of Europe, excluding Russia and the Ukraine (Spiekermann and Wegener 1994). Figure 1(a) provides actual spatial relationships and is calibrated on a homogeneous travel speed of 60 km per hour^{-1}. Figure 1(b) provides a picture of temporal relationships, based on the 1993 rail transport network. Note that Paris is 'closer' to major cities of Switzerland, The Netherlands, and Amsterdam, while in East Europe, Bucharest and Sophia are both 'further' from one another and from Central Europe. Time/space convergence is associated with globalization and the emergence of the time-sensitive economy (Janelle and Beuthe 1997).

Large reductions in transport costs have resulted in equally large increases in transport demand. Figure 2 shows the increase in US passenger-miles for private vehicles and for domestic air service, 1960 through 1995. Figure 3 shows the increase in ton-kilometers of surface freight transport for 10 European Union (EU) countries, 1970 through 1996.

1.3 Declining Transport Costs and Increased Flows are Associated with Development of the Space Economy

Historical development of the space economy is explained in part by declining transport costs. In the preindustrial era, nonmotorized transport was slow and difficult. There was little exchange between cities, because transport costs exceeded benefits at very short distances. Technological changes that reduce transport cost, e.g., 'space adjusting technologies,' allow regions to exploit comparative advantage, engage in regional specialization, and expand their areas of economic influence (hinterlands).

Nonmotorized modes of the preindustrial era were replaced with motorized modes in the nineteenth century: steamships and railroads. These technological advances greatly reduced the cost of intercity travel and hence led to large increases in both passenger and goods transport. The railroads in the US connected vast regions, resulting in the emergence of an integrated national economy. Railroads also contributed to the development of the national economies in Europe. Change accelerated in the twentieth century with the emergence of paved roads, autos and trucks, and the development of commercial air transport.

A famous example of the impact of reduced transport costs is the Erie Canal, built in 1825 to open a waterway between Lake Erie and New York by connecting Lake Erie to the Hudson River. The

Figure 3
Freight transport trends, 10 ECMT countries

reduction in transport cost was dramatic: over-the-road transport cost 20 times as much per ton-mile as shipping via canal; travel time was 20 days over the road and 6 days via canal. Goods movement greatly increased. New York's hinterland was extended through the entire northeast region and its position as the US center of international trade and the dominant city in the US urban hierarchy was consolidated.

Empirical research on the relationship between transport and economic development is mixed. Research on both developed and less developed countries indicates that transport infrastructure is a necessary but not sufficient condition for economic development (Hoyle et al. 1998). The first links of major networks (rail, highway) have generally had significant impact, while the impact of additional links tends to be marginal (Munnell 1992). There are many failed examples of transport infrastructure investments made to promote trade and economic development, as for example the US efforts to promote economic development in the Appalachian region.

1.4 Transport and Urban Spatial Structure are Interdependent

Urban spatial structure is the outcome of economic, social, political, and cultural forces. Within the complex process of urban evolution, however, transportation has played a major role. The historical relationship between transport and urban form is well-established (Muller 1995). With faster and cheaper transport has come more decentralized and dispersed spatial structure, and as activities have become more spread out, travel has increased. Decreased accessibility has been offset by increased travel speeds.

US cities in the latter half of the nineteenth century were crowded and congested. Industrialization had generated a surge of urbanization. The lack of motorized transport forced population and businesses to co-locate in close proximity to one another. Electricity-powered rail transport proved to be the breakthrough technology. Starting in the late 1880s, urban railways allowed cities to grow outward as workers took advantage of the new mode to seek less crowded residential locations outside the city core, and gave the city center special dominance as the center of the intracity transport network. Urban rail was followed in the 1920s by the automobile and truck. Development of the highway network proceeded rapidly, increasing travel speed, and allowing ever more rapid decentralization. The post-World War II freeway era continued these trends, with both jobs and population decentralizing, and with the emergence of suburban activity centers. European cities have followed a similar trajectory, but under quite different social, economic, and political conditions, and with—to date—less dramatic spatial change.

The relationship between transportation and urban form has been the subject of much theoretical research. The familiar 'standard model' of urban location and spatial structure as developed by Alonso (1964) and others, serves to illustrate the close relationship between transport costs and urban spatial structure. Consider the simple case of a city where all employment is located at the center, transport cost is a linear function of distance, and households trade off housing and commuting costs in making their residential location decisions. How will workers locate themselves with respect to the city center? Clearly net wages will be highest at the city center, where transport

costs are near zero, hence workers will prefer location near the center, and locations near the center will be valued higher than locations away from the center. If workers could bid on locations, the result would be a gradient of both land prices and population density that declines with distance from the center. Declining transport cost results in less steep density gradients, as the relative value of living near the city center declines. Decreases in the density gradient have been documented for metropolitan areas around the world (Mills and Hamilton 1994).

2. Research Issues

Increasing concerns regarding the social and environmental consequences of urban transport, structural changes resulting from development of information and communications technologies, and a changing institutional context in transportation policy decision-making are affecting the research agenda of transport geographers (e.g., Hanson 2000). This section discusses three areas of current research: travel behavior; transportation, land use, and environmental costs; and transportation and information technology.

2.1 Travel Behavior

Transport geographers have examined personal travel at both aggregate and disaggregate levels of analysis.

2.1.1 Aggregate models. Various forms of spatial interaction models have been applied in aggregate analysis, most commonly the gravity model. The gravity model incorporates two basic factors that affect the level of flow between places: the population of each place (or some measure of potential for flow), and the distance between them:

The model in Eqn. 1 states that flow from origin i to destination j is a positive function of (a)

$$T_{ij} = O_i \frac{A_j d_{ij}^{-\beta}}{\sum_{\kappa} A_k d_{ij}^{-\beta}} \tag{1}$$

the potential of the origin zone for generating trips and (b) the relative attractiveness of the destination zone, and is a negative function of the distance between them. Gravity models have been applied to many topics, from intercity transport to local shopping flows. They have been extended to account for alternative travel destinations (intervening opportunities) as in the example above, differences in nodal characteristics, and differences in travel costs across modes or links (Taaffe et al. 1996).

The widespread availability of geographic information systems (GIS) has made possible the use of gravity formulations to measure accessibility patterns of different modes or population segments and hence analyze such policy issues as the distribution consequences of urban transport investment. The gravity model plays an integral role in state-of-practice urban transportation planning models: trip distribution (the allocation of trips to specific zonal destinations) is accomplished using a model that accounts for the relative attractiveness of zones as destinations and expresses distance as a generalized cost.

2.1.2 Disaggregate models. Understanding the travel patterns of individuals is a more complex task. Geographers and economists began to address the issue in the 1970s with the application of utility theory. In this case, travel decisions are discrete choices made on the basis of the utility of each alternative available. The utility of an alternative is a function of its attributes and the attributes of the individual making the choice. Since utility cannot be observed directly, utility-based models estimate the probability that a given alternative will be chosen.

The first applications of discrete choice were made to mode choice problems; later applications included destination choice, route choice, and car ownership. Mode choice models are now routinely used in transportation planning applications. Models have been extended to account for conditional or sequential choices, as for example, mode choice given car ownership. Multilayered models are one approach to developing integrated transportation planning models (Anas et al. 1998).

A major theoretical issue in travel behavior analysis is what should be predicted: the trip or the underlying behavior that motivates the trip. Given that travel constitutes a disutility, it is argued that understanding travel requires understanding activity patterns. Termed activity analysis, this approach to travel behavior predicts travel choices as a function of activity choices (Kitamura 1988).

The roots of the activity analysis approach to travel behavior lie with the Swedish school's time-space geography (Hagerstrand 1970). In this case the individual has a set of resources (time, money, vehicles) and a set of constraints (schedule, physical, and coupling constraints) that define the feasible set of activities they may accomplish over the course of a day. Hagerstrand terms this feasibility area the space-time prism. Activity-based models seek to capture the complex process of choosing a set of daily activities and their location, timing, and sequencing, given feasibility constraints.

Utility-based models assume rational behavior. Travel choices are a function of resources, preferences, and supply characteristics. Some geographers and planners argue that the rational behavior assumption is too strong; people act as much on attitudes and

perceptions as on resources and constraints. Travel choices are joint choices (resources and tasks are allocated among household members) which reflect (and affect) underlying attitudes and perceptions. They therefore borrow somewhat from the disciplines of sociology and psychology.

2.1.3 Travel as having positive utility. Travel has historically been considered a derived demand. However, some recent research suggests that this may not be the case (Mokhtarian and Salomon 2001). People may derive pleasure from travel to a far greater extent than assumed. They may conduct activities outside the home in order to travel, or they may travel to more distant destinations because the travel itself is part of the activity experience (e.g., take a drive and go out to dinner). Transportation planners have consistently underpredicted the growth in travel demand, even accounting for unanticipated changes in demographics, income levels, fuel prices, and other key factors. Positive utility of travel may explain people's greater-than-predicted propensity to travel.

The concept of travel as having positive rather than negative utility has significant policy implications. On the one hand, it helps to explain why travel demand is highly inelastic. On the other, it suggests that efforts to reduce travel for environmental or other reasons will be most difficult to accomplish.

2.1.4 Travel budgets. Finally, many geographers argue that time budgets determine travel. People make about four (one-way) trips per day and spend an average of about 1.3 hours each day traveling. These averages have been observed consistently both over time and across places, ranging from preindustrial agrarian villages to the major developed nations of the world. This consistency has led to the concept of a time budget: people allocate a given amount of time to traveling (Zahavi and Talvitie 1980). Hence distance traveled is a function of transportation technology and infrastructure. As travel speeds increase (say by construction of a new highway or rail line); people will use travel time savings to travel further distances. There are two main criticisms of the time budget. First, taken to its logical extreme, it conflicts with notions of rationality and utility-maximizing behavior. Second, the empirical observation may be an artifact of central tendency, and therefore may have little value as an explanation for human behavior.

2.2 Transportation, Land Use, and Environmental Costs

Transportation provides many benefits to society. As noted earlier, an efficient transportation system is critical to economic growth. People have greatly benefited from cheap and efficient mobility. The value placed on mobility is revealed in willingness-to-pay: households devote a significant portion of income to transportation, and the public has been remarkably willing to tax itself to invest in transportation infrastructure. However, mobility generates an array of environmental costs, notably air and noise pollution, traffic congestion, accidents, damage to the natural environment, and possibly global warming (Greene et al. 1997). In addition, everyone has not realized the benefits of mobility. Those without access to a private vehicle, for example, have suffered a relative decline in accessibility as activities have dispersed and public transport has become an increasingly poor substitute for the car. Concerns about these external costs are intensified by observation of current trends (Fig. 2 and Fig. 3). Extrapolation of these trends leads many to believe that policy actions must be taken to move toward a sustainable transport system (Newman and Kenworthy 1998). Hence transport is a key issue in the sustainability debate.

Sustainable transport has many dimensions. Strategies to increase sustainability range from improving transport technology to reducing travel via regulation, pricing, or land use policy. Transport geographers have focused on land use. The relationship between accessibility and travel is well known. Some geographers make a distinction between accessibility and mobility (e.g., Hanson 1995). Accessibility measures potential—the relative location of opportunities—and is a function of spatial form and transportation supply. Mobility measures outcomes—how much a person travels. Mobility is a function of both accessibility and travel resources. It follows that as accessibility increases, activities can be conducted with less travel, all else being equal. It is therefore argued that one promising strategy for sustainable transport is to promote higher density development. Proponents argue that such a strategy preserves accessibility while reducing mobility: activities can be accomplished closer to home, and greater access may allow more non-motorized travel. The overall effect is to reduce private vehicle travel and its associated external costs.

A corollary to this strategy is to expand public transport while imposing restrictions on the private vehicle. Public transport is seen as less damaging to the natural environment and contributing to urban quality of life. Effective public transport depends upon concentration; supportive land-use policies will create the trip densities required to support transit. Conversely, the presence of transit will promote higher density development (Newman and Kenworthy 1998).

Whether such strategies can succeed in reversing current trends in transport and urban structure is the subject of many debates. A positive correlation between development density and measures of private vehicle use has been observed in several empirical studies, but their validity is questioned on several

grounds, e.g., whether less car use is offset by congestion, whether the relationship is significant at densities that realistically could be achieved, or even whether a causal link exists. Studies that control for household characteristics and other relevant factors show a much weaker (and sometimes insignificant) relationship between density and private vehicle use for all but extremely high densities (Pickrell 1999). Other research has examined neighborhood level characteristics and its relationship to transit use or walks trips, with very mixed results.

The empirical research examines whether travel patterns would change, if land use and transport policies were used to promote reconcentration and less private vehicle use. The more interesting question is whether reconcentration and reduced private vehicle use at a scale sufficient to generate significant environmental benefits is feasible. Views on this question are decidedly mixed. Some argue that long-term economic and technological trends suggest continued decentralization and dispersion, while rising incomes will generate increasing demand for private vehicle travel (e.g., Morrill 1991, Giuliano 1999). Hence environmental costs should be addressed via technology, pricing, and regulation. Others argue that the social and environmental consequences of not changing these trends are enormous, and it is assumed that the political will necessary to achieve major change will therefore be found (e.g., Newman and Kenworthy 1998).

2.3 Transportation and Information Technology

The emergence of the information economy is an increasingly important theme of transport research. Advances in information and communications technology (ICT) are affecting all aspects of society and the economy. Transport geographers have focused primarily on direct effects of ICT: to what extent does ICT serve as a substitute for transport? Most of this research addresses telecommuting (working at home or at a nearby work center by communicating electronically with the office) (Mokhtarian 1998).

Telecommuting eliminates or shortens the daily commute. Remote offices, home offices, and mobile offices also reduce the work trip. Empirical research shows that travel savings from fewer trips to and from work are not entirely offset by nonwork travel. People are more likely to telecommute if they have very long commutes, generating travel savings in the short run, but suggesting that the opportunity may also motivate people to live even farther from their jobs. In addition, social and institutional constraints have so far prevented telecommuting from becoming a common practice.

Far more widespread than telecommuting is the use of telecommunications in place of personal contacts. Of course the telephone has served this purpose for a century. The difference now is in the variety and efficiency of communications devices, notably the now ubiquitous email. Interaction is growing; business and personal networks are increasingly complex and extensive. It seems reasonable to expect that more interpersonal connections would result in more rather than less physical interaction.

The impacts of ICT on work patterns are potentially far more extensive than these direct substitution effects. ICT is fundamentally changing the structure of the workplace and the organization of work. Labor statistics show that temporary work and self-employment are increasing more than proportionately with job growth. There is some evidence of declining job tenure. Changes in the structure of work will no doubt affect commuting and residential location patterns. Will households increasingly choose residences on the basis of neighborhood quality and other amenities, given uncertainty of future job location? Will access to job opportunities become more important, promoting location close to large job centers? Research on these questions is just beginning.

The impacts of ICT on firm location and on the structure of production also have enormous implications for transport. Outsourcing, customized production, flexible production, and just-in-time management of production and distribution characterize restructuring. The emergence of spatial production networks implies increased goods movement and growing dependence on an efficient global transport network.

Preliminary research indicates strong complementarity between ICT and freight transport (Plaut 1997). The freight transport sector has rapidly adopted ICT to increase speed and efficiency of freight flows. The growth of multinational firms and global trading networks also suggests more long distance passenger transport. While ICT allows for rapid and cheap electronic communications, the need for face-to-face communication among global managers remains. Hence the rapid increase of commercial air transport observed since the 1980s.

Time/space compression is bound to increase as the boundaries between transportation and communication break down. Indeed, ICT calls into question the very notion of accessibility as an essentially physical concept (Hodge and Janelle 2000). The direct and indirect effect of ICT will be a major area of future research in transport geography.

Transportation Planning

Planning for the movement of people, goods, and ideas about cities and regions requires a systems framework. This reflects the intimate, two-way relationship that exists between transportation facilities and the social, economic, and environmental quality and character of places that are served. It is in this broader, more inclusive context of transportation planning that the field finds itself in the midst of a paradigm shift.

1. A Balanced Approach to Transportation Planning

Historically, transportation planning has been about ensuring efficiency in movement—that is, getting from point A to point B as quickly and as safely as possible. In the industrialized world, expansive overpasses and monumental expressways that criss-cross metropolitan areas stand as edifices of this philosophy. However, with time the cumulative impacts of planning for speedy, effortless movement, or for mobility, have revealed themselves—in some ways, positively, such as increased economic productivity and modernization, but in other ways, negatively, in the form of air pollution, worsening traffic congestion, wasteful sprawl, severance and degradation of neighborhoods, and isolation of people by class, race, and physical abilities. For this reason, some critics call for a more balanced, ecological approach to the field, one that accepts limits and acknowledges co-dependencies and connections (Ewing 1995). Other objectives besides mobility that need to enter the mix include accessibility, livability, and sustainability.

The risks of planning principally for mobility are underscored by US experiences. The United States averages 750 automobiles per 1,000 inhabitants, making it the world's most automobile-dependent society. The nation's economic prosperity is intimately tied to systems of highways, railways, and air transport that allow for efficient collection and distribution of people, raw materials, goods, and ideas. However, with under 5 percent of the world's population, the United States consumes 25 percent of petroleum-based fossil fuels and produces a comparable share of all energy-related carbon dioxide emissions. Cities like Los Angeles and Denver suffer from some of the worst photochemical

smog anywhere. As poor countries of Africa and Asia prosper and begin to mimic the vehicle ownership patterns of the United States and other industrialized nations, the world's finite resource base and capacity to absorb the astronomical increases in greenhouse gases without adverse climate change, many fear, will be pressed to the limits.

1.1 Mobility Planning

Time is a much-valued, irretrievable resource, thus planning for speedy movement has always been, and will always be, central to transportation planning. The standard methodology for mobility-based planning is the four-step travel-demand forecasting model. This involves a series of sequential, independent mathematical steps which lead to bottom-line forecasts of future vehicle trips on major highways and transit lines in a metropolitan area. The programming and construction of capital improvements like new highways or rail-transit extensions are based on the outputs of this four-step model.

Step one, called 'trip generation,' estimates numbers of trips per household by purpose (e.g., to work, for shopping) based on factors like household size, income, and number of motor vehicles. Step two, called 'trip distribution,' projects the flows of estimated trips to competing destinations, whether employment centers, shopping plazas, entertainment venues, or elsewhere. Traditionally, a gravity model is used to distribute estimated trips spatially—for example, a shopping mall with a million square feet of floor space can be expected to draw twice as many trips as one with a half million square feet, adjusted for impedance effects of travel time or distance. The third step, called 'modal split,' divides forecasted travel flows, by purposes, among competing modes, like drive-alone car, carpool, public transit, or walking. Discrete choice models that estimate the likelihood of selecting a particular mode based on its service-price attributes and characteristics of the traveler (e.g., income) are normally used. The final step, called 'traffic assignment,' involves computerized loading of predicted flows by mode on planned highway and transit networks to evaluate performance, with performance defined mainly in terms of average speeds.

In recent years, transportation planners have sought to refine the four-step model in several ways. One is to represent the dynamic, synergistic relationship between transportation and urban settlements patterns—to reflect, for example, that while new growth generates traffic, as roadways start filling up, growth starts migrating elsewhere (Putman 1991). Another is to model household activities as opposed to vehicle trips. Called 'activity-based micro-simulation,' this approach uses nonlinear mathematical programming tools to simulate activity patterns across a metropolitan landscape and the vehicle trips as well as tailpipe emissions that will result. In the United States, the Los Alamos National Laboratory has developed a micro-simulation package, called TRANSIMS, that projects movement of individuals in Portland, Oregon second-by-second according to where future activities are most likely to be sited. The model aims to capture the many behavioral adjustments that are made to changing traffic conditions—e.g., when a trip takes too long, people seek out other routes, switch from car to bus, leave at different times, or opt to forego the trip altogether.

1.2 Accessibility Planning

An alternative to planning for movement is to plan for places by making them more accessible. This can be achieved by bringing origins and destinations (e.g., homes and workplaces) closer to one another or by increasing speeds on the channelways that connect them. Accessibility planning embraces the notion that transportation is a secondary activity—it involves people going to places, be they places of work, of recreation, of worship, of retailing, etc. People do not consume transportation for its own sake, but rather for purposes of reaching oft-visited places. If anything, people want to minimize the time spent moving so that they can spend more time at desired destinations, rather than on the road. Focusing on accessibility as opposed to just mobility leads to a whole different set of planning strategies—for example, instead of laying more asphalt to expedite cars and trucks, mixed-use communities can be designed that reduce the spatial separation of activities. Many in-vogue land-use planning approaches, like jobs-housing balance, transit villages, and compact, neo-traditional development, are centrally about making cities and regions more accessible (see Calthorpe 1994, Bernick and Cervero 1997). The difference between planning for mobility versus accessibility is the difference between planning for cars versus planning for people and places.

So far, the Netherlands has made the most headway in reforming regional transportation planning to give equal emphasis to accessibility and mobility (Tolley and Turton 1995). Dutch planners draw mobility profiles for new businesses which define the amount and type of traffic likely to be generated. They also classify various locations within a city according to their accessibility levels. For example, sites that are well served by mass transit, that are connected to nearby neighborhoods by bike paths, and that feature mixes of retail shops receive high accessibility marks. Such locations are targeted for land uses that generate steady streams of traffic, such as college campuses, shopping plazas, and public offices. More remote areas that can be conveniently reached only by motorized means are assigned land uses that need not be easily accessible to the general public, like warehouses and factories. Thus, to make sure the 'right

businesses' get the 'right locations,' Dutch planners see to it that the mobility profile of a new business matches with the accessibility profile of a neighborhood.

1.3 Planning for Sustainability and Livability

As a rapacious consumer of natural resources and emitter of pollutants, the transportation sector must also be judged on the basis of sustainability—maintaining or improving, as opposed to harming, the natural environment (see Newman and Kenworthy 1999). Sustainability argues for resource-efficient forms of mobility, such as metrorail systems that link planned urban centers in the case of big cities and dedicated carpool and bus lanes that reward efficient motor-vehicle use in smaller ones. Congestion pricing, parking restraints, and the development of alternative-fuel vehicles are other strategies that embrace sustainability principles.

Livability applies principles of sustainable planning to the scale of the neighborhood. It is about the human need for social amenity, health, and well-being. Many European cities have brought livability to the forefront of transportation planning, opting for programs that tame and reduce dependencies on the private car (see Pucher and Lefèvre 1996). Traffic calming is one such approach, pioneered by Dutch planners who have designed speed humps, realigned roads, necked down intersections, and planted trees and flowerpots in the middle of streets to slow down traffic. With traffic calming, the street is viewed as an extension of a neighborhood's livable space—a place to walk, chat, and play. Automobile passage becomes secondary. After traffic calming its streets in the early 1990s, the city of Heidelberg, Germany witnessed a 31 percent reduction in accidents and a 44 percent reduction in casualties (Beatley 2000).

Car-sharing and car-limited communities have also gained popularity in European cities as ways of enhancing the quality of in-city living. Car-sharing relieves residents of the financial burden of owning one or more automobiles, allowing them instead to lease cars on an as-need basis through a cooperative arrangement. Car-share members can efficiently tailor car usage to specific purposes (e.g., small electric cars for in-neighborhood shopping and larger ones for weekend excursions). They also economize on travel by opting to move around by foot, bike, and mass transit more often. Presently, over 50,000 members share some 2,800 vehicles in 600-plus cities across Germany, Switzerland, Austria, Denmark, the Netherlands, Norway, Sweden, and Great Britain. More extreme is car-limited living, which is being actively promoted in parts of Amsterdam, Bremen, Germany, and Edinburgh, Scotland. In Amsterdam's Westerpark district, only 110 permanent parking spaces are provided for residents of 600 housing units. The project has attracted a number of middle-class families with children who value living in a setting where space is used for common greens and play areas, rather than for parking cars.

2. Coming Challenges and Policy Responses

Many powerful mega-trends are working against the broader objectives of transportation planning—namely, in favor of increased automobile dependence and usage at the expense of concerns like accessibility, sustainability and livability. The postindustrial world has given rise to 'travel complexity'—the trend toward irregular, less predictable work schedules, the geographic spreading of trips, and increased trip-chaining (e.g., linkage of trips, such as from work to the child-care center to the grocery store to home). All of these trends favor drive-alone, 'auto-mobility.' The share of trips by carpools and vanpools has fallen throughout US cities over the past two decades, despite the construction of dedicated high-occupancy vehicle (HOV) lanes and aggressive rideshare promotion (Pisarski 1997). Ridesharing's decline in metropolitan Washington, DC, traditionally one of America's strongest vanpooling markets, is rooted in the shift from predominantly government to increasingly high-technology employment; many of the region's software engineers and Internet-industry workers keep irregular hours and rely on their cars during the midday break, making it nearly impossible to share a ride to work. The entry of women into America's workforce, which soared from 26 million in 1980 to 63 million in 1997, has fueled trip-chaining—nearly two-thirds of working women stop on the way home from work, often to pick-up children at day-care centers (Sarmiento 1998). Telecommunication advances continue to diminish the need for spatial proximity, hastening the pace of new growth on the edges of metropolitan areas and in far-flung rural townships. As growth continues to spread out, there is a widening mismatch between the geography of commuting (tangential and suburb-to-suburb) and the geometry of traditional transportation networks, which tend to be of a radial, hub-and-spoke design. Circuitous trip patterns and mounting traffic congestion, especially in the suburbs and exurbs, have resulted.

Collectively, evolving economic, demographic, and urbanization trends have formed new space-time arrangements, conspiring against all forms of movement except the private car. Figure 1 portrays this evolution along a space–time continuum. The traditional monocentric city with concentrated activities (e.g., downtowns and 8-to-5 work schedules) supported point-to-point rail services reasonably well. As technology advances gave rise to polycentric settlements and less regular time schedules, more flexible forms of collective-passenger transport, like bus tran-

Figure 1
Travel complexity in a space–time continuum

sit and carpools, prospered. As cities and the regions of the future become increasing 'noncentric' and time schedules less certain and predictable, the frontier of space-time possibilities has expanded considerably. An immense challenge faced by the transportation planning profession is how to pursue the balanced agenda of mobility, accessibility, sustainability, and livability in light of these protracted, complicating trends.

2.1 Induced Demand

One of the most compelling reasons for more balanced, ecologically based transportation planning is the well-documented phenomenon of induced travel demand. Time and again, experiences show that building new roads or widening existing ones, especially in fast growing areas, provides only ephemeral relief—in short time, they are once again filled to capacity. A study using 18 years of data from 14 California metropolitan areas found every 10 percent increase in highway lane-miles was associated with a 9 percent increase in vehicle-miles-traveled four years after road expansion, controlling for other factors (Hansen and Huang 1997). Similar findings have been recorded in the United Kingdom (Goodwin 1996). In the United States, regional transportation plans, such as in the San Francisco Bay Area, have been legally contested by environmental interest groups on the very grounds that they failed to account for the induced travel demand effects of road investments and expansions.

Expanding road supply produces both near- and long-term shifts. In the short run, expanded capacity prompts behavior shifts—people change modes, routes, and times-of-day of travel. For example, once a new road is opened, many who previously commuted on the shoulders of the peak shift to the heart of the peak. Over the longer term, structural adjustments occur, such as people and firms locating on parcels near interchanges to exploit the increases in accessibility provided by a new freeway.

The challenge of transportation planning is to create constructive channels for the induced shifts prompted by new transportation infrastructure. To encourage 'green' modes of transportation, like vanpools and shuttles, for instance, planners can set up HOV lanes along corridors which are the recipients of shifted trips. Time-of-day swings in trip-making can become more efficient by relaying real-time information on travel conditions and least-congested paths via Internet web sites and on-board navigational systems. Locational shifts can be of a more compact, mixed-use, walking-friendly form through zoning, tax policies, and other instruments that reward efficient and sustainable patterns of development.

2.2 Technology

Worldwide, billions of dollars are being spent on making roadways and cars smarter, under the guise of the Intelligent Transportation System (ITS). These initiatives seek to increase the efficiency of automobile movements many orders of magnitude, relying on the kind of technology and intelligence gathering once reserved for tactical warfare. In Great Britain, Germany, and France, over 200,000 motorists currently subscribe to Trafficmaster, a nationwide traveler information system. Infrared cameras located every six kilometers automatically record the license plates of passing vehicles and transmit the data via radio to a centralized data center. By matching license plates across different camera locations, a megacomputer calculates the average speed of travel for each roadway segment and relays the information in encrypted form to small receivers and visual displays mounted on the dashboards of subscribers' cars. Alternative routes are suggested for avoiding traffic jams. One concern of making automobiles smarter is that travelers will flee buses and trains in droves. Mass transit must therefore also become smarter, through advanced technologies which optimize routing for door-to-door shuttles and which relay information on schedule-adherence to drivers and on expected times of arrival to waiting customers.

The one area where all sides agree that technology could yield important social, environmental, and economical benefits is by allowing for marginal-cost pricing, such as the collection of congestion tolls (Gómez-Ibáñez 1999). This is happening in Singapore, where an electronic road pricing (ERP) scheme was introduced in 1998 (Cervero 1998). The system applies

a sophisticated combination of radio frequency, optical detection, imaging, and smart card technologies. With ERP, a fee is automatically deducted from a store-valued smart card (inserted into an in-vehicle reader unit) when a vehicle crosses a sensor installed on overhead gantries at the entrances of potentially congested zones. The amount debited varies by time and place according to congestion levels. Cameras mounted on gantries snap pictures of violating vehicles to enforce the scheme. The system can identify a vehicle, deduct a charge, and capture a clear photo of its rear image at speeds up to 130 kilometers per hour. During its first year of implementation, traffic volumes declined by 15 percent on a major freeway along Singapore's eastern shoreline, matched by comparable patronage increases along a parallel mass rapid transit (MRT) route.

Another promising direction for new technologies which supports sustainability and livability objectives is the modification of vehicle propulsion systems. Hybrid electric propulsion can boost energy efficiency by an estimated 30 to 50 percent by electronically recovering braking energy, temporarily storing it, and then reusing it for hill climbing and acceleration. Visionaries see a future of ultralight hybrid vehicles that combine the advantages of regenerative electronic braking with on-board fuel cells (Von Weisäcker et al. 1997).

2.3 Institutional Reforms

Even with the most sophisticated technological breakthroughs, little progress can be made unless there is the institutional capacity to coordinate and implement new transportation programs and ideas successfully. Worldwide, transportation planning is mired by bureaucratic inertia and redundancies. In Bangkok, Thailand, for instance, more than thirty government agencies are responsible for the city's transportation planning, management, and operations. Many economists promote privatization of public transportation as a means to cut costs and spur innovations, however even increased competition can backfire without a workable institutional arrangement. This is underscored by experiences in Rio de Janeiro, where more than 60 private bus companies serving the city have independent timetables and fare structures, penalizing many users who must transfer across bus routes.

Germany and Switzerland have formed regional federations for coordinating mass transit services, called *verkehrsverbunden*. Greater Munich's federation, for example, functions as an umbrella organization for planning routes, services, and fares across the 5500-square-kilometer region's many rail and bus service offerings (Cervero 1998). Besides coordinating schedules and timetables, the federation pools farebox receipts and reallocates them to ensure socially equitable fares are charged while also rewarding individual operators for being productive and cost-effective.

Another noteworthy institutional reform in Europe has been the functional separation of roadbed ownership and maintenance (including highways and rail tracks), which remain in the public domain, from service delivery and which is open to public and private providers through competitive tendering (see Pucher and Lefèvre 1996, Cervero 1998). Within the confines of standards set by government sponsors (e.g., regarding timetables, fares, and routing), the lowest-cost provider delivers the service. Thus, the public sector retains control over how services are configured, leaving it to market forces to determine at what price.

In the United States, the eyes of the transportation planning profession are on the state of Georgia, where an all-powerful regional transportation authority has recently been formed. Called the Georgia Regional Transportation Authority (GRTA), the organization not only oversees the planning and expenditure of funds for all urban transportation improvements in the state, but also has broad control over regionally important land uses, like shopping malls, industrial parks, and sport stadia. Local land-use decisions must conform to regional transportation and development goals, otherwise GRTA can effectively veto decisions by threatening to cut off all state infrastructure funds. GRTA's formation was largely in reaction to decades of poorly planned growth in metropolitan Atlanta, matched by ever-worsening traffic congestion. The announced plan of a large high-technology employer to relocate out of Atlanta because of unsustainable traffic congestion and a declining quality of life was a political wake-up call. The region's new planning philosophy—one of balancing urbanization and transportation investments—aims to enhance mobility while also placing the region on a pathway that promises a more sustainable and livable future.

Transportation, Psychology of

The psychology of transportation is a field of applied psychology. It entails the study of human behavior and well-being in conjunction with the regularized movement of people, goods, and services regarding work, personal life, and community activity systems. In addition, it involves the interface of humans with transport vehicles and facilities, including their design for optimal operation, provisions for human needs, forms of utilization, and social impacts.

1. Overview and Scope

The domain of transportation has great relevance for psychology, precisely because of its salience in the routines of daily life and its importance for meeting personal, family, and organizational goals. Because various elements of transport systems are operated by people, psychology has an important role in system development, efficiency, and safety. Human cognitive, personality, and performance factors affect vehicle operation. Moreover, transport systems shape the structure of our communities and have a significant impact on both personal and community well-being.

The progress of human societies has always been associated with mobility and transportation. People respond to environmental constraints on mobility and strive to enhance well-being. What happens on a particular journey depends on many intertwined psychological elements, including personality disposition, attitudes about the origin and destination of the trip, and resources for choosing alternative travel modes and schedules, including telecommuting. This provides a vast terrain for psychological research and application of psychological knowledge. The creation and use of transportation systems, the experience and behavior of people in transportation conditions, and the effects of mobility constraints on personal and community health, are broad areas entailed by the psychology of transportation field.

Human factors have long been recognized as being intrinsically involved in the operation of vehicles; however, the psychology of transportation is much broader in scope than the interface between the human operator, the vehicle, and the road design (Rothengatter and Vaya 1997). It entails travel-mode decisions, driver attitudes and performance, the interplay between work and family, emotional well-being, and major societal issues such as the needs of special populations, the definition of the workplace, and the provision of transportation facilities.

The field of transportation has been dominated by engineers, urban planners, and economists; but the contributions of psychologists and sociologists are increasingly integrated into this arena (Altman et al. 1981, Wachs and Crawford 1992). Discussions of the social costs of transportation are now common, and psychological elements are given weight in such considerations. Because individuals, families, and work organizations recognize that they absorb hidden costs associated with traffic congestion, air pollution, and traffic noise, there is considerable merit for the role of psychology in understanding how to optimize transportation systems and to assess the consequences of travel constraints (Stokols and Novaco 1981).

2. Historical Development of the Field

Involvement by psychologists in the field of transportation began in the 1920s when transport companies and government agencies sought to improve the selection of drivers of public transport vehicles, and psychometric testing began to be used in choosing the operators of buses, trams, and trains. A central concern was to minimize accident risk, and psychological tests were used to screen applicants who could be anticipated to be accident-prone. Wartime studies of adjustment among military personnel and the early psychological formulations of stress, adaptation, and coping that resulted from observations made by psychological researchers working with the military extended nicely to the subject of driver performance demands and safety risk. In addition,

industrial psychology research on fatigue at the workstation transferred to the issue of vigilance in professional train and road drivers (Barjonet 1997).

As the motor car came to dominate travel in Western societies in the 1950s and 1960s, car ownership grew dramatically and accident rates and road deaths became serious public health problems. For example, in most European countries the number of deaths on the road doubled between 1955 and 1970. Public safety policies, such as speed limits, penalties for drunk driving, and ultimately seat belts, were instituted to curtail casualties, and research into the human causes of accidents came into play. Social psychological knowledge was used in public persuasion efforts, and theories and techniques of learning found fertile ground in driver education and rehabilitation. As the advent of the computer augmented the capacity to analyze and integrate data, the approach in the 1970s and 1980s to understanding driver-based safety risk often took the form of psychological modeling that incorporated personal background, attitudinal, motivational, and emotion variables, as well as ergonomic factors.

The growth in automobile commuting that occurred between 1960 and 1980, especially in the USA, prompted interest in modeling how trips were generated, how they were distributed across travel zones, and how trips were split across available transportation modes (car, bus, train). The boom in automobile commuting followed from substantial growth in the number of jobs, in the working age population, and in the number of women in the labor force. In addition, homes and jobs shifted to suburban locations. Because neither highway nor transit systems were designed for suburb-to-suburb commuting, traffic congestion in metropolitan areas became a salient issue. In the USA, the use of private vehicles between home and work almost doubled from 43 million users in 1960 to 83 million in 1980. At the same time, alternative modes of travel and vehicle occupancy declined and national investment in highway infrastructure fell far behind the demand for road use (Pisarski 1987).

European cities, with their treasured historic centers having limited road space and parking facilities, became concerned about the detrimental effects of traffic congestion and pollution and were keen to impose access restrictions. These trends spurred interest in the travel behavior of individuals. Computer-analytic methodology spurred development of travel demand modeling, which blended consumer theory in economics with choice theory in psychology, which assumes that people use some utility or value function in assessing choice alternatives.

Attention to the transportation needs of special populations, such as working mothers, the elderly, and those affected by physical disabilities, also came into focus during the 1970s and 1980s. An important component of the auto-commuting boom was a large increase in the number of women in the labor force (Grieco et al. 1989, Pisarski 1987). Single women with children who lived in suburbs were very dependent on the automobile (Rosenbloom 1992). In the USA, most trips made by working mothers and their children cannot be made by transit, and the impact of travel constraints on the quality of family life is an important topic. In the 1990s, telecommuting emerged, partly as a way to reduce strain on family life. The convergence of technological, economic, social, and psychological factors made work less place-dependent, and telecommuting was heralded as a viable alternative to auto-commuting (Mokhtarian 1990).

In the 1990s, the information age had many effects on transportation systems. The development of intelligent transport systems, such as in-vehicle devices to aid navigation (e.g., route guidance and congestion warnings), as well as the increased sophistication of driver panel displays, raised the importance of driver control, visual search efficiency, and mental load on driving proficiency. On the horizon of advanced technologies are Intelligent Vehicle Highway Systems, which control steering, speed, and spacing automatically. However, having a vehicle travel under the control of a computerized system raises psychological issues of personal control and freedom, which have been themes intrinsic to car ownership and driving.

3. *Human Factors and Driver Performance*

Psychological variables affect the operation of transport vehicles, as can be seen in studies of driver error and performance decrements (cf. Rothengatter and Vaya 1997). Fatigue has been the most researched topic in this regard. Ordinarily understood as physical exhaustion, it can also involve conditions characterized by boredom, task aversion, uncontrollable sleepiness, hypnotic trance-like states, or loss of alertness. Importantly, driving performance decrements occur before the driver is aware of the fatigue subjectively. Fatigued drivers become complacent and underestimate the effort needed to maintain driving performance. Hours of service limitations are implemented for professional drivers and pilots to guard against fatigue-related safety errors. Physiological correlates of fatigue have been studied in both driving simulator studies and open-road tests. Heart rate decreases with prolonged driving time, but results across studies have not been uniform. Focal fixation, detected by eye-tracking, is associated with fatigue, but it also occurs in conjunction with hazard perception.

Driver alertness is clearly related to collision avoidance. The driver, as an information processor, must be proficient in making time-to-collision judgments—e.g., time to collision is underestimated for smaller vehicles. Raising the rear brake light signal was a vehicle design modification to reduce rear-end collisions. The use of reflectors, warning signs to reduce speed on curves, and edge lines are road-design features intended to

enhance the input of safety information. Generally, the more enriched the visual environment, the lower the underestimate of time-to-collision.

Driver expectations and interpretations, however, interact with visual information. Expectancies developed from driving experience may have adverse effects. The person may omit perceiving relevant cues or fail to give them appropriate weight in estimating a hazardous condition. 'Driving experience' does not guarantee expertise, as an experienced driver may have fixed expectations about how a driving situation will progress, which may interfere with accurate perceptions and interpretations of relevant cues. Driver behavior is a function of what drivers believe and feel they can do, as well as what they see and are told.

4. *Driver Risk-taking, Attitudes, Motivation, and Emotion*

The study of driver performance lends itself to experimental lab analyses of perception, decision-making, and reaction time. In contrast, the research on driver risk-taking has been conducted largely by questionnaires. Driver attitudes and personality have been studied as indicators of the propensity to commit driving errors and traffic-code violations, thereby raising accident liability. Thus, rather than focus exclusively on the driver's psychomotor or perceptual skills, attention is given to higher-order cognitive processes and motivation (cf. Rothengatter and Vaya 1997)

Self-reported violations and risky driving behavior, as assessed by driver behavior questionnaire measures, have been found to predict involvement in accidents, independent of the amount of yearly driving. Because self-evaluations of driving habits are longitudinally predictive of driving violations and accidents, it then becomes feasible to identify problematic drivers and augment their safety motives. Since these relationships hold strongly for young men, they are commonly a target group for intervention.

The most consistent finding about driver risk-taking is its association with a sensation-seeking personality, which is thought to have a biological basis. High-sensation seekers are more likely to drive drunk, exceed speed limits, take risks in passing and lane changing, not use seat belts, receive citations for traffic violations, and have crashes. These findings have been obtained in studies conducted in several European countries, Canada, and the USA.

Human behavior is highly adaptive, and drivers adjust to changes in the intrinsic safety of the driving environment. In hazardous weather, drivers slow down and sharpen alertness. Alternatively, as safety in the driving environment is enhanced through improvements in roadway conditions and vehicle design, drivers may be inclined to drive faster, shorten the distance in following, overtake more readily, or be less attentive to hazards. Therefore, improved vehicle safety features may lead some drivers to overcompensate for perceived risk reduction, driving less safely because they feel more insulated from collision or injury.

Aggressive driving and its alias 'road rage' have become prominent topics in the traffic-safety field in many countries (Brewer 2000, Shinar 1998). However, aggression has been part of driving since chariots careened around the *Circus Maximus* in ancient Rome. Indeed, the symbolization of the automobile has been infused with themes of aggression, which is evident in vehicle names and designs. Uncontrolled anger and aggression on roadways do constitute a significant driver behavior issue, but neither the magnitude of the problem nor its societal trend is clear. While human aggression springs from many causes, aggression on roadways is a product of various disinhibitory influences (Novaco 1991), such as anonymity, opportunity to escape, increasingly fortified vehicles, and strong elevations in physiological arousal produced by driving situations. The personalized territoriality of the vehicle and diffusion of roadway aggression scripts in the media also facilitate antagonism in driving when the behavior of other drivers is viewed as provoking.

5. *Driver Selection, Training, and Rehabilitation*

Psychologists have helped to develop aptitude tests to insure public safety on road, rail, and air travel. Driving safety has been viewed classically as involving the three 'Es': engineering, enforcement, and education. Accident liability is primarily due to underestimation of risks, negligence or carelessness, personality, attitudinal disposition, or substance misuse, rather than to roadway or vehicle engineering. Hence, reduction in risky driving hinges on detection of problematic drivers and on driver training and rehabilitation programs. There is wide variability across countries in how systematically this is approached.

Reconviction for traffic offenses and for serious traffic offenses have been found in New Zealand national data, gathered prospectively, to be a function of age at first conviction, being male, number of prior convictions, and having a traffic conviction as the most serious offense; moreover, statistical models have achieved high predictive power in identifying traffic offenders at high risk for reconviction for an alcohol-related driving offense. In Germany, an association of psychologists has formed a commission of experts for quality management regarding driver diagnosis and improvement. In addition to developing psychological models for the prediction of re-offending drivers, their rehabilitation courses have reduced significantly drunk-driving recidivism. Such specifically targeted driver-education programs have been successful, but it has generally been found that secondary-school driver-

training programs do not reduce accidents, because it is inconsequential whether young people learn to drive from relatives, friends, or schools.

6. Travel Demand and Alternative Modes of Travel

Transport-systems planners use mathematical theories about choice in modeling travel demand, and psychological variables add to what is otherwise offered by economic models. Because choices are often grounded in perceptions and subjective valuations, psychological research methods help to ascertain the relationship between travel time and the desirability of travel-mode options or goodness-of-fit with personal needs. Travel time, cost of alternative modes, availability of mass transit, activity plans, work demands, and personal preferences are weighed by the traveler in making transportation choices.

Psychological theory has been applied to change travel behavior, such as using reinforcement theory to boost transit-ridership. Transit use has been promoted by offering cash and travel prizes through lottery-type drawings, as well as distributing value coupons and tokens (for food, goods, and services) with bulk purchases of transit passes or dispensing them to people on boarding a bus. Similarly, inducements for ridesharing have been given by providing special lanes on congested freeways for multiple-occupancy vehicles. Such schemes are more effective when the special lane has been added to the road, as opposed to when an existing lane has been converted. Other efforts to reduce solo driving have involved the provision of priority parking facilities and/or reduced parking rates for carpools and vanpools.

Embedded in the issue of transit use is its social image, particularly with regard to buses. In many countries, persons of high social status commonly do intercity travel by rail for work commutes and discretionary trips, but bus travel typically has the image of being less than prestigious. In addition, people may be disinclined to use the bus because of a desire to avoid crime victimization on the bus and at bus stops. Psychological knowledge can be utilized in modifying unfavorable images of transit use and to reduce unwarranted fears about safety risk.

7. Commuting Stress

Exposure to traffic congestion is stressful by virtue of impedance—the blocking or thwarting of movement and goal attainment. Travel impedance has both physical and perceptual dimensions (Novaco et al. 1990). 'Physical impedance' can be objectively measured by the distance and time of the journey, along with the number of road exchanges—each representing a node of congestion. Time of day is relevant, because congestion is greater in the evening, and commuting stress is compounded by strains from the workday. 'Subjective impedance' is the person's perception of commuting constraints, assessed by questionnaire items or structured interview. Because the commute is sandwiched between the home and the job, the demands and affordances of each of these domains, as well as personality factors, bear on the commuting experience.

Commuting stress has been found to be associated with elevated blood pressure, negative mood on arrival at work, negative mood at home in the evening, lowered frustration tolerance, cognitive performance impairments, illness occasions, work absences, job instability, lowered residential satisfaction, and decrements in overall life satisfaction (Koslowsky et al. 1995). Female solo drivers in high impedance commutes are most negatively affected, independent of job-involvement and household income. Because women tend to have more logistical responsibilities for home and family, they are perhaps more sensitized to stress on high-impedance routes (Novaco et al. 1991).

A useful concept in understanding commuting stress is 'inter-domain transfer effects,' whereby the psychological consequences of environmental conditions in one life domain (home, commuting, work, or recreation) transfer to another, either positively or negatively (Novaco et al. 1990, 1991). An example of a positive transfer effect is that a high level of residential choice buffers commuting stress. Examples of negative transfer effects are that exposure to commuting stress affects negative mood at home in the evening, controlling for a great many other relevant variables, and that commuting stress prospectively leads to job location change, independent of job satisfaction.

Dissatisfaction with the commute is a cost the employee absorbs, often with delayed effects on health and family life. However, commuting stress affects work organizations, as well. People will change jobs to cope with traffic congestion, but commuting stress is more often manifested in illness-related absences from work and with impaired work performance.

8. Important Future Topics for Transportation Psychology

Transportation mobility restrictions present important psychological issues for a number of special populations, such as single working mothers with children, people who are physically or developmentally disabled, and the elderly. Perhaps the most important problem area will be the needs and functioning of older adults, because of the growth in that sector of the population. In the USA in 1900, people aged 65 and over accounted for 4 percent of the population. By 1990, this percentage had grown to 12.5 percent, and it is estimated that by 2030 it will be over 20 percent.

Transportation problems for the elderly are exacerbated by suburbanization and by the vast majority of older adults being accustomed to driving automobiles. Decrements in visual, cognitive, and psychomotor skills that occur progressively with aging present societal challenges in scrutinizing the driving proficiency of older adults, for whom the loss of the driving license constitutes a major stressful life event (Sandeen 1997). Without transit alternatives, older people become a transportation-deprived group. Many older adults adjust progressively to the decline in driving skills by ceasing to drive at night or avoiding turns across oncoming traffic; but such adaptations do not suffice for long, leaving a great many elderly people unable to be licensed to drive.

Advanced technologies, such as automated roadways, are expected to ease transportation difficulties for the general population, but if automotive vehicles become significantly more cognitively complex to operate, this may be disadvantageous to the elderly. It can be expected that there will be substantial societal pressure to develop innovations in transportation to meet the needs of older adults who cannot drive and who do not have access to normal transit services. The development of flexible and perhaps individualized transportation services for the elderly to facilitate grocery shopping, receiving health care, and going to religious, recreation, and cultural events is an important societal agenda that beckons for psychological input.

9. *Adaptation: An Overarching Concept*

A core concept in the psychology of transportation is behavioral adaptation. Drivers and transport users will adjust to conditions in the transportation environment, whether that be in their overall commuting scheme, roadway or transit conditions, vehicle conditions, or changes in skill level or state of functioning. Thus, adaptation occurs at different levels of analysis, ranging from 'high-level' trip and travel-mode decisions to 'low-level' vehicle control behaviors that maintain safety margins. When behavioral adjustments involved in adaptation are unsuccessful in the long term, more substantial behavioral coping can be expected, as when someone changes jobs to reduce commuting strain or stops driving because of age-related driving skill decrements. Innovations in information technology, by decreasing the need for vehicle trips, may progressively facilitate adaptation to travel constraints imposed by congested roadways and to unwanted reductions in mobility for some populations.

Transportation: Supply and Congestion

1. *Congestion*

Transportation facilities are prone to congestion because of peaks in travel demand, inflexibility of supply and inability to store transport services. Urban road traffic congestion and congestion in air travel impose significant economic costs. Traditional policies to alleviate congestion such as building new roads

have had at best, limited success. Congestion pricing has the greatest theoretical potential because it can affect all dimensions of travel behavior.

2. Introduction

Technological advances in transportation since the industrial revolution have spurred the growth and spread of cities, enabled people to live far from where they work, and made long-distance business and recreational travel commonplace. Yet growth in travel has been accompanied by increasing adverse side effects: noise, air pollution, accidents, and congestion—the subject of this article. To be sure, congestion is not a recent phenomenon. Two thousand years ago chariot riding was banned in Rome during peak hours because of traffic jams (Gibbs 1997). But the automobile and other motorized forms of transportation have increased the prevalence of congestion in surface travel, and congestion in air travel has become a serious problem.

The most widespread and costly form of congestion is travel delay. Delay on the roads is manifest as reduced speeds, and queues at intersections and entrances to freeways. Air travelers suffer delay in checking in, passing through security, boarding an aircraft, waiting to take off and land, clearing customs and immigration, and retrieving baggage at the destination. A fishing vessel on busy waters endures delay in procuring the catch when other vessels get in its way (Walters 1987). These examples feature delay systems in which users experience delays but eventually complete their trips. Delay systems differ from loss systems, which have a finite capacity to accommodate users and reject further demand once their capacity is reached so that service becomes unavailable. For example, a flight cannot be booked if all seats have been reserved. A given transportation facility can sometimes be a delay system and sometimes a loss system. A bus is a delay system when it stops for passengers and waits for them to board and alight and a loss system at full occupancy. And an airport is a delay system if arriving aircraft have to queue prior to landing, and a loss system if aircraft get diverted to another airport.

Crowding is a third form of congestion that is commonly experienced on buses, subways and waiting platforms, in using luggage compartments on trains and aircraft, etc. Delay, unavailability of service, and crowding are problems not only in transportation but also in facilities associated with travel including hotels, restaurants, sports stadiums, recreational areas, and telecommunications. These facilities will however not be treated explicitly here.

3. Why Does Congestion Occur?

Transportation facilities are prone to congestion because of three characteristics of travel demand and supply: demand varies over time, supply is relatively fixed over long time periods, and output is not storable.

3.1 Temporal Variation in Demand

Travel demand has pronounced temporal fluctuations. Systematic daily and weekly variations are driven by work and school schedules, and by the operating hours of businesses, shopping, and entertainment establishments. Annual variations in travel are induced by the timing and length of school holidays and religious festivals, by sporting event schedules, and by the seasonal nature of outdoor recreational activities. Travel demand also fluctuates irregularly due to sporting meets, fairs, and other 'special events.'

3.2 Rigidity of Transportation Supply

Transportation supply consists of infrastructure and mobile plant. Infrastructure is generally long-lived and very costly and time-consuming to alter. Mobile plant comes in smaller and cheaper units than infrastructure, and has a shorter lifetime, but it still lasts much longer than the time scale of demand fluctuations. The scope to alter the supply of vehicle services is limited by the mobility of the plant itself (little or none for subways and trams) and by the degree to which differences between regions and traveler groups in the timing of peak demands can be exploited.

3.3 Output is Not Storable

A traveler or freight shipment must be present to be transported. Thus, like other services such as haircuts and concerts, but unlike commodities such as grain and steel, production cannot be stored to smooth imbalances between supply and demand.

As a consequence of demand fluctuations, rigid supply and the impossibility of storage, the utilization rate of transportation facilities varies over time. Variations in utilization are magnified by intermittent reductions in capacity due to accidents, strikes, bad weather and so on. Because land is scarce and capacity is expensive, it would be prohibitively expensive to build enough capacity to prevent congestion at all times.

Congestion is exacerbated by two further considerations. First, travelers usually lack incentive to account for the congestion costs they impose on other users. Usage fees are not charged on most roads, and the costs of registration, licensing and insurance do not vary with distance traveled—let alone traffic volumes. Access fees are levied at facilities such as waterways and airports, but the fees are usually either fixed or

vary at best crudely with usage. Thus, congestion is a negative externality because its adverse side effects are not priced in markets. Second, transportation supply tends to lag growth in population and travel. Many countries experienced substantial increases in vehicle use per kilometer of road from 1977 to 1987 (Small and Gómez-Ibáñez 1999, Table 1). Air travel volume in passenger-kilometers grew at an average annual rate of 8.9 percent from 1960 to 1995 (ICAO 1999), spurred by airline deregulation in the US in the late 1970s and subsequently in Canada, Australia, New Zealand, and Europe. Airport planning authorities, meanwhile, failed to invest adequately in runway capacity and air traffic control, or to price usage of airports efficiently.

4. *The Costs of Congestion*

Congestion imposes a range of costs on travelers: increased fuel consumption and vehicle wear and tear; extra travel time; the inconvenience of using an alternative travel mode or rescheduling, combining or canceling trips; disutility from crowding; and (in the longer run) the costs of relocating jobs and residences. Delays are also costly for freight shippers and unreliable deliveries can upset just-in-time manufacturing and increase the need for inventories.

Because delays in passenger travel are a dominant component of the total cost of congestion it is important to measure accurately the cost of travel time—known as the Value of Time (VOT). VOT depends on mode of travel, trip purpose, time of day, household time pressures, and other individual and trip-specific factors. As for as automobile commuting trips, Small (1992, p. 44) concludes from an extensive literature survey that: '… a reasonable average value of time for the journey to work is 50 percent of the gross wage rate, while recognizing that it varies among different industrialized cities from perhaps 20 to 100 percent of the gross wage rate, and among population subgroups by even more.' Estimates of VOT for air travel are generally higher than for driving, in part because many air travelers are on business trips with tight schedules and in part because individuals with high VOT prefer to take fast modes of transport. There is limited evidence that VOT is higher for congested than uncongested travel (Calfee and Winston 1998).

Various estimates of the economy-wide costs of congestion have been compiled. For traffic congestion in the US Schrank and Lomax (1999) report a value of $72 billion for a set of 68 large urban areas in 1997. This figure includes time delay valued at $12 per hour (88 percent of the total) and extra fuel consumption. For Western Europe the European Commission in 1995 reported the costs of traffic congestion to be two percent of Gross Domestic Product (Prud'homme 1997)—more than double the equivalent US figure just mentioned. An extreme case is Bangkok, where congestion is alleged to consume 35 percent of gross annual output (Gibbs 1997). Aggregate statistics on the cost of air traffic congestion are patchy. In 1995, the US Federal Aviation Administration estimated that delays cost the industry approximately $2.5 billion per year in higher operating expenses. This excludes costs borne by passengers and freight shippers. In Europe a third of all flights are delayed by more than 15 minutes, at a cost to airlines and passengers of about $10 billion.

For several reasons aggregate statistics such as these should be interpreted with caution. First, they usually include only the more readily measured costs of congestion. Second, valuing time delay with a single number for VOT ignores differences across travelers as well as possible dependency on trip duration and the severity of the congestion encountered. Third, because eliminating congestion is not a practical option, measuring the total costs of congestion under actual travel conditions is not indicative of what might be gained from policies aimed at congestion relief (on this point see also Sect. 4).

These caveats notwithstanding it is instructive to compare the costs of congestion with the costs of other transportation externalities. Estimates from various countries reported in Greene et al. (1997) suggest that for road traffic, congestion costs are considerably smaller than accident costs, but at least as important as noise, air pollution and global warming costs. For air travel Levinson et al. (1998) estimate that noise is the largest cost, followed in order by congestion, air pollution, and accident costs. Thus, the costs of congestion appear to be appreciable both in absolute terms and relative to other externalities.

5. *Modeling Congestion in Transportation Facilities*

Transportation congestion modeling has been taken furthest for road traffic. Various approaches are described in Small (1992), Daganzo (1997), Hall (1999), and Lindsey and Verhoef (2000). Modeling the behavior of individual drivers is a daunting task not only because of their sheer number but also because drivers—being self-interested, fallible, and heterogeneous—do not behave like atoms according to universal and immutable physical laws. Computer simulation models have been developed that track the second-by-second motion of thousands of vehicles on complex traffic networks (Howard 1997). Useful insights into the economics of traffic congestion can nevertheless be obtained by using conventional supply–demand diagrams in which the dynamics of traffic are ignored and vehicles are treated as a homogeneous continuum.

Consider Fig. 1, but ignore all its details for now—which will be covered later in Sects. 4 and 5. The

Figure 1
Trip costs, equilibrium and optimal usage in a delay system

Average Cost (*AC*) curve passing through points *F, G, J* and *M* depicts the cost borne by each driver to take a particular trip as a function of the traffic volume; i.e. the number of vehicles that make the trip per hour. Average cost includes vehicle operating cost plus travel time, which is assumed to be valued equally by all drivers. At low volumes vehicles are far enough apart that they can proceed under free-flow conditions, so that the trip cost curve is horizontal between *F* and *G*. At higher volumes drivers are forced to slow down to maintain a safe following distance. Travel time rises and *AC* slopes upwards. The shape of *AC* depends on road design, speed limits, vehicle size and handling characteristics, weather conditions, and driver reaction times and preferences for risk-taking. Due to changes in these factors over time, driving speeds have increased and following distances have decreased, thereby boosting effective road capacity and shifting the *AC* curve down.

The *Marginal Social Cost* (*MSC*) curve in Fig. 1, passing through *F, G, H* and *L*, is derived by adding to *AC* the cost of the congestion that each driver imposes on others. The *MSC* curve coincides with *AC* over the interval from *F* to *G*, and lies above *AC* elsewhere. To determine how many trips are taken, a demand curve can be added as shown by the downward-sloping curve passing through *A, H, M, S* and *U*. In the absence of traffic control or other means of regulation, equilibrium is established at point *M* where the marginal willingness to pay for a trip as measured by the demand curve matches the cost, *AC*. The unregulated equilibrium number of trips is *OR*. By contrast, the socially optimal number of trips, *OK*, is found at point *H* where the demand curve intersects *MSC*. Fewer trips per hour are taken than in the unregulated equilibrium, although travel is still congested because trip cost, *JK*, exceeds free-flow cost, *OF*. One way to support the optimum is to impose a toll equal to *HJ*: the difference between *MSC* and *AC* with traffic volume at *OK*. This is the basis behind congestion pricing, to be discussed in Sect. 5.2.

At the unregulated equilibrium the congestion cost imposed by each driver is *LM*. Various studies have estimated this quantity empirically. Some find it to be about equal to the average cost that drivers bear themselves: *MR* (Small and Gómez-Ibáñez 1999 p. 1942). Other studies estimate *LM* to be several times as big as *MR* during peak periods in large cities. To get a figure for aggregate congestion costs it is tempting simply to multiply *LM* by the number of trips, *OR*, to get area *LMDB*. But this is inappropriate since the number of excessive trips taken in equilibrium relative to the social optimum is only *KR*. Similarly, it does not make sense to evaluate the congestion cost at the optimum, *HJ*, and multiply it by *OK* to get area *HJEC*. Yet as Prud'homme (1997) points out, some studies have identified either *LMDB* or *HJEC* as the total cost of congestion.

A more practically useful measure of congestion costs is the difference between the net social benefits of travel at the optimum (area *AHJE*) and at the unregulated equilibrium (area *AMD*). This difference can be decomposed into the reduction in costs on the *OK* trips that continue to be taken at the optimum (diagonally shaded area *IJED*) minus the loss of benefits on the *KR* trips that are no longer taken (vertically shaded area *HMI*). The difference in net social benefits can also be determined by computing the net social cost of the *KR* excessive trips taken in equilibrium. This quantity is equal to area *HLM*, which must therefore equal *IJED–HMI*.

Note that the cost of travel under free-flow conditions plays no role in the calculations. One could of course calculate the difference in cost between equilibrium and free-flow conditions, *MQ*, and multiply it by *OR* to get area *MQFD*. But this would be relevant only if it were somehow possible to maintain free-flow conditions at any traffic volume. Traffic volume would then increase from *OR* to *OV*, and a better measure of the gains would be the increase in net social benefits: area *MUFD*.

Supply–demand diagrams such as Fig. 1 are applicable not only to automobile traffic but also to other delay systems such as airport runways, bus service, waterways, and pedestrian walkways. In the case of loss systems the *AC* curve is approximately horizontal up to capacity flows and it is therefore optimal to use the facility to capacity while avoiding queuing or other wasteful forms of rationing access. In practice, demand cannot be predicted perfectly and a (probabilistic) tradeoff exists between unused capacity and congestion. Airlines deal with this tradeoff by using sophisticated yield management software that set fares according to the average fraction of seats that are occupied on a given flight.

Though useful, the simple supply–demand approach does abstract from various real-world features

of transportation congestion. First, roads, airports and other facilities are components of transportation networks. Costs at one facility can depend on usage at other facilities because of conflicts between traffic flows, spillovers of queues and so on. Second, users differ in the congestion they create. Traffic engineers make allowance for differences between road vehicles in size, speed, and maneuverability by using passenger car equivalents that depend on grade and other road characteristics. Third, the static supply–demand approach ignores fluctuations in travel demand over time and does not address trip-timing decisions. Queuing theory is often useful for handling these aspects (Newell 1982).

6. *Ways to Alleviate Congestion*

Many policies have been adopted to relieve congestion. Some—such as land-use controls—have additional objectives, whereas policies such as road pricing are targeted at congestion. A comprehensive review of policies in urban transportation is found in Small and Gómez-Ibáñez (1999, Sects. 2.2–2.5). Discussion will be limited here to three policy instruments: capacity investment, congestion pricing, and information technology.

6.1 *Investment*

The traditional approach to congestion relief is to expand capacity. Investment shifts the *AC* curve in Fig. 1 down, as shown by the dashed line passing through points *P* and *S*. A new unregulated equilibrium is established at *S*. Two benefits result: a reduction in travel costs for the *OR* pre-existing trips; and the benefit to travelers from the *RT* new trips. But because the new trips contribute to congestion, travel costs decline by only *MN* rather than by *MP*, and this partly undoes the cost savings to previous users. Generation of new trips is a manifestation of so-called latent (hidden) demand that was not apparent prior to the investment. Though the increase in usage can be appreciable if the demand curve is relatively flat, the effect of latent demand has frequently been overlooked in engineering and cost-benefit studies of investment. Even worse than latent demand, capacity expansion on one link of a transport network can induce shifts of demand to more congestion-prone routes or travel modes that actually raise overall travel costs (Arnott and Small 1994).

Unlike the unregulated equilibrium, investment always yields a positive gross benefit for the social optimum. The effects can be assessed by tracing the rightward shift of the *MSC* curve (not shown in Fig. 1). Depending on the strength of latent demand, the benefits may be greater or smaller than for the unregulated equilibrium. More generally, the benefits of investment, and hence optimal capacity too, depend on how traffic is regulated and priced.

6.2 *Congestion Pricing*

Economists have promoted congestion pricing since the 1950s. It makes use of the price mechanism, with all its advantages of decentralized decision-making. And, unlike other policies, congestion pricing restrains latent demand. The biggest potential gains from congestion pricing in transportation appear to be for road traffic and airport runways.

6.2.1 Road pricing. Road pricing technology has come a long way since drivers were obliged to stop and pay cash at tollbooths. Thanks to advances in automatic vehicle identification and electronic toll collection, tolls can be levied anonymously using prepaid smartcards while vehicles maintain highway speeds. The biggest virtue of road pricing is that it can influence all dimensions of travelers' choice. It is also consistent with the 'user pay principal.'

The optimal toll in the static supply–demand framework of Fig. 1 is *HJ*. Imposition of this toll raises travel cost by *HI* relative to the no-toll unregulated equilibrium. That road pricing tends to make drivers worse off is one of the reasons for longstanding opposition to it. Another is that road pricing is often seen as 'just another tax.' There is growing recognition that to generate political support for road pricing, toll revenues must be used to benefit travelers without undoing incentives for them to curb their travel. Possibilities include improving public transit, reducing gasoline taxes, and investing in roads themselves. New self-financed private toll roads are showing promise as a market-oriented approach to alleviating congestion (Gómez-Ibáñez and Meyer 1993).

The simple supply-demand approach of course abstracts from various real-world complications in the implementation of congestion pricing, including setting tolls on a network, varying tolls over time, charging for parking, and avoiding harm to lower-income drivers. These and other aspects are discussed in Button and Verhoef (1998) and McDonald et al. (1999).

6.2.2 Pricing airport runways. Traditional means of allocating runway space are a far cry from congestion pricing. Access to runways has been determined by scheduling committees that may be dominated by representatives of major airlines operating at the airport. And landing fees have been based on aircraft weight, which reflects congestion cost only crudely. Congestion pricing of runways would be administratively easier to implement than road pricing because takeoff and landings are recorded at airports

anyway, and since the transactions costs for a flight are spread over many travelers.

The virtues of congestion pricing of runways were recognized in the late 1960s. Pricing encourages airlines to schedule flights off peak, to use lower-cost airports, and to deploy larger aircraft, which create less delay per passenger. The potential gains are large. Morrison and Winston (1989) estimate that optimal pricing at US airports would reduce delays by up to 50 percent, and yield nearly $4 billion in net benefits. An alternative to charging for every use of runways is to auction tradable take-off and landing slots. Slot trading was introduced in 1986 at Washington National, Chicago O'Hare, and New York's La Guardia and Kennedy airports, and has worked well. Runway pricing and slot trading, as well as pricing of airport terminal services are described in Doganis (1992).

6.3 Information Technology

Development of Intelligent Transportation Systems (ITS) began in the 1970s, and expensive research programs are under way. One of the long-term goals of ITS is to assemble information about travel conditions and make it available to travelers at public places, by phone or Internet, or directly to vehicles equipped with on-board computers and Global Positioning Systems receivers. Computer simulations suggest that information can help drivers avoid hot spots of congestion by switching routes, changing departure times, and canceling trips. Travelers without access to information may also benefit from the adjustments made by informed travelers.

Despite these encouraging research findings, the potential of ITS is limited by the fact that they do not make drivers pay for the congestion they create. Indeed, provision of information can make congestion worse if it induces drivers to overreact; e.g. by switching *en masse* to Route 2 after learning about an accident on Route 1 (Ben-Akiva et al. 1991). And, similar to the effects of capacity expansion, congestion can be exacerbated if information induces people to travel more, or to concentrate their travel on congestion-prone routes and at peak times. These drawbacks can in principle be avoided by implementing road pricing in tandem with ITS.

6.4 General Policy Conclusions

From a theoretical perspective congestion pricing is the most effective means of controlling congestion because it influences all travel choices and also contains latent demand. But for various reasons—including the cost of pricing all links on travel networks, equity concerns and the need to maintain safety—nonprice constraints on travel such as air traffic control and regulations on the movement of heavy road vehicles will persist. The battle against traffic snarls, delays in the air, and congestion on other transport modes must continue to be waged on several fronts.

7. Looking Ahead

Despite the hazards of forecasting it is tempting to speculate about how congestion in transportation will evolve in the years to come. Consider first traffic congestion in the US, which is costly in an absolute sense and receives regular attention in the press. Aggregate congestion indexes suggest that congestion is getting worse in major urban areas. But average speeds and commuting times have remained fairly constant over the last 25 years. After growing for decades, auto ownership per capita is near saturation. And average commuter vehicle occupancy, which fell from 1.18 in 1970 to 1.09 in 1990, cannot fall much further (Schrank and Lomax 1999). These and other factors have led analysts such as Meyer (1999) to conclude that radical policies to affect sweeping changes in automobile travel patterns are not warranted.

Technological innovations such as air conditioning, car stereo systems, books on tape and cellular phones have made driving more pleasant and allow people to make productive use of time in the car. Similarly, laptops, cellular phones and executive lounges at airports make delays in air travel less onerous. And people can adapt to congestion by adjusting departure times, destinations, residential location and other choices. As a result, their tolerance for delay increases (Calfee and Winston 1998). Congestion costs are also held in check by the trend toward flexible work times, late night and weekend shopping, and extended hours of other services. And, most fundamentally, the costs of congestion are borne largely by travelers themselves. Congestion is a self-limiting phenomenon in the sense that the private cost of travel can never exceed the private benefit derived from it.

Travel is governed by resource constraints and other influences that vary greatly from region to region, and evolve over time. Two regularities in travel data have nevertheless been documented. One is that the amount of time spent traveling per person has remained relatively fixed at 1–1.5 hours per day. The second is that people spend a relatively constant fraction of their income on travel. These observations led to the constant travel time budget hypothesis and constant travel income budget hypothesis (for a summary see Schafer and Victor 1997). The two hypotheses are not logically inconsistent because as incomes rise people can switch to faster and more expensive modes of travel. To the extent that the hypotheses are valid they are useful for forecasting general trends in travel and congestion. Rising living standards will induce people to travel further each year. Faster economic growth in

developing countries will mean faster expansion in travel there. Shifts toward faster modes of travel suggest that congestion in air travel will grow most quickly. Schafer and Victor (1997) forecast that by 2050 high-speed transport (air and high-speed rail) will account for about 50 percent of total distance traveled.

To what extent might new technology alleviate congestion by reducing travel demand? Attention has been focused on teleconferencing, teleshopping, FAX, electronic mail, the Internet and other telecommunications technology. Spread of computers into homes has made telecommuting perhaps the most promising application. Nevertheless, it has some limitations (Mokhtarian 1997). People may value the journey to work as a buffer between their home and work roles, desire interaction at the workplace, or fear being overlooked for promotion if they stay at home. The option of telecommuting may encourage people to live in more remote locations, so that when they do commute they have further to go. Part of the time freed up from commuting may be used to make other trips, as the constant travel time budget hypothesis predicts. And any reductions in travel by telecommuters may be partially offset by latent demand from the rest of the population. Still, by reducing peak-period travel, telecommuting may alleviate congestion and permit savings in expenditure on infrastructure. And even if the increased use of telecommunications as a whole does not reduce travel, it may yield benefits in increased work productivity and greater personal flexibility. Perhaps the safest prediction is that congestion and efforts to alleviate it will persist for the foreseeable future.

Transsexuality, Transvestism, and Transgender

'Transexuality' or 'transsexuality' (with two 's's'—for an explanation of these orthographic differences, see below) and 'transgender' are terms often used inte-

rchangeably in contemporary political activism and social scientific writing, as is the associated term 'transvestism.' Despite the overlap, these terms have different histories and a complex relationship with one another.

The donning of garments of another gender (so-called 'cross-dressing') has a long recorded history. Only in the late nineteenth and early twentieth centuries, however, did cross-dressing come to be viewed specifically as a psychosexual disorder. At this point, cross-dressing became 'transvestism,' a term first used by the German sexologist and sexual rights activist Magnus Hirschfeld in his study, *Die Transvestiten* (*Transvestites*), published in 1910. Hirschfeld coined the term from the Latin *trans* ('across') and *vestis* ('dress'), to refer to individuals whose principle source of erotic pleasure arose from dressing in the clothes of the opposite sex. Hirschfeld's understanding of cross-dressing and his term 'transvestism' have been debated in the sexological and psychoanalytic literature ever since his study appeared (the English sexologist Havelock Ellis, for example, argued that Hirschfeld focused too narrowly on clothing and should also have considered the appeal of the social role of the opposite sex. He suggested the term 'eonism,' which he invented, using the name of the eighteenth century cross-dresser, the Chevalier d'Éon; see Bullough and Bullough 1993, pp. 203–25). However, contemporary psychiatric discourses have largely followed Hirschfeld in characterizing transvestism in terms of (primarily heterosexual male) erotic cross-dressing.

In contemporary psychiatric classification, transvestism is distinguished from transexualism, which is regarded as a separate pathology. Whereas transvestism is considered a psychosexual disorder characterized by an erotic focus on clothing, transexuals are defined as individuals who have a 'gender identity' that is at odds with their assigned gender. In other words, transexuals are considered to be individuals whose core identification of themselves as male or female is at odds with the gender by which they are socially desginated. Transexualism involves a wide range of psychiatric and medical interventions, including the surgical alteration of genitals and secondary sex characteristics, and hormonal supplements to attain the physical appearance of the desired sex/gender.

The development of transvestism and transexualism as medical categories must be understood as an outgrowth of the social and cultural discourses that developed in the late nineteenth and early twentieth centuries, when the dominant paradigm for understanding and regulating gender and sexuality shifted from the various Christian churches to the state and to various branches of the developing medical sciences. Modern discourses on transexualism have their historical roots in nineteenth century debates about the management of hermaphrodism, which is the medical term for a range of conditions which give rise to non-normative genitals in a small segment of the population (the term 'intersexuality' has recently been coined by intersex activists to replace 'hermaphrodism,' which they regard as saturated with medical stigma). Michel Foucault has argued that the centuries-old understanding that intersexed individuals had two sexes came to be replaced during the nineteeth century with the view that they must have a single, 'true' sex; one that once it became identified by medical science and certified by juridical institutions could never be changed. This concern to 'strip the [hermaphrodite's] body of its anatomical deceptions' (Foucault 1980, p. viii) and discover its truth was part of a much broader move that occurred during this period towards the medical and juridical management of the sexual behavior and bodies of all individuals, especially those who engaged in nonprocreative sexual acts, or who transgressed gendered boundaries.

Current understandings of categories like hermaphrodism/intersex, homosexuality, transvestism, and transexualism all arose during this historical period, and are linked to one another and to the medical and legal classifications that created them as social categories. Transexualism itself, however, is essentially a mid-twentieth century phenomenon. It arose together with the modern, surgical techniques that made it possible. As such, 'transexuality' only became available as a medical category, a surgical possibility, and a personal identity around the middle of the twentieth century.

While there were attempts at surgical changes to sex (from male to female) prior to the 1950s (the first attempt to create an artificial vagina through surgery was in 1904), only 31 cases of surgical alteration or change of sex are known prior to the 1950s. It is likely that these were mainly early attempts to intervene in cases of intersexuality or hermaphrodism in the nascent field of plastic surgery. Sensationalist media reports of early intersexual surgeries provided the impetus for many individuals who would be described as male-to-female transexual in contemporary medical terms to demand surgical reassignment. The case of Christine Jorgensen, who received *sex reassignment surgery* (SRS) in Denmark in 1952, brought this phenomenon to the attention of the public and the medical community in the United States. However, it was mainly through the efforts of a New York endocrinologist, Harry Benjamin, that the term 'transsexual' (spelled with two 's's') gained force as the term to describe the growing number of people appealing to surgeons and doctors for SRS following the publicity surrounding the Jorgensen case and others that followed. The term 'transexualism' was now used to distinguish these people from transvestites who cross-dressed but did not want SRS. It was also through Benjamin's efforts that the first 'gender identity clinic' opened in the US at Johns Hopkins in 1965. The first SRS was completed there in 1966, the same year

Benjamin's classic in the field, *The Transsexual Phenomenon*, was published.

In the late twentieth century, some of the categories of 'dis-order' that were part of what Foucault calls the 'deployment of sexuality,' such as that of homosexuality, have, to an extent, extricated themselves from purely medical discourses. Transexualism, however, because of its links to surgery, is by definition a 'condition' that requires a close relationship between a transexual and the medical profession. SRS requires skilled surgeons, endocrinologists, urologists, and others, and the path to this surgery is controlled by psychiatrists and counselors. Furthermore, SRS is still regarded as a cure which aims at managing a pathology. Access to this cure, though, is predicated on an appropriate diagnosis. However, the history of the development of such diagnoses has not been an even or unproblematic development.

Within the medical community, the period 1953–65 was characterized by resistance both to the adoption of transexualism as a diagnostic category and to performing SRS. However, by the 1970s, an entire subfield of specialty had developed in the area, along with new terminology. The term 'gender dysphoria' (and the associated 'gender identity disorder') came increasingly to dominate the literature on transexualism and transvestism, to a certain extent incorporating and replacing these latter terms. The term was partly an attempt to include a growing number of phenomena that psychiatrists and doctors were seeing in patients who did not conform to the classic descriptions of transexualism, in particular children who displayed non-normative gender behaviors and individuals who claimed a nonassigned gender identity but did not desire surgical transition. Indeed, Norman Fisk, who coined the term, saw 'gender dysphoria' as a liberalizing concept, allowing surgery to more people (Fisk 1974). By 1979, gender dysphoria was the primary working concept of those in the field, although 'transsexual' was, and still is, used as a diagnostic and descriptive category.

King (1993, p. 63) notes that there are several consequences of this change in terminology, the most important being that it shifts the focus from the individual to a condition and invokes a disease model. In doing so, the concept of gender dysphoria reaffirms medical authority. It also widens the scope of diagnosable people to include the physically intersexed (hermaphrodites) and even gay men and lesbians. The definition is so broad that 'indeed possibly all of us suffer from it in a mild form' (King 1993, p. 64).

Another consequence of the adoption of the term 'gender dysphoria' is that it encourages the idea that such a disorder existed long before it was 'discovered' and named by doctors and psychiatrists. A quotation from a 1986 review of the collaboration between various branches of the medical establishment is indicative: '[t]he concept of gender dysphoria and its specific forms have been known since antiquity and have been described in the classic literature from Herodotus to Shakespeare' (Pauly and Edgerton 1986, pp. 316–17).

Despite the widening use of 'gender dysphoria' as a trans-historical category, transexualism itself, as noted above, is a medical category of the latter half of the twentieth century. However, until 1980, when transexualism (and the associated category of 'gender identity disorder') was included in the *Diagnostic and Statistical Manual of Mental Disorders*, 3rd edn., (hereafter *DSM-III*), and when the Harry Benjamin International Gender Dysphoria Association published its document on Standards of Care (Harry Benjamin International Gender Dysphoria Association 1985 [1980]) for treating transexuals and 'gender dysphoric' persons, psychiatrists had no standardized criteria by which to judge whether a person was a 'good candidate' for SRS. Hence, they did so on the basis of a variety of fluctuating guidelines set by a variety of writers in the field.

The basic preconditions for SRS that became established in 1980 are as follows: a person seeking SRS should, prior to surgery, have the recommendation of at least two psychologists/psychiatrists; have been on hormonal treatment for periods varying from six months to one year; and have lived exclusively in the role of the chosen gender for periods varying from one to two years. Alongside this are other factors which are considered to make a 'good candidate,' including lack of sexual activity and no history of prostitution.

The publicity surrounding the Jorgensen case led many people to identify themselves as transexuals and seek SRS. This is indicative of one of the most striking aspects of transexualism in psychiatric terms: virtually all transexuals are 'self-diagnosed.' Transexuals challenge the medical establishment at the very root of its claims to authority, the privilege of diagnosis. This has set into motion a chain of related themes: distrust of transexual self-reports of their conditions and an emphasis on third party confirmation, attempts to come up with a stable list of criteria by which access to SRS can be regulated, and a push toward developing a psychiatric diagnosis for transexualism (or the broader term, gender identity disorders) that does not rely on self-reports, but on perceived objective criteria.

Despite the consistencies and patterns that have emerged, however, the history of the establishment of a stable diagnosis for transexualism and its related terms is neither simple, nor even. Some writers have denied that there is a diagnostic category at all, or that transexualism should not be a diagnosis but rather is a 'wish' that is a feature of other, underlying psychopathologies. The self-diagnosis of transexuals complicates the field. Benjamin wrote in 1966 that 'it is true that the request for a conversion operation is typical only for the transsexual and can actually serve as a definition' (1966, p. 21). However, this definition came increasingly under scrutiny as follow-up studies

in the 1970s and 1980s showed a significant (between 5 and 15 percent) 'dissatisfaction' with or 'negative outcomes' of surgery. There are a number of factors here, but significantly, medical practioners associated dissatisfaction primarily with giving the 'wrong' people SRS. In other words, clinicians no longer regarded requests for SRS as a definition or a diagnosis of transexualism. In fact, they tended to treat all such requests with suspicion, potentially as expressions of psychosis or even schizophrenia.

It was only in 1980, in the third edition of what is often referred to as the 'psychiatrists' bible,' the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM*), that transexualism was included as a mental disorder (transvestism was included from the original publication of the *DSM* in 1952). Some writers link the formal inclusion of transexuality or gender identity disorder in *DSM-III* to the exclusion of homosexuality from the *DSM-II* in 1973 after pressure brought to bear on the American Psychiatric Association (APA) by gay and lesbian activists. Scholars have noted that the work and writing of some APA members (particularly those who opposed the deletion of homosexuality) indicates the extent to which the diagnosis of gender identity disorder has become a justification for psychiatric interventions in cases of young children who are seen to be in 'danger' of becoming homosexual. Since 1980, two more editions have been prepared: the revised third edition in 1987, and the fourth edition in 1994. An analysis of the shifting categorization of transexuality and transvestism over these three editions complicates claims that gender dysphoria or gender identity disorder is a transhistorical, cross-cultural phenomenon with a certain universal stability and truth. The changes across three editions within 14 years indicate a far less stable set of concepts which are malleable, constructed, and negotiable.

This movement toward categorization and diagnostic criteria should not be seen to represent a monolithic set of attitudes and practices. Instead, it should be understood as the outgrowth of attitudes towards, and practices around, psychiatric diagnosis, relationships with patients, and the production of data and empirical evidence/knowledge in a field of power relations. This field of power has been generated by, and in turn has generated, a whole subdiscipline of medicine with a coalition of clinicians from numerous disparate fields coming together in a new category of theory and practice. Over the past 40 years, these clinicians have debated, produced, and to an extent consolidated a series of meanings and practices that have had specific, though varying, effects on the lives of individual people. Alongside the development of diagnostic criteria, there has also been a concern with follow-up and assessment, which has been central to generating the data upon which diagnostic criteria are based. In addition, clinicians implemented 'charm schools,' which train successful (male-to-female) candidates in culturally-specific gender behaviors and ideals.

Critics of such 'charm schools' have observed that they are almost entirely focused on male-to-female transexuals. This fact was seized upon by an early and still-influential line of radical feminist thought which argues that transexualism 'constitutes a sociopolitical program that is undercutting the movement to eradicate sex-role stereotyping and oppression' (Raymond 1994, p. xxi). In an era when women are increasingly rejecting rigid sex roles, this criticism maintains, patriarchal social structures are responding by 'molding and mutilating *male* flesh, but for the purpose of *constructing women*' (Raymond 1980, p. xvi, emphasis in original). From this point of view, individuals identifying as transexual need consciousness raising, not surgery, which these critics regard as socially sanctioned mutilation that should be outlawed.

That most medical attention has focused on managing male-to-female transexuality also highlights the broader issue of the category 'transexual.' *DSM* claims there are larger numbers of male-to-female transexuals than female-to-males. Many female-to-males/transexual men dispute this, and argue that medical discourses and statistics obscure a large population of transexual men. These men, like a number of scholars, give a variety of reasons for the medical concern with male-to-female transexuality, including the cost and unsatisfactory outcomes of surgeries for transexual men, the statistically lower socioeconomic position of female-born people, the relative ease of passing as a man with only hormonal interventions, cultural unease with the possibility of surgically constructing men (Judith Halberstam [1994, p. 215] quips 'If anyone could have [a penis], who would want one?'), and a broader social anxiety surrounding femininity in male-born people.

A significant development in conceptualizations about transexuality has been the development during the 1990s of the term 'transgender.' The phrase, adopted from a usage coined by Virginia Prince (1971), originally signified a person who chose to live full time in a nonassigned gender without surgical or, in some cases, without hormonal interventions. While 'transgender' is still often opposed to 'transexual' in this sense, it has become more frequently used as a collective term to describe a range of disparate groups which had previously been seen as distinct: transexuals, transvestites or crossdressers, drag queens, and even intersex people. Other terms, such as Richard Ekins's (1997) 'male-femaling' or Judith Halberstam's (1998) 'female masculinity,' have been proposed in the social science literature as a way of analyzing this range of people who cross or transgress gendered boundaries. However, 'transgender' has increasingly become the accepted generic term.

The category 'transgender' arose primarily in the northeastern and western United States (New York and California) in the early 1990s as a way of achieving

a diverse set of political, social, and cultural goals: the depathologization of gender difference in psychiatric and popular discourses, the recognition of gender variant people as a political constituency and a social group, and the achievement of social justice around such issues as exposure to violence and discrimination. In the brief years since then, 'transgender' has become ubiquitous in progressive community-based organizations, identity-based political movements, popular media accounts, international human rights discourses, academic debates, cross-cultural descriptions of gender difference, and is even finding its way into medical discourses, the very discourses that 'transgender' has been opposed to. Like transgender, 'transexual' with a one 's' spelling (the usage we adopt here), was coined by activists in opposition to medical categories, as in the New York-based direct action group 'Transexual Menace.' Other linguistic innovations abound, including formulations like 'transmen' or 'transwomen,' 'transcommunities' or 'person of transgender/transexual experience,' all of which attempt to describe phenomena without being constrained by standard medical terms.

The collectivity of 'transgender' also takes into account complexities of lived identities and experiences in a way that medical categories such as 'transsexual' or 'transvestite' do not. While *DSM* diagnostic criteria, for example, insist that transvestism is particular to heterosexual men, in fact self-identified heterosexual women, lesbians, and gay men also engage in erotic cross-dressing. Likewise, the line between cross-dressers and transexuals is not clearly drawn, nor is the line between butch lesbians and transmen. A cross-dresser or transvestite, who in psychiatric diagnostic criteria is a heterosexual man who cross-dresses for erotic pleasure, may also take hormones, and in some cases, transition to live full-time as a woman. 'Transgender' is useful, therefore, in bringing together a range of individuals who share an experience of gender variance.

However, 'transgender' as a category is not without its complexities either. While some activists use it in the collective sense described above which includes postoperative transexuals, others insist on the narrower definition which includes only those who choose not to have surgery. Further, while some self-identified transgender activists profess a desire to remove 'gender identity disorder' from *DSM* in an attempt to depathologize gender variance, others have demanded that some diagnostic criteria remain in place in order to allow for insurance reimbursement of the costly surgeries involved in sex reassignment. Similarly, many of those who are grouped under 'transgender' as a category are opposed to the inclusion of others, claiming that their particular experiences are diluted or effaced by their inclusion in such a broad category. Further, some transexual men argue that transgender privileges a male-to-female model which elides the particular experiences of transexual men. Most interestingly, medical professionals themselves are beginning to use the term, at least partly in deference to the growth of an active and vocal activism which seeks to overturn the power of medical professionals in the field. Indeed, 'transgender' works in some ways like the medical concept 'gender dysphoria' in that it groups together a wide array of individuals who may not necessarily see themselves as being part of the same category. The important distinction, however, is that as a community-based term, 'transgender' contains none of the implications of pathology apparent in formulations such as 'gender dysphoria' or 'gender identity disorder.' 'Transgender' then is characterized as much by disputes and contradictions as it is by its efficacy in highlighting issues of social justice in the fields of politics, medicine, law, and social service provision.

A related point of complexity is the insistence in many activist contexts on the distinction between 'transgender' issues on the one hand and 'gay and lesbian' issues on the other. In contemporary US politics and theory, for example, gay and lesbian identities are seen to be rooted in sexual orientation, whereas transgender identities are understood to be rooted primarily in gender identity. This has been the source of some tension in contemporary sexual and gender politics, and some gay and lesbian organizations resist the inclusion of transgender issues in their political and social activism. However, as some transgender activists have pointed out, much of the discrimination and violence experienced by gay- and lesbian-identified people is directed at a perceived gender transgression. These activists often prefer to use constructions like 'gender variance' or 'gender difference' to include both transgender-identified and gay- and lesbian-identified people in order to stress these connections and to avoid the kinds of essentializing identity-based discourses which often characterize progressive sexual and gender politics.

Treatment of the Repetitive Criminal Sex Offender: United States

Designation of a specific subclass of sex offenders as 'repetitive' derives from sexual psychopath legislation that has sought, over the past half of the twentieth century, to confine sex offenders for indeterminate periods under civil commitment. In response to horrendous crimes committed by a few sex offenders recently released from prison, states passed a series of laws providing for the involuntary, civil commitment of individuals identified as 'sexually dangerous persons,' 'sexual psychopaths,' or 'mentally disordered sex offenders.' Thirty states passed such laws, but over time they fell into disuse or were successfully challenged in court and most were legislatively repealed. In 1990, however, a sex offender recently released from a prison in Washington state abducted, raped, and castrated a 7 year old boy. An outraged public demanded a response, and involuntary commitment was resurrected. The legality of the Washington statute, as well as other similar laws, were immediately challenged, and a Kansas statute, identical to Washington's statute, reached the United States Supreme Court.

1. *The* Hendricks *Era*

The single most influential court decision in the decade of the 1990s has been *Kansas vs. Hendricks*, -U.S.-, 117 S. Ct. 2072 (1997). The Kansas statute established procedures for civil commitment of persons who, due to a 'mental abnormality' or a 'personality disorder' are likely to engage in 'predatory acts of sexual violence.' *Kan. Stat. Ann. Sec.* 59-29a01 1994; *Kansas v. Hendricks*). The state invoked the Act for the first time to commit Leroy Hendricks, a 60 year old man with a long history of taking 'indecent liberties' with children, and who was scheduled for release from prison shortly after the Act became law.

Hendricks had a 'serious mental disorder' (pedophilia) that rendered him dangerous because of a 'specific, serious, and highly unusual inability to control his actions' (from Justice Breyer's dissenting opinion) (Cornwell 1998, p. 397). The clear implication is that pedophiles are incapable of controlling their impulses to molest children. Indeed, in those instances where diagnostic criteria may be inferred, the predominant behavioral criterion for the old sexual psychopath statutes and the new sexual predator statutes involves some form of volitional impairment (i.e., an inability to control impulses to engage in acts of sexual aggression). Impaired impulse control is, at least in principle if not in reality, associated with 'repetitive' offenses. Thus, the 'modal' individual committed under these statutes is a repetitive or habitual sex offender. Importantly, the use of the word 'repetitive' in statutory lexicon tells us relatively little about the individual, clinically or dynamically. All offenders with multiple known sexual crimes may be classified as 'repetitive,' resulting in a highly heterogeneous group.

2. *Treatment of the Institutionalized Sex Offender*

To improve the constitutional viability of civil commitment for 'sexual predators,' treatment had to be

offered. The model for treating these 'repetitive' sex offenders is no different, however, from the model used to treat sex offenders not classified as predators or as repetitive. The cognitive-behavioral model is an adaptation of relapse prevention, and the many elaborations and revisions of this model have been the subject of considerable commentary (cf., Laws 1989, Schwartz and Cellini 1995, 1997; see *Sex Offenders, Clinical Psychology of*). The rationale for the modification of any unwanted behavior stems from the informed consideration of those factors that are most importantly associated with the emergence and the sustenance of the behavior. From the ample research on addictive disorders, particularly alcoholism, smoking, and obesity, there has emerged a substantial literature on preventing relapse (Brownell et al. 1986). Relapse prevention, as a model, has been revised and adapted for use with sex offenders (cf. Laws 1989, Laws et al. 2000). Although sexual aggression derives from a substantially more complex amalgam of factors than most addictive disorders and typically reflects a chronic pattern of maladaptive behaviors, the underlying principles remain the same. That is, before designing strategies for modifying sexually aggressive behavior, we first must identify those factors that are most importantly related to the behavior (i.e., determinants of relapse). Although the factors discussed here are, by no means, inclusive, they do represent the core components of most contemporary treatment programs.

3. *Core Elements of Most Treatment Programs for Sex Offenders*

3.1 *Impaired Adult Relationships*

Impaired relationships with adults reflect a broad dimension of social competence that is temporally stable and multiply determined. Although social skills training is one of the most frequently included components of treatment for sex offenders, its role in relation to sexual aggression remains unclear. Because there are many facets to social competence, specifying what aspect one is assessing is critical. For instance, although there is reasonable support for the conclusion that rapists have assertiveness problems, differences in other areas of social competence are less evident. Likewise some child molesters, such as 'pedophiles,' have a variety of social and interpersonal inadequacies.

Although the question of the etiologic importance of social competence remains uncertain, the inclusion of techniques to address social skills deficits is still clinically appropriate. In addition to social skills training, the modalities that are most often used to improve relationships with adults include assertiveness training, relaxation training, systematic desensitization, sex education, and self-esteem enhancement.

3.2 *Lack of Empathy*

In all domains of interpersonal violence, a general lack of empathic relatedness for one's victim can be regarded as a powerful disinhibitor. Alternatively, the presence of empathic concern may serve to inhibit aggression. There is a clear clinical rationale for assuming the presence of such deficits and targeting interventions to enhance empathy.

Hildebran and Pithers (1989) described the importance of developing empathy for all victims of sexual abuse as an essential first stage of treatment, followed by the development of empathy for one's own victims. At this point most sex offender treatment programs include a separate component for increasing victim empathy. Indeed, Knopp et al. (1992) found in their survey of treatment programs in North America that 94 percent included victim empathy training. In addition to the standard exercises and tapes (video and audio) used in victim empathy training, expressive therapy may be used to increase the offender's emotional or affective response to the distress of the victim. Some programs introduce victim advocates, victim counselors and occasionally victims to increase further the emotional impact. Moreover, increasing the offender's affective appreciation of his own childhood experiences of victimisation can instill a greater awareness of his victim's experience of abuse.

3.3 *Degree and Nature of Anger*

The degree and nature of anger evidenced in the assault has long been assumed to differentiate between offenders who were—and those who were not—willing to use extreme force to gain victim compliance (cf. Prentky and Knight 1991). Sex offenders differ considerably in the nature and extent of their anger and the ways that anger manifests itself in their crimes. Sex offenders who intend only to force victim compliance are likely to vary widely in the amount of aggression evident in their offences. When the aggression clearly exceeds what was necessary to force victim compliance, the motivation and manifestation may also vary considerably. In some cases the anger may be undifferentiated with respect to victims (i.e., the offender may be globally angry and express his anger at any available target), and in other cases the offenders may be focally angry at women (i.e., misogynistic anger) and displace their anger at women in general or on specific groups of women (e.g., prostitutes or the elderly). Similarly, child molesters who intentionally inflict considerable physical injury on their victims may be focally angry at children.

The recognition of the critical importance of anger as a driving force in sexual offenses has resulted in the inclusion of treatment techniques to reduce and contain anger. The most commonly employed of these techniques is an anger management group which uses

cognitive-behavioral strategies to increase self-control as well as the timely and appropriate expression of angry feelings. In addition, Relapse Prevention, which also focuses on increasing self-management skills, and Stress Management can assist the offender to gain control over chronic and situationally-induced anger. Finally, early life experiences of victimization can fuel lifelong anger that is periodically triggered by real or imagined provocations. A group that focuses on childhood victimization can help the offender to master these traumatic events.

3.4 Cognitive Distortions

Cognitive distortions are 'irrational' ideas, thoughts, and attitudes that serve to: (a) perpetuate denial around sexually aggressive behavior, (b) foster the minimization and trivialization of the impact of sexually aggressive behavior on victims, and (c) justify and sustain further sexually aggressive behavior. Cognitive distortions are presumed to be learned attitudes that are instilled at an early age by caregivers, reinforced by peers during childhood and adolescence, and further strengthened in adulthood by the prevailing social climate.

The social and cultural forces that have been hypothesized to contribute to sexual violence include the permissive responses of a wide variety of social systems and institutions that function to perpetuate rape myths and misogynistic attitudes, the objectification and exploitation of children and women in pornography, and the often similar but more subtle messages conveyed in advertising that support, or at least condone, sexual harassment (cf. Stermac et al. 1990). The importance of cognitions in moderating sexual arousal has been repeatedly demonstrated. Moreover, clinical observations have suggested that many sexual offenders harbor offense-justifying attitudes and that these attitudes are importantly related to the maintenance of the 'sexual assault cycle.' Thus, the modification of irrational attitudes has been a major focus of treatment intervention. Although there are a variety of treatment modalities that may impact these distortions, the most commonly employed technique is cognitive restructuring. For cognitive restructuring to be most effective, it is critical that cognitive and affective components be addressed. That is, it is insufficient merely to confront the 'distorted' nature of the attitudes, to discuss the role that such distortions play for the individual, or to provide accurate information about sexual abuse (all cognitive components). It is equally important to create discomfort by focusing on the victim's response (e.g., fright, pain, humiliation)—the affective component. This latter exercise is also integral to victim empathy training.

In addition to cognitive restructuring, a group that focuses on childhood victimization can also be very helpful. Since the origin of these distorted attitudes is often a primary caregiver who was an influential role model, as well as exposure to peer role models, often in institutional settings, a group that focuses on these early life experiences can help to trace the cognitions to their source, thereby challenging their generality and diminishing their 'truth' or their 'reality.'

3.5 Sexual Fantasy and Deviant Sexual Arousal

Sexual fantasy refers to cognitive activity that focuses on thoughts and images having sexual content, and deviant sexual arousal refers to an arousal response that is prompted by thoughts, stimuli (visual or auditory), or behaviors that are defined as unconventional or antisocial by society. Studies investigating the relation of sexual fantasy to sexual aggression have typically employed plethysmography to assess sexual arousal to auditory and visual stimuli that purportedly tap specific sexual preferences. The guiding premise of these studies has been that deviant sexual fantasy is highly correlated with deviant sexual arousal and that both deviant fantasy and deviant arousal patterns are important precursors of deviant sexual behavior (cf. Prentky and Knight 1991).

The frequent targeting of such fantasies for therapeutic intervention reflects the widely held belief that the modification of deviant sexual fantasies and deviant sexual arousal patterns is critical for the successful treatment of sex offenders. Indeed, the presence of deviant sexual fantasies does appear to increase the likelihood of subsequent deviant sexual behavior. Moreover, the moderate success at increasing nondeviant arousal and behavior by applying techniques aimed solely at modifying arousal to deviant sexual fantasies supports the hypothesis that deviant fantasies not only lead to and maintain deviant sexual behavior but also impede normal sexual adaptation.

Behavioral techniques for modifying sexual arousal patterns are grouped into two categories, those that decrease deviant arousal (e.g., covert sensitization, aversion, masturbatory satiation) and those that increase appropriate arousal (systematic desensitization, fantasy modification and orgasmic reconditioning). Although numerous behavioral techniques have been reported in the literature, the most widely used method has involved some variant of aversive therapy.

In addition to the repertoire of behavioral interventions, somatic treatment has become increasingly popular as a complement to psychological treatment. These organic or drug treatments consist primarily of antiandrogens (e.g., Bradford 1989) and antidepressants (e.g., Kafka 1991). The antiandrogens (e.g., medroxyprogesterone acetate and cyproterone acetate) reduce sexual drive by reducing the level of testosterone. The antidepressants that are used are primarily the selective serotonin reuptake inhibitors, such as fluoxetine. Although the neuroregulation of

sexual drive remains unclear, there is some evidence that enhanced central serotonin neurotransmission inhibits sexual arousal. In addition, there is clinical evidence that uncontrollable sexual urges and compulsive sexual behaviors are associated with dysthymia and major depression.

3.6 Antisocial Personality/Lifestyle Impulsivity

In research on sexual offenders, impulsive, antisocial behavior has proven to be a critical risk factor for recidivism (e.g., Hall 1988, Prentky and Knight 1986). There is increasing evidence even within noncriminal samples (e.g., college students) that the likelihood of engaging in sexually aggressive behavior is greater among those who are more impulsive (Prentky and Knight 1991).

Clinicians have long recognised the importance of impulsivity for relapse and have introduced self-control and impulsivity management modules into treatment. In addition to groups that focus specifically on impulse control, most treatment programs include components of Relapse Prevention. Relapse Prevention begins by identifying the chain of events and emotions that lead to sexually aggressive behavior. Once this 'assault cycle' is described, two interventions are employed: (a) strategies that help the offender avoid high risk situations, and (b) strategies that minimize the likelihood that high risk situations, once encountered, will lead to relapse. This is an 'internal self-management' system (cf. Pithers 1990) that is designed to interrupt the seemingly inexorable chain of events that lead to an offense. Relapse Prevention is potentially helpful for interrupting patterns of behavior that eventuate in specific outcomes, such as sexual assault, as well as patterns of behavior that are more global, such as impulsive, antisocial behavior.

4. Conclusion

Given the failure of more traditional correctional remedies, such as deterrence and incapacitation, for reducing the level of sexual violence in society, other interventions must be actively sought. One potentially effective intervention for known offenders is treatment. The verdict as to the efficacy of treatment for sexual offenders will inevitably be a complex one that addresses: (a) optimal treatment modalities for specific subtypes of offenders, (b) optimal conditions under which treatment and follow-up should occur, and (c) selection (or exclusion) criteria for treatment candidates. At the present time, the most informed and dispassionate conclusion must be that the jury is still out. The evidence submitted thus far, however, is encouraging.

The essential point, of course, is the legislative intent of laws that commit sexual offenders for indefinite periods of treatment. If the primary intent of the law is preventive detention, as Pacht (1976) argued 25 years ago, and treatment is merely thrown in so that the law will pass constitutional muster, then it is very unlikely that the law will promote a marked diminution in recidivism among released offenders. The task of effecting behavior change in seriously characterologically disordered individuals is, in itself, considerable. When these individuals have not chosen treatment but are placed in treatment by the court (as is often the case), and when the treatment occurs in the context of a dangerous prison environment where the goal is survival not therapy (as is often the case), then the task becomes immeasurably more difficult. When the treatment provided is suboptimal, the conditions (i.e., prison) are highly problematic and the therapists are inadequately trained and supervised, the task may well be impossible. Under these onerous conditions it would be an egregious error to draw any conclusions about the presumptive inefficacy of treatment with sex offenders.

Trials: Cultural

1. Introduction

It is tempting to adopt the definition of trials offered by Lon Fuller, leading modern authority on adjudication, who defines a trial as a process of adjudication which permits disputants 'an opportunity for the presentation of proofs and reasoned arguments' in order to give 'formal and institutional expression to the influence of reasoned argument in human affairs.' As such, trials 'assume a burden of rationality not borne by any other form of social ordering' (Fuller 1981, pp. 93–4). Although this description probably captures cultural assumptions about the contemporary Western trial, it fails to encompass the idea of a trial more generally. It treats human rationality as a given rather than a variable, and it assumes that the primary focus of trials is to resolve disputes, rather than to proclaim truth or to assert authority.

I suggest an alternative: a trial is a process by which proof is authoritatively established. Rationality can be but is not necessarily involved in the process, parties affected may or may not have an opportunity to offer proofs or to make reasoned arguments, and there may or may not be a 'dispute.' This more general definition is useful in accounting for a greater variety of processes that are generally understood to be trials, although in widely different settings, including so-called simple or primitive societies, intensely religious societies, and modern Western societies. It also includes processes in which there are no 'disputes,' and where disputes are not 'resolved' so much as they are processed (see *Courts and Adjudication*).

A good place to start in thinking about this more generic definition of trial is Max Weber's analysis of rational and irrational forms of legal decision-making (Weber 1954, Trubek 1972). For Weber, *forms* of legal decision-making vary along two dimensions: the nature of their rationality and their degree of formality. By rationality Weber meant the presence or absence of 'general rules' that are to be invoked in decision-making. A rational legal system (and decision), according to Weber, involves use of abstract, calculable, and general principles that are invoked when deciding a particular case. In contrast, an 'irrational' system does not rely on the application of general rules to particular facts or cases, but is guided by a holistic process that may not be determinable in advance of the particular decision. Similarly, Weber pointed out, legal decision-making varies in its degree of formality. At one end of the continuum is a formal legal system that is autonomous; it has a distinct set of 'legal' norms and procedures to guide legal decision-making, and perhaps also a distinct set of offices and officials to make decisions. At the other end of the continuum are not casual, informal norms but rather an array of substantive norms, a mixture of legal, religious, moral, and practical precepts that are intermixed and undifferentiated, and so do not constitute a separate and distinct set of (formal) legal norms. In this way Weber distinguished *formal* justice from *substantive* justice. In proceedings dispensing substantive justice, religious, traditional, societal, ethnic, and family norms may blend with distinctively legal norms; here, strictly legal decision-making and decision-makers are not always distinguishable from other realms of social behavior and social actors (see *Weber, Max* (1864–1920)).

Legal decision-making can vary independently along both dimensions, so Weber developed a set of ideal types that has often been used to characterize distinct forms of legal decision-making across time and across cultures. They are presented in Table 1.

Table 1 generates four identifiable types of 'trials': (I) informal irrational (substantive irrationality); (II) informal rational (substantive rationality); (III) formal irrational; and (IV) formal rational. The two extremes on the diagonal (cells I and IV) are familiar to many students of law and the social sciences. Readers of Weber are familiar with the example for cell I—the decision by a *khadi* (an Islamic clerical judge), who after hearing a case hands down a ruling without explicit reference to any general rules. Weber believed that the outcome is understood in Islamic culture as an expression of divine inspiration transmitted through the *khadi*, and that the ruling applies only to the particular case in hand. By contrast, cell IV represents the trial in the modern, rule-of-law state. Facts are introduced and testimony is taken according to a clear and precise set of procedures, and this evidence is judged in light of predetermined rules. It is this type of decision-making that Fuller had in mind in his

Table 1
Weberian typology of legal decision-making (adapted from Inverarity et al. 1983)

	Degree of rationality (presence or absence of general rules) Irrational	Rational
	I	II
Informality (substantive justice)	Substantive irrationality khadi justice	Substantive rationality cost/benefit analysis
Degree of formality		
	III	IV
Formality (formal justice)	Formal irrationality trial by ordeal	Formal rational modern Western trial

discussion of the forms and limits of adjudication. Turning to Weber's two other types of decision-making, cell II represents substantive rationality, a form of decision-making that does not entail a distinct and separate legal sphere but melds law with norms in other social realms (or, more precisely, separate realms are not differentiated). Examples include legal decisions based upon cost-benefit analysis or religious precepts. Such decisions are 'substantive' not 'formal,' since they do not derive legitimacy from a distinct and separate legal sphere. Yet they are 'rational' in that they specify clear norms, rules, and procedures. Cell III describes a process that is formal in that it depends upon specialized and distinct legal procedures. But because decisions flow from an ineffable process rather than from general rules, the process is irrational. A familiar example is the establishment of proof through appeals to divine intervention—ordeal by fire, ordeal by water, or other attempts to invoke supernatural signs. Whatever its defects, this last set of procedures for establishing proof had one virtue, if only for true believers: certainty of outcome (see *Law and Development*).

The discussion above suggests that what Fuller had in mind as the essence of the trial is in fact only one of several forms of legal decision-making. However, he is not so far from the mark. Weber's purpose in developing the typology outlined above was not only to emphasize structural variability in legal decision-making, but also to set the stage for his theory that modernization requires the adoption of formal legal rationality. He saw formal rational adjudication, like bureaucratization, as one of the essential features and defining characteristics of modernity. It is therefore important to understand what is lost by abandoning the other three forms of decision-making in his typology, and what is gained by adoption of the fourth form. According to Weber, modern law undermines competing forms of authority. To the extent that modern law triumphs—and law is notoriously good at triumphing—legal precedent, legal decision-making, and hence the modern trial overshadow tradition, custom, the family, and religion as sources of authority. In this sense it simplifies and rationalizes autonomous legal authority. The modern idea of the rule of law also aspires to precision; it identifies legal entities and separates them from other forms of control. Thus it offers both a sense of freedom and predictability at the same time. In a modern system the ruling at a trial trumps other commitments, other relationships, and other rule systems. That is, the modern trial privileges the state: as officials of the state, modern judges are part of the state-made legal system, and must apply only state-made law. Modern trials undermine other legal systems and challenge the idea of legal pluralism. However, there is a continuing debate about how autonomous modern law is or must be (Nonet and Selznick 1977).

2. *The Multiple Functions of the Trial*

Privileging state law and trials, as formal rational forms of decision-making do, does not mean that there are no differences in the nature and function of trials in modern states. Forms and functions of trials vary widely in modern societies. Damaska (1986) argues that states with traditions of strong government rely on trials not only as means to handle disputes between the parties, but also as opportunities to reassert and to implement state policies. In contrast, weak states tend to view trials in conflict-resolution terms. European countries with traditions of strong central government and civil law systems are examples of the former, while Great Britain and the United States, less-centralized states and common law systems, are examples of the latter. Predictably, settlements in lieu of trial are formally discouraged in the former set of countries and encouraged in the latter. This doubtless helps to explain why in England and the United States a much higher proportion of cases commenced in courts are eventually settled short of trial, relative to most countries with civil law systems (Jacob et al. 1996). Political scientist Martin Shapiro, who has explored some of the same themes developed by Damaska (Shapiro 1981), maintains that always and everywhere, courts—including trial courts—in addition to being institutions for conflict resolution, are important

agents of social control. He means that in all societies courts are used by the dominant political regime to help promote its agenda. Trials, therefore, always serve two simultaneous and symbiotic functions: they resolve conflicts among the immediate parties, and they provide an opportunity for a type of micromanagement, in the pursuit of regime interests. When trial courts strive to assert independence and do not or will not serve the latter function, Shapiro argues, their jurisdiction will be curtailed. For example in the mid-twentieth century, when English courts failed to rule in favor of labor unions frequently enough at trial, their jurisdiction was curtailed and special labor relations courts, more favorable to labor, were established.

In a more generalized analysis, Durkheim's ideas of social solidarity rest in part upon his understanding of the social functions served by the legal process, including trials (Durkheim 1964). Although his writings focus on punishment and the criminal process, his overall theory emphasizes the solidifying function of a variety of legal institutions, including the trial. Much of the dramaturgy associated with the process of punishment is also found in the rituals of the trial. Trials, and public reactions to them, represent an important and visible expression and reassertion of Durkheim's 'conscience collective.' Labeling theorists in the social sciences have seized upon this symbolic function, and have explored its relevance for the criminal trial. In a classic article, Garfinkel described the criminal trial as possessing all the necessary 'conditions of a successful degradation ceremony' (Garfinkel 1956). Similarly, Stuart Scheingold (1977) and others have argued that trials, and particularly high-profile trials, function to foster a 'myth of rights,' which serves to undermine disruptive political struggles. Symbolic victories at trial give the appearance—but not necessarily the reality—of change, and as a consequence they foster political quiescence (Scheingold 1977). Others have explored the more overtly political functions of some trials. Otto Kirchheimer has identified a particular type of trial, the 'political trial,' which, he argues, serves the primary purpose of communicating political lessons rather than resolving conflicts or holding people accountable (Kirchheimer 1961). The Nuremberg trials for the war crimes of Nazi officials in the aftermath of World War II, and other more recent war crimes trials, are good examples. So too are Stalin's 'show trials' of the 1930s, and those of some of the American protesters of the Vietnam War in the 1970s (see *Political Trials*).

Clearly one of the basic functions of trials is to resolve conflicts. Yet, some social scientists question even this seemingly obvious notion. Unlike mediation, where the parties participate by mutual consent, a trial is a process in which at least one party is an unwilling participant. Consider, for example, the criminal defendant whose appearance must usually be coerced. Moreover, modern law does not necessarily express the deeply valued norms of any tightly-knit community or even widely held norms. As a consequence, both the institutional framework and the norms applied may be regarded with suspicion, if not hostility, by one or more of the participants at trial (Shapiro 1981). Various scholars of legal pluralism emphasize just how problematic these challenges are, and often criticize governments and other scholars for giving pride of place to the formal legal trial as the preferred institution for dealing with conflicts (Galanter 1974). In light of these and related concerns, it is conceivable that a verdict by a *court* may not always be an effective way to *resolve* conflicts, especially in the eyes of the losing party. Consequently, many people who lose at trial continue to press their claims in other forums (Abel 1982, 1983). Others do not even bother to seek redress in courts (Felstiner et al. 1980–1) or seek out formal alternatives to adjudication (see *Parties: Litigants and Claimants*, *Disputes, Social Construction and Transformation of*, *Law, Mobilization of*).

3. *Trial Complexity and its Consequences*

One distinctive feature of modern trials is the replacement of reliance on divine intervention with modern empirically based decision-making. Factual evidence subjected to scrutiny has replaced the evidentiary value of supernatural signs. Eyewitness testimony has superseded oath-taking by the accused. And gathering, sifting, and pondering evidence has been transformed from an informal process into a disciplined arrangement governed by detailed procedures and formal rules. Consider that the earliest-known juries convened in criminal cases in Anglo-Saxon England consisted of men from the local community who had firsthand knowledge about the case and/or the character of the accused. By the nineteenth century, a jury was a group legally barred from any firsthand knowledge of the facts of the case before it, and could receive only evidence screened by highly complex rules and introduced according to complicated procedures. In most ordinary cases, the medieval trial was a relatively informal and brief affair handled by the parties involved in the dispute. But the modern trial is dominated by lawyers—highly-trained and highly-paid professional advocates for the parties to the dispute—who must contend with the proliferating subtleties of modern substantive law, and who must practice according to increasingly complex rules of evidence and procedure.

Differences in the structure of the trial process produce a number of important differences in effects. In systems with jury trials, proceedings are likely to rely heavily on oral evidence. But in European and other legal systems that do not have or do not rely so heavily on juries, the trial often proceeds by written

submissions to the court. The court confronts a dossier containing statements of facts and conclusions and sworn testimony (depositions), not a series of witnesses telling their stories in open court. Additionally, in systems with juries, the trial once begun is likely to run continuously until each side has rested its case. By contrast, a trial by dossier is likely to be intermittent and extend over a much longer period of time. These differences also affect the pace of true closure to the litigation. Cases in courts with active juries are almost always concluded within a few days of commencement, and verdicts are typically handed down very shortly thereafter. But in systems without juries, with trials by dossier, evidence-gathering is far more protracted, and final judgments are not necessarily issued shortly after submission of the final bit of evidence. Thus, ironically, although the jury-trial system is often criticized as inefficient, it may actually foster expeditious trial proceedings (see *Procedure: Legal Aspects*, *Juries*).

The nature and form of different trial systems have other consequences as well. The conventional understanding is that Anglo-American legal systems have developed elaborate rules of evidence and procedure in order to restrict the power of jurors, who are untrained lay decision-makers. Since civil law systems have had no such need, they have simpler rules. Although these claims have been vigorously disputed, there is no doubt that rules of evidence and procedure in civil law systems with no juries or weak juries are far simpler than those in common law systems with predominant juries. The 'quest for perfect justice' invoked to justify the complexity of common law trial proceedings may be counterproductive (Pizzi 1999). Trials are swifter, cheaper, and perhaps fairer in many civil law countries than they are in the United States and England. Feeley and Lester (1994) have traced increases in length and complexity of trials in England in the eighteenth and nineteenth centuries, and attribute the changes to the growing complexity of rules of evidence and procedure as well as the greater use of representation by lawyers. Examining the comparative effects of European and American trials in the late twentieth century, Kagan (2001) has shown that the expansion of 'adversarial legalism' in the United States dramatically increased the cost and length of trials without offering any corresponding increase in benefits (see *Litigation*, *Legalization*).

This tendency to increase trial complexity and adversariness in the quest for judicial perfection led legal historian John Langbein to liken the modern adversarial criminal trial to Medieval European proceedings (Langbein 1976, 1978). Both systems, he argued, aspired to 'perfect justice' but in fact precipitated disastrous results. Impossibly high standards of proof in medieval law led jurists to transform torture into a legal expediency in order to fulfill their need for certainty (which confession could provide). Contemporary jurists have developed a functional equivalent, the coercive practice of plea-bargaining, to facilitate a similar objective (see *Plea Bargaining*). Certainty of outcome in both cases, Langbein argued, becomes a mere legal nicety, since both arrangements depend upon coercion. Both torture and plea bargaining are little more than loopholes to circumvent unrealistically high standards of proof. Simpler proceedings and more realistic expectations, Langbein and many others have maintained, would result in fairer and more workable trials (see *Legal Formalism*, *Civil Law*, *Torture: Legal Perspectives*).

Finally, in a very real sense the term 'trial' is misleading and is perhaps an outmoded concept. It implies a single coming together of the parties in a forum where facts are presented and issues resolved. Although a great many cases are handled in a single session, most cases involve a series of hearings and/or decisions that may extend over a significant period of time. Consider a putatively 'simple' criminal case; a suspect is arrested and taken to court for an arraignment, at which time she is asked to enter a plea and bail is set. If pretrial release is not effected, there may be subsequent bail hearings. There may be separate hearings on such issues as a request for representation by a legal aid attorney, probable cause, a motion to suppress evidence, a motion to dismiss, or separate trials for co-defendants; there may be a hearing to determine guilt, a sentencing hearing, and appeals on any of the issues just mentioned. Each one of these separate proceedings can be considered a trial in that it can result in an adjudicated determination of an issue. Contrast this simple criminal case with complex civil cases, which can involve dozens of such issues and hearings. Under such conditions, it does not make much sense to talk about either a 'case' or a 'trial,' since contested issues have been authoritatively resolved at any number of different hearings; issues may have moved from trial courts to appellate courts and back several times, and indeed the name of the 'case' may have changed (Feeley and Rubin 1998). European legal scholars are more likely to understand the term 'trial' in this greatly elaborated sense than are Anglo-Americans, who are more familiar with the idea of concentrated, continuous oral proceedings. Yet, the ambiguity of the word is likely to persist in the context of most modern, complex systems of litigation. In light of this, it may be more useful to use the term 'dispute-processing.' This term better captures the dynamic, multi-step systematizing of most contemporary judicial proceedings, and it implicitly acknowledges that legal conflicts may at best only be 'processed,' rather than 'resolved,' at trial (Abel 1982, 1983).

Triangulation: Methodology

1. Introduction

Triangulation refers to the strategy of using multiple operationalizations of constructs to help separate the construct under consideration from other irrelevancies in the operationalization. At its simplest level, triangulation refers to the use of multiple measures to capture a construct. The triangulation strategy, however, also can be applied to multiple operationalizations of treatments and manipulations and to the use of multiple theories, analyses, analysts, methodologies, and research designs, to name but a few. At a basic level, the triangulation strategy requires an acknowledgment that no one measure in the social sciences is a perfect measurement of the construct under consideration. With only one measure of the construct, the error and biases inherent in the measure are inextricably confounded with the construct of interest. By using different measures with different irrelevancies, a researcher can bring into better focus the construct of interest. Although this triangulation logic was initially explicated in the social sciences in terms of measures (e.g., Campbell and Fiske 1959), the same logic can be extended to treatments, settings, populations, and many other aspects of the research enterprise. Although simple in concept, triangulation 'carries with it a host of implications regarding the proper conduct of social research, the effects of imperfection or unreliability of measurement operations on the development of theory, and the manner in which our field might gradually attain the status of the more developed sciences' (Crano 1981, p. 320).

2. History of Triangulation Concept

Over 40 years ago, social scientists called for triangulation of research measures as a means of more adequately capturing the essence of the construct under consideration (Campbell and Fiske 1959, Webb et al. 1966). The term 'triangulation' was probably borrowed from surveying, where multiple measures from different vantage points are used to locate an object in space, and explanations based on physical analogues are instructive. (See, for example, Crano's 1981 example of locating a radio signal by using multiple directional antennae.) Social scientists suggested that social and psychological constructs, as well as physical objects, could be brought into clearer focus

by using multiple measures from different vantage points with unique sources of error. The uses of triangulation quickly expanded to include triangulation of methods, sources, and theories, as well as measures (e.g., Denzin 1978, 1989).

Some researchers adopted the triangulation strategy whole-heartedly and launched large-scale, multi-investigator, multimethod, multisite, multimeasure studies of social problems (e.g., Lewis 1981). The need to contend with conflicting results that arose from different methods and measures in the same study led to extensive discussions of the use of qualitative and quantitative research methods and data, across and within the same project (e.g., Reichardt and Cook 1979). Recently the focus of discussion has shifted to triangulating among multiple paradigms (Greene and Caracelli 1997, Greene and McClintock 1985), multiple stakeholders, multiple analysts, multiple theoretical and value frameworks, and multiple targets within a study, a concept Cook calls 'multiplism' (1985). Developments in analysis techniques have also promoted the use of triangulation, either at the measurement level, as in causal modeling (Joreskog and Sorbom 1984), or at the method level, as in meta-analysis (Glass et al. 1981, Rosenthal 1991).

3. *Logic of Triangulation*

Triangulation strategies can be contrasted with what Cook and Campbell (1979) termed 'mono-operation bias.' Whenever a construct is operationalized in only one way in a research study, the error attached to the method of operationalization, as well as any random error in the operationalization, is inextricably linked with the true essence of the construct under consideration. This relationship is captured by the simple equation $X = T + e$, meaning that every data point (X) is composed of part True Score (T) and part error (e). (See, for example, Crano 1981 for further discussion). With only one measure of a construct, the error caused by method bias, response sets, or investigator bias, to name but a few, cannot be disentangled from the true measure of the construct. (See Cook and Campbell 1979, Webb 1978 for discussions of myriad types of error). By triangulating, or operationalizing the construct in several ways, the sources of influence on the data point can be disentangled, leading to clearer understanding of the construct under consideration. Campbell and Fiske's classic discussion of the multi-trait, multimethod matrix (1959) lays out a strategy for such specification.

The acknowledgment of the necessity of triangulation represented a maturing of the social sciences beyond the paradigm envy which had previously gripped the field (Crano 1981). Early social scientists had attempted to gain acceptance and legitimacy by adopting much of the research trappings of the physical or 'hard' sciences. Operating from the positivist view of science (Cook 1985), social scientists attempted to achieve parsimonious explanations of events and circumstances that would hold across times and settings, much as physical scientists were claiming to do. They sought the precise, well-calibrated measures, the elegant, critical experiments, and the straightforward analyses of the hard sciences. In some areas of research, this approach could be fairly successful. For example, a social scientist could operationalize 'response time' as 'the amount of time that is recorded on this particular calibrated recording device between stimulus and response,' with stimulus and response both being defined in terms of their operationalizations (e.g., 'the onset of the light' and 'pushing the button,' respectively). But as soon as the social scientists ventured beyond the laboratory and basic research, they discovered that mono-operationalization was inadequate to capture the true essence of the constructs, that simple research methods were inadequate to tap underlying relationships accurately, and that simple analysis strategies were inadequate to describe the complicated interactive patterns in the data.

For example, social scientists quickly discovered that they could not define 'family size' as 'the number of people listed on the interview schedule under the heading Family' and be confident that they had captured the true essence of the construct 'family size.' Beyond the problems with deciding whom to list as 'family' (such as deciding what to do with people who are not biologically related but may be committed to the unit and people who are biologically related but rarely present), social scientists realized that some people are not going to report accurately, either because they misunderstand the question, because they are not aware of the true situation, or because they choose to report incorrectly.

To compensate for these problems with error and bias, researchers began to use multiple-operationalizations of key constructs, and many claims of triangulation in research design are based solely on the use of multiple items to tap a construct. But, as Webb (1978) and others pointed out, using multiple instances of measures that share critical components of error does not improve the research much beyond identifying some random error. To be most useful, multiple measures must have differing sources of error, including method error, and errors due to response bias and self-presentation, among many others. Campbell termed this important qualification the 'heterogeneity of irrelevancies' (Brewer and Collins 1981).

So, for example, having the same interviewer ask the same respondent 'how many people live in this house?' in a dozen different ways during the same face-to-face interview does not advance the construct validity of 'family size' very much. A respondent who really does not know that her daughter's boyfriend has been living upstairs will report incorrectly every time. A respon-

dent who does not want to reveal that a cousin who is in the country illegally lives there will consistently not report that person as living in the house. An interviewer who consistently reverses threes and fives will do that every time. So repeated questioning only reduces the error associated with not understanding a particular question or with random errors made by the respondent or the interviewer. This is not to imply that reducing such error is unimportant, but triangulation can be much more powerful when used across types of measures instead of within one method of measurement.

Partly in response to the shared error inherent in verbal responses, (Webb et al. 1966) suggested the use of unobtrusive measures as a means of tapping constructs without the error inherent in verbal responses. Unobtrusive measures are not without error, but their usefulness comes from the fact that many of their error sources are different from the error sources that plague verbal responses (e.g., social desirability, response set). In one famous example, researchers measured the popularity of different museum exhibits by measuring the wear and tear on floor tiles surrounding different displays (Webb et al. 1966). Another researcher measured level of activity among nursing home residents by measuring how dirty adhesive tape attached to their wheelchair wheels became. And Mosteller (1955, cited in Webb 1978) measured the usage of various sections of the *International Encyclopedia of the Social Sciences* by noting how worn and dirty various sections of the book were. (Note to reader: Feel free to smudge, bend, and dog-ear this page.)

4. *Extensions of Triangulation*

The logic of triangulation was quickly extended to methods, treatments, theories, settings, and other aspects of the research enterprise. Denzin (1978) compared the pictures of reality obtained from different researchers using different methodologies at different times to the changing images within a kaleidoscope, sharing some common elements but greatly influenced by the circumstances of viewing. This is not to imply that there is no objective reality, but rather, even if there is an objective reality, it is filtered through the researcher's assumptions, research choices, and the factors unique to that point in time. In much the same way that Heisenberg pointed out to physical scientists that the very act of observing or measuring a physical object can alter the reality of that object, social scientists were coming to appreciate the extent to which their own assumptions, choices, historical time frame, and even mere presence influenced the data they collected.

Denzin (1978) outlined four basic types of triangulation: data, investigator, theory, and methodological. He further divided data triangulation into the three subtypes of time, space, and person. Data triangulation across time refers to both time of day as well as historical setting, which has been referred to as population changes associated with time (Campbell and Stanley 1963). Some time effects are profound and obvious. For example, attitudes toward national security in the middle of the Gulf War could be seriously effected by historical time frame. Other time effects are less obvious. For example, attitudes toward daycare among women who engage in telephone interviews during the day might be very different from attitudes of women who respond in the evening (and presumably might have been at work during the day). Similarly, space could have obvious or nonobvious effects. That gun attitudes might vary by geographic locale is fairly obvious, but the geographic effects on altruism might be less apparent. Similarly, with person effects, bosses and employees might have different views of the workplace, but so might workers near and far from the elevator.

A strength of triangulation is that the researcher does not need to understand completely the variation inherent in the data collection methods. In the same way that random assignment distributes error randomly across conditions in a true experiment even if the researcher is unaware of the importance of the error, triangulation captures and makes somewhat tractable irrelevancies of the research situation, even if the researcher is unaware of the importance of those irrelevancies. Of course, in the same way that true experiments can be strengthened if the researcher has identified problematic outside variables and blocked on those variables (i.e., randomized within levels of those variables), research designs can be strengthened if researchers can specify which outside factors might be problematic and can triangulate in such a way as to capture those irrelevancies. For example, if a researcher suspects that age of respondent will relate to the variables of interest, the researcher should specifically select for a variety of ages among respondents and analyze the data specifically to examine age effects, instead of just hoping that triangulating over samples will capture those irrelevancies.

Beyond data triangulation, Denzin (1978) also advocates investigator triangulation, whereby multiple investigators bring their unique perspectives and biases to the research project. This is an acknowledgment that people, no matter how well trained, are not robotic recorders of social events. Again, if the researcher has *a priori* reason to suspect that some characteristic of the investigator, such as gender, might introduce error into the observations, care can be taken to select equal numbers of male and female investigators and to analyze for differences between the observations of men and women. But the use of multiple investigators should reduce effects of irrelevant observer factors, even in the absence of the researcher's awareness that such factors could be

important. Of course, only irrelevant factors that vary among the investigators will be ameliorated.

In a similar vein, Denzin (1978) proposed that researchers approach projects from the perspectives of multiple theories, taking care to extend the scope beyond the theoretical orientation most comfortable for the researcher. He further suggested that rather than pit only two theories against each other in research, projects should be specifically designed to capture as many theoretical orientations as possible. Hypotheses derived from all of these theories could then be tested, and conclusions could be drawn about the relative strengths and weaknesses of the theories. The logic of triangulation is the same as with previous examples: by using multiple theoretical views, the researcher is better able to bring the research question into focus.

Finally, Denzin (1978) described both within-method and between-method triangulation. Within a single method, such as a telephone survey, multiple items that are intended to tap the same construct can provide much clearer measures of the construct under consideration. Multiple items can be combined via a wide assortment of scaling techniques, ranging from simple additive scales to elaborate factor analytic scales. Again, the triangulation strategy does not result in items measured without error, but, rather, it allows the error that is not shared among the items to be identified and removed. The resulting scale should reflect only the 'true' component of the construct measured plus any error shared by the various items. For example, items that all cause the respondent to respond in a socially desirable manner will not allow the researcher to separate out social desirability components from components that actually tap the construct under consideration. But if some of the items have a response set bias and others do not, the use of multiple measures will allow the response set bias to be identified (within limits).

Because within-method triangulation can leave varying amounts of error inextricably linked to the key construct, researchers are encouraged also to triangulate between methods (Brewer and Hunter 1989, Campbell and Fiske 1959, Cook 1985, Cook and Campbell 1979, Denzin 1978, Reichardt and Cook 1979, Webb et al. 1966). By combining methodologies as different as participant observation and survey research, for example, researchers can study processes under vastly differing assumptions, biases, and errors. For example, the Reactions to Crime Project (Lewis 1981) involved participant observation, content analysis, telephone surveying, and in-person interviewing, all within one large framework. The approach used by the Reactions to Crime Project was sequentially multimethod, with the participant observation being completed first, followed by the telephone survey, and finishing with the in-person interviewing. With sequential multimethod work, researchers can use results from previous to stages to inform design at later stages. Although this sequential strategy has strengths, Greene and McClintock (1985) point out that concurrent multimethod work, in which all methods are implemented at the same time, avoids contamination of one method with results from another, and produces a purer triangulation.

Probably the most extensive elaboration of triangulation logic was provided by Cook (1985) who described research that involves multiple stakeholders, multiple data analyses, multiple definitions, multiple methods, multivariate causal modeling, multiple hypotheses, multiple populations, multiple settings, and multiple times. He states that such multiplism allows the researcher to approximate the 'ultimately unknowable truth through the use of processes that critically triangulate from a variety of perspectives on what is worth knowing and what is known. Triangulation requires generating multiple instances of some entity and then testing whether the instances converge on the same theoretical meaning despite the irrelevant sources of uniqueness that any one instance may contain' (p. 57). Like previous writers, however, Cook is quick to point out that 'multiplism is no panacea, for we can multiply replicate the same mistake or the same parochial set of assumptions' (p. 58). Although triangulation can be vastly expanded in scope, its strengths and weaknesses remain the same.

5. *Limitations of Triangulation*

As Flick (1992) and Fielding and Fielding (1986) have suggested that proponents of triangulation mistakenly believe triangulation solves all construct validity problems. To the contrary, early proponents of triangulation were sounding a warning about the inherent weaknesses of all measures, and the proposal to use multiple measures with nonoverlapping irrelevancies was an acknowledgment of the profound problems inherent in measuring. In a discussion of the distance between desired and achieved measures of social science constructs and hence of the hypotheses the operationalized measures test), Campbell (1969, p. 52) concluded that 'direct knowing, nonpresumptive knowing, is not to be our lot.' Therefore, one important limitation of triangulation is that it does not produce perfect measures.

Another limitation inherent in the triangulation strategy is that time, financial resources, and respondent goodwill conspire to prevent a researcher from triangulating on all the constructs in the research program. One can easily imagine how attempting to triangulate on theoretical orientations, research designs, and measurement strategies could quickly lead to a program of research that could never produce a single result, because it could never be completed. The successful researcher must therefore choose where to invest his/her triangulation resources, and the soundness and usefulness of the research outcomes depend

to a large extent on the wisdom of those choices during the research design phase.

The amount of effort a researcher chooses to devote to triangulating on a construct should reflect both the importance of that construct for the research question and the level of difficulty in achieving a good measurement. For example, if age is a crucial variable for a research question, investigators might invest extra resources in accessing birth records as well as asking for age and birthrate in a survey. If age is less crucial to the question at hand, the researchers might decide to rely on the verbal replies only. Similarly, a true experiment performed in a laboratory might provide adequate for testing a hypothesis about visual processing, but researchers investigating hypotheses about reactions to stress might need to invest in multiple methods to achieve clarity about the processes under investigation.

The researchers' choices about constructs for triangulation resources can have significant effects on the results of the research. For example, if a researcher believes Family Income to be a more important construct in explaining school achievement than Parental Education Level and consequently devotes more effort to triangulating on the measure of Family Income than Parental Education Level, analyses might well reveal a stronger relationship between School Achievement and Family Income than School Achievement and Parental Education. If the researcher had made the opposite assumption and had devoted more resources to measuring Parental Education than to Family Income, the results might well have shown the opposite effect. The utility of triangulation, therefore, is limited by the soundness of the researchers' initial decisions about resource allocation.

6. *Advances in Triangulation*

The logic of triangulation is inherent in both causal modeling (Joreskog and Sorbom 1984) and meta-analysis (Rosenthal 1991). Causal modeling is an analysis technique that relies on multiple measures (manifest variables) of some underlying construct (latent variable). Researchers specify which manifest variables relate to which latent variables, and the analysis strategy pulls out common variance among the manifest variables that feed into a latent variable. Variance in the manifest variable that is not shared with the other manifest variables for that latent variable is identified as 'error.' Error terms can be allowed to correlate with other error terms. This is a sophisticated extension of the logic used by Campbell and Fiske (1959) in their explication of the multitrait multimethod matrix. They pointed out that only part of what researchers are measuring is the key construct they are intending to measure. The rest of the measure includes method variance, random error, and possibly other types of error and bias. Causal modeling requires researchers to identify error explicitly in their models, which makes very clear the frailty of any one measure in isolation. In addition, causal models show clearly how error terms from similar measures correlate, increasing researchers' awareness of such measurement effects.

In a similar vein, meta-analysis exploits multiple studies, with multiple operationalizations, multiple investigators, multiple methods, multiple sites, multiple populations, and many other differences to arrive at a summary statistic that reports the strength of underlying relationships across studies. Instead of requiring one researcher or research team to approach a research question from multiple perspectives, theories, and methodologies, meta-analysis capitalizes on natural variations among research programs to achieve triangulation. A main benefit of meta-analysis is that methodological variation can be explicitly built into the analysis. For example, in a recent review of the research on environmental and genetic effects on aggression, Miles and Carey (1997) reported that observational measures in laboratory studies showed no genetic effects and strong environmental effects, while self-report and parental rating measures showed both genes and environment to have strong relationships with aggression. Because variance associated with particular methods and measures can be explicitly analyzed in meta-analyzes, the increased understanding afforded by triangulation strategies becomes apparent. And the conflicting results from different methods, far from being a nuisance or drawback to triangulation approaches, are rich clues to contingencies that need to be brought to light if social research is ever to reveal fully how these processes operate (Cook 1985).

The importance of triangulation is also revealed by the prevalence of statistical interactions in social research. Evaluation researchers and others who study social problems rarely find simple, main-effect effects capture the richness (some would say messiness) of the world beyond the research laboratory (Cook 1985). Evaluators no longer ask 'Does this work?' but, rather, 'For whom does this work, in what settings, with what constraints?' The prevalence of interactions pushes researchers to branch out to different populations, different time frames, different methods, in other words, to triangulate across many factors in the research setting.

Social research has come a long way from the days when researchers sought pure measures, elegant, simple designs, and straightforward analysis strategies. The norm for social research now is multiple measures, elaborate multimethod design, and analysis strategies that clearly indicate the multiple causation and interactive patterns apparent in the social world. In no small part, this march toward increasing complexity of the research enterprise was begun by early explications of the logic of and necessity for triangulation.

Tribe

The notion of tribe emerged in the seventeenth and eighteenth centuries in the course of colonial expansion. Abandoned increasingly by the majority of anthropologists from the middle of the twentieth century onward, the term nevertheless lived on in certain anthropological constructions, until waves of criticism dealt final blows to a concept that is now largely defunct as a general comparative category. Those anthropologists and historians who retain the contested concept of tribe use it mainly as an equivalent to vernacular terms referring to certain local conceptions of collective sociopolitical identity, while agreeing that a precise general definition is almost impossible. This results in working definitions which see tribes as medium-sized, centralized, or acephalous entities displaying a combination of basic characteristics:

(a) They are usually associated with a territory, homeland, or tribal area, while using nonterritorial criteria to distinguish between members and nonmembers. The degree of control of the tribal territorial base, and its extension and location, tend to change as a result of struggles with states or other opponents. To the outside world, access to territorial usage appears to be confined to members of the tribe, although neighboring groups and superior authorities may also enjoy rights of usage, of tribute, or of taxes. Internally, access to territorial usage may be differentiated according to gender, age, status, wealth, and other aspects of power.

(b) Ideologically and socially, tribal members usually share some dominant idiom of common origin, such as descent from a single ancestor, emphasizing group cohesion over outside interests and internal differentiation. This may also serve to legitimize a preference for 'marrying within the tribe,' which in practice, however, is observed far less often than it is upheld in theory. On the contrary, some amount of intertribal and interethnic marriage is indispensable to ensure all kinds of (political, economic, social) alliances with other groups.

(c) Although part of the tribal population live more or less permanently in the tribal territory, a considerable portion may live in the world outside. Ritual and kinship ties and obligations are enacted to ensure and strengthen intimate networks among 'home' groups and 'outside' groups, serving as one among several inventories of group adherence within a wider world. In the course of these interactions, tribal group membership may change in many ways: individuals or groups may enter or leave a specific tribe; and whole tribes may also collapse or be created.

1. *Tribes and Colonialism*

The concept of tribe dates from the earliest phases of anthropology's history, carrying assumptions that are now being criticized and questioned inside and outside academia. Most governments of colonial times used the term for their specific practical interests of administration and dominance, while often constructing such 'tribes' themselves for that purpose. Beyond these practical interests, colonial settler regimes also valued the term ideologically, since it tended to portray local groups as 'backward' and 'primitive,' which helped to justify a colonial 'mission' of development and civilization. For basically the same reason, many post-colonial governments and national elites reject the term as being counterproductive to their own claims toward national unity, progress, and modernity.

During decolonization, the term tribe therefore attained a largely negative and pejorative meaning in dominant opinions in many parts of the world. In public discourses concerning these areas, the terms 'ethnic groups' or 'indigenous peoples' are usually preferred to 'tribes,' although the latter usually designates smaller groups. Legal terminology nevertheless may continue to apply the term, and in many regions even native speakers may use it with dignity.

In parts of central and western Asia, however, as well as in North Africa, particularly in those areas influenced by Islam, the term tribe and its local equivalents have never had a predominantly pejorative meaning. On the contrary, the term here is usually associated with notions of pride and autonomy, of honor and of independence from colonial and local states. Also, notions of 'indigenous' or 'ethnic' groups do not apply well to many of these specific ethnographic contexts. Both of these factors are therefore responsible for the continuing, stronger importance of the term tribe in academic and public discourses inside and about these regions.

2. *Tribes in Anthropology*

Before anthropology's emergence, travelers, missionaries, and scholars had used the concept since the seventeenth century in describing those indigenous peoples whom European powers were about to colonize. Ancient Middle Eastern and Graeco-Roman literature served as sources of reference to depict the newly colonized peoples as representing some kind of forerunners to the 'advanced nations,' equivalent to the *tribus* of the ancient Mediterranean world. The construction of this 'forerunner' image could follow either more sympathetic lines, by emphasizing the enlightened aspect of a noble savage who basically was 'like us,' or it could enhance the more discriminating image of backwardness.

Both ideas presupposed a search for origins, taking European culture as the climax of humanity. In its basic conceptualization, a tripartite world had thus already been constructed, which early anthropology inherited and further elaborated. 'Primitive' cultures consisted of foragers, and pastoral and agrarian 'tribes,' whereas 'oriental' cultures were associated with agrarian states, cities, and with writing. Anthropological evolutionism (e.g. Morgan 1877, Smith 1903) elaborated and specified this conceptual inventory, in which, by and large, tribes constituted the decisive transitory stage between early hunters and gatherers and the rise of agrarian states. In a long-term archeological perspective, this may still serve as a valid distinction for certain regions and periods, if liberated from its earlier ideological underpinnings.

Classical anthropological evolutionism collapsed, however, because the increasing body of empirical data showed the failure of any general laws of development, including those regarding tribes. By contrast, the new school of 'historical particularism' or cultural relativism that came to dominate US anthropology around 1900 emphasized the situated, fluid contextualization of each local and tribal group. While this prepared the ground for an empirical orientation that is still valid at the time of writing, the inherent relativism rejected almost any comparative meaning for the concept of tribe. The comparative aspect, by contrast, was elaborated explicitly by anthropological functionalism, largely of British and Northern European provenance. In an earlier variant, Evans-Pritchard (1940) outlined the 'structural relativity' of many tribal group relations around a basic social organization of 'nested' group segmentation.

In fact, such segmentary relations do represent a dominant model among many local (tribal) groups in Africa and Asia, often being expressed in the prevailing idiom of unilineal genealogy. In these terms, the 'descendants' of one ancestor are contradistinguished, under some conditions, against those from another ancestor, while under different conditions the same group of descendants may split up and oppose each other. Mutual threat, equality of group status, and reproduction of social equilibrium are inherent to this indigenous model, taken up and reconstructed as an anthropological model. Major critiques, however, pointed to implications of timeless stability

and secluded cohesion, which to some degree corresponded well with the ideologies of late colonialism.

Gellner (1981, 1990), who was most influential in transferring the segmentary model from Sub-Saharan Africa to North Africa and the Middle East, reacted to some of that criticism with an increasingly more refined variant. According to him, Middle Eastern tribal societies interact constantly out of the peripheries with each other and with the states in their centers, sometimes being absorbed or reshaped in the course of these interactions, and sometimes themselves destroying and recreating central states. These processes always promote tribal centralization, inequalities, and tendencies to fusion and fission, which are simultaneously more or less countered by applying the local segmentary model. Jamous (1981) has shown in more detail than Gellner how these tendencies to feuding and conflict may be embedded in idioms of 'honor and shame.' His account illustrates how these tensions, which favor the emergence of ephemeral 'big men,' are countered through mediation by third parties, who in many cases are of superior, holy status.

While Marxist, late functionalist, and neo-evolutionist critics (for example, Fried 1975, Godelier 1973, Southall 1970) were the first to radically criticize current ideas about tribes in the 1960s and early 1970s, a few anthropologists held on to a general, neo-evolutionist conception of tribe. Sahlins (1968) elaborated a distinction between acephalous 'segmentary lineage' tribes and more centralized 'chiefdoms.' On the other hand, in Middle Eastern studies the concept gained new respect in the Gellner/Jamous variant, by its consideration of formerly neglected aspects, such as historical dynamism; ideological, political and social factors; and some hierarchies and contradictions. A second wave of academic criticism throughout the 1980s and early 1990s came from feminist, postmodern, and postcolonial writers, who deconstructed profoundly the colonial legacy in the concept, and exposed the complete negligence of economic factors and of female lives in the 'tribal' model (Abu-Lughod 1986, Gilsenan 1996).

3. *Current Readings*

In present discussions, the debate is therefore oscillating between complete rejection of the term 'tribe', and its more or less restricted, critical elaboration for specific times and regions. Most scholars, however, would agree that the concept is obsolete as a general comparative category outside particular areas. In addition, historical and archeological research might continue, for parts of Africa and Asia at least, to find some conception of tribe to remain useful. Such a restricted, critical elaboration of the concept would, of course, have to take into account seriously previous critiques.

Some of the more recent criticism was creatively synthesized by Bonte and Conte (Bonte et al. 1991). Their late structuralist and post-structuralist approaches basically privilege historical change over repetition, interaction over system, status rivalry over group equality, and, most importantly, marriage and other forms of alliance over descent and ancestry. This helps to outline internal hierarchies among local tribal groups, including the constraints and fields of agency encountered by women, while demonstrating simultaneously how tribal organization is used to defend states, to support struggles for central power, or to engage in civil war for various interests (Gingrich 1995).

The postcolonial condition seems in fact to encourage such a restricted, critical elaboration of the concept, rather than discarding it totally. Under the conditions of advanced globalization after the Cold War, and of increased competition within as well as among weakened local states (ranging from Mauritania, Algeria and Somalia to Afghanistan and Bangladesh), ideologies of ethnicity, but also of tribalism, are gaining significance in many local arenas. It would amount to a strange paradox if anthropologists limited themselves defensively to deconstructing completely the concept of tribe, while many parts of the world in fact go through retribalization of some sort. In view of these developments, an active reformulation of the concept seems to be a more productive alternative. With this alternative, ideological movements of 'tribalism' will have to be distinguished more clearly from 'tribes,' parallel to concepts of nationalism and of nations. Tribalism and its activists strive more or less successfully to create imagined communities of tribes, with ideological pretexts of 'origins' and of 'cohesion' that serve competition over power and resources. In this perspective, anthropologists are as critical and skeptical about tribalist ideology as they are with regard to nationalism. All the same, they would not deny from the outset that nation states and tribal groups exist: rather, they would insist on exploring the interrelations between such local entities, their ideological activities, and the world around them.

Tropospheric Ozone: Agricultural Implications

While stratospheric O_3 protects life by absorbing damaging solar UV radiation, ground-level O_3 can harm life by oxidizing living tissue. Under appropriate meteorological conditions, anthropogenic emissions of nitrogen oxides, volatile organic compounds, and carbon monoxide can trigger O_3 pollution episodes with ground-level concentrations enhanced by factors of 2 or more. One consequence of these enhancements can be a reduction in agricultural crop yields.

1. *Atmospheric Ozone*

Ozone is a 3-atom allotrope of oxygen and thus has the chemical formula: O_3. It is gas with a pungent odor and hence its name, which is derived from the Greek word *ozien* meaning smell. Christian Fredrick Schobein generally is credited with first identifying O_3 as a compound in the laboratory in 1840, and John Hartley is credited with demonstrating its ubiquitous presence in the atmosphere in 1881.

O_3 is one of a myriad of atmospheric *trace species*, so called because their atmospheric abundances are of the order of one part per million (ppm) or less, where 1 ppm of a gas signifies an atmospheric abundance of 1 molecule for every million atmospheric molecules. In fact, in the case of O_3 there are on average about 3.5 O_3 molecules for every 100 million atmospheric molecules. If the entire atmosphere were compressed to a pressure of 1 atmosphere (i.e., the pressure at the earth's surface), it would have a height of about 8.5 km. If the same were done to atmospheric ozone (O_3), it would have a height of only 0.3 cm.

Despite its seemingly minute concentration, atmospheric O_3 has an enormous environmental impact. As a constituent of the stratosphere, where about 90 percent of the atmosphere's O_3 resides, it protects life from harmful uv radiation from the sun. In the troposphere, O_3 plays a key role in determining the oxidizing capacity of the atmosphere, facilitating the process by which the atmosphere is flushed of a wide range of pollutants. O_3 at ground level represents a small but important component of the overall tropospheric O_3 burden. Because of its properties as a powerful oxidant, ground-level O_3 can have adverse effects on human health, agricultural crops, and forests

As illustrated in Fig. 1, O_3 concentrations generally increase with increasing altitude throughout the troposphere (the lowest 10–15 km of the atmosphere) and much of the stratosphere. O_3 concentrations typically range from about 30 ppb near the ground to about 100 ppb or more near the top of the troposphere, where 1 ppb O_3signifies an abundance of 1 molecule of O_3 for every billion molecules of air. However, ground-level O_3 concentrations can exceed 100 ppb during air pollution episodes and especially in urban areas (see *Air Pollution*). The highest hourly-averaged O_3 concentration on record in North America is apparently 680 ppb measured in downtown Los Angeles in 1955. When ground-level O_3 concentrations reach these levels, they threaten rather than sustain life. In particular, they can damage agricultural crops, ultimately causing a reduction in the crop yields grown in affected regions.

2. *The Generation of Tropospheric O_3*

The basic chemical mechanism responsible for the generation of O_3 in the stratosphere was first worked out by Sidney Chapman in the 1930s. However, it would take a few more decades before scientists began to understand the chemical reactions that produce tropospheric ozone.

Stratospheric O_3 production involves two reactions (see Fig. 1). The first is the photolysis and dissociation of molecular oxygen (O_2) by uv radiation from the sun. The second reaction involves the combination of an oxygen atom produced from the first reaction with another O_2 molecule.

Because ultraviolet radiation from the sun capable of photolyzing O_2 does not penetrate into the tropo-

Figure 1
Tropospheric and stratospheric ozone (O_3). Graphic on left illustrates average vertical distribution of O_3 with the O_3 abundance expressed in units of parts per billion (ppb), that is, molecules of O_3 per billion molecules of air. The central schematic illustrates the photochemical processes that produce O_3 in the stratosphere and troposphere

sphere, it was believed for a number of decades following Chapman's work that O_3 is an inert constituent of the troposphere. It was argued that the downward transport of O_3-rich air from the stratosphere is the source of tropospheric O_3 and reaction with material on the earth's surface (a process referred to as dry deposition) removes O_3. However, the appearance of photochemical smog in Los Angeles in the 1950s, and the realization that O_3 was a major product of this pollution forced a gradual reappraisal of this simple picture. Today, it is recognized widely that chemical production of O_3 occurs throughout the troposphere, at relatively modest rates within the more pristine regions of the atmosphere and at significantly accelerated rates in polluted regions.

2.1 The Chemical Reactions that Produce Tropospheric Ozone

A scientist by the name of A. J. Haagen-Smit first unraveled the chemical mechanism that produces O_3 in the lower atmosphere. Working in Los Angeles in the early 1950s, Haagen-Smit became interested in understanding how photochemical smog was formed and what was in the smog that made it noxious. He irradiated mixtures of volatile organic compounds (VOC) and nitrogen oxides (NO_x) in a reaction chamber. (Both VOC and NO_x are emitted into the atmosphere by automobiles and other industrial processes and NO_x represents the sum of nitric oxide or NO and nitrogen dioxide or NO_2.) After a few hours, Haagen-Smit observed the appearance of cracks in rubber bands stretched across the chamber. Knowing that ozone (O_3) can harden and crack rubber, Haagen-Smit correctly reasoned that photochemical smog was caused by photochemical reactions involving VOC and NO_x, and that one of the major noxious constituents in this smog was O_3 (see Fig. 1).

Since Hagen-Smit's work, more sophisticated laboratory experiments, along with advanced chemical monitors and computer simulation models have made it possible to further elucidate the chemical reactions that form O_3 in the troposphere. A typical reaction sequence might include:

(a) $RH + OH \rightarrow R + H_2O$
(b) $R + O_2 + M \rightarrow RO_2 + M$
(c) $RO_2 + NO \rightarrow RO + NO_2$
(d) $RO + O_2 \rightarrow HO_2 + \text{carbonyl}$
(e) $HO_2 + NO \rightarrow OH + NO_2$
(f) $2 \times (NO_2 + h\nu \rightarrow NO + O)$
(g) $2 \times (O + O_2 + M \rightarrow O_3 + M)$

NET: $RH + 4O_2 + 2\ h\nu \rightarrow 2O_3 + \text{carbonyl} + H_2O$

In the above, *RH* represents a hydrocarbon (i.e., a type of VOC), *R* is a hydrocarbon radical or compound fragment (e.g., CH_3CH_2 for RH = ethane), *hν* represents a photon from the sun and *M* is a nonreactive, energy absorbing molecule referred to by chemists as a 'third body.' In the atmosphere, this third body is most often molecular nitrogen (N_2) or molecular oxygen (O_2). Carbon monoxide (CO) can replace the VOC. In this case the reaction sequence is initiated by

(h) $CO + OH \rightarrow CO_2 + H$

(i) $H + O_2 + M \rightarrow HO_2 + M$

and then followed by Reactions (e), (f), and (g).

In the above reaction sequences, VOC and CO are oxidized and consumed, while NO_x acts as a catalyst. Collectively these three compounds are often referred to as *O_3 precursors*. The by-product labeled 'carbonyl' is itself a VOC and can react and produce more O_3. The OH radical, which triggers the sequence by reacting with VOC or CO, is generated initially in the atmosphere from O_3:

(j) $O_3 + h\nu \rightarrow O^* + O_2$

(k) $O^* + H_2O \rightarrow 2OH$

where O* is an electronically excited atom of oxygen. Because the OH consumed by Reaction (a) or (h) is regenerated by Reaction (e), and, because more OH can be generated during the breakdown of the carbonyl produced by Reaction (d), the reaction sequences listed above are net sources of O_3.

In clean regions of the troposphere, O_3 is produced primarily by the oxidation of isoprene (C_5H_8) and/or methane (CH_4), hydrocarbons that are emitted into the atmosphere by biogenic processes, as well as CO. The catalyst NO_x largely is supplied by lightning as well as soil emissions. In polluted regions, VOC from automobiles, solvents, and various industrial processes become important, and the NO_x arises largely from automobiles and power-plant emissions.

2.2 *Ozone Pollution Events*

Ground-level O_3 concentrations tend to be largest during specific periods or episodes when meteorological conditions favor the production and accumulation of pollutants within the *atmospheric boundary layer*. (The atmospheric boundary layer denotes the first 1–2 km of the atmosphere where winds are slowed by frictional resistance with the earth's surface. The frictional resistance, in turn, creates turbulence within the layer that tends to keep pollutants and other chemical constituents uniformly mixed. For this reason the atmospheric boundary layer is also referred to as the *mixed layer*.) These conditions are often associated with summertime, slow-moving high-pressure systems that can extend over thousands of kilometers. Ground-level O_3 concentrations during these pollution episodes tend to be highest in and around urban areas. However, suburban sprawl, growing numbers of automobiles and expanding roadway networks (see *Land Use and Cover Change*; *Development and Urbanization*) coupled with the large spatial scale of the meteorological conditions that foster the pollution, can lead to enhanced O_3 concentrations over thousands of kilometers, encompassing agricultural as well as urban areas. To distinguish this type of pollution from more localized or urban-scale pollution, it is often referred to as *regional air pollution*. The repetition of regional air pollution episodes in agricultural areas over a growing season can produce a pattern of chronic exposure that can, in principle, reduce crop yields. The extent of crop-yield reduction depends upon both the degree of exposure and the sensitivity of the crop to O_3, as discussed below.

3. *Ozone Effects on Crops*

The first documentation of O_3 damage to crops arose out of studies of the effects of photochemical smog in Los Angeles in the 1940s and 1950s. Subsequent research by scientists throughout the world have provided a rudimentary understanding of the mechanisms by which O_3 can affect vegetation and the development of semiquantitative relationships between exposure to O_3 and crop yield.

O_3 damage to vegetation most often occurs as a result of penetration into the leaf interior through the stomata and then reaction with the cell's plasmalemma (i.e., cell membrane) and/or mesophyl (i.e., cell interior). Field studies using open-top chambers to control the O_3 concentrations in contact with crops growing under otherwise ambient conditions have established that crop sensitivities to O_3 vary from crop to crop and, within a given crop, from variety to variety. In general: (a) O_3 damage to crops becomes observable when concentrations exceed a threshold of about 50–70 ppb; (b) the effects of repeated intermittent exposures above this threshold tend to accumulate over a growing season; and (c) the higher the O_3 concentration above the threshold the greater the damage.

Because O_3 damage to crops accumulates over a growing season, any metric used to quantify crop exposure to O_3 must integrate over all pollution episodes occurring in that season. One such metric is the so-called 'SUM06' that represents the sum of all daytime, 1-hour-averaged O_3 concentrations in excess of 60 ppb over a 3-month period. Analysis of data from the US National Crop Loss Assessment Network suggests that the average yields of crops grown in North America are reduced by about 10 percent when SUM06 exposures are about 15–25 ppm-hours, where 1 ppm-hour is equivalent to 1,000 ppb-hours. Expo-

sures of this magnitude are not uncommon in rural areas of many industrialized and developing nations.

3.1 Implication for World Food Production

O_3 damage to crops is likely to be most severe in those areas where there is an intermingling of the urban and industrial activities that lead to the emissions of VOC, CO, and NO_x and agricultural activities on spatial scales of thousands of kilometers. It turns out that such an intermingling of the urban and industrial with the agricultural is quite common in the developed world and is most pronounced in three regions of the northern mid-latitudes: (a) Eastern North America (25–50°N, 105–60°W); (b) Europe (36–70°N, 10°W–90°E); and (c) eastern China and Japan (25–45°N, 100–146°E). Within each of these regions, urban–industrial and agricultural activities tend to cluster together into a single large network or plexus of human-impacted land-use categories. The term Metro-Agro-Plex (or MAP) is sometimes used as a shorthand to describe this intermingling of agricultural and urban-industrial activities within a developed or developing geographical area. The term Continental-Scale Metro-Agro-Plexes (or CS-MAPs) is in turn used to specifically refer to the three large MAPs of the northern mid-latitudes.

Collectively, the CS-MAPs represent a major force in the global economy and also in environmental change. Although they comprise only 23 percent of the earth's land surface, the three CS-MAPs account for about 75 percent of world's consumption of commercial energy and fertilizers and about 60 percent of the food crop production and food exports. They are also major source regions for atmospheric pollutants including the O_3 precursors. Estimates using a global atmospheric chemistry model indicate that, because of these emissions, about 10–35 percent of the world's cereal crops currently are exposed to potentially damaging O_3 pollution within the CS-MAPs. The net effect of this exposure to the world's total production of cereals and other food staples probably amounts to few percent decrease in total production. However, the presence of other pollutants that accompany O_3 in photochemical smog most likely exacerbate the crop losses. For example, the haze associated with photochemical smog and O_3 pollution reduces the amount of sunlight that reaches the earth's surface and this likely also reduces crop yields. Moreover, as pollutant emissions increase in developing nations the impacts on agriculture within these areas will become more severe. The economic implications of such crop losses have yet to be assessed. However, in countries like China, where growing populations and rising standards of living may soon begin to strain food production capacities, the effect of O_3 and related pollutants on agriculture could conceivably have adverse or even dire consequences (see *Food Security*).

4. Tropospheric Ozone and Global Change

The spread of O_3 pollution may extend beyond the regional scale to the continental, and even hemispheric scale. Analyses of late nineteenth and early twentieth century O_3 datasets indicate that tropospheric O_3 in the northern hemisphere has undergone significant variations over the past century and continues to vary in some regions of the globe today. The evidence for long-term variations in free tropospheric O_3 is strongest in Europe where measurements of O_3 date back to the 1800s. For example, German scientists Volz and Kley (1988) used current techniques for measuring O_3 to recalibrate O_3 measurements made in Paris in the late nineteenth century. Their analysis indicates that tropospheric O_3 concentrations at the end of the 1800s were about a factor of 2 less than current concentrations over Europe. Subsequent analyses have reached similar conclusions. The implications of such a long-term O_3 trend for understanding O_3 pollution effects on humans and ecosystems have yet to be fully explored but could be considerable.

Trust: Cultural Concerns

1. *The Concept of Trust in Modern Sociology*

The roots of the concept of trust are to be found in philosophy, theology, sociopolitical thought, and ethics (cf. Silver 1985, Misztal 1996). In this article the discussion will be limited to the domain of sociology, where during the last two decades of the twentieth century the new wave of theoretical concern with trust has emerged.

In 1979 Niklas Luhmann related the phenomenon of trust to the growing complexity, uncertainty, and risk characterizing contemporary society. For the first time, there was a suggestion that trust is not an obsolete resource typical of traditional society, but just the reverse, it gains in importance with the development of modernity. In 1983 Bernard Barber reviewed the manifestations of trust in various institutional and professional settings introducing the category of 'fiduciary trust.' In 1984 Shmuel Eisenstadt and Louis Roniger identified trust as a core ingredient in the patron–client relations, as they appear in various guises from antiquity to modernity. In 1988, Diego Gambetta brought together a number of authors looking at trust and distrust in various domains, from various perspectives, and later himself presented the analysis of trust in closed, exclusive communities, like the mafia (1993). In 1990, James Coleman provided an exemplary analysis of trust as a purely rational transaction, within the framework of rational-choice theory. This avenue was followed in a number of contributions in the 1990s by Hardin (1991, 1993). From a macrosociological perspective Anthony Giddens approached trust as the characteristic feature of late modernity, elaborating on Luhmanian themes of complexity, uncertainty, and risk. In 1995, Francis Fukuyama provided the comprehensive exposition of trust as an indispensable ingredient of viable economic systems, basing his argument on the experience of China, Japan, and other South-East Asian societies. In 1997, Adam Seligman presented an interpretation of trust as a specifically modern phenomenon linked with the division of labor, differentiation, and pluralization of roles and the consequent indeterminacy and negotiability of role expectations. In 1999, Piotr Sztompka offered a synthetic treatment of trust as a cultural resource necessary for viable functioning of society, illustrating his argument with the vicissitudes of trust in postcommunist societies of Eastern Europe.

The importance of trust derives from some fundamental qualities of human action. Interacting with others we must constantly articulate expectations about their future actions. Most often we lack the possibility of precise and accurate prediction or efficient control. Facing other people we remain in the condition of uncertainty, bafflement, and surprise. And yet, most often we cannot refrain from acting—to satisfy our needs, to realize our goals. Then we have to face risks that others will turn against us.

Trusting becomes the crucial strategy to deal with an uncertain, unpredictable, and uncontrollable future. Trust consists of two main components: beliefs and commitment. Placing trust in others, people behave 'as if' they knew the ways in which other people will act. But trust is more than just contemplative anticipation. People must also face the future actively, by committing themselves to action with at least partly uncertain and unpredictable consequences. Thus, people gamble, making bets about the future actions and reactions of partners. To sum up, *trust is a bet about the future contingent actions of others*.

2. *Targets of Trust*

We vest trust in various objects. First, there is trust in the members of our family, pervaded with strongest intimacy and closeness. Then comes the trust toward people we know personally, whom we recognize by name, and with whom we interact in face-to-face manner (our friends, neighbors, co-workers, business partners, etc.). Here trust still involves considerable degree of intimacy and closeness. The wider circle embraces other members of our community, known at most indirectly, by sight, and directly only through some individual representatives (inhabitants of our village, employees of our firm, professors at our university, members of our political party). The widest circle includes large categories of people, with whom we believe we have something in common, but who are mostly 'absent others,' not directly encountered, and constructed as a real collectivity only in our imagination ('imagined communities' of our compatriots, members of our ethnic group, of our church, of our race, of our gender, of our age cohort, of our generation, of our profession, etc.). Here trust in

concrete persons shades off imperceptibly into trust in more abstract social categories.

The next target of trust is social roles. Independent of the concrete incumbents, some roles evoke *prima facie* trust. Mother, friend, doctor of medicine, university professor, priest, judge, notary public—are just some examples of the trusted personal roles, or offices of 'public trust.'

An even more abstract case is the trust directed at institutions and organizations. The school, the university, the army, the church, the courts, the police, the banks, the stock exchange, the parliament, are typical targets for this type of trust. An interesting variant of trust in institutions may be called procedural trust. It is trust vested in institutionalized practices or procedures. A good example is trust in science as the best method for reaching the truth, or trust in the democratic procedures (elections, representation, majority vote, etc.) as the best ways to reach reasonable compromise among conflicting particular interests.

The next important category of objects endowed with trust are technological systems ('expert systems,' 'abstract systems,' cf. Giddens 1990). In modern society people live surrounded by them: by telecommunications, water and power systems, transportation systems, air-traffic control systems, military command networks, computer networks, financial markets, etc. The principles and mechanisms of their operation are opaque and cryptic for the average user. People usually take them for granted and do not even notice their pervasive presence. And everybody has learned to rely on them, to the extent that their failure produces a major crisis.

Finally, the most abstract objects of trust are the overall qualities of the social system, social order, or the regime. Trust in them engenders feelings of existential security, continuity, and stability.

The various types of trust reviewed above operate according to the same logic. Most importantly, behind all of them there looms the primordial form of trust—in people and their actions. Appearances notwithstanding, all of the above objects of trust, even most abstract, are reducible to human actions. Ultimately we trust human actions, and only derivatively their conglomerates, effects, or products.

3. *The Substance and Grounds of Trust*

The trusting expectations can be arranged along a sort of scale: from least demanding to the most demanding, and respectively from the weakest, least risky bets, to the strongest, most risky bets of trust. First, we may expect only some instrumental qualities of actions taken by the others: (a) regularity (orderliness, consistency, coherence, continuity, persistence), (b) reasonableness (giving grounds, good justification for actions, accepting arguments), (c) efficiency (competence, consistency, discipline, proper performance, effectiveness).

The second class of expectations is more demanding. We may expect some moral qualities of actions performed by the others: (a) we expect them to be morally responsible (i.e., engaging in principled, honest, honorable conduct, following some moral rules, showing integrity), (b) we expect them to be kind, gentle toward ourselves, treating us in human fashion, (c) we expect them to be truthful, authentic, straightforward, (d) we expect others to be fair and just (applying universalistic criteria, equal standards, due process, meritocratic justice). Generally speaking, betting on moral virtues of others is more risky than believing merely in their basic rationality.

We may also make the strongest bets and expect from others what Barber called the 'fiduciary' conduct and defined as 'duties in certain situations to place others' interests before our own' (Barber 1983). This category is exemplified by: (a) disinterestedness (i.e., acting without consideration of one's own interests or even against such interests), (b) representative actions (acting on behalf of others, displaying concern for the welfare of others, serving their interests, cf. Dahrendorf 1979), (c) benevolence and generosity (caring, helping, protecting, expressing sympathy, sensitive to the sufferings of others). This is the strongest, most risky bet because the probability that most people will be disinterested is low, and that they will take representative duties and engage in altruistic help is even lower.

There are three grounds on which decisions to trust (to place the 'bets') may be based: reflected trustworthiness, personal trustfulness, and trust culture.

As far as trust is a relationship with others, granting trust is based on the estimate of their trustworthiness. Trust in this case may be considered as 'reflected trustworthiness' of the partners: our perception of their reputation, performance, or appearance. The probability of well-placed trust rises with the amount and variety of true information about the trustee. Without such knowledge trust is blind and the chances of the breach of trust are high.

But trust is not only a calculating relationship, but also a psychological impulse (Wilson 1993). Innate trustfulness may push people to trust quite independently of any estimate of trustworthiness. This has nothing to do with knowledge about the partners of future engagements. Rather, the impulse derives from past history of diverse relationships pervaded with trust, primarily in the family and later in other groups, associations, or organizations.

People may also be encouraged to trust by the surrounding cultural rules. Normative rules may push toward trusting, defining trust as proper. If the rules demanding trust are shared by a community, and perceived as given, and external by each member, then they exert strong constraining pressure on actual acts of granting trust. They may modify significantly the

rational estimates of trust, as well as inherent trusting impulses.

4. Trust Culture

Trust culture is a system of such rules—norms and values—regulating and granting trust as well as reciprocating trust. There are the normative obligations to trust and there are the normative obligations to be trustworthy, credible, reliable. One locus of both types of obligations is the social roles. There are social roles that refer to trusters and include a normative imperative to trust others. This is true of 'helping professions': the doctor of medicine, the defense counsel, the social worker, the priest, etc. There are other social roles that refer to trustees and place strong emphasis on trustworthiness (the demand for meeting trust, i.e., acting reliably, morally, caringly). For example, university professors are expected to be truthful and responsible for their words, judges to be fair and just in their verdicts, football referees to be impartial. The more general rule of '*noblesse oblige*' demands exemplary conduct from those who have attained elevated positions in social hierarchy endowed with high esteem.

All those are role-specific rules of trust. But there are also more diffuse expectations to trust, which become pervasive in some societies at some periods of time. Fukuyama (1995) makes a distinction of 'high-trust cultures,' where he includes several countries of the Far East, and 'low-trust cultures,' where he includes some countries of the West. Putnam and Stivers complain about the demise of high-trust American culture of the nineteenth century and the emergence of the culture of cynicism in our time (Putnam 1995, Stivers 1994).

There are also culturally diffuse rules demanding and enforcing general trustworthiness. Mediaeval guilds, firms with long tradition, famous corporations, gold and diamond dealers, elite newspapers and journals, established publishing houses, etc, put great emphasis on fulfilling the obligations and meeting the trust of their clients. The 'pride of the profession' or the 'honor of the firm' become general normative guidelines embracing various sorts of activities.

Once the trust culture emerges and becomes strongly rooted in the normative system of a society, it becomes a powerful factor influencing decisions to trust, as well as the decisions to reciprocate trust. It may become the strong stabilizing force guaranteeing persistence and continuity of trust.

5. The Etiology of Trust Culture

Several macrosocietal circumstances may be postulated hypothetically as conducive to the emergence of a trust culture. The first is normative coherence, as opposed to normative chaos, or anomie. The norms—of law, morality, custom—provide the solid skeleton of social life and their effective enforcement assures their binding nature. This makes social life more unproblematic, secure, orderly, and predictable, as there are fixed scenarios indicating what people should do and will do. Such normative ordering of social life raises the likelihood that other people will meet our expectations. The resulting feeling of existential security and certainty encourages the bets of trust. But apart from that there are enforceable norms more immediately relevant for trust, demanding honesty, loyalty, and reciprocity. Their presence raises the likelihood of such conduct, and assures us that our partners will fulfill obligations and extend mutual trust.

The second structural condition is the stability of the social order, as opposed to radical change. If the network of groups, associations, institutions, organizations, and regimes is long lasting, persistent, and continuous, it provides the firm reference points for social life, a feeling of security, support, and comfort. Repeated routines which people follow allow us to predict their conduct. Similarly, meeting obligations and reciprocating trust becomes not so much a matter of duty, but rather an unproblematic, habitual response ('second nature'). People simply do not entertain the possibility that one could act otherwise. Trust may therefore be more easily offered, as the chances that it will be met, repaid, or mutually extended are high. By implication, social change is compatible with trust only if it proceeds gradually, regularly, predictably, in a slow rhythm, and consistent direction.

The third contextual, macrosocietal factor relevant to the propensity to trust is the transparency of the social organization, as opposed to its pervasive secrecy. The easy availability of information about the functioning, efficiency, levels of achievement, as well as failures and pathologies of groups, associations, institutions, organizations, and regimes provides the feeling of security and predictability. People are apt to relate to them with trust, because they are assured about what they may expect.

The fourth factor is the familiarity or its opposite the strangeness of the environment in which people operate. We mean by the environment the immediate 'life-world,' natural, technological, and civilizational milieu which surrounds the people. It includes various components: landscapes and topography, architecture, interiors, designs, colors, tastes, smells, images, etc. This factor, like the earlier one, has to do with accustomed routines. The experience of familiarity provides one with the feeling of security, certainty, predictability, and comfort. In effect, it produces a trust-generating atmosphere, where it is easier to believe that trusting predictions will be borne out, that entrusted values will be cared for and returned, and that others will reciprocate with mutual trust.

The fifth condition is the accountability of other people and institutions, as opposed to arbitrariness and irresponsibility. If there is a rich, accessible, and properly functioning set of institutions, setting standards and providing checks and controls on conduct, the danger of abuse is diminished, and the regularity of procedures safeguarded. If people can resort to such institutions when their rights are not recognized, or the obligations of others toward them not respected, then they acquire a kind of insurance or backup option and therefore feel safer. Everybody is confident that standards will be observed, departures prevented, and that even if abuse occurs it will be corrected by recourse to litigation, arbitration, restitution, etc.

6. *Functional Substitutes for Trust*

Trust has generally beneficial consequences for the partners in social relationships, the groups to which they belong, as well as the peaceful, harmonious, and cohesive quality of the wider social life. We may suspect that when trust is missing the resulting vacuum will be filled with some alternative arrangements providing similar functions and meeting universal cravings for certainty, predictability, and order. These will be the functional substitutes for trust.

The typical and widespread ways of coping with deficiencies of trust may acquire a normative sanction, turn into cultural rules prescribing certain conduct, or even into complex institutions. The danger is that some of these practices, strategies, and institutions may be clearly pathological. Appearing as functional substitutes to correct for the unfulfilled functions of trust, they themselves produce dysfunctional consequences for the wider society.

The first adaptive reaction is providentialism; invoking of supernatural or metaphysical forces—God, destiny, fate—as anchors of some spurious certainty. They are thought to take care of a situation about which nothing seemingly can be done. This may bring some psychological consolation, but at the social level it produces disastrous effects—apathy, passivism, and stagnation.

The second, quite perverse substitute for trust is corruption. Spreading in a society it provides some misleading sense of orderliness and predictability, some feeling of control over chaotic environment, some way to manipulate others into doing what we want them to do. The sane tissue of social bonds is replaced by the net of reciprocal favors, 'connections,' the cynical world of mutual manipulation and exploitation.

The third mechanism is the overgrowth of vigilance, taking into private hands the direct supervision and control of others, whose competence or integrity is put into doubt, or whose accountability is seen as weak, due to the inefficiency or lax standards of enforcing agencies. Private security forces, the walled communities with sentries, private possession of weapons, burglar alarms in cars and apartments, private agencies for debt collection—all those are clear indicators that trust has collapsed.

The fourth mechanism is excessive litigatiousness. If trust is missing, the handshake will no longer do. People will try to safeguard all relationships formally: draw meticulous contracts, insist on collaterals and bank guarantees, employ witnesses and notaries public, and resort to litigation in any, even miniscule, event of breaching trust by their partners.

The fifth mechanism may be called ghettoization, i.e., closing in, building impenetrable boundaries around a group in an alien and threatening environment. The diffuse distrust in the wider society is compensated by strong loyalty to local tribal, ethnic, or familial groups, matched with xenophobia and hostility toward foreigners. People close themselves in ghettoes of limited and intimate relationships, isolated and strictly separated from other groups, organizations, and institutions. By cutting the external world off, they reduce some of its complexity and uncertainty.

The sixth reaction may be called paternalization. When trust is missing, people seek protection in a father-like figure, a strong autocratic leader, a charismatic personality who would restore, if necessary by force, the semblance of order, predictability, and continuity in social life. When such leaders emerge they easily become a focus of blind, substitute trust. A similar craving for abdication of responsibility is also satisfied by other institutions: spreading cults, sects, 'voracious communities,' demanding full loyalty and total undivided commitment. They become quasi-families, with a strong substitute father taking full care of the members.

The seventh reaction may be called externalization of trust. In the climate of distrust against local politicians, institutions, products, etc., people turn to foreign societies and deposit their trust in their leaders, organizations, or goods. Such foreign targets of trust are often blindly idealized, which is even easier because of the distance, selective bias of the media, and lack of direct contrary evidence.

Trust: Philosophical Aspects

Trust is agreed to be essential for securing the goods of cooperation; however, philosophers disagree about how trust is best analyzed. On the simplest account, trust just is reliance. On more restrictive accounts, trust also requires something else: that the truster be disposed to respond to a breach of trust with reactive attitudes such as resentment; that the one trusted proves trustworthy because of being trusted; or that the reliance involved in the trust is grounded in an assumption of goodwill. In addition to the question of how to analyze the concept of trust, other central questions include how to generate trustworthiness, when trust is justified and whether trust and trustworthiness are virtues.

1. The Importance of Trust

Trust makes it possible for us to enter, willingly and with confidence, into relationships of dependency and, as Williams points out, 'if there are to be continuing practices of cooperation, then people must be motivated, one way or another, to enter into dependent positions' (1988, p. 8). Such dependencies may be economic (for example, when goods must be paid for prior to receipt), political (when power is entrusted to elected representatives), professional (when patients depend on their physicians), social (the mutual dependence of voluntary associations), personal (dependencies among family members), or epistemic (when laypersons defer to experts). Dependency brings with it risk: one may be left worse off than one would have been had one not depended. Trust makes such risks seem worth the taking.

Recent work in the social sciences (Putnam et al. 1993, Fukuyama 1995, among others) suggests that trust is an important form of social capital, the absence of which hampers economic development. Societies with high levels of trust present more economic opportunities than societies with low levels of trust. Moreover, trust enables transaction costs to be lowered by reducing the need for expensive substitutes for trust such as legal remedies and close monitoring of performance. Monitoring and legal remedy presuppose a relatively determinate understanding of what counts as an acceptable discharging of the responsibilities of a dependency relationship. Trust allows the truster to give trustees discretionary powers with respect to how they fulfill that trust (Baier 1986, p. 237). Discretionary powers greatly enhance the usefulness of dependency relationships: often the truster cannot precisely specify in advance what it is that they are counting on the other to do either because the truster does not have the ability to predict the contingencies that must be planned for (think of the discretion given to babysitters), or because they do not have the knowledge to specify what would count as an appropriate response to such contingencies. Subjective benefits also follow from assigning discretionary powers—trust lets us inhabit a simpler and less threatening world in which we need not plan for every contingency (Luhmann 1973). The limits of the trustee's discretionary powers are only vaguely specified and this vagueness opens up the possibility for abuse—an untrustworthy trustee might conceal subtle breaches of trust as appropriate uses of her discretionary powers. Assigning discretionary powers thus brings with it additional risks as well as benefits.

Trust is required for the proper functioning of divisions of economic and epistemic labor, divisions that can greatly increase the speed with which goods, including knowledge, are produced and, thus, the complexity and scope of the projects that can be undertaken. In these ways, trust is shown to have instrumental value insofar as it contributes to bringing about the goods of cooperation. However, trust has more than instrumental value since it is also constitutive of relationships that are valuable in themselves, such as the relationships between family members and friends.

This brief catalogue of some of the ways in which trust is important points to the significance of developing an account of what trust is, how trustworthiness can be elicited, and when trust is justified. These are the topics of the next three sections.

2. Accounts of Trust

While trust might appear to be a dyadic relation of the form 'A trusts B' (for example, the citizens trust their government), trust is best analyzed as a three place relationship: A trusts B to do Z (Baier 1986, Holton 1994). Even among close friends, trust seldom extends to all domains of interaction and there is typically some background assumption in place about that with respect to which the other is trusted. The triadic nature of trust shows that trust need not be an all or nothing affair—one can trust with respect to the performance of some actions, but not others. This opens up the possibility of incrementally increasing trust by gradually extending the range of actions that the other is counted on to do. Paradigmatically, the 'A' and 'B' of the schema 'A trusts B to do Z' stand for persons. However, non-natural agents, such as corporations and governments can also fill either role, as can perhaps nonhuman animals. Furthermore, on some accounts of trust, but not others, things such as machinery and ropes can occupy the role of B.

The single most important question that occupies the philosophical literature on trust concerns how and whether to separate trust from reliance. On the simplest model, trust just *is reliance*. On this model agents can trust machinery and ropes as well as other agents, natural and artificial. However, agents will count as trusting even when they do not expect a favorable outcome. For example, someone may decide to rely on a frayed rope which they do not believe strong enough to hold them—perhaps it is better to risk probable death or injury from a fall than certain death from the oncoming fire. A trust-as-reliance model conforms to ordinary linguistic usage, for it would not be incorrect to say that such a person preferred to trust the rope than to take their chances with the fire. Nevertheless, the trust-as-reliance model identifies too heterogeneous a class of dependencies to support useful generalizations and thus does not provide a useful classification for the purposes of social scientific and other theorizing. For example, the claim that trust contributes to social capital and reduces transaction costs is false if trust is understood as reliance with or without confidence. Someone who relies while expecting the worst will be on the lookout for alternatives to such reliance and will cease to rely once another option is open to them. Such wary and reluctant dependence cannot be thought of as social capital. If we are to have a category that supports useful generalizations, we need a richer conception of trust.

According to Thomas Hobbes, '[t]rust is a passion proceeding from the belief of him whom we expect or hope for good, so free from doubt that upon the same we pursue no other way' (1994: IX 9). Call this the *trust-as-confidence* model. Confidence can be grounded in all sorts of properties of that which is trusted. An agent might trust someone to do Z because they are motivated by self-interest, goodwill, fear, or just because they are in the habit of doing Z. Trust-as-confidence remains a comparatively thin conception of trust and can be enriched in one of several ways.

First, notice that on this model someone can trust when the other is unaware of their trusting and when the other acts from reasons not in anyway connected with the fact that they are being relied on. Consider Kant's habit of taking a walk at exactly the same time everyday (Blackburn 1998). Knowing his habits, his neighbors could use Kant to find out the time. Should we say that Kant's neighbors trust Kant for the time? Again, such usage would not be improper, but it seems to group together rather different phenomenon. Philosophers have tried different strategies to capture the difference between the kinds of phenomenon grouped together by this account. Hollis (1998) uses the distinction between predicative and normative expectations, or the distinction between expecting *that* and expecting *of*. I may expect that the rope will hold and may build that expectation into my plans. I may thus be said to trust, in the predicative sense, that the rope will hold. I may also expect of you that you will keep your promise and may build that expectation into my plans. In this case I may be said to trust, in the normative sense, that you will keep your promise.

Holton seeks to capture the same distinction in a different way: according to Holton, trusting essentially requires taking the 'participant stance' towards the one-trusted (1994, p. 66). The participant stance is characterized by the readiness to have reactive attitudes such as resentment or gratitude towards the other. While we might be annoyed at, or frustrated by things that disappoint us, we will not feel betrayed and resentful should they let us down. According to this account, trusting someone 'involves relying on them to do something, and investing that reliance with a certain attitude' (1994, p. 67). To return to the example of Kant: on the reliance-with-participant-stance account, as long as Kant's neighbors are treating Kant's walking habits as a mere sign of the time of day, much like they would treat a clock, and have no reason to believe that Kant is aware of their use of his clockwork schedule, then they rely on Kant for the time, but do not trust him to provide it. Suppose, however, that Kant came to believe that his neighbors were counting on his regular habits for their time-keeping, and the neighbors knew this—perhaps Kant promised to continue his helpful habits—then they might come to invest their reliance with the attitudes appropriate to the participant stance and become disposed to feel

resentful should Kant let them down. If so, then they would be trusting Kant for the time.

Hardin seeks to distinguish cases of trust from mere reliance in the following way: 'it is trust I have, and not merely inductive expectations *if* I think that you have a reason in some way grounded in me for fulfilling my trust. For example, I might well expect you to rise every morning at 7:00 because I know your habits very well, but I do not trust you to do so if I have no reason to suppose that you do so somehow on my behalf.' (1998, p. 12) The reference to 'on my behalf,' should not, however, be taken to indicate that Hardin thinks trust requires attributing to the one-trusted a direct concern for the truster's welfare. Hardin thinks that typically the one-trusted will have self-interested reasons for not letting the truster down.

Other accounts see reliance on self-interest as incompatible with trust. Baier analyses trust as reliance on the goodwill of the other, rather than on other features of their psychology or on external constraints (1986, p. 234). However, this account is vulnerable to the objection that, while the conman relies on his victims' goodwill in order to manipulate them, he cannot be said to trust them (Holton 1994, p. 67). The account would need to explicate the sort of reliance on goodwill that is distinctive of trusting reliance. A somewhat different account that shares the intuition that goodwill is central but that stresses the importance of affect or emotion, is offered by Jones (1996) who defines trust as an affective attitude of optimism that the goodwill and competence of the other will extend to cover the domain of your interaction, together with the confident expectation that the other will be directly and favorably moved by the thought that you are counting on them. Although many cases of trust undoubtedly do involve optimism about the competence and goodwill of another—for example, the trust between friends and family members takes this form—it seems that not all instances of trust involve an element of affect and not all presuppose goodwill. If accounts of trust that do not distinguish it from bare reliance are too broad, will-based accounts appear too narrow and appear to take as paradigm trust in interpersonal relationships rather than trust in governments and institutions. Thus, it is preferable to have a more general model as an account of trust in all its forms, while continuing to note that there can be important differences in the kind of trust that results from confidence in the good will of the one trusted and in their responsiveness to being relied on.

3. *Generating Trustworthiness*

If trusting is to bring about the goods of cooperation, it must be met with trustworthiness. Trust in the untrustworthy breeds exploitation and abuse. Moreover, the costs of misplaced trust are frequently borne by others more vulnerable than the truster—think, for example, of child abuse. For this reason, being trusting is not a virtue. Likewise, the endorsement of trustworthiness must be qualified: sometimes one is required to respond to trust with judicious untrustworthiness. Nevertheless, trustworthiness in the service of unobjectionable or praiseworthy ends is a good thing, and trustworthiness is almost always something it is valuable to increase.

The problem of generating trustworthiness can be brought into focus by considering the following games: consider two agents, A and B. A must choose whether or not to rely on B. If A chooses to rely, B must choose whether to exploit or fulfill that reliance. Suppose the payoffs are, and are known to be, as represented in Fig. 1 (Brennan 1998, p. 199). If B is rational, then, if A chooses to rely on B, B will choose to exploit that reliance, since the payoff of exploiting is higher than the payoff of fulfilling. But if A believes B to be rational, then A will know that B will choose the option with the highest payoff and thus will choose to exploit. Since the payoff for A of relying and being exploited (-1) is worse than the payoff of not relying at all (0), A, if rational, will choose not to rely. Thus, both players will be left worse off than they would be had they been able to rely and respond to that reliance with reliability, since they both miss out on the goods of cooperation (the (2,2) payoff).

Consider an alternative game which, following Brennan (1998, p. 200), we can call the 'dependence game.' As before, A must choose whether or not to rely on B and, if A chooses to rely, B must choose whether to exploit or fulfill that reliance. The difference between the two games lies in the payoffs, which are as illustrated in Fig. 2. With these payoffs, if A believes B to be rational, it will be rational for A to rely on B, and for B to respond to that reliance with reliability, since the payoff for B of fulfilling the reliance is greater than

Figure 1
The reliance predicament

Figure 2
The dependence game

the payoff of exploiting it. Both agents can now achieve the goods of cooperation.

The problem of how to convert a reliance predicament into a dependence game is the problem of how to make B trustworthy with respect to the exchange in question. There are three ways to do this: by decreasing the payoff for B of exploiting (this is the strategy illustrated in Fig. 2), by increasing the payoff of cooperating, or by increasing and decreasing the relevant payoffs at the same time. Any of these solutions will work provided that B's payoff for fulfilling is greater than B's payoff for exploiting. The payoffs can be divided into subjective and objective components (Brennan 1998, p. 201). The subjective component refers to features of the agent's motivational set that will increase or decrease the utility she assigns to the outcome—examples include feelings of guilt at letting someone down and feelings of satisfaction at fulfilling their trust. The objective component refers to institutional incentives that increase or decrease objective utilities. Thus, each of the three strategies can be pursued either by adjusting the agent's subjective or objective payoffs or by pursuing a mixed strategy that affects both.

Among the strategies that can be pursued to structure the agent's objective payoffs are mechanisms for detecting and penalizing exploitative behavior. Thus, one way of building trustworthiness is to have in place mechanisms of distrust; mechanisms, that is, that provide checks against untrustworthy behavior.

Incentives are often cheaper than penalties. An important incentive is provided by the fact that, should B prove untrustworthy, A will not trust in future encounters. When there is the possibility of repeated plays of the game, the cost of losing the benefits of future cooperation can in itself be enough to adjust the payoffs towards trustworthiness. Thus Hardin (1991, 1998) can claim that trustworthiness is produced by self-interest; including especially by the trustee's interest in having an on-going relationship with the truster. Moreover, reputation for trustworthiness can encourage the reliance of others. For the reputational effect to be significant, background conditions must be met. In particular it must be possible for potential trusters to have information about the trustworthiness of potential trustees. Institutional design (such as structures that ensure openness and accountability) contribute to determining whether these background conditions are met. In these ways, institutional design can support (or erode) individual trustworthiness. While trust in individual actors cannot be entirely eliminated and replaced with trust in social institutions, social institutions can create a confluence of motives for trustworthiness. Working out which structures support, and which undermine, trustworthiness is thus a question of the first importance for institutional design.

It is widely observed (for example, Baier 1986, Jones 1996) that trust and distrust are self-confirming. Trusting is often met with perceived trustworthiness and distrust with perceived untrustworthiness. In part, this is to be explained by perception—someone who trusts will interpret the one-trusted's actions through the lens of that trust. An action that might have been seen as indicative of untrustworthiness will be explained away as compatible with trustworthiness. Equally, someone who distrusts will tend to interpret actions that could be given a favorable interpretation as nevertheless revealing motives indicative of untrustworthiness ('what does she want from me that she is being so nice?'). In part, it is to be explained by opportunities to prove oneself trustworthy: where possible, one steers clear of those one does not trust and so they are never given the chance to demonstrate their trustworthiness. But, in large measure, the self-fulfilling nature of trust and distrust is to be explained by trust-responsiveness (Pettit 1995) and its corollary distrust-responsiveness.

Trust-responsiveness is the 'disposition to prove reliable under the trust of others' (Pettit 1995, p. 203). Trust-responsive agents assign higher degrees of utility to performing actions that they are being counted on to perform than they would ascribe to those actions were they not being so counted on. The very act of relying, and conveying that reliance, itself contributes to adjusting the payoffs in the way needed to move from a reliance predicament to a dependence game. Trust-responsiveness can be grounded in a variety of elements in an agent's motivational set, including positively valued traits such as loyalty, virtue, and prudence. But it can also be grounded in agents' desire for the good regard of others. By openly relying, a truster can convey their assumption that the other is trustworthy. Since the desire to be thought well of by others is widely shared, conveying good-regard, or the promise of good-regard should the other fulfill the trust, is likely to be motivating (Pettit 1995). In this way, trust can be self-fulfilling.

Trust-responsiveness has a negative corollary in distrust-responsiveness. If others become aware of our

distrust, either because we refuse dependency, or because we engage in intrusive surveillance, we risk undermining the positive effect of trust-responsiveness and, further, we risk alienating the one being monitored and thus activating untrustworthiness. Surveillance generates resentment, undermines internal motivations towards trustworthiness, and encourages even the honest to attempt to beat the surveillance system (Kramer 1999, p. 591). Thus, strategies for converting the reliance predicament into the dependence game must be carefully crafted least adjustments in objective payoffs have unintended consequences on subjective payoffs and so offer no solution at all.

4. *Rational Trusting*

If the problem of trustworthiness can usefully be thought of as the problem of how to convert reliance predicaments into dependence games, the problem of rational trusting can usefully be thought of as arising when the assumption that the truster automatically knows what the trustee's payoffs are is abandoned, as it surely must be in real life. No matter how trustworthy the trustee would prove to be, the goods of cooperation will remain elusive unless it is reasonable for the truster to think that trust will in fact be met with a trustworthy response. Trust-responsiveness provides a mechanism which allows trusters to bootstrap their way to rational trust. Any means of communicating information about the potential trustee's motivations can also serve to ground rational trusting. Transparent social structures that reveal what incentives are in place can serve this communicative function, as can mechanisms, from gossip, to watchdog authorities, which spread abroad information about past performance with respect to trustworthiness. Would-be trustees have reason to convey that they can be trusted. Often, however, this cannot be conveyed directly: '"Trust me!" is for most of us an invitation which we cannot accept at will—either we do already trust the one who says it … or it is properly responded to with, "Why should I and how can I until I have cause to?"' (Baier 1986, p. 244). Trusted third parties can thus be important brokers for new trust relationships.

How much, and what sort of information agents need before it is rational for them to trust depends on the climate of trustworthiness they inhabit, on what it is that the other is being trusted to do, and on the cost of misplaced trust (Jones 1996). When the climate is sufficiently bad it might be reasonable to begin from a default stance of distrust and move towards trust only when there is considerable evidence of the trustworthiness of the other. In such climates, trust-responsiveness is undermined, for a truster cannot credibly convey to the trustee that she thinks them trustworthy if hardly anyone ever thinks another trustworthy (Pettit 1995, p. 221). Some actions, such as refraining from harming others as they go about their business, require only minimal decency and no particular competence and thus, unless the climate of trust has broken down completely, it can be assumed that trust is warranted. Other actions will be such that their performance demands competencies or motivational resources that cannot be assumed to be widely distributed—in such cases, the truster will require specific evidence about the trustworthiness of the other. Such evidence may take the form of marks that indicate that the trustee belongs to some subset of the population in which trustworthiness with respect to the required action will be the norm (for example, board-certified surgeons), or it may take the form of evidence about motivations and competencies specific to the trustee. The consequences of misplaced trust also affect how much evidence is required for rational trust—holding constant climate and kind of action to be performed, it will take more information before I am justified in trusting when I risk a grave loss should the other prove untrustworthy than when the loss is less.

5. *Trust and Epistemic Dependency*

Some of our most significant dependencies are epistemic: laypersons depend on experts for information about everything from the best cancer treatments, to the probable effects of an interest rate hike. Moreover, we rely on a vast array of technologies and intermediaries to convey this information. Nor is such trust limited to the relationship between experts and laypersons: experts must trust other experts in the design and maintenance of experimental equipment and must rely on the results of others in constructing and testing their theories. Hardwig reports the case of an experiment measuring the life of charm particles that took 280 person-years to perform and was reported in a paper with 99 authors (Hardwig 1991). No one person has, or could acquire, the expertise necessary to vouch for all the parts of the experiment even if it were physically possible for the experiment to have been conducted single-handedly. Such epistemic dependency was always present—consider day-to-day reliance on the testimony of others for directions—but the explosion of knowledge and of technologies for its dissemination, brings questions of epistemic dependency to the forefront of epistemology and raises questions about the design of knowledge generating and certifying institutions, such as the academy and the peer review process. Interdisciplinary inquiry into which structures support the truth-seeking aims of science and which undermine them is thus of the first importance (Goldman 1999) and can be seen as the extension to the realm of the epistemic, of the sorts of inquiries that are being undertaken into the trustworthiness of social and political institutions.

Trust, Sociology of

Trust is an expectation, a disposition, or a virtue. It is cognitive, emotional, moral, or some combination of the three. There is, in fact, no universally consensual conception, but by any definition trust involves a social relationship in which one person makes themself vulnerable to another who can do them harm if the trust is misplaced. That second person is either trustworthy or not, and much of the literature revolves around the evaluation of the trustworthiness of the trusted by the trustor. The two terms, trust and trustworthiness, are distinct but so implicated with each other that it is impossible to consider the first without also considering the second.

1. The Term 'Trust'

Trust is a word so common in everyday parlance that any effort to transform the term into a useful social science concept is fraught with difficulties. Yet, given the seeming importance of trust in interpersonal relations at home, at work, and on the street, in the relationships between citizens and their governors and governments, and even, possibly, among states, it is useful to clarify not only what we mean by trust but also to specify what work it actually does. To what extent trust is essential to well-ordered and productive relationships in contemporary societies is an empirical question as yet unresolved.

There are several distinct literatures on trust and several ways to categorize them. One typology differentiates trust among those who know each other intimately (personal trust) from trust among strangers or relative strangers (interpersonal, social, or generalized trust), which in turn is distinct from trust of government, firms, and other institutions (political, institutional, or organizational trust). Another involves the distinction between dyadic and embedded relations of trust. Yet another is according to disciplines, of which the most contributory to the discussion are philosophy, law, sociology, psychology, economics, and political science. There are approaches to trust that rely on rational choice, others that call upon structural functionalism, and yet others that evoke social identity theory. There are surveys of trust, experiments on trust, and formal models of trust. Yet, the concept remains elusive.

Some minimal consensus does exist, nonetheless. Trust is relational, involving at least one individual making themself vulnerable to another individual, set of individuals, or institution that possesses the potential to do harm or betray. Trust implies a judgment of risk in conditions of uncertainty. Moreover, trust is seldom unconditional; it is given over specific domains. A client may entrust a banker with money but never consider leaving a child in the banker's care; citizens may entrust their lives to their government during wartime but not new taxes to legislators who promise improved public services.

Trustworthiness is also relational but in a more limited sense. Even when there is no call for trust, a person or institution can possess the attributes of trustworthiness, attributes that assure potential trustors that the trusted will not betray a trust. Trustworthiness has two dimensions. The first involves the commitment to act in the interests of the trustor due to moral values about promise-keeping, caring about the

trustor, or incentive compatibility, or some combination of all three. When we call someone trustworthy, we often mean only this commitment, but there is in fact a second dimension, competence in the domain over which trust is being given. The trustworthy will not betray the trust as a consequence of either bad faith or ineptitude.

This minimal consensus does not resolve the conceptual ambiguity that surrounds the social science usage of the terms trust and trustworthiness. Confidence, reliance, and assurance are related concepts that some scholars conflate and others distinguish albeit in a variety of ways.

2. Research on Trust and Trustworthiness

Trust has a long intellectual history and a flourishing contemporary industry of research. In political philosophy, Thomas Hobbes argued that where there is trust, there is no reason to search for a better way to achieve a good, and John Locke emphasized the importance of mutual trust between the governors and the governed within legitimate polities (Dunn 1990). In sociology, it is a concept used by scholars as various as Talcott Parsons, Peter Blau, Harold Garfinkel, Niklas Luhmann, and Bernard Barber in their efforts to understand the construction of social order, cooperation, institutions, and organizations, and even everyday interactions. To the economist Arrow (1974), 'Trust is an important lubricant of a social system' because it can enhance efficiency. There are two major strands of work on trust, one that emphasizes trust as reigning where the market, contract, and modern institutions do not and the other emphasizing the underlying importance of trust in modern exchange, societal, and institutional relations. What ties these perspectives together is the recognition of trust as a means to cope with uncertainty; what distinguishes these perspectives is how trust comes about, when it should be relied upon, and what kinds of interactions it enhances.

The recent burgeoning of the social science literature on trust is a response to the perception that political and social trust is in decline and in part to an argument that trust is essential to a good society. The fact that there are now decades of responses to the same survey questions and that they indicate a reduction in both political and social trust in the advanced industrial democracies has generated an effort to explain and correct this trend. The emphasis on the importance of social capital and the claim that it, too, has decreased over time is another factor producing a focus on trust. Both Coleman (1990) and Putnam et al. (1993) included trust as a critical element in their original accounts of social capital.

Economists and organizational theorists have come to share Arrow's and others' view that more than formal incentives or credible commitments may be necessary to account for productive internal relationships and innovative change within firms and organizations (Kreps 1990, Miller 1992, Kramer and Tyler 1996). Social theorists attempting to explain variation in the capacity for collective action and cooperation (Gambetta 1988) and better governance (Braithwaite and Levi 1998) are also reconsidering the roles trust and trustworthiness play. And they are hardly alone in discovering, or rather revisiting, these concepts, as recent books by Fukuyama (1995), Seligman (1997), and others attest.

2.1 Motivational Assumptions About Trust

Why does someone trust? There are at least four possible kinds of motivations: dispositional, moral, social, and instrumental.

In one widespread perspective, trust is a disposition, that is, some individuals are more inclined to trust or be trustworthy than others due to factors of personality or character. A dispositional view of trust leads to investigations of variation among the population in the propensity to trust and be trustworthy. There is little agreement in the trust literature, however, on the sources of such a disposition. It could be a result of innate character, childhood experience, learning and updating, instrumental manipulation, knowledge, social networks, social bonds, or social norms. The assumption of trust as a disposition fails to capture important elements of trust: Trust always has both an object, the person, persons, or institution being trusted, and a domain, what the person, persons, or institution is being trusted to do.

By some accounts, trust is motivated by morality. Individuals are trusting because they believe trust is the act of a good person. Trust as a virtue is a very unsatisfying account of motivation, however. To trust a conman or to trust a corrupt politician is hardly virtuous by any common language sense of virtue. Trust may reflect a normative ordering that demands deference and obedience to certain kinds of authorities, but it is important to maintain the distinction between the normative features of trust and the claim that trusting behavior is either morally motivated or a moral good. What may well have moral motivation is trustworthiness, which generally implies commitments, promise keeping, and obligations. We are more likely to consider someone trustworthy, ceteris paribus, when we believe they have ethical values that make it unlikely for them to betray a trust.

A third possible motivation is social in the sense that individuals derive their identity and self-esteem from their relations to others and thus trust or are trustworthy in keeping with their sense of self or to enhance social status, or both. Although the social motivation is intentional, the end sought has more to do with identity than with the achievement of some material

benefit. This leads many of the adherents of social motivation to claim that it is neither interest-based nor calculative.

A final kind of motivation is, in fact, instrumental and calculative. Trust is given when it is a means to a particular end and when there is reason to believe the trust will be rewarded. There is a positive expectation that the payoffs from taking a risk are worth the possible costs. It is easiest to trust when the risks are sufficiently low, and it may well be worth the risk when the returns are sufficiently high. There are some circumstances, however, when the cost of misplaced trust is so high that trust is rarely given or given only when there is considerable insurance. Trusting one's child to the care of another or investing one's life savings are two such cases.

The development of a reputation for trustworthiness can also be instrumental. The trustworthiness of an individual may enlarge her possibilities for valued exchange and cooperation, and the trustworthiness of a government or organization may enhance the voluntary compliance and consent of those subject to its rules. Trustworthiness is also likely to increase the range of discretion given to the trusted, which is an issue of particular importance to agents, be they legislators or union officials or managers, acting on behalf of principals who lack the same intimate knowledge of the situation and the alternatives.

2.2 Conceptualizing Trust

In conceptualizing trust in order to engage in empirical research, two crucial distinctions exist: cognitive vs. noncognitive trust; dyadic vs. embedded trust. There is no empty cell in this matrix; a scholar can be concerned with either of the first and either of the second.

Assumptions about motivations are closely linked to whether the conceptualization of trust that informs empirical research is noncognitive or cognitive. Those who argue for motivations based on morality or social bonds tend to have a noncognitive approach, and those who argue motivations are instrumental generally have a cognitive view. The dispositional motivation can fit with either, depending on one's view of disposition formation.

The noncognitive conception of trust draws on the work of psychologists concerned with social identity, particularly Henri Tajfel and John C. Turner. It is advocated by contemporary social psychologists, such as Robyn Dawes, Tom Tyler, Rod Kramer, and Marilyn Brewer, and by social theorists, such as Allan Silver, who perceive trust as having a moral basis that contrasts with, although often complementing, the world of contracting and impersonal transactions. Individuals trust because of their attributions of motives to the person or institutions that must be trusted. If they attribute trustworthiness, they are more likely to trust, and they are most likely to attribute trustworthiness when there are social bonds or group identification between the trustor and the trusted. This perspective is rooted more in the emotions and morals of an individual than in her capacity to reason. It reflects personal relations and cannot be easily regulated by the impersonal relationships embodied in bureaucracy, market, or formal law. The cognitive conception of trust builds on the work of economists, political economists, and social exchange theorists, such as Kenneth Arrow, James S. Coleman Russell Hardin, and Diego Gambetta. The act of trust, of making oneself vulnerable, requires a thoughtful assessment of risk, informed by a rational expectation or a rational belief that the trusted will be trustworthy. Such an expectation or belief is generally grounded in knowledge of the other's past behavior or present motives and constraints. It can be affected by the existence of institutions, sanctions, and incentives that affect the probabilities that the trusted will act in the interest of the trustor.

The second distinction is between dyadic and embedded trust. Trust is relational in either case, but embedded trust permits conceptualization of generalized trust and institutional trust, and not just trust at the individual level. Dyadic trust depends upon expectations about or social bonds with a particular other. Embedded trust rests in social networks and institutional arrangements that permit expectations about or social bonds based on the social roles, categorization, and rules affecting others.

2.3 Measuring and Observing Trust

The most common methods for studying trust include surveys, experiments, and case studies, sometimes but not always informed by formal models. The surveys attempt to measure either political or social trust, but there is considerable controversy about how well they measure either. This is particularly true for the questions in the National Election Studies, which seem to be more about confidence in or positive assessment of elected officials than of political trust, and for those in the general social surveys, which seem to be tapping issues of social anxiety rather than social trust. The World Value Survey asks about both institutional and interpersonal trust, but its questions have similar limitations as the American versions. These major surveys do have the advantage of asking the same questions over the course of several decades, but there remains the issue of whether the time range covered is adequate to capture real changes in trust. Moreover, it is possible that people asked at one point in time understand a question differently than when they are asked at a later point in time. Surveys designed explicitly to capture the relationships of trust are even less likely than the major surveys to enhance understanding of changes in trust relations over time, and

their questions still tend to be open to multiple interpretations.

Some survey work does offer insight into trust relations, nonetheless. For example, Toshio Yamagishi uses survey evidence, often in combination with experimental work, to provide some interesting observations on variations in trust within and across populations and countries. Comparing the United States and Japan, Yamagishi and Yamagishi (1994) conclude that the embeddedness of the Japanese, at least until recently, in such tight social networks meant that they did not need to develop the capacity for discerning who and what to trust that has long been characteristic of Americans.

Experimental work on trust has different strengths and weaknesses. At their best, experiments can control for factors that might influence or be confused with trust and trustworthiness, they can investigate choice behavior and not just the attitudes captured by surveys, and they can be designed so as to clarify the conditions under which individuals are likely to trust. There have been interesting experiments linking trust to issues of exchange and collective action, and there has been some work attempting to get at the effect of dispositional variations within a population. Most of the experiments, however, focus on dyadic relationships, although there are experiments that investigate the operation of social networks. Moreover, much of the experimental work to date has conflated cooperation and trust. For these experiments to be more compelling, they need to clarify the roles that trust plays in producing cooperation rather than assuming that where there is cooperation, there is trust.

Several other approaches to the study of trust also deserve mention. The trust game and other formal models have proved useful to organizational theorists and economic historians attempting to understand the role trust plays in the relationships between principals and agents and in long-distance trade. There have been statistical analyses of indicators of trust in order to determine variation over time, and there have been case studies that attempt to capture the attributes of trustworthy government or trust that affects economic interactions and productivity in and across firms, industries, groups, regions, and countries. However, this research, although multiplying rapidly, is still in fairly early stages of development.

3. *Is Trust a Useful Concept?*

There is some question of whether a concept like trust is even necessary if the purpose is to explain phenomena that rely on impersonal, multi-person, and anonymous interactions. Williamson (1993) makes a case that it is not; to him trust exists only in personal relations with incentives, interests, and institutions regulating political, market, and large-scale social interactions. Silver (1985), coming from a totally different perspective, offers a similar argument. Hardin (1998) claims that trust, as he defines it, can exist only in the rather limited set of cases where the trustor has sufficient knowledge of the trusted to believe that their incentives are compatible; he is wary of such concepts as trust in government. Levi (2000) claims that trust is not always the solution to distrust. There are, after all, numerous functional alternatives to trust that rely more on assurance or coercion than on trust, such as: third-party insurers; contracts and other legal enforcement devices; professional ethics; fictive kinship; and a variety of social networks and institutional arrangements.

The argument of the social identity theorists and those who come out of the sociological tradition of Durkheim or the liberal political tradition of Locke is that trust most certainly matters and is, in fact, essential to a well-ordered society. It is constitutive, in this view, of the moral and personal glue that enables modern societies to function. These scholars tend to decry the loss of trust and seek to halt its further decline by advocating the maintenance and creation of community, republicanism, and more personalized interactions, even in large-scale organizations. On the other hand, those relying on instrumental and cognitive theories treat the work trust does as an empirical question. Relationships of trust are but one of many means to achieve given ends, and whether they are the best means is still open to considerable research and debate.

Truth and Credibility: Science and the Social Study of Science

The natural sciences occupy a special place in modern culture. Scientific knowledge substantially defines our culture's notion of truth, and the overwhelming credibility of that knowledge in our society is widely taken to be sufficiently explained by its truthfulness. The social sciences traditionally have concurred in these assessments and have paid the natural sciences the compliment of emulation. Yet that emulation largely has proceeded by way of textbook idealizations of natural scientific knowledge and how it is produced, while the idealizations themselves—produced by both academic epistemologists and reflective scientists—are much more variable than generally is supposed. It has not been until fairly recent times that social scientists have attempted wholly naturalistic inquiries into how scientific knowledge is produced and how it comes to be believed. The sociology of scientific knowledge that emerged from the early 1970s purposely set aside epistemological evaluation and took as its primary task understanding scientific credibility. How is it that scientific claims succeed, or fail, in being believed? This article surveys a number of considerations that recent social studies of science have found to be widely relevant to the interpretation of scientific credibility.

1. *Scientific Truth: As Evaluation and Resource*

'Truth' appears only occasionally as a vernacular term, nor does the special notion of intellectual quality the word connotes in academic philosophy figure much in everyday usages. Professional epistemologists worry how to reliably sort genuine knowledge from belief, opinion, or mere knowledge-claims, and this is the major context in which academic theorizing about truth takes place. Many theorists are agreed that knowledge (properly so-called) is 'true belief,' but there is no philosophical consensus about the definition of truth, about the domains in which we can expect to have genuine knowledge, about the grounds for establishing truth, or, indeed, about what it is that can be said to be true (propositions, facts, theories, thoughts, concepts, beliefs, etc.). The major battle pitches correspondence theories against coherence theories of truth, while skirmishes are fought along the margins between conventionalist, pragmatist, performative, redundancy, disquotational, and miscellaneous other theories (or antitheories) of truth.

In ordinary life, the word truth often crops up as a special-purpose term whose employment indicates that some out-of-the-ordinary guarantees are being sought for promises, professions, or claims to knowledge, or that there is some specially occasioned doubt about their genuine status, as in legal proceedings when witnesses are ceremonially sworn 'to tell the truth, the whole truth, and nothing but the truth' (Lynch and Bogen 1996), or in intimate social relationships when one has misgivings about one's lover's sincerity and looks for explicit warrants of affection: 'When my love swears that she is made of truth,/I do believe her, though I know she lies.' Perhaps even more commonly, everyday actors, and even philosophers in many circumstances, use the words true or truth just as a way of giving added emphasis or value to assertions of what is the case, the lexical equivalent of thumping the table.

The category of everyday actors may be taken, for the most part, to include professional natural scientists engaged in their ordinary knowledge-producing practices. While their expert employments generate knowledge whose content, methods of production, and value are widely said to differ markedly from lay beliefs about the world and lay modes of cognition and evaluation, epistemological reflection does not occupy much of scientists' time, nor is it customary for them to engage in metascientific inquiries into the nature and status of their knowledge. The result is a situation in which the bodies of expert knowledge that are widely taken as the touchstone of truth in our culture, and the object of vast amounts of epistemological reflection by philosophers, tend to be produced

by practitioners who rarely concern themselves reflectively or systematically with the nature of their knowledge, or its standing vis-à-vis nonexpert knowledge, or with the methods that produce their so-highly-valued knowledge. The paucity of practitioners' reflection on the nature and quality of their knowledge is an important feature of the modern natural sciences, and the social sciences and humanities are quite different in this respect.

Practicing natural scientists seem to take scarcely any notice of epistemologists' debates or dicta. Indeed, in the natural sciences, epistemological and metascientific musings, as well as sociological reflections, are often taken as a sign of emeritus (or, unkindly, 'past it') standing. They are sometimes explicitly condemned as irrelevant, unprofessional, or even pathological: it may be what philosophers or sociologists do, but (it is said) it is not what practicing scientists ought to do. In the nineteenth century the experimental physiologist Bernard (1865/1957, p. 49) vigorously disengaged the scientific production of truth from scientists' possible reflections on truth or on how truth was produced: 'To find scientific truth, we … have little need to know how our mind reasons; it is enough to let it reason naturally …'. Bridgman (1955, p. 157) was one of many modern physicists taking a jaundiced view of philosophers' attempts to characterize both scientific truth and scientific method: philosophers' 'abstractions' tended to attract a 'veneration' that was wholly undeserved. C. P. Snow—a one-time chemist and latterly a spokesman for science—bumptiously admitted that 'By *truth*, I don't intend anything complicated … I am using the word as a scientist uses it. We all know that the philosophical examination of the concept of empirical truth gets us into some curious complexities, but most scientists really don't care' (Snow 1961, p. 247). Albert Einstein famously celebrated, rather than condemned, what he took to be the fact 'that the man of science is a poor philosopher.' If, Einstein said (1936/1954, p. 296, p. 318), 'you want to find out anything from the theoretical physicists about the methods they use, I advise you to stick closely to one principle: don't listen to their words, fix your attention on their deeds.' Moreover, the small number of empirical studies we now have of natural scientists' grasp of the principles of formal logical reasoning strongly suggests that the power and reliability of scientific knowledge do not spring from the superior reasoning capacities of individual scientists (Mahoney 1979, Mahoney and DeMonbreun 1977).

When one considers the content of such scientists' musings about truth as are occasionally produced, further problems are posed for any social science wishing to model its epistemic goals on those of the natural sciences. Many academic, and some lay, views of the natural sciences point to scientific facts, laws, and theories as enjoying the status of accredited truth, and to the proper goals of scientific inquiry as the production of such truth. Yet important strands of practitioners' metascientific stipulations identify the goal of producing truth as illegitimate, and such special status for scientific representations as a lay misunderstanding of what genuine science is about. Some scientists do indeed say that science aims at, or even arrives at, one universal truth. However, others say that the truths of sciences are plural, or that science is just 'what works' and that truth—or even correspondence with the world—is none of their concern—just 'what stands the test of experience,' or 'what seems to be the case to the best of our current efforts and beliefs.' Oppenheimer (1954, p. 4) followed the nineteenth-century Scientific Naturalists in warning science to shun 'metaphysical' notions like 'real' and 'ultimate' in talking about its concepts and theories: if we say that physical theories are true, we must say so in a carefully qualified non-metaphysical sense. Einstein (1929/1954, pp. 261–2) found it 'difficult even to attach a precise meaning to the term "scientific truth." Thus, the meaning of the word "truth" varies according to whether we deal with a fact of experience, a mathematical proposition, or a scientific theory.' Bridgman (1955, p. 158) noted that 'In physics we have been forced to recognize … that there are different kinds of truth, depending on the method used for establishing "truth."' Bridgman's student Oppenheimer (1954, p. 95) vigorously agreed: 'Perhaps only a malignant end can follow the systematic belief that all communities are one community; that all truth is one truth.' Just as epistemologists espouse widely varying conceptions of truth, so too do those natural scientists occasionally drawn to philosophizing, while most practicing scientists seem well content to leave philosophy to the philosophers.

2. *From Truth to Credibility: Science as a Topic*

For these reasons alone, the posture of the social sciences vis-à-vis the natural sciences, and, especially, with respect to emulating their truth-criteria, is problematic. Should social scientists really wish to pattern themselves on the natural sciences in order to solve problems of intellectual identity, authority, and quality, they would find it no easy thing to do, such is the diversity of natural scientific practices and sensibilities, and of professional metascientific stipulations about the natural sciences (Mills 1959, pp. 119–31). This diversity is seldom adequately reflected in textbook accounts of scientific method and scientific knowledge, nor is it apparent when one particular natural science—typically some version of modern physics—is made by fiat to stand for all the rest (Shapin 1999a). Yet once this variability is properly appreciated, it becomes clear that the social sciences will have to make their own claims to knowledge and support them as best they can, using whatever resources and warrants are available and are deemed legitimate.

However, misguided emulation is not the only possible mode of social scientific engagement with the natural sciences. Social scientists can study the cultures of the natural sciences, seeking to understand how a range of natural scientists collectively produce their knowledge, how they make it persuasive, and how they render their intellectual evaluations. This has been the task taken up by the sociology of scientific knowledge over the past 30 years or so. Indeed, the founding gesture of modern sociology of scientific knowledge was the rejection of epistemological evaluation as the proper basis for sociological accounting. Traditional sociology of knowledge—descended from Marx and Mannheim—had reckoned, almost as a matter of course, that true and false beliefs should be explained differently. False beliefs might customarily be referred to distorting social and psychological factors, while the truth of true beliefs—their adequate evidential base, or their logical coherence, or their production and assessment using transparent and impersonal rational methods—could count as its own sufficient explanation (Mannheim 1936, pp. 239, 261, Phillips 1974). It was not considered that much of sociological interest could be said about true beliefs, and therefore about the body of currently accepted scientific knowledge. That is why traditional sociology of knowledge explicitly exempted accepted scientific beliefs from its scope.

Bloor's (1976/1991) *Strong Programme* in the sociology of scientific knowledge enjoined sociologists professionally to set aside external judgments of truth and falsity and to explain the acceptance of both reputed true and reputed false beliefs using the same resources. It was not that sociologists were to account all beliefs of equal value—that would itself be an act of epistemological assessment—rather it was that sociologists, in doing sociology, should be impartial with respect to the reputed truth or falsity of beliefs, as true and false seemed to the individual sociologist or as the beliefs were routinely sorted in the culture of which the sociologist was an everyday member. Bloor here identified generally acknowledged academic virtues that would flow from adhering to this maxim of method and academic vices that had traditionally stemmed from rejecting it. On the one hand, it was not the proper business of the social scientist to engage in epistemological assessment; on the other hand, inscribing external judgments of truth and falsity in social scientific accounts illegitimately blocked the free inquiry and rendered explanation circular. In Bloor's view, the sociologist could and should be as curious about why some cultures—in this case, our own—classify the cassowary as a bird as they had traditionally been about such cultures as the New Guinea Karam that classify what we call cassowaries and what we call birds in different taxa (Bulmer 1973, Barnes 1973, Barnes and Bloor 1982).

The *Strong Programme* did not mean to ban consideration of truth and falsity but, rather, to encourage sociologists to take a fuller naturalistic interest in the problem of how actors themselves sorted beliefs as between true and false. Actors' truth-judgments, or judgments of what is the case about the world, were not to be just an asymmetrical resource but a central topic of sociological inquiry. Or, put another way, this newer form of the sociology of knowledge placed the credibility of beliefs at the center of its intellectual agenda. Suppose, taking up the toy taxonomical example, one asked a member of the Karam why it was that they classified cassowaries in a different taxon than the rest of what we call birds. After translating the question into their own vocabulary, the Karam might reply in the prevalent folk-epistemological idiom, rolling their eyes, or saying that the matter is self-evident, or citing all sorts of obvious and important empirical differences between the big, ground-dwelling cassowary and the small, aerial bird-of-paradise. Pressed further, the Karam might point to the views of legitimately respected elders and experts, as sanctioned by custom and use. And so it might plausibly strike the Western social scientist that the grounds of credibility of Karam taxonomy had a lot to do with authority, custom, socialization, and with the vehicles that routinely transmit and maintain culture, including classificatory culture.

Patterns of routine socialization are not the only considerations in explaining structures of credibility—indeed, the anthropologist who most closely studied the particular case in question laid greatest stress upon the supposed functions of Karam taxonomy in sustaining social order (Bulmer 1973)—but socialization is everywhere pertinent to giving accounts of what people find credible, whether the socializing agencies are those of Karam agricultural society or departments of zoology in modern American universities (Barnes 1972, p. 271). So, if the sociologist were to put a parallel classificatory question to an academic practitioner of modern Linnaean taxonomy, it is arguable that the responses received would structurally resemble those supplied by the Karam, and, again, patterns of socialization would be major aspects of any explanation the sociologist might offer of the grounds of credibility of taxonomic beliefs in our own expert culture. Note that the empirical adequacy of Linnaean classification is not thereby disparaged—though there is substantial controversy about its theoretical and evidential adequacy within expert taxonomic culture—but the sociologist of scientific knowledge holds that standards of empirical adequacy, and the particular goals towards which classificatory schemes are oriented, are themselves objects of socialization (Dean 1979). All institutionalized beliefs about nature are causally connected to reality, and 'all beliefs are on a par with one another with respect to the causes of their credibility. It is not that all beliefs are equally true or equally false, but that regardless of truth or falsity the fact of their credibility

is to be seen as equally problematic' (Barnes and Bloor 1982, p. 23, Barnes 1992). The 'paradigms' of what Kuhn called 'normal science' are exemplary items of technical knowledge, and they are also learned bits of culture. Since this culture is transmitted in authoritative institutions, the sociologist's whole range of resources for dealing with socialization and its consequences is, therefore, pertinent to explaining the credibility of technical scientific knowledge among expert practitioners (Polanyi 1958, Kuhn 1962, Barnes 1982).

3. *Accounting for Credibility: Mundaneness and the Moral Order*

So the sociologist of scientific knowledge studies credibility. What actors find credible, and how they account it credible, may include specially occasioned judgments of truth or they may not. The distinction is not crucial, since the credibility of any such reflective truth-judgments (by way of correspondence or coherence or any other criterion) may also be a matter for inquiry. The sociologist, qua sociologist, here differs from the philosopher (and maybe from the layperson): 'Instead of defining (knowledge) as true belief, knowledge for the sociologist is whatever people take to be knowledge,' what they find credible (Bloor 1976/1991, p. 5). And patterns of socialization are everywhere pertinent to giving a sociological account of the credibility of beliefs. These are, so to speak, ground-conditions for the sociological study of science, and, as such, they are not themselves answers but necessary conditions for arriving at particular answers to particular questions about particular bodies of knowledge—answers that are sociologically proper, constructive, and interesting. For sociologists to say that they are interested in credibility is not to say that they are concerned with a specific aspect or 'factor' bearing on knowledge. Credibility is not a factor in the sense in which, for traditional sociology of knowledge, 'class-allegiance' or 'religious affiliation' counted as 'social factors' contingently bearing upon knowledge—sometimes pertinent, sometimes not (e.g., Barber 1952, p. 60). Credibility is the state achieved when knowledge-claims become knowledge, and the means for achieving credibility are the assemblage of means by which knowledge-claims become knowledge. From a pertinent point of view, credibility is the only topic for the sociologist of knowledge. As the philosophers might say, credibility has a transcendental character for sociologists of knowledge: no credibility, no knowledge, no object of sociological study (Shapin 1995a, pp. 257–8).

It might also be said, no credibility, no moral order. To give an account of what a community finds credible, and how it comes to find it credible, is tantamount to giving an account both of what that community is and how it experiences the world (Douglas 1975, p. 238). So to say that sociologists of science should shift attention from truth to credibility is a way of orientating practitioners to the proper domain of inquiry, a way of discouraging them from arbitrarily limiting inquiry, and, finally, a way of reminding them of the potential pertinence of a range of social scientific and everyday resources that are available to give accounts of what people find credible.

No matter how highly valued or how technical the form of belief, the sociologist can usefully draw attention to the mundane means by which belief is made credible. In the ethnomethodological tradition, this was a maxim of method derived from the phenomenologists (especially Alfred Schutz) and from the later writings of Wittgenstein. Attention was to be directed to the 'behavior of seeking truth … the institutional and public character of truth, in contrast to the usual psychological and semantic descriptions that depict private disembodiments of that behavior.' For the sociologist, there is no other proper way of engaging with truth save through the study of what people collectively do: 'Truth resides in the rule-guided institutional procedures for conceding it.' In doing sociology, one should accept 'that there are no adequate grounds for establishing criteria of truth except the grounds that are employed to grant or concede it' (McHugh 1970, pp. 320–1, 333–5). This sensibility strongly influenced the ethnographic study of science that began to emerge in the 1970s, especially with the work of Collins and co-workers (Collins 1975, 1983, 1985/1992), but it also left a mark on historical studies of science concerned with how past communities established facticity, proof, and legitimate inference (e.g., Shapin 1994, Dear 1995, Porter 1995, Poovey 1998, Burke 2000).

If, indeed, the practices for making and maintaining credible knowledge are co-extensive with the moral life of a community, then there are very few aspects of that life which do not potentially bear upon the credibility of belief. It follows that there can be no simple and coherent master-recipe for how credibility is to be achieved or model for understanding it. Much will depend upon the items of knowledge in question, the precise scenes in which the knowledge is assessed, and the state of transmitted background belief. Truth—like God and the devil—is in the details, and the sociologist wanting to understand why it is that a specific individual, or group of individuals, finds the special creation of species, or Darwinian evolution, credible may find it pertinent to consider a long list of mundane, and even some apparently trivial, features of cognition and social interaction (Shapin 1999b, pp. 7–8, Lynch 1993, pp. 278–88), while much work in the sociology of scientific knowledge during the 1970s and 1980s pointed to differences in collective goal-orientations (or social interests) as pertinent considerations in judgments of the credibility of scientific claims (e.g., Shapin 1982, 1995b).

4. Accounting for Credibility: Economies of Trust

A large body of recent historical and sociological work has studied the means by which the veracity of scientific claims or the legitimacy of inference has been made persuasive. Because most natural knowledge—that possessed by experts as well as by the laity—is held on the basis of trust, deferring to others whose knowledge is understood to be more direct or competent, even belief in matters of fact has to be actively secured: how persuasively to communicate the experience to be credited? how linguistically (and gesturally) to display one's entitlements to trustworthy knowledge? Studies of both historical and present-day episodes have drawn attention to the rhetorical constitution of authorial transparency, virtue, and intellectual entitlements; to the rhetorical invocation of allies leagued with the author and of the consequences of giving or withholding assent; and to the range of rhetorical means by which authors in general seek to assist the translation of individual claims into collectively credible knowledge (Latour 1987, Shapin 1984, 1994; Dear 1995, Golinski 1998, Chap. 4).

Recognizing the ineliminable role of trust in the credibility of knowledge is consequential for two diametrically opposed reasons. First, many situations present themselves—both within science and between scientific experts and the laity—in which the relative trustworthiness of sources is in doubt or is contested. The role of scientific expert testimony in courts of law, for example, is one important setting in which lay jurors are set the task of finding the signs of credibility in conflicting scientific accounts, and some studies emphasize the role of common-sense procedures in that task—monitoring testimony for manner and its sources for biasing interest (Brannigan and Lynch 1987, Lynch and Jasanoff 1998). Wynne's (1995) work on the public understandings of science, and specifically on the credibility of environmental radioactivity risk-assessments, stresses the complex array of considerations that bear upon lay attitudes towards which scientists, and which scientific pronouncements, are trustworthy. Epstein's (1996) study of the relations between AIDS researchers and AIDS activists is a richly detailed investigation of the grounds of trust in a situation where the very identity of laypersons and experts has been made problematic. Porter (1995) has asserted the crucial role of 'trust in numbers' in modern, complex, and highly differentiated societies, in which, as he argues, personal and familiar warrants for credibility are lacking or deemed inadequate. Jasanoff has examined how trust in expertise is secured in modern environmental science where conflicts over credibility are endemic (Jasanoff 1992), and Hilgartner's (2000) work on a series of highly contested nutritional reports by the US National Academy of Sciences has drawn attention to the performative aspects of trust in modern expertise.

In the passages of modern 'extraordinary science' studied by Collins (1975), where the existence of specific physical phenomena and the competence of detecting instruments were simultaneously contested, members of a scientific 'core-set' reached out for a diverse array of contingent considerations to locate trustworthiness, and, therefore, to assess the credibility of technical claims: including the personal characteristics of claimants, the reputation of the institutions in which they worked, their allies, their track-records, etc. Historical studies of scientific controversy (Shapin 1994, esp. Chap. 6) have drawn attention to the imputed trustworthiness of the early modern gentleman in managing scientific controversy, in deciding the credibility of diverging claims, and even in deciding which controversies ought to be left undecided in favor of maintaining the interaction order.

In such lines of research, reposing trust in scientific claims and claimants appears as an actor's practical problem. Looking to see how and why actors reckon trustworthiness is a way of understanding how they deal with problematic credibility when experts disagree or when it is unclear who indeed is to count as an expert. There are plenty of such occasions in modern science, and especially in those sectors of science in which public participation in decision-making is mandated or pertinent. Is global warming a fact, and, if so, what is to be done about it? Who is to be believed about the risks of genetically modified foods and what policies should be framed for producing and labeling such foods?

Yet the second reason why trust is important in connection with scientific credibility is that the scientific community very often does speak—if not with one voice—then in a comparatively concerted way. Scientists in modern society are regarded as enormously trustworthy, and the credibility of what they concertedly deliver about the natural world is very great. Scientists are masters at trusting each other and they are masters at generating public trust in themselves. That is just another way of saying that consensual scientific knowledge is regarded in our society as the touchstone of truth. Scientific credibility may be an occasional problem, and a vitally important one, but it is also interesting to note how often in our culture the credibility of science does not manifest itself as problematic. Sociologists do not yet adequately understand how scientists achieve and maintain this trustworthiness and the resultant powers of professional credibility (Barnes 1985, Chaps. 2–3), but the consequences of this trustworthiness for the social and intellectual order of modern society cannot easily be exaggerated (Bauman 1992, p.71, Shapin 1995a). To understand the grounds of scientific credibility is to understand quite a lot about modern society. Scientific credibility is so blended into modern society's institutional life—its schools, universities, government, medicine, the military, and the media—that one cannot readily imagine credible science without the

institutions which maintain and transmit it, nor credible institutions without the knowledge which gives them much of their legitimacy.

Truth, Verification, Verisimilitude, and Evidence: Philosophical Aspects

The point of an inquiry is to get at the truth—not the whole truth, but the whole truth of some matter at hand. This truism generates the central problems of epistemology: What is truth? What kinds of things are true? How can we get at truth, or know when we have attained it? Will any old truth do, and is any old falsehood a failure?

1. *Truth and its Bearers*

Truth seems to be a simple affair. That snow is white is *true* if … well, snow is white! That snow is hot is *true* if … snow is hot! We know what it would take for snow to be white. A certain kind of stuff—flaky frozen water—has to have a certain appearance. So we know what it takes for it to be *true* that snow is white, and since the stuff has the appearance, it is true that snow is white. One could be forgiven for thinking that there's an end of it. The so-called redundancy theory of truth elaborates this insight (Ramsey 1927, Horwich 1990) although it is also the main motivation behind the so-called *correspondence* theory.

But what exactly are the bearers of truth and falsity? One answer is *sentences*. Sentences (grammatically correct strings of letters like 'Snow is white') appear familiar, unproblematic, concrete. Another answer is *propositions* (or whatever it is that sentences *mean*). These appear more abstract and remote than sentences. The 'linguistic turn' in philosophy, a widespread presumption against abstract entities, and Tarksi's ground-breaking definition of sentential truth (Tarski 1969), have all favored sententialism.

How many sentences are there on the next line?:

Snow is white. SNOW IS WHITE. *Snow is white*.

The answers, *one* and *three*, are both defensible. We distinguish *sentence types* (of which there is just one here) from *sentence tokens*, individual instances of a sentence type (of which there are three here). A type is not identical with any of its instances, or with a set of them. A set cannot change its members—its identity is given by its members—whereas the number of instances of a sentence type is in constant flux. A type, even a sentence type, is an abstract entity. That 'Snow is white' is true is a claim about the sentence *type*. So eschewing meanings in favor of sentences does nothing to rid the universe of abstract entities (Church 1956).

That 'Snow is white' is true is a fact about English, but the fact that snow is white is not. 'Snow is white' expresses a truth which can be expressed in other languages, suggesting *language-independent truths* (Frege 1984). Given continuous space–time the trajectory of a single particle generates nondenumerably many truths. Since any learnable language contains at most denumerably many sentences, the totality of truths outstrips the totality of sentences of any learnable language. So the *primary* bearers or truth cannot be sentences. Without meaning, it is obscure what the truth of a sentence would consist in. 'Snow is white' is true *in virtue of* its expressing something which in fact obtains. A meaningful sentence expresses a meaning and that, in conjunction with the state of the world, determines whether it is true or false.

2. *Verifiability*

To determine whether 'Snow is white' is true one must know what it means. And to know what it means one must know what the world would look like were it true. So meaning seems related to an ability to *ascertain* truth. The *verificationist theory of meaning*, the battle cry of the logical positivists, articulates this conviction: that a sentence is meaningful if and only if it can be verified by observational means (Schlick 1979).

The positivists took their inspiration from Einstein's analysis of simultaneity. In his 1905 relativity paper, Einstein argued that claims about simultaneity are physically meaningless until we agree on a procedure for determining simultaneity. Einstein supplied a verification procedure for 'A is simultaneous with B,' thereby precipitating a fundamental revolution in the physics of space–time. The positivists co-opted the approach to effect a similar revolution in philosophy (Schlick 1979). (Einstein later repudiated his early verificationism with the now famous put-down: 'One shouldn't tell a good joke twice.')

The verificationist theory serves the twin desiderata of positivism: endorsing science while disenfranchising

metaphysics, religion, and (perhaps embarrassingly) ethics. Sentences reporting observations ('There is a red patch in my visual field') are paradigmatically meaningful. Sentences like 'The Nothing nothings,' 'God is omnipotent,' and 'Torture is wrong' are meaningless, since there are no possible observations which could verify them.

Verificationism dovetails nicely with an uncompromising epistemology. A true sentence must be meaningful, hence verifiable, and so knowable. The facts cannot outstrip our means of discovery. This consequence attracted devastating criticisms, mostly leveled by the rigorously self-critical positivists themselves. For example, the theory deems scientific theories themselves meaningless, since they make wildly general claims. Newton's gravitational theory, for example, claims that any two masses anywhere in space–time attract each other. All the observational data that we will ever have is but a tiny fragment of the plethora of predictions the theory makes. Even a simple claim like 'metals expand when heated' goes beyond any finite amount of data. For this reason, scientific theories are unverifiable (Popper 1963).

This is a variation on Hume's notorious problem of induction. Whenever we make a prediction about the unobserved we go beyond what has been verified. But it is precisely because it does this that science is so interesting and useful. Science at its best gives us *depth*—profound and contentful theories which go far beyond the actual and possible data—and depth pulls away from the positivists' goal of *certainty* (Watkins 1984).

The positivists made special provisions for logical and mathematical truths, as well as philosophical claims like verificationism itself. These are not established by observation, for they are not *factual* claims at all. Rather, they are *analytic*—true in virtue of the meanings of constituent terms—like 'Bachelors are unmarried males.' Some can be obtained by analysis of meaning, others by deduction from established analytic truths. Deduction is justified by appeal to the meanings of logical terms such as 'and,' 'not,' 'all.'

A first cousin of verificationism is thus the doctrine that mathematical truth and provability coincide. The refutation of this also came from the ranks of the movement. Gödel proved that any consistent axiomatization of elementary arithmetic fails to yield some arithmetic truths. Given any such axiomatization, we can construct a true arithmetic sentence not provable in that system. Strengthen that system (perhaps by adding that very sentence as a further axiom) and you have a new system generating its own unprovable truths. Mathematical truth outstrips provability (Gödel 1986).

The verificationists tried weakening their core doctrine, but the accounts failed to endorse science while repudiating metaphysics. Verificationism has, somewhat surprisingly, experienced a recent revival in the guise of *antirealism* (Dummett 1978). This version of it is also motivated by the desire to cut content down to verifiable size, eschewing depth in favor of certainty, and it faces the same kinds of objections.

3. *Truth Conditions*

The standard counterexamples to verificationism are sentences with this feature: we know what it would take for them to be true, even though we have no way of verifying them. We do know what 'Metals expand when heated' *means* although it is unverifiable. The meaning of a sentence is given by the condition which would *render* it true, rather than to any procedure which would *verify* its truth. The *truth-conditional* theory of meaning is that the meaning of a sentence is its truth condition, not its verification condition.

One objection to abstract entities, like propositions or truth conditions, is that they do not have clear-cut criteria of identity. There is no criterion telling us when we are dealing with one or two or more such entities. Quine's slogan, 'no entity without identity,' demands we make do without them (Quine 1981). Carnap, perhaps the most important verificationist, laid the foundations for verificationism's successor: the possible-worlds account (Carnap 1947).

As it happens, it snowed in Boulder, CO, on 1 January 1999, but it might not have. The actual world is one complete way for the world to be, but it is not the only way it could be. It is not *logically necessary* that the world be the way it is. We countenance a space of different possibilities just one of which is actual. A claim divides the class of complete possibilities into two. It induces a *mapping* from the collection of complete possibilities (the logical space) to the two truth values. A set can be thought of as just such a mapping—it maps its members to a positive indicator (True), and nonmembers to a negative indicator (False). So a proposition is associated with a set of worlds. The possible-worlds account says there is no more or less to a truth condition than that (Lewis 1986). The account utilizes Quine's paradigm of a clear-cut criterion of identity—the identity condition for sets. Sets are identical just in case they contain the same members. Propositions (sets of worlds) are identical if and only if they contain the same worlds. We can now tap set-theory for a unifying account of many logical phenomena.

For example, entailment is standardly understood in terms of truth preservation: P entails Q if the truth of P guarantees the truth of Q. This becomes: P is a subset of Q. Transitivity of entailment falls out of the transitivity of the subset relation. Disjunction is set-theoretic union, conjunction is intersection, and negation is complementation. A proposition is (logically) possible if it is true in some world; impossible if true in no world; necessary if true in all worlds. Modal principles—for example, that the negation of a necess-

ary proposition is impossible—also fall out of set theory. Logical relations between sentences thus piggyback on the propositions they express. A proposition is true *simpliciter* if it contains the actual world, and a sentence is true if it expresses a true proposition.

Despite its explanatory power, this account cannot be the whole story. A necessary proposition is true in all worlds, but only one set of worlds contains all worlds. 'One plus one is two' expresses a necessary truth, as does 'Two is two.' Hence, on this account, these two sentences express one and the same proposition. However, the former expresses a mildly interesting truth about addition, while the latter expresses something trivial. Since what they express is different, what they express cannot be just a class of worlds. The account is too coarse-grained. While the sentential approach can make these fine-grained distinctions, it is *too* fine-grained. ('*Une piu une fa due*' expresses the same truth, in Italian, as 'One plus one is two,' but they are distinct sentences.)

There are a range of fine-grained theories of meanings which accommodate these distinctions without resorting to sentences (Bealer 1982, Tichý 1987). These theories do not need to dispense with possible worlds and some are built on them. Provided a proposition *induces* a mapping from worlds to truth values, even if it can not be *identified* with such a mapping, we can reap the benefits of the possible-worlds framework.

4. *Falsifiability*

That metals expand when heated is false in any world in which one piece of heated metal does not expand. Since we cannot check every piece of heated metal, the proposition cannot be shown to be true. By contrast, it *can* be shown to be false, or *falsified*. The observation of one nonexpanding piece of heated metal will do the trick.

Karl Popper (1963) was one of the first to stress the fallibility of scientific theories and the asymmetry of verification and falsification. If the positivists took inspiration from Special Relativity, Popper took it from General Relativity—specifically, its prediction of the bending of light near massive bodies. He was impressed that Eddington's eclipse experiment of 1919 could verify neither Newton's nor Einstein's theory, but could have refuted either, and actually refuted Newton's. Thenceforth he took falsifiability to be the hallmark of genuine science. Pseudoscientific theories (Popper's examples were psychoanalysis and astrology) are replete with 'confirming instances.' Everything that happens *appears* to confirm them only because they rule nothing out. Popper argued that genuine theories must forever remain *conjectures*. But science is still rational, because we can submit falsifiable theories to severe tests. If they fail, we weed them out. If they survive? Then we submit them to more tests, until they too fail, as they almost assuredly will.

There are three serious problems with falsificationism. First, it does not account for the apparent epistemic value of confirmations. The hardline falsificationist must maintain that the appearance is an illusion. Second, it cannot explain why it is rational to act on the unrefuted theories. Confidence born of experimental success reeks of inductivism. Third, pessimism about the enterprise of science seems obligatory. Although truth is the goal of inquiry, the best we can manage is to pronounce a refuted theory false. We return to these in succeeding sections.

Other criticisms stem from Duhem's problem (Duhem 1954). Duhem noted that predictions can be deduced from theories only with the aid of auxiliary assumptions. One cannot deduce the path of a planet from Newton's theory of gravitation without additional hypotheses about mass and position of the Sun and the planets, and the absence of other forces. It is not Newton's theory alone, but the conjunction of the theory with these auxiliaries, which faces the tribunal of experience. If the conjunction fails it is not clear which conjunct should be blamed. Since we can always blame the auxiliaries, falsification of a theory is impossible.

Quine generalized Duhem's point to undermine the positivist's distinction between factual truth and analytic truth. If no sentence is 'immune to revision' in the face of anomalies, no sentence is true simply by virtue of its meaning. Not even the law of excluded middle s sacrosanct, and meaning itself becomes suspect (Quine 1981).

Kuhn used Duhem to undermine the rationality of scientific revolutions. Since a theory cannot be refuted by experiment, it is not irrational to stick to it, tinkering with auxiliaries to accommodate the data. 'Normal science' consists precisely in that. A revolution only occurs when a bunch of scientists jump irrationally from one bandwagon to another. In Kuhn's famous phrase (which he later regretted) a revolution is a 'paradigm shift' (Kuhn 1962).

Feyerabend followed Kuhn, maintaining that proponents of different paradigms inhabit incommensurable world-views which determine their perception of the so-called observational 'facts' (Feyerabend 1993), thereby setting the stage for *constructivists* who maintain that science is a human construct (obviously true) with no controlling links to reality (obviously false). From constructivism it is a short leap into postmodernist quicksand, the intellectual vacuity of which has been brutally but amusingly exposed (Sokal 1996).

The more extreme lessons drawn from Duhem's simple point may sound sexy, but they do not withstand sober scrutiny (Watkins 1984). It is just false that each time a prediction goes awry it is one's whole global outlook that is on trial, and that one may rationally tinker with any element at all. In the nineteenth century, Newton's theory was well confirmed by myriad observations and applications, but it

faced an apparent anomaly in the orbit of Uranus. Because the theory was well confirmed, scientists looked to the auxiliary assumptions, such as the assumption that there are no unobservable planets affecting Uranus's trajectory. It was far more probable, in the light of the total evidence, that there should be an as yet unobserved planet in the solar system than that Newton's theory be false. It was eminently reasonable to postulate such a planet and search for it. The subsequent discovery of Neptune was a resounding success for the theory.

This rejoinder, of course, requires a positive account of probability and confirmation, one which falsificationism does not supply.

5. *Confirmation*

Having jettisoned verifiability, the positivists turned to the theory of probability to ground a rigorous logic of confirmation and induction, comparable to deductive logic (Carnap 1950).

The logical probability of a proposition is a measure of its area in logical space. It is a normalized measure, so the probability of the whole space (the necessary proposition) is 1; the probability of the impossible proposition, the empty set, is 0. Other propositions have a probability somewhere between 0 and 1, depending on the proportion of the space they cover. Conditional probability—the probability of P *given* Q, written $\Pr(P|Q)$—is a kind of generalized entailment and is defined as a ratio of unconditional probabilities: $\Pr(P\&Q)/P(Q)$. If Q logically entails P then $\Pr(P|Q)$ is maximal, 1. If Q is logically incompatible with P then it is minimal, 0. In between these cases, the closer P is to entailing Q, the closer $\Pr(P|Q)$ is to 1. Evidence E *confirms* hypothesis H just in case conditioning on E *raises* the probability of H: $\Pr(H|E) > \Pr(H)$. If H entails E, $\Pr(E) < 1$ and $\Pr(H) > 0$, then if E is verified, E confirms H.

Where do the logical probabilities come from? Carnap searched for plausible *a priori* constraints on logical probability. The most obvious is given by the principle of indifference: all possible worlds have an initially equal probability. Logic does not play favorites. Unfortunately, this measure yields counterintuitive results. If the universe is infinite, and the evidence consists of a finite number of reports of the expansion of heated metals, it does nothing to raise the probability of the hypothesis that metals expand when heated. Even if the universe is finite, no amount of such data will raise our confidence that the *next* piece of heated metal will expand.

The search was on for a measure that yields more palatable results. However, there is one rather pressing problem. If the universe is infinite, then there will be an infinite number of mutually exclusive possible theories pretty much on a par in the absence of evidence. So they should all receive the same initial logical probability, which must therefore be zero. Now no evidence can ever raise the probability of an hypothesis if its initial probability is zero. So confirmation is impossible.

Inductive logicians turned to the task of motivating initial probability distributions which would give differential finite weight to generalizations, but the upshot was an embarrassment of riches, a plethora of 'inductive methods' (Hintikka and Suppes 1966). The failure to motivate a single preordained measure of logical probability is not a fatal blow to confirmation theory, however. The probabilist can allow a range of distributions, reflecting distinct *subjective* degrees of confidence. *Bayesianism*, as the position is called, places two objective constraints on rational belief (Howson and Urbach 1989). First, one's degrees of belief must obey the probability calculus. Second, one must update degrees of belief by conditionalization on incoming evidence. Together these constraints motivate the convergence of rational opinion. Given suitable initial conditions, in the long run differences in initial distributions will be overwhelmed by incoming evidence.

The basic problem with Bayesianism, however, is that probability, like verifiability, strongly favors certainty over depth. The less content a theory has, the larger the region of the logical space it covers, and the more probable it is. The whole truth is just a tiny speck in logical space—the proposition which entails all true propositions is clearly the singleton of the actual world. Any deep theory which comes anywhere close to the truth will likewise be of very low probability. We want deep theories that are close to the truth. How can that be reconciled with the demand for evidential support?

6. *Truthlikeness*

Newtonian physics superseded Aristotelian physics, but it in turn was superseded by Einsteinian physics. Newton's theory is now known to be false. Does it follow that Newton did no better at realizing the aim of physical inquiry than Aristotle? If truth is the goal, are all falsehoods alike in being total failures?

Take a simple query: 'What is the number of the planets (Π)?' The ancients gave the false answer $\Pi = 5$, but the answer has been steadily revised upwards to $\Pi = 9$, and let us suppose that is the truth of this matter. $\Pi = 5$, $\Pi = 6$, $\Pi = 7$ and $\Pi = 8$ are all false, but each makes some progress towards the truth over its predecessor. We have here a sequence of four falsehoods which increase in their *truthlikeness* or *verisimilitude*.

Probability and truthlikeness are easily conflated. Subjective probability is, if you like, *seeming like* truth. Truthlikeness is *being similar to* truth. However, the two concepts are completely different. Probability is an epistemic concept, truthlikeness is not. $\Pi = 8$ is

closer to, more *like*, the truth ($\Pi = 9$) than $\Pi = 5$, completely independently of the evidence. Moreover, it remains closer to the truth even after the probability of both falls to 0 with the discovery of Pluto. So having minimal probability is compatible with great truthlikeness. Or consider the logically necessary truth. This is not only true but certain, but it is not close to the truth about Π. Having maximal probability is thus compatible with low truthlikeness. Now consider the following sequence of truths:

$$5 \leqslant \Pi \leqslant 9$$
$$6 \leqslant \Pi \leqslant 9$$
$$7 \leqslant \Pi \leqslant 9$$
$$8 \leqslant \Pi \leqslant 9$$
$$\Pi = 9$$

This sequence exhibits decreasing probability, but increasing truthlikeness. So probability and truthlikeness, like certainty and depth, tend to pull in opposite directions. A proposition cannot be close to the whole truth without being deep. It cannot be probable without being shallow. The whole truth (the proposition which is true in just one world, the actual world) is undoubtedly closest to the whole truth. It is the deepest, correct proposition. But on any actual measure of subjective probability it will have probability 0 or close to 0.

Popper was the first to realize the importance of the concept of truthlikeness (Popper 1963). Popper wanted to be a *realist* (truth might outstrip our means of discovery), a *fallibilist* (any general theory is likely to be false), and an *optimist* (we can and do make epistemic progress). If all we can say for sure is 'missed again!,' a miss is as good as a mile, and the history of inquiry is a sequence of such misses, then epistemic pessimism follows. But if some false hypotheses are closer to the truth than others, then realism and fallibilism are compatible with optimism. The history of inquiry could turn out to be one of steady progress towards our goal, and there may be empirical indicators of that.

Popper also formulated the first rigorous account of the notion, in terms of the true and false consequences of theories. According to Popper, a proposition P is closer to the truth than Q if P entails more truths than Q, and no more falsehoods (or, fewer falsehoods, and no fewer truths). Unfortunately, this elegant theory implies that no false theory is closer to the truth than any other. (Surprisingly it took nearly 10 years before this defect was noticed (Miller 1974, Tichý 1974).) Let G be some truth implied by P but not by Q, and let F be any falsehood implied by P. Then F&G is a falsehood implied by P, but not by Q. (If Q implied F&G then Q would also entail the second conjunct, G—contradiction.) We cannot add truths to P without adding falsehoods (also, we cannot subtract falsehoods without subtracting truths).

A different approach takes the *likeness* in truthlikeness seriously, meshing this with a possible-worlds approach to propositions (Tichý 1974, Hilpinen 1976, Oddie 1986).

Suppose possible worlds exhibit degrees of similarity to one another, and distance between worlds is a measure of dissimilarity. If we could find a natural and plausible way of measuring the distance between subsets of the space we would have a measure of distance between propositions. Suppose T is the whole truth about some matter (as $\Pi = 9$ is the whole truth about the number of the planets). Answers to a query, whether partial (like $7 \leqslant \Pi \leqslant 9$) or complete (like $\Pi = 7$), would then be ordered by their distance from the truth ($\Pi = 9$). This provides a schema for a theory, the details of the similarity metric and of propositional distance to be filled in.

There are two important criticisms of this likeness approach. First, any similarity metric is sensitive to the set of properties deemed salient (Miller 1974). If all possible attributes are salient, then distinctions of similarity collapse. So if the selection of attributes is to be objective, then some properties must 'carve nature at the joints.' That involves a robust version of realism about properties, but one the scientific realist might not mind embracing (Armstrong 1978).

Second, a dilemma: if we know the truth we do not need truthlikeness; and if do not know the truth we cannot know which theories are truthlike. Either way the concept is a useless addition to our intellectual armory.

Both horns are weak. First, even once we have attained the truth it is interesting to trace our history of attempts to reach it, and characterize the progress. Second, even though degree of truthlikeness is typically an unknown magnitude, with a measure of probability we can *estimate* its value in the usual ways. Expected degree of truthlikeness is epistemically accessible. Truthlikeness would then dovetail nicely with decision theory. Suppose there are cognitive utilities, just as there are noncognitive utilities. The point of inquiry would be to maximize cognitive utility. The best cognitive state to be in is, Godlike, to embrace the whole truth—the proposition with maximal truthlikeness. Embracing propositions far from the truth is cognitively bad. So it is natural to identify cognitive utility with degree of truthlikeness. However, the injunction to maximize objective cognitive value does not provide a *selection* procedure since, as in the practical case, we have no direct epistemic access to states with high utility. So we must be guided by *expected* cognitive utility preferring those theories with higher *expected* truthlikeness (Niiniluoto 1987).

7. *Conclusion*

This decision–theoretic approach is an interesting compromise between the positivists's concern with

truth and probability and the falsificationist's apparently conflicting concern with depth. But as so often happens, this offspring exposes defects in both its parents. The positivists were misguided in concentrating on truth and probability. A theory can be true and have high probability and yet very low truthlikeness. The tautology is an extreme example, but trivial contingent truths can be very well confirmed, and still be far from the truth. Being true, or being likely to be true, is not where the action is. Such theories may lack depth. But the falsificationists were wrong to demonize falsity and exhalt falsification. A false and falsified theory can still be close to the truth, with good evidence that it is so (Newton's theory). Falsifying a theory shows it is not the best, but the best theory is not the only good theory. A falsehood may not hit the bullseye, but it can come very close.

Coherent defensible accounts of truth, probability, and truthlikeness can be combined. The goal of inquiry is the whole truth. Actual progress occurs when truthlikeness increases. The epistemic indicator of truthlikeness is expected truthlikeness. This can be high even when a proposition is refuted, low even when it is confirmed. The conflict between the depth and certainty poles, between which epistemologists have been oscillating for 400 years, can thus be resolved.

Tversky, Amos (1937–96)

1. Amos Tversky

Amos Tversky was born in Haifa, Israel, on March 16, 1937. His father was a veterinarian, his mother a member of Israel's Parliament, the Knesset. He fought in Israel's 1956, 1967, and 1973 wars, and received its highest honor for bravery. He received his BA in psychology at the Hebrew University of Jerusalem, in 1961. In 1965, he received his Ph.D. from the University of Michigan's mathematical psychology program. He worked there with Clyde Coombs (his

doctoral advisor), Ward Edwards, and David Krantz, among others. He returned to Jerusalem as a faculty member in 1967, moving to Stanford in 1978. A year at the Center for Advanced Study in the Behavioral Sciences provided Tversky and Kahneman with concentrated time to develop their approach to judgment under uncertainty.

Tversky died of melanoma, on June 6, 1996, in Stanford, California. At his death, he was Professor of Psychology at Stanford University, where he was also a Principal of its Center on Conflict and Negotiation. He held positions at Tel Aviv University, as Visiting Professor of Economics and Psychology and Permanent Fellow of the Sackler Institute of Advanced Studies. His wife, Barbara, is Professor of Psychology at Stanford, studying perception. He had three children, Oren, Tal, and Dona. He was known for his great energy, joy of life, and sense of humor.

Tversky made fundamental contributions to the understanding of human thought processes, and the mathematical foundations of the behavioral sciences. His work was distinguished by elegant formal models, tested in simple, illustrative experiments. Throughout much of his career, he worked together with Daniel Kahneman, on studies of judgment and decision making under conditions of risk and uncertainty. On these topics and others, he also collaborated with other scholars from psychology, economics, political science, law, statistics, philosophy, and mathematics. These projects, and the personal interactions surrounding them, helped to integrate these disciplines, at a time of increasing specialization. Among his many honors were the Distinguished Scientific Contribution Award of the American Psychological Association, a MacArthur Fellowship, and honorary doctorates at Yale, Chicago, Göteborg (Sweden), and New York at Buffalo. He was a member of the US National Academy of Sciences. It served as one venue for pursuing his life-long commitment to encouraging peace and understanding among diverse people.

2. *Axiomatic Theories of Choice*

An early paper (Tversky 1969) typifies his approach. Normative theories of choice provide rules that individuals should follow, in order to make effective decisions. The most prominent of these is utility theory, founded on a set of intuitively appealing axioms. It describes options in terms of a set of attributes, or features, that an individual might like or dislike about them. When buying a car, the attributes might be (price, size, styling, reliability, comfort). According to utility theory, an individual should consider all relevant attributes, then rank the options according to their attractiveness (or 'utility'). That ordering should have the property of *transitivity*. Someone who prefers Car A to Car B and Car B to Car C should also prefer Car A to Car C.

Transitivity is a decision-making norm that most people would endorse. If it accurately described their behavior, they would be better off. So would scientists and policy makers. The former would find it relatively easy to predict behavior, knowing that there is a stable overall ranking, which can be identified without examining every possible paired comparison. The latter would be able to create policy options (e.g., parks, housing, insurance schemes, transportation systems), knowing that the public's response will be relatively predictable and consistent.

Tversky showed systematic violations of transitivity, with experimental tasks, similar to choices encountered in everyday life. Moreover, he went beyond merely showing that utility theory described behavior imperfectly. Such a limited demonstration could have been easily attacked as a destructive curiosity that does little to help scientists do their job of explaining and predicting behavior. However, Tversky showed that intransitivity arose from essential psychological processes, which he captured in a simple, but insightful model. These processes reflect the limits to human information processing capacity. In situations without the opportunity for trial-and-error learning, people can at best be boundedly rational, working in an orderly way on a subset of the problem (Simon 1957).

The coping process that Tversky proposed has people comparing options initially on the most important attribute (e.g., car price), then checking whether differences on the second attribute (e.g., reliability), and perhaps others, are so great as to change the choice. For example, imagine sequential comparisons between overlapping pairs of cars (A with B, B with C, C with D, and so on). The sequence is arranged so that each new car is both cheaper and less reliable that the previous one. Looking primarily at the price would make each new option more attractive, while the reductions in reliability slowly mount up. At some point, though, if the first car were compared with the last car, a buyer might decide that reliability has gotten so low that the reduction in price is insufficient compensation. In that case, the first car, which was long ago rejected, would suddenly be preferred.

Such intransitivity could, in principle, turn people into 'money pumps,' willing to pay something to move from one option to the next, but eventually going back to the first option and starting over again. As Tversky noted, car salespeople may exploit this cognitive weakness by adding options (and costs) to a favored car. Unlike the experimenter, though, they hope to stop just short of the point where customers balk at the increased price and revert to the stripped-down model. Hanson and Kysar (1999) discuss the implications of such exploitation for marketplace regulation.

Two themes in this research recur in Tversky's work. One is that choices, especially novel ones, can be very sensitive to how the options are presented. That insight is central to prospect theory (see below), which

also provides expression for results from a long tradition of psychological research into 'context effects.' The second theme is that descriptively valid formal theories of human behavior should be assembled from psychologically plausible assumptions, rather than derived from normatively postulated principles.

The latter insight is expressed in many of Tversky's projects, which articulate the formal structure of particular choice situations in ways that allow the expression of plausible behavioral responses (e.g., Tversky 1967, 1972). In some cases, these theories adapted existing mathematical approaches. In other cases, they drove the mathematics. The fundamental mathematical research associated with this research is summarized in three landmark volumes (Krantz et al. 1971/1989/1990). The study of alternative choice rules for dealing with multiattribute options has become a cornerstone of a *conjoint measurement*, a family of procedures used widely in applied research (e.g., marketing multiattribute consumer products).

3. *Prospect Theory*

These strands of research came together in Kahneman and Tversky's (1979) 'prospect theory.' Published in a central economics journal, it offered an alternative to utility theory, the core of that discipline. It claimed to achieve greater descriptive validity—but at the price of abandoning the normative aspirations of economics. It depicted individuals as thinking in an orderly, sensible way when faced with choices. However, the rules that people follow differ from those prescribed by the axioms of utility theory, in ways that produce systematic violations. People are sensitive to features of choice tasks that have no representation in utility theory, and insensitive to features that are in the theory.

Superficially, prospect theory resembles utility theory. 'Prospects' (i.e., options) are represented as sets of possible consequences. The value (rather than 'utility') assigned to a prospect is the sum of the values assigned to each consequence, weighted by the chances of it happening. However, the components of this evaluation differ from their utility theory analogs in ways designed to make the theory more realistic psychologically (Tversky and Kahneman 1991):

(a) The evaluations are made relative to a *reference point*, rather than with respect to an individual's *net asset position* (or entire worth). That reference point is typically the status quo. However, it could be another salient value (e.g., evaluating a raise relative to what one expected to get or to what others got, rather than relative to one's current salary). This feature of prospect theory reflects people's widely observed sensitivity to changes.

(b) People care less about a given absolute difference in gains or losses as the overall change increases. The idea the people care less about a fixed gain as they have or win more is shared with utility theory. However, the idea that people care proportionately less as losses mount up is not. Utility theory explains insurance buying (among other things) in terms of people's special aversion to large losses. Prospect theory reflects the psychological principle that the just-noticeable difference between situations is greater when the overall change is larger—whatever the direction of change.

(c) Before being combined with value judgments, the probabilities of the consequences are subjected to a 'probability weighting function.' It reflects the observation that people pay particular attention to sure things, while being relatively indifferent to probability differences in the middle range (e.g., the difference between 0.35 and 0.45 matters less than that between 0.90 and 1.00).

As combined in the theory, these principles (along with some others) predict (among other things) *framing effects*. Changing the reference point can reverse choices, in ways that have no reflection in utility theory (which has no such point). For example, an emergency medical intervention that could save 200 of 600 possible lives is more attractive when described in terms of the 200 lives saved than the 400 lives lost. Prospect theory's challenge to utility theory evoked vigorous responses. One extreme involved radical methodological skepticism. Partisans attacked any aspect of prospect theory's research method that could, conceivably, have contributed artifactually to behaviors offered as evidence supporting the theory. Although some of these critiques were ad hoc claims, disconnected from the research literature, others raised fundamental questions with theoretical and methodological implications.

One such question concerns the conflicting norms of experimental economics and experimental psychology regarding the provision of financial incentives. Economists typically believe that what people say and do has little meaning, unless they are rewarded for their performance. In this view, even if they are systematic, responses to hypothetical question could reflect no more than acquiescence to implicit task demands. In contrast, psychologists typically view all behavior as 'real,' with the attendant challenge of determining how individuals have construed their task. Even a hypothetical choice can induce high intrinsic and extrinsic motivation, as individuals try to impress themselves and those watching them. Camerer and Hogarth (1999) summarize the evidence, regarding the varied impacts of monetary rewards on decision-making performance. The other extreme involves economists who accept the validity of prospect theory's results and attempt to reshape their science in its light. Some have examined its implications for the axiomatic basis of utility theory, either by refining those axioms to fit the data better or by replacing them with ones expressing different normative principles.

Others have examined the expression and implications of non-rational behavior in real-world circumstances, prompting new fields like behavioral finance, which questions widely accepted efficient market theories.

Still others have sought to help people reduce such inconsistencies in their preferences. These 'constructivist' approaches assume that people's inconsistencies arise because evaluating options requires an inferential process, whereby people derive a specific valuation from more general, basic values. If that process is incomplete, then people will be unduly influenced by the initial problem presentation. Reducing that risk requires a more interactive process, explicitly considering alternative perspectives—trying to balance those suggestions, so that people come to know what they want. Fischhoff and Manski (1999) show the convergence among economists and psychologists concerned with these questions.

4. *Judgment under Uncertainty: Heuristics and Biases*

For economists and psychologists concerned with decision making, values are a matter of personal preference. As a result, showing them to be suboptimal means demonstrating inconsistencies. With beliefs, suboptimality can be found by comparing judgments to one another (looking for inconsistency) and to an accepted external standard (looking for error). In their first collaboration, Tversky and Kahneman (1971) demonstrated errors in the judgments of mathematical psychologists and statisticians, when estimating the statistical power of research designs. These individuals knew how to perform the relevant calculations. However, when forced to rely on intuition, they systematically exaggerated the chances of observing anticipated results—acting as though the law of large numbers applied to samples with small numbers of observations.

Tversky and Kahneman (1974) proposed that these judgments arose from relying on the *representativeness* heuristic. According to this rule of thumb, an event is judged likely to the extent that it captures (or 'represents') the salient features of the situation that might produce it. Conversely, reliance on representativeness should lead to neglecting factors lacking a salient role in such processes, even if they are normatively relevant. Sample size is such a factor. If a situation can produce an event, why should it matter how much one observes? A second normatively relevant factor with no role in representativeness is the relative frequency of an event in the past. Such *base-rate* (or *a priori*) information should guide predictions unless there is strongly diagnostic *individuating* information, showing why a specific case is different from the norm. (Medical students are sometimes told, 'When you hear hoof beats, think horses, not zebras,' at least in North America.) However, studies have found that even flimsy evidence can attract the lion's share of attention. It is natural to think about how well someone fits the image of an engineer (or how much a mammogram image looks like a tumor). It is not so natural (or easy) to combine that vision or theory with a statistical summary of how frequent engineers (or tumors) are in the population. There have been many subsequent demonstrations of underweighting base rates (including in the interpretation of mammograms), as well as vigorous debate (sometimes with data, sometimes not) regarding the conditions determining its extent (Gilovich et al. in press, Kahneman et al. 1982).

Analogous reasoning led to predicting that reliance on representativeness would encourage underestimating regression to the mean and exaggerating the predictability of random sequences. The latter was demonstrated in studies showing an illusory belief in being able to identify streaks in basketball free-throw shooting. Both collegiate and professional players (and fans) interpreted patches of random sequences as reflecting transient 'hot hands' (Gilovich and Tversky 1985).

Tversky and Kahneman (1974) proposed the representativeness heuristic as one exemplar of a general strategy that people use when confronted with unfamiliar tasks (and no opportunity for systematic study or calculation). A second such heuristic, *availability*, judges the probability of an event by the ease with which examples come to mind. That rule has some validity (in many domains, things that one hasn't seen tend to be less likely than things that one has). However, it can predictably lead one astray, as when the news media disproportionately report one risk (e.g., homicide vs. asthma) (Slovic 1987). Subsequently, Tversky and Koehler (1994) formalized the relationship between evaluations of evidence and probability judgments in 'support theory.' Like its predecessors, it predicts the conditions under which simple, intuitive thought leads to good and bad judgments. A third heuristic, also with historical roots in psychology, is *anchoring and adjustment*. Users begin an estimation process from a salient value (the 'anchor'), then adjust from there, in response to other concerns that come to mind. Typically, that adjustment is insufficient. If the anchor is far from the correct value, then the resulting estimate will be as well.

One cross-cutting theme in Tversky's judgment research (as with that on choice) is questioning the normative standards used to evaluate people's performance. Here, too, the result has been reevaluating those standards and their domains of applicability (Shafer and Tversky 1985). Another recurrent theme is the importance of comparison processes in judgment. Representativeness asks how well an event fits the process that would have to produce it. Availability asks how well an example fits the archetype of the category whose probability is being predicted. In a parallel research program, Tversky (1977) created a

theory of similarity judgments, based on measure-theoretic concepts and, again, simple, elegant experiments.

U

Unconscious: History of the Concept

The history of the concept of the unconscious in western thought will be discussed in three phases of its development:

(a) from as early as the sixth century BC to the seventeenth century, when the concept was not usually distinguished from other, wholly metaphysical concepts in which it was embedded;

(b) the beginning of the attempt, under the influence of Descartes, to distinguish the concept of the unconscious from its metaphysical moorings, and to submit it to scientific examination;

(c) the modern period, in which the concept very commonly is assumed by researchers in the social sciences despite doubts by some about whether the concept's separation from its metaphysical origins is, or ever can be, complete.

1. Metaphysical Beginnings

The idea that people are sometimes unaware of their own mental processes while they are going on and may even be incapable of later retrieving them introspectively, has had a long life of its own independent of and prior to its uses in modern experimental psychology, psychoanalysis, cognitive science and linguistics. However, the idea's early occurrences do not appear tagged by a single term translatable as 'the unconscious'; rather, the idea commonly occurs as a corollary of (a) the rationalist doctrine of innate ideas, and more broadly, of (b) the even more ancient idea of the microcosm, the traditional world-view according to which each mind contains the universe, in miniature, within itself (Levy 1967). Since the microcosm concept can be thought of, at least in part, as the view that all ideas are innate, the rationalist doctrine, for example, of Descartes, for whom only some ideas, e.g., of God, or of thought, are innate, is implied by, but does not imply the microcosm view.

Since, presumably, human subjects are never consciously aware of having all ideas within their minds, the concept of the unconscious is implicit in the idea of the microcosm; and to the extent that one might never consciously reflect on (what Descartes meant by) the idea of God or of thought, the concept of the unconscious is implicit in the doctrine of innate ideas, as well. However, rationalists often accepted the microcosm model, too, as for example, Leibniz, who writes of souls that they are 'perpetual living mirrors,' each representative of the entire universe; and Plato, who used the example of a young slave untrained in geometry, led only by questioning to the discovery of a mathematical truth, to show the boy 'recovering the knowledge out of himself' where the possibility of this 'recovery of knowledge,' (*Meno*, 85D), which Plato called recollection (*anamnesis*), rests on the claim that '… as all nature is akin, and the soul has learned all things, there is no reason why we should not, by remembering but one single thing … discover everything else (*Meno*, 81C-D). Since neither Plato nor Leibniz meant to say that any human subject could consciously experience themselves 'mirroring' the universe or consciously recall having known the recovered mathematical truth at some earlier time, the concept of the unconscious implicitly employed by them is a thoroughly metaphysical one.

2. Descartes and the Beginning of Scientific Scrutiny

Descartes's views require separate comment, since, unlike Plato and Leibniz, he had no attachment to the microcosm concept; yet although he had no difficulty with the existence of unconscious mental states insofar as his doctrine of innate ideas implied them (Cottingham 1998), he has nevertheless gained the reputation of having defined them out of existence as a consequence of his mind-body dualism and his supposed identification of conscious awareness as the essential attribute of mind. Whyte goes so far as to write, 'Descartes … by his definition of mind as awareness, may be said to have provoked as reaction, the European discovery of the unconscious mind … Descartes … had no clear conception of the unconscious mind, for to him all that is unconscious is physiological' (Whyte 1962, p. 80). But it is thought, not awareness that Descartes defines as essential to mind (*Meditation II*), and Descartes takes seriously the possibility, concerning his ideas of the external world, that there is some 'faculty not yet fully known to me, which produces these ideas without any assistance from external things; this is, after all, just how I have always thought ideas are produced in me when I am dreaming' (*Meditation III*). Such a faculty in him, by implication unconsciously active, apparently would need an intellectual substance to inhere in (*Meditation VI*), so it cannot, presumably, be purely physiological in nature. What finally persuades Descartes that such a deceptive and unconsciously acting

mental faculty does not exist is not the thought that the idea of it is incoherent in itself (as would be natural if his view were as Whyte supposed), but rather that once God's existence has been proved, the existence of that faculty is incompatible with God's perfect goodness (*Meditation V*).

What it was in Descartes's philosophy capable of provoking the somewhat desperate efforts to defend the as yet unnamed (Whyte 1962, pp. 25, 60) concept of the unconscious against him can more properly be found in his rejection of the comforts of the microcosm model, and his insistence on accepting as true only things that are clearly and distinctly perceived, things for which there are 'sure signs' (*Meditation I*). For when such a standard is applied to the concept of the unconscious, its defenders as well as its detractors are at least temporarily at a loss, since no-one then knew, nor is there complete consensus even now, as to where the defining line separating conscious from other mental states is to be drawn. How exactly it can be proved that an unconscious part of the mind exists in reality, i.e., that it is more than a mere conceptual possibility (if even that), and what sure signs ought to be required of specific contents in it, remain subjects of debate. The contrast on these points with the conscious mind and its states appears quite stark. It was Descartes who first made necessary the project of attempting to separate the concept of the unconscious from the metaphysical moorings that had until that time shrouded it from scrutiny. The concept of the unconscious was itself about to enter consciousness. The search was on for its manifestations in empirical phenomena that could be examined in a scientific way.

3. *The Modern Period*

By the end of the nineteenth century, a wide range of psychological phenomena had been identified as seeming to need unconscious mental activity for their explanation; ordinary perception and habit-formation, hypnosis and post-hypnotic suggestion, dreaming and neurotic symptom-formation, to name a few. According to James (1890), however, all such 'proofs' of the existence of the unconscious would fail, since the very idea of the unconscious mind is an 'unintelligible and fantastical' notion, and more parsimonious explanations of the phenomena in question are in all cases available, e.g., explanations in terms merely of (a) 'brain-processes to which no ideation seems attached,' (b) 'perceptions and volitions … performed consciously, only so quickly and inattentively that no *memory* of them remains,' or (c) 'split-off' consciousness, without any reference to unconscious mental activity having to be invoked. By the end of the twentieth century, the range of psychological phenomena offered in support of the concept of the unconscious had expanded to include language acquisition and 'subliminal perception,' 'blindsight,' and cognitive dissonance and self-perception attribution processes (Nisbett and Wilson 1977). However, skeptics have continued to doubt the existence of unconscious mental activity entirely, for reasons roughly similar to those laid down by James, though with more sophisticated arguments (Searle 1992, Strawson 1994).

There is here an evident lack of prior agreement about what conditions a phenomenon must meet for it to be a genuine instance of unconscious mental activity; one side of the debate assumes that more (and more exotic) examples are needed to make their case, while the other side is already committed to the view that no possible example can succeed. At least it can be said of those who use the sorts of cases mentioned to support the existence of unconscious mental activity that they agree about what criteria determine the contents of the unconscious in any given case, and of what those contents are; there is, e.g., no dispute among them about what stimulus is unconsciously perceived in any given subliminal perception experiment, or what forgotten order the subject is obeying in posthypnotic suggestion even if there are many questions about the way these stimuli are unconsciously processed.

By contrast, the psychoanalytic evidence raises different problems on this point, since there is no agreement concerning what Freud thought the criterion of truth in psychoanalysis is, and of what the consequences of adopting one criterion or another would be. It is widely supposed (e.g., by Grünbaum 1984, Rey 1998) that Freud thought therapeutic success is the only (or best) evidence of the correctness of psychoanalytic interpretations. The acceptance of such a criterion of correctness seems to leave Freud vulnerable to the well-known criticism that therapeutic success could as easily be due to suggestion or placebo effects as to interpretive truth. By contrast, Wittgenstein (1966) and Levy (1996) attribute to Freud the view that assent by the subject of an interpretation is ultimately the sole, or main criterion of its correctness. Which criterion Freud accepted, and which he ought to have accepted, are questions impossible to settle here; however, in favor of the assent criterion as the answer to both questions, it can be said first that the assent criterion seems more in accord with Freud's own most extensive discussion of the matter (Freud 1937). Indeed, he even considers there the possibility that in some cases the mark of a true 'construction' will be that the patient's symptoms and general condition are not improved but rather aggravated (Freud 1937, p. 265). In addition, that criterion also allows interpretations to be true outside the therapeutic situation, where the danger of suggestion and placebo effects can more easily be avoided. Of course, in cross-cultural anthropological testing of non-individual psychoanalytic hypotheses (e.g., on the Oedipus complex, Whiting et al. 1958, Stephens 1962, Spiro 1982), neither the assent nor therapeutic success cri-

terion is directly applicable. Lastly, it is wishes and ideas, for Freud, that inhabit the unconscious, not desires and beliefs (Freud 1893, p. 251, 1895, p. 10, 1915a, p. 152, 1915b, p. 178). However, ideas and wishes, whether conscious or unconscious, lack the tight connection with behavior to be found in desire and belief; it is plausible to say, in many cases at least, that the character of a subject's ideas and wishes is ascertainable only by way of the assent and self-ascription the subject provides, whereas the comparable claim about desires and beliefs would have very little plausibility. This provides further evidence that Freud accepted the assent criterion, after all.

Regardless of which criterion is accepted, the question remains whether unconscious ideas and wishes as referred to psychoanalytically provide genuine exceptions to James's requirements. Without trying to resolve this matter here, it should be noted that the presence or absence of a brain-process cannot hinge on the assent of the person whose brain it is; so if the assent criterion were assumed, explanations of James's type (a) would be foreclosed. How, if at all, unconscious contents as psychoanalytically interpreted, might also elude his explanation types (b) and (c) remains to be seen. More broadly, whether psychoanalytic interpretations are capable of being tested experimentally, and how (if at all) to resolve the difficulties that arise when such testing is attempted are also unanswered questions (Edelson 1984, Erdelyi 1985, Erwin 1996).

Underclass

The term 'underclass' has found its way into the common vernacular to describe a subset of the poor whose cultural traits are thought to be at odds with the rest of society. Its use, however, has been the subject of much scholarly debate, not only the meaning of the term and its value as a social category, but also the social processes that generate and reproduce those segments of the poor population that fall under the label. The outcome of these debates has important implications for finding a lasting solution to the problems of those at the very bottom of the urban social structure.

1. The Poor are Different

Distinguishing between the poor based on cultural differences has a long history in industrialized countries. For decades, the British establishment

raised public concerns about whether 'the rabble,' 'dangerous classes,' 'lumpen,' or 'vagrants,' were morally unfit and a potential threat to social order. They were often contrasted with others who, despite their poverty, more or less conformed to the social expectations of the upper and middle classes. Similarly, in the USA, early poor laws distinguished between the incapacitated poor and the able-bodied. This distinction restricted the amount and type of public aid the latter could benefit from and also differentiated the poor in terms of 'deserving' and 'undeserving' subgroups (Katz 1989).

With the advent of the industrial revolution, European social scientists began to think of the poor as victims of the technological revolution, which was changing the way work, especially manual labor, was being performed. These notions found their way to the USA and resulted in a great deal of thoughtful inquiry about the causes and consequences of persistent poverty. The recent 'underclass' label was first used in the USA by Gunner Myrdal, a European economist, in the context of theorizing about the increasing polarization of American society (Myrdal 1962). Myrdal observed that a growing segment of the poor, because of a paucity of marketable skills and lack of access to institutional supports, such as adequate schools and government support, were being consigned to the bottom of the class structure, if not outside it altogether.

Myrdal's initial insight into the structural underpinnings of the underclass was given new life by Wilson (1978), who used the term to call attention to the growing disparity between the middle class and chronically poor, urban blacks who suffered the brunt of the deindustrialization visited on northern US cities in the preceding years. Wilson (1987) later refined his definition of the underclass to describe a 'heterogeneous grouping of families and individuals who are outside the mainstream of the American occupational system … individuals who lack training and skills and either experience long-term unemployment or are not members of the labor force.' Without denying the existence of maladaptive culture, Wilson argued that this was 'a response to social structural constraints' which proliferate in areas of concentrated poverty. Apart from Glasgow's provocative book, *The Black Underclass* (1980), which affirmed the complex relationship between economic restructuring, long-term unemployment, and prosocial orientations, few liberals sought to highlight this relationship.

Reviving acrimonious debates between liberal and conservative scholars over the relative merits of cultural versus structural explanations of poverty which raged in the USA in the 1960s and 1970s, conservative explanations for the existence of an underclass focused on the cultural deficiencies of the poor. In *The Underclass*, journalist Ken Auletta (1982) underscored the character flaws of this subgroup of the poor. Other publications such as George Gilder's (1981) *Wealth and Poverty*, Charles Murray's (1984) *Losing Ground*, and Lawrence Mead's (1986) *Beyond Entitlement* also characterized the underclass in terms of cultural inadequacies and a predilection for idleness, dependency, and deviance.

Undoubtedly, these publications resonated with the public's difficulties in understanding the escalating rates of personal and property crimes in the major cities of the USA, despite the hundreds of millions of dollars that were spent to combat urban social problems during the 1960s and 1970s. Public discomfort was also fueled by journalistic accounts with lurid descriptions of depravity, squalor, and crime among the urban poor (*Time* 1977). Several empirical assessments of the size and growth of the underclass did appear during this time, but for the most part, rather than help to draw attention to the underlying causes of chronic poverty, these studies contributed to the perception that the underclass were, as a group, synonymous with deviant practices (Ricketts and Sawhill 1988, Lehmann 1986, Nathan 1987). Growing public opinion that the poor were incapable of self-regulation gave credence to those who argued for more punitive policies rather than incentives and assistance (Katz 1993).

Concern about the existence of an underclass has not been limited to the USA. Recent social, economic, and immigration trends occurring in the UK have resulted in a great deal of speculation about whether they portend the emergence of a British underclass. Initial attempts to chronicle the rise of a highly disadvantaged, heterogeneous group focused on issues of class inequality and citizenship rights. Dahrendorf (1985) argued that the defining characteristic of the underclass in that country is the marginal status of the group in terms of its representation by, or involvement in, social and political organizations, a marginalization which has largely occurred because of macroeconomic shifts and contractions in the welfare state. Unlike in the USA, however, the British underclass is less likely to be spatially segregated in high-poverty urban areas.

More recently, the discussion has centered on amoral and deviant behavior as the root cause of persistent poverty, a turn influenced in part by American conservative thought, especially that of Murray (1990). As in the USA, research on the effects of structural barriers and economic marginality must compete with postulations about whether the chronically poor are different in character and comportment.

2. *The Relationship Between Economic Restructuring and the Urban Underclass*

Proponents of the structuralist approach claim that culture-centered explanations of the underclass fail to sufficiently acknowledge the role played by the social

transformation occurring in many US inner cities during the 1960s and 1970s. New social and economic conditions in the nation's oldest cities were creating a confluence of forces which were effectively isolating a subsection of the poor from the rest of society. Economic restructuring in urban areas in the northeast and midwest brought about a dramatic decline in demand for low-skilled workers in the goods-producing sector of the economy, which disproportionately hurt poor unskilled black male workers and helped to elevate poverty rates in inner-city neighborhoods.

The out-migration of nonpoor families also contributed to the growth of concentrated inner-city poverty. Encouraged by technological advances, improvements in transportation, and increased employment opportunities outside of metropolitan areas, whites, by 1968, had already begun their out-migration from the inner cities. In addition, because of the Civil Rights Acts of 1964 and 1965 and the Fair Housing Act of 1968, oppressive restrictions on black employment opportunities and residential patterns were outlawed. This increased the access of black skilled and semiskilled workers to higher paying jobs in the broader economy. Greater labor market opportunities, a concomitant improvement in their standard of living, and a reduction in the overt discriminatory practices of banks and real estate brokers, which had long mired blacks of all socioeconomic groups in some of the most dilapidated areas of the cities, resulted in a significant out-migration of middle class blacks from urban ghettos beginning in the early 1970s.

The declining economic fortunes of black unskilled workers and the neighborhoods they resided in resulted in the increasing 'ghettoization.' In other words, poor urban blacks who had weak attachments to the labor force, had become more spatially, socially, and economically segregated from more advantaged areas (Wilson 1987). Accordingly, any discussion of dysfunctional cultural traits of a ghetto underclass ought to be conjoined with a discussion of the structural forces which undergrid the social and economic life of central cities.

3. *Structure and Culture in Poor and Jobless Neighborhoods*

A more nuanced view of underclass or ghetto-related cultural traits is slowly taking shape, one that avoids some of the unproductive debates surrounding the culture-of-poverty thesis. In this view, the existence of a ghetto cultural milieu which influences the behavior of the poor in ways that are often counter-productive, is explicitly acknowledged. However, it also highlights the complex interrelationship between structural circumstances and behavioral and attitudinal responses by showing how both the cultural milieu and dysfunctional behavior are themselves shaped by the social constraints faced by poor ghetto residents (Wilson 1996).

A considerable body of literature now exists which posits that economic stratification in high-poverty neighborhoods has deleterious effects on the social aspects of community by corroding cohesion among neighbors, lessening the likelihood that people will find work through personal acquaintances, and undermining the institutional framework which anchored these neighborhoods (Brooks-Gunn *et al.* 1997a, 1997b). These conditions create the seedbed for what Wilson (1996) later referred to as 'ghetto related' behavior or the cultural adaptations of the ghetto poor to their spatial and social exclusion from mainstream America. Building on his earlier conception of the underclass, Wilson now explicitly associates the concept of 'underclass' with the dual problem of marginal economic position and social isolation in concentrated poverty areas (Wilson 1991). In other words, what distinguishes members of the underclass from those of other economically disadvantaged groups is that their marginal economic position or weak attachment to the labor force is uniquely reinforced by their neighborhood or social milieu. The dual problem of weak labor force attachment and neighborhood disadvantage is not captured by the standard designation 'lower class.'

Despite this attempt to formulate discussions of the term 'underclass' in more theoretical terms to increase its scientific import—that is, its role in the description, explanation, and prediction of behavior—both journalists and scholars alike continue to appropriate the label and imbue it with meanings that serve their own ideological ends. Many of the scholars who used the term in earlier writing, including Gunner Myrdal, never intended it to be a generic label for a host of traits that supposedly characterize a deviant, often criminal, faction of the poor who disavow the normative orientations of mainstream society. To be sure, crime is a characteristic feature of high-poverty neighborhoods, but criminal activities are as abhorrent to the majority of the chronic poor who must live in these depressed communities as it is to the rest of society that disparages them. Furthermore, welfare dependency and unemployment are as much an anathema to the poor who must endure them as they are to those who see these conditions as self-inflicted.

4. *Social Policy*

Changes in the global economy are creating daunting challenges for governments in the USA and Europe to improve or sustain existing employment rates at a time when national labor markets are increasingly subject to the vicissitudes of a global economic system. Growing numbers of people, including those who are socially isolated in concentrated poverty areas, are being excluded from the workforce because of lack of

minimal skills and have to rely on the state to maintain even the most meager economic subsistence. In the USA, the growing conservative backlash against swelling welfare rolls has resulted in punitive welfare reform aimed at curbing a so-called dependency mentality, while the inequality and social dislocation brought on by global economic processes is largely ignored.

As in America, efforts to address social and economic inequities in other parts of the world are becoming mired in debates about whether joblessness should be addressed at the individual or the national level. It is imperative that whatever terminology is used to describe the heterogeneous amalgam of people who reside in impoverished areas and are forced to operate outside the labor force, that efforts be made to increase public understanding of their economic and social woes. Support for public policy options will very likely depend on how effectively we communicate the following message: the plight of the underclass has much more to do with dwindling opportunities for unskilled and semiskilled people to eke out a living than with individual choices to remain poor, unemployed, or dependent on state handouts.

Unemployment and Mental Health

1. The Term Unemployment

How unemployment is defined and operationalized determines who is included (and excluded) as participants in empirical unemployment research and thereby to whom findings generalize as well as having important administrative, political and ideological assumptions.

Until recently, in so-called 'developed' industrialized countries, unemployment has been widely operationalized in terms of eligibility for State funded unemployment-specific financial support. However, although this embodies politically and administratively useful criteria, it is arbitrary from a social scientific perspective. Changes in the number of people who cease to be recorded as unemployed are not always the same as changes in the numbers of people at risk of psychological consequences of unemployment.

The International Labour Organisation counts people as unemployed if they have not undertaken any paid employment in the survey reference week, have looked for a job within the previous four weeks, and are available to start one within two weeks. This is preferable to the claimant count, but should jobless people who cease to actively look for employment due to hopelessness, depression, and/or demoralization, be considered any the less unemployed for social and behavioral purposes, especially if the psychological states which militate against active job search turn out to be consequences of unemployment?

The Broad Labour Force Survey counts all those who do not have but want a paid job and are available to start within two weeks but who have not necessarily been actively looking for a job. However, preferable though this operationalization is, it may still greatly underestimate the number of people who do not self-perceive themselves as satisfactorily employed and who are looking for employment. Many unemployed people take places on employment and training schemes only through fear of losing their state financial support if they decline. Others take part-time, short-term, or insecure jobs or become 'underemployed' only quasivoluntarily.

These people, along with those indicated by the Broad Labour Force Survey, constitute the so-called 'slack' labor force.

2. *The Size of the Unemployment Problem*

These different ways of operationalizing unemployment suggest very different numbers of unemployed people. For example, in late 1999 in the UK, unemployment as indicated by 'claimant eligibility' stood at 1,209,600. As indicated by the International Labour Organisation the figure was 1,714,000, while the Broad Labour Force Survey gave a figure of 2,396,000 for the same period. The slack labor force, on the other hand, gave a figure of 4.6 million. Beyond the UK, the International Labour Organisation calculated unemployment to stand at 34 million in the countries of the Organisation for Economic Cooperation and Development in 1996.

3. *The Relationship Between Unemployment and Mental Health*

There have been valid grounds for concern about the social, physical, and mental health consequences of unemployment for at least 200 years, and this has been beyond reasonable doubt since the 1930s (Eisenberg and Lazarsfeld 1938, Lazarsfeld-Jahoda and Zeisel 1933). In the early days, fear, frustration, irritability, declining self-respect, decreasingly meaningful sense of time, loneliness, apathy and resignation, and poorer physical health were noted. These were broadly confirmed by substantial empirical research and scholarship in the 1980s but standardized measures checked for reliability and validity were preferred. Anxiety, depression, positive and negative self-esteem, and a variety of measures of affect were studied repeatedly. Rather than 'demoralization,' researchers wrote of 'psychological well-being' and the General Health Questionnaire was used widely. That there are negative mental health consequences of unemployment is being reiterated currently by sophisticated reviews and meta-reviews (see *Depression, Hopelessness, Optimism, and Health*.

Research clarifying the relationship between unemployment and mental health has been carried out in Australia, New Zealand, USA, and many European countries over many decades. The resulting large literature has operationalized mental health in a wide range of ways, has been carried out using just about every viable research method, has been supported by diverse funding arrangements, and has been undertaken from a variety of ideological starting positions. Of course the impact of unemployment is not homogenous: some are affected more negatively than others, and a number of moderator variables have been identified. Effective coping with unemployment is also widespread. However, the degree of consensus is startling. Groups of unemployed people almost always have poorer mental health than groups of otherwise similar but employed people and unemployment is overwhelmingly found to be the cause of poor mental health rather than the result of it.

For many, the well-designed, longitudinal studies, which have tracked large, carefully matched, samples of people in and out of paid jobs using standardized measures, are the key studies. Some of the most persuasive longitudinal quantitative studies of all were done with young people. Typically, these studies measure the mental health of large groups of young people in school and follow them out into the labor market, periodically measuring the mental health of those who get jobs and those who do not, and comparing group mean scores cross-sectionally and longitudinally. Groups of unemployed youngsters repeatedly are demonstrated to have poorer mental health than their employed peers but statistically significant differences are seldom found between the scores of the same groups when at school.

Many such studies have been done, but three research programs have been particularly influential. The first was the 1980s research program based at the Social and Applied Psychology Unit in Sheffield, England (see Warr 1987 for an overview). The second program was based at The Flinders University of South Australia (see Feather 1992 for an overview). The third was based at the University of Adelaide (see Winefield et al. 1993 for an overview). In brief, such studies provide powerful evidence that unemployment causes, rather than merely results from, poor psychological health.

Recently, sophisticated meta-reviews have reiterated that social causation is involved. For example, Murphy and Athanasou (1999) conducted a meta-review of 16 longitudinal studies using valid and reliable measures and published in the last 10 years in English-language scientific journals. They concluded that 'the results from the 16 longitudinal studies suggest that unemployment has reliable (negative) effects on mental health' and that 'effect size information … suggests that moving from unemploy-

ment to employment not only produces a reliable change to mental health, but a change that is "practically significant."'

It was never remotely plausible that mass unemployment was caused by mass, sometimes organizationally confined, epidemics of mental illness, but of course, in some individual cases, pre-existing mental health problems do predispose people to loss of, and/or failure to get, a job. However, even here social causation processes may be hard to discount completely. For example, during economic recession some employers ratchet up the criteria they use to select employees with the result that people are excluded from employment on mental and physical health grounds at one stage of the economic cycle, who would have been employed in other economic circumstances. Other conceptual and methodological concerns suggesting the stark dichotomy between social causation and individual drift may be unhelpful are discussed more fully in Fryer (1997).

In conclusion, research has persuaded most researchers in the field that unemployment has mental health consequences that are negative and widespread.

4. *Disguised Unemployment*

According to Dooley and Catalano (1999), in the US 'under-employment (involuntary part-time or poverty wage) both appears increasingly common and seems to have health effects more like those of unemployment than adequate employment.' Part-time work, on-call contracts, fixed-term contracts, seasonal work, agency work, home-working, tele-working, freelancing, self-employment, and informal work are all on the increase. In 1992, 9.3 percent of workers in the European Union were on temporary contracts, with more than three out of five of such jobs being in low-skilled occupations. About 15 percent of the European workforce was employed part-time in 1991, and the percentage is increasing year on year. However, there is massive variation between countries: Nearly a third of employment in the Netherlands is part-time as opposed to less then 4 percent in Greece, for example. More than half of part-time work in the European Union is done by low-skilled, low-paid workers. Twice as many women as men are employed part-time. The trend looks set to continue. In May 1999, the OECD recommended member countries to make working practices more flexible: abolishing employment protection policies; ensuring minimum wages for young people are not too high; switching from unemployment to in-work benefits.

What are the psychological consequences of disguised unemployment? As long ago as 1938, it was recognized that 'just having a job itself is not as important as having a feeling of economic security. Those who are economically insecure, employed or unemployed, have a low morale' (Eisenberg and Lazarsfeld 1938). Advances in clarifying the concept of job insecurity came with Hartley et al. (1991). Studies in Israel, the Netherlands, and the UK showed that job insecurity is associated with experienced powerlessness, impaired mental health (depression and reported psychosomatic symptoms), reduced job satisfaction, reduced organizational commitment, reduced trust in management, resistance to change, and poorer industrial relations. Burchell et al. (1999) reported that job insecurity has increased gradually since the 1960s for both men and women in both full-time and part-time employment and is now higher than at any time since 1945. While job insecurity traditionally has been accepted as problematic for blue-collar workers, professional workers, who in 1987 were the most secure workers, were found to be the most job insecure 10 years later. Job insecurity was associated with poorer psychological wellbeing, poorer family relations, and organizational demotivation. Both physical and mental wellbeing was found to continue to deteriorate rather than stabilize with continuing job insecurity.

Evaluation of mental health consequences of participation in employment and training schemes reveals a complex picture. Some cross-sectional research found trainees' mental health was not significantly worse than that of an employed comparison group and was significantly better than an unemployed comparison group. However, other research found that trainees were significantly more depressed than an employed comparison group and not significantly less depressed than an unemployed comparison group. Still other research revealed a multifaceted experience of 'community program' with participants positive about some aspects and negative about others. The nature of the labor market context, quality of training and job placement, and degree of experienced compulsion are probably critical. Some research has found that unemployed people, of any age (male or female), who were coerced into employment through workfare-type programs used medical facilities more frequently. Their use of primary care decreased if they became unemployed again

Re-employment is likely to be at a lower level, yet re-employment in poor-quality jobs can be as psychologically corrosive as unemployment. Kaufman (1982) reported that 20 percent of his re-employed professionals were under-employed (in terms of salary, type of work, and skill use), and less than 50 percent said their lives had returned to normal after re-employment. Fineman (1987) found 'those re-employed in jobs which they felt to be inadequate were experiencing more stress and even poorer self-esteem, than they had during their period of unemployment.' Graetz (1993) showed that 'the benefits of employment are confined to those, albeit a majority, who manage to find a satisfying job. In contrast, those who do not end up in

a satisfying job—approximately one in every five workers—report the highest levels of health disorders. At the same time, the adverse consequences of job loss are confined to those who were satisfied with their former jobs.' More recently still, Leana and Feldman (1995) report that 'unsatisfactorily re-employed workers reported significantly higher levels of anxiety and psychological distress than those who were satisfactorily re-employed; they also reported significantly lower levels of life satisfaction than those who were unemployed.'

5. *Methodological Issues*

The method of choice of most recent research on unemployment and mental health has been to contrast the better mean mental health of employed with the worse mean mental health of unemployed people in both cross-sectional and longitudinal designs. In the past the mental health of employed groups has been reliably better than that of otherwise comparable unemployed groups. However, should the mental health of the majority of those in employment deteriorate, the formerly reliable finding that unemployed respondents have poorer mean mental health than otherwise similar employed people would no longer be found, without it being the case that unemployment was any the less pathogenic. With the apparently inexorable march of the 'flexible labor market,' it may now be only a matter of time until that happens. The realization that comparison of labor market transition outcomes is unsatisfactory in certain economic circumstances should alert researchers to the fact that it has always relied upon ideologically problematic assumptions about the salutogenic nature of employment.

Rather than relying on discovering differences in outcomes, researchers must increasingly try to uncover the detailed multilevel processes through which the social causation of mental health problems by unemployment occurs. This is likely to require use of a much wider range of ecologically contextualized and collaborative research methods, including qualitative, action research, and participatory methods. Given the vast scale of socially caused health problems attributable to unemployment, training clinicians and treating negatively affected individuals one at a time is practically impossible as well as ineffective and offensive. Prevention and structural intervention must be priorities.

6. *Future Directions of Theory and Research*

Radical rethinking of the alleged dichotomy between employment and unemployment is required. The problems of unemployment are still widely and mistakenly seen as merely the problems of the absence of employment. For many unemployed people the search for employment and the hoops through which they have to jump in order to keep body and soul together is a stressful low-status, insecure, part-time, poorly paid job in itself, carried out in poor working conditions, with virtually no negotiating rights or scope for collective action under potentially punitive state surveillance and with a high risk of occupational strain. Unemployment is ready for job redesign.

Unemployment: Structural

1. Definitions

It is an old tradition in labor economics to distinguish between structural, frictional, and cyclical unemployment. Structural unemployment is then envisioned as a result of the institutional set up of the economy, including private and government organizations, types of market arrangements, demography, laws, and regulations. In the literature, the importance of these institutional features for structural unemployment is tied particularly to their implications for demand for and supply of labor, price and wage formation, and the efficacy of search and matching processes in the labor market. Frictional unemployment may be regarded as a subset of structural unemployment, mainly reflecting temporary unemployment spells as the result of job search and matching difficulties in the connection with quits, new entries to the labor market, and job separation because of the employers' dissatisfaction with individual workers.

Cyclical unemployment differs from structural and frictional unemployment by basically being tied to short-term economic fluctuations. An empirical illustration of the importance of structural unemployment as compared to cyclical is that variations in actually measured unemployment rates have turned out to be much larger between cycles than within cycles, presumably reflecting differences in structural unemployment (Layard et al. 1991). For example, the average unemployment rate over the business cycle in Western Europe has moved from about 3 percent in the mid-1960s to 6 percent in the mid-1970s and to 10 percent from the mid-1980s to the late 1990s. But as pointed out below, various unemployment-persistence mechanisms blur the distinction between cyclical and structural unemployment.

In economic theory, structural and cyclical unemployment usually are regarded as disequilibrium phenomena in the sense that they reflect excess labor supply at existing wages and hence that the labor market does not clear. Then, individual employers informally ration jobs. Nevertheless, technically (analytically) structural unemployment often is analyzed in terms of the concept of *equilibrium unemployment*. This means that the aggregate-unemployment level is in a 'state of rest': existing excess labor supply is assumed to last as long as certain characteristics (parameters) of the economy are unchanged. If this equilibrium is dynamically stable, unemployment equilibrium may also be described as an unemployment level toward which the economy moves as long as new disturbances do not emerge. (The term 'equilibrium' is used in several different ways in economics. It refers sometimes to the equality between demand and supply in a market, i.e., to traditional 'market-clearing,' in other cases to a state that tends to continue over time regardless of whether the market clears or not. The concept of 'equilibrium unemployment' is an example of the latter.)

It is useful to distinguish between two main analytical approaches to equilibrium unemployment: *stock approaches* and *flow approaches*. Stock approaches focus on the difference, at a given point in time, between the workforce desired by firms (aggregate *stock demand* for labor) and the number of workers willing to work (aggregate *stock supply* of labor). Flow approaches deal with the difference between the flows in and out of the unemployment pool during a certain period. Flow-demand for labor is represented then by the supply of 'job slots,' and flow-supply by offers of workers to fill such slots. These two approaches are related because stock demand and stock supply may also be derived in flow approaches. Let us start with stock approaches.

2. Stock Equilibrium

Milton Friedmans's celebrated 'natural unemployment rate' is a stock-equilibrium concept of structural unemployment: 'the level that would be ground out by the Walrasian system of general equilibrium equations, provided there is imbedded in them the actual structural characteristics of the labor and commodity markets, including market imperfections, stochastic variability in demand and supplies, the costs of gathering information about job vacancies and labor availabilities, the costs of mobility and so on' (Friedman 1968). Apparently, this concept of equilibrium unemployment covers structural and frictional unemployment as described earlier.

The nonaccelerating inflation rate of unemployment (NAIRU) is close to Friedman's natural rate, though it emphasizes (more than Friedman does) the non-clearing character of the labor market. The NAIRU is defined explicitly as the unemployment rate at which inflation is constant. It is derived from an expectations-augmented Phillips curve, i.e., a function that assumes that the price-inflation rate is a decreasing function of the unemployment rate and an increasing function of the expected rate of future inflation (Phelps, 1967). In the simplest possible terms (with linear relations):

$$\pi = -au + b + c\pi^e \qquad (1)$$

where π is actual inflation, u is the unemployment rate, and π^e is expected inflation. For given values of the (positive) parameters a, b, and c, the equation may be depicted as a set of downward sloping short-term Phillips curves (SR_i), one curve for each set and for each value of π^e (see Fig. 1).

In the context of this model, usually (and realistically) it is assumed that economic agents ask for full compensation for expected inflation in the *long run*;

Figure 1
Phillips curves and the NAIRU

thus $c = 1$ in that time perspectives. It is usually also assumed that economic agents do not make *systematic* expectational errors in the long run; thus $\pi = \pi^e$. The only unemployment rate consistent with these two assumptions is, from Equation (1), $u^* = b/a$, where * denotes the equilibrium unemployment rate. It is often also assumed that inflation in this situation is constant over time (and not just that actual and expected inflation coincide), because agents have no reason to revise their price and wage setting behavior when inflation is exactly what they had expected when they formed their decisions. u^* is then the NAIRU (the unemployment rate at which inflation is constant), geometrically represented as a vertical long-run Phillips curve, *LR* in Fig. 1. Inflation increases to the left of that level and falls to the right. Because inflation in this framework in the long run is independent of unemployment, there is no long-run trade-off between these variables. But it has been argued by Lucas (1972) that there is not even a *systematic* short-term trade-off if economic agents have 'rational expectations' (thus, if they never make systematic expectational errors), and if various agents are free to revise their prices and wages in response to changes in expectations. Such a trade-off will then only arise due to random (non-systematic) expectational errors, e.g., due to random shocks or randomized government policy.

An alternative exposition of stock-equilibrium in the labor market, and hence structural unemployment, gained ground in the 1980s and 1990s; it emphasizes the requirement of consistency of price- and wage-setting behavior (Shapiro and Stiglitz, 1984, Layard and Nickell, 1986). Figure 2 gives a simple diagrammatic illustration, with aggregate employment (N) on the horizontal axis and the aggregate real-wage level (w) on the vertical. The *LS* curve is the traditional aggregate labor supply curve, i.e., the sum of labor supplied by households. The *PS* curve is the price-setting curve of firms: for alternative unemployment levels and given nominal wages, the curve defines the price level desired by profit-maximizing firms that operate in imperfectly competitive product markets. Or the *PS* curve can be described as a labor-demand relation, because it also expresses the combination of employment and real wages desired by profit-maximizing firms. Unemployment is then the horizontal difference between the *PS* and *LS* curves.

The *WS* curve defines wage-setting behavior. It depicts the influence of the (un)employment situation on the real-wage rate that the wage-setting process generates. The intuition is that firms feel compelled to offer higher real wages and that workers and unions demand higher real wages when the labor market is tight (low unemployment) than when it is slack. So by contrast to models with perfectly competitive labor markets, a distinction is made between labor supply (by households) and wage setting (by firms, unions, or more realistically a bargaining process).

The equilibrium real-wage rate is now w_0, equilibrium employment N_0 and equilibrium unemployment U_0, the latter being the only unemployment level at which there are no incentives for agents to change prices relative wages and vice versa (corresponding to the equilibrium unemployment rate u^* in Fig. 1). This model will be called the *PS–WS* model of equilibrium (structural) unemployment.

As an illustration, suppose that the real-wage rate in Fig. 2 is initially w_0 but that aggregate employment happens to be above N_0, e.g., as a result of positive demand shocks to which nominal magnitudes have not yet adjusted. Firms and workers are then dissatisfied with the existing real wage w_0. Workers and their unions try to raise nominal wages (at existing nominal prices), as can be read off from the *WS* curve, and firms try to raise prices (at existing nominal wages), as can be read off from the *PS* curve. The result is a wage-price spiral, as described by the expectation-augmented Phillips-curves model. Firms also start cutting their work force because their desired level is lower than the actual one. Aggregate employment continues to fall until it reaches the unique equilibrium level N_0. The same reasoning, *mutatis mutandi*, holds if aggregate employment is initially lower than the equilibrium level.

3. *Flow Equilibrium*

Flow approaches to structural unemployment instead emphasize the flow of workers in and out of un-

Figure 2
The PS—WS model of equilibrium unemployment

employment (Phelps 1970, Hall 1979, Diamond 1982). These approaches explicitly grant the heterogeneity of jobs and workers, which means that agents in the labor market must devote time and costs to search to match up idiosyncratic preferences, skills, and skill requirements. In the process, unemployment and vacancies coexist because the latter are not eliminated immediately by the hiring of workers in connection with decentralized negotiations of wages between firms and work applicants.

For simplicity, let us regard the size of the labor force (L) as constant. Further, let s denote the job separation rate, i.e., the fraction of employed workers (N) who lose their jobs in each time period. Let f denote the rate of job finding, i.e., the fraction of unemployed workers (U) who find a job in each time period. We assume that both fractions are constant. The equilibrium unemployment rate (u^0) is then defined as a situation when the number of individuals finding jobs equals the number of individuals who are separated from jobs; hence $fU = sN$. Noting that $N = L - U$, i.e., that the number of unemployed workers equals the labor force minus the number of employed, we get $fU = s(L - U)$. Rearranging terms and dividing both sides by L, we obtain the equilibrium, or structural, unemployment rate $u^0 = U/L = s/(s + f)$. As expected, the higher the rate of job separation (s), the higher the equilibrium unemployment rate. And the higher the rate of job finding (f)—due to greater intensity and efficiency of job search and hence better job matching—the lower the equilibrium-unemployment rate.

Though the model basically is designed to highlight frictional unemployment, as described earlier, unemployment in the connection with job search and matching may also be due to continuing changes in the composition of demand and supply of different types of workers. This means that flow models of search and job matching also cover elements of what usually is regarded as structural unemployment, which illustrates the previous assertion that frictional unemployment may be regarded as a subset of structural unemployment.

It is natural and feasible to integrate flow and stock approaches to (un)employment determination. For instance, the efficacy of search and matching processes influences the positions of the *PS* and *WS* curves in Fig. 2 (and the positions of the Phillips curves in Fig. 1). The longer it takes firms to find the right workers for their vacancies, and the longer it takes work applicants to acquire suitable job offers, the more costly it is to hire workers, and the lower will be the labor-demand curve—the *PS* curve in Fig. 2. A poorly functioning search and matching process will force recruiting firms to offer higher wages than otherwise; the result is also a higher *WS* curve. In this way, flow models are related to previously-discussed stock models. Search and matching processes may also be seen as part of the short-term *dynamics* by which stock equilibrium is reached, with positive gross flows in and out of unemployment, netting to zero when there is flow and stock equilibrium.

4. *Microeconomic Foundations*

All these macroeconomic models of structural unemployment assume that unemployed workers are not able or willing to get jobs by underbidding the prevailing wages of incumbent workers. The most obvious microeconomic explanation of the absence of wage underbidding is perhaps *minimum wage laws*. But there seems to be rather general agreement among labor market economists that minimum wages have not been high enough in developed countries to explain much of aggregate structural unemployment in that part of the world. But in some countries, minimum wage laws are binding for specific types of workers, such as inexperienced, unskilled, and physically or mentally handicapped people. (In the special case when a firm has a monopsonistic position in a local labor market minimum wages may, up to a certain wage level, increase rather than reduce employment. In this case, the minimum wage simply prevents the firm from keeping down wage costs by holding back its demand for workers.)

There may also be informal *social norms* against the underbidding of the wages of incumbent workers. In other words, wage underbidding may not be socially acceptable behavior among workers, and the acceptance of such offers may not be socially acceptable

behavior among firms. Legislation may support such norms.

But more elaborate microeconomic foundations of structural unemployment have been developed since the 1980s. In the *union monopoly model*, unions are assumed to strive for a trade-off between real wages and unemployment. Often, this trade-off is derived formally from a model where unions maximize the expected utility of union members—including those who are employed and those who wind up unemployed due to the union's wage policy. So labor unions are assumed conscientiously to choose a real-wage rate that generates some structural unemployment.

In *union-bargaining models*, the real wage is instead set in a bilateral bargaining process between a union and a firm or an association of firms. Such models qualitatively yield the same result as the union-monopoly model, though the real wage will normally be lower and hence the employment level higher, because the firm is assumed to strive for a lower real-wage rate than the union. But neither type of union model answers the questions why there is no underbidding of existing wages by nonorganized workers and why unemployed union members do not leave the union.

There are also theoretical reasons and empirical evidence why the organization of bargaining, such as the degree of coordination and centralization of bargaining, would influence the outcome of the bargaining process and hence also the unemployment level. The most generally accepted hypothesis is probably that both highly centralized and highly decentralized bargaining are more conducive to employment than wage bargaining on levels in between, such as industry-level bargaining (Calmfors and Driffill 1988).

The *insider–outsider* theory of unemployment emphasizes the asymmetric market powers of incumbent workers, *insiders*, and disenfranchised workers without jobs in the formal labor market, *outsiders* (Lindbeck and Snower 1988). Because hiring and firing costs protect incumbent workers, they can push up their wages above the reservation wage of outsiders without losing their jobs. Another way for insiders to prevent wage underbidding is by refusing to cooperate with underbidding outsiders in the production process and by threatening to harass them if underbidding workers are actually hired. With the help of such noncooperation and harassment threats, insiders (possibly with the support of unions) may also be able to create and sustain social norms in their own interest against wage underbidding.

In *efficiency wage* models, by contrast, the microeconomic foundations of structural unemployment are based on the incentive structure of firms (Yellen 1984). Firms, which are assumed to have all market powers in wage formation, set wages high enough to get a good selection of work applicants and to discourage workers from shirking and quitting. More specifically, firms set wages to balance the cost of higher wages against the productivity increase of having a more efficient work force. Only by accident would the wage level that is optimal for firms clear the labor market.

All these microeconomic theories are rather silent about the employment situation in *informal* labor markets, where minimum wages are not always respected, unions may not exist, collective bargaining agreements are not binding, efficiency wages are not important, and labor turnover costs are very low and hence insider-outsider mechanisms not important. Extreme examples are sellers of flowers or newspapers on street corners, shoeshine boys, and workers in the underground economy. One conceivable explanation why some workers who are excluded from the *formal* labor market remain unemployed rather than choose to work in informal labor markets may be an unwillingness to take jobs that are regarded as highly insecure and demeaning. Generous unemployment benefits help them to make this choice. It is significant that informal labor markets are particularly important in countries without unemployment insurance.

In the popular discussion of structural unemployment, it is often believed that labor-saving technological progress and related increases in labor productivity will necessarily result in higher unemployment. Workers are asserted to become redundant because machines replace workers—a vision of *technological unemployment* as a special variation on structural unemployment. A usual conclusion is that some kind of work sharing is necessary to avoid ever-increasing unemployment. An obvious flaw of this argument is that a gradual rise in productivity will normally be accompanied by higher real wages and profits in the long run, and hence of real income. In this sense, productivity growth creates the foundation for higher demand for output, though deficiencies in aggregate demand may occasionally occur and contribute to recessions. In fact, no long-term trend of the unemployment rate can be detected during the twentieth century.

So work sharing—in the form of a lower general pension age, more generous rules for early retirement, or fewer working hours—is not necessary to prevent gradually rising labor productivity from resulting in rising unemployment. Indeed, the literature in the field clarifies that work sharing is not even likely to contribute to reduced unemployment except in the very short run; one reason is that a reduction of the labor force tends to push up wages. But there is nevertheless a potential problem with continuing productivity growth. Some national economies may fail to adjust to changes in the *composition* of the demand for labor in the connection with uneven rates of productivity growth among sectors and types of workers (sector shifts or skill shifts in the labor market). This is a respectable explanation as to why

unemployment rates among low-skilled workers have increased so much (in percentage points) in Western Europe, where relative wages are quite rigid.

5. Unemployment Persistence

One serious limitation of the concept of unemployment equilibrium as an expression of structural unemployment is that this concept is difficult to distinguish empirically from unemployment persistence, i.e., inertia of unemployment after temporary shocks that have shifted the unemployment rate. Estimated equilibrium rates of unemployment tend to shadow the actual rate, which is an indication of unemployment persistence. Important examples of unemployment persistence are the persistently high unemployment rates after the deflationary policy pursued in several developed countries in the early 1920s and early 1930s; after the oil-price hikes in mid- and late 1970s; and after the restrictive monetary (and in some cases also fiscal) policy in the late 1980s and early 1990s. These experiences raise the suspicion that attempted statistical measurements of equilibrium unemployment also reflect the consequences of various persistence mechanisms. It is hard to find good reasons why the equilibrium unemployment rate in Western Europe should have increased as dramatically as the actual unemployment rate in the 1980s and 1990s.

There are also reasonable microeconomic explanations of unemployment persistence. While some explanations emphasize the behavior of outsiders, others point instead to the behavior of insiders. Examples of persistence mechanisms of the former type are the loss of skill among individuals who have been unemployed for a long time; endogenous changes in preferences in favor of leisure or household work; and the breakdown of social norms in favor of work and hence the emergence of unemployment cultures. We would expect reduced job search in all these cases. Long spells of unemployment may also functions as a negative signal to prospective employers about the quality of individual workers. An example of a persistence mechanism that operates via the behavior of insiders is that they (possibly supported by unions) may exploit subsequent business upswings to push up their wages, hence discouraging firms from expanding their workforce. All this suggests that unemployment persistence is an important factor behind what is usually regarded as structural unemployment. A basic conclusion is that endogenous changes of private behavior after a temporary unemployment-creating shock make the concept of *equilibrium unemployment* too narrow as a description of structural unemployment. For instance, it is realistic to regard prolonged high unemployment in Western Europe after the mid-1970s as the combined result of macroeconomic shocks and institutional rigidities that contribute to unemployment persistence. Hence, cyclical unemployment is asserted to have developed into structural unemployment. The result is strong 'history dependence' of the unemployment rate. So it is reasonable to widen the concept of structural unemployment to also include unemployment persistence.

6. Policies that Influence Structural Unemployment

Leaving the issue of legislated work sharing aside, what are the influences of government policy on structural unemployment? In the schematic *PS–WS* model presented earlier, the positions of the *PS*, *WS*, and *LS* curves reflect this influence. The discussion below is confined to taxes, transfer programs, regulations of job-protection, union powers, education/training, and other types of active labor market policy.

Taxes on labor insert a wedge between the labor costs paid by firms, the product wage $(1 + t_w)w$, and the return to workers, the consumption wage, $(1-t_i)w$. t_w and t_i then denote the wage tax (payroll tax), and the income tax. *The tax wedge*, expressed as the ratio between the product wage and the consumption wedge, is then

$$(1+t_w)/(1-t_i) \tag{2}$$

A consumption tax would enter the tax wedge in the same way as the wage tax. For example, in terms of Fig. 2, an increase in t_w shifts the labor-demand relation (the *PS* curve) down, e.g., to *PS*': at every real-wage rate (w), the demand for labor will be lower than before because the firm must now pay $(1 + t_w)w$ for its labor. As long as the *WS* curve is unchanged, the equilibrium position shifts from point *a* to point *b* in the figure, and the equilibrium employment level (N) and the real-wage rate (w) fall. These effects are relevant in the short run. The long-run effects are less obvious, and they depend on the extent to which wage setting adjusts to the tax wedge, which in turn depends on what happens to alternative incomes of workers, such as unemployment benefits and the return on household work. But for low-skilled workers, wages are often tightly regulated, which means that the wage costs for firms are likely to rise and labor demand will fall for this specific group of workers.

The results of empirical studies on these matters are somewhat ambiguous. But on balance, it seems that aggregate employment is negatively affected by wider tax wedges not only in a short- and medium-term perspective but also in the long run (Nickell and Layard 1999).

More generous *unemployment benefits* enable workers to be more selective about offered jobs and hence search for longer time periods—as highlighted by the earlier discussed search approach. Frictional unemployment (or *wait unemployment*) will then increase. Because the income loss in connection with

unemployment becomes smaller, firms must offer higher wages to prevent shirking and to keep down quits, as highlighted by efficiency wage models. Moreover, workers and unions become less hesitant to ask for high wages, as emphasized by union and insider–outsider models. This tendency is accentuated by the fact that unemployment benefits are, as a rule, financed by taxes rather than by insurance fees directly tied to specific workers. In terms of Fig. 2, the net effect of all this is that the *PS* curve is shifted down and the *WS* curve is shifted up, with rising equilibrium unemployment as a result. Unemployment persistence would also be predicted to increase.

Casual observation and systematic empirical studies, including cross-country regressions, suggest that generous unemployment benefits that may be kept for long periods (in some cases for several years or indefinitely), in fact, have effects of this type (Layard et al. 1991). Other evidence is that the exit rate for individuals from unemployment increases substantially in the US as soon as the benefit period expires after 26 weeks (Katz and Meyer 1990).

Job-security legislation is often singled out as another factor that tends to raise structural unemployment. Basically, such legislation raises the costs of hiring and of firing workers, the former because firms must consider the possibility of future firing costs when hiring workers. Firms will be less anxious to fire workers in recessions but also less interested in hiring workers in business upswings. A predicted effect is that employment tends to be stabilized at the actually existing level whatever this happens to be. In other words, (un)employment persistence would be expected to increase.

Since such legislation increases the market powers of insiders, this helps them to push up their wages. The predicted effect is an increase in the average unemployment rate over the cycle. Moreover, the market power of insiders and unions depends also on other legislation. Important examples are rules that extend the coverage of bargaining agreements to nonunion firms and give large freedom for unions to use conflict weapons, such as the rights to sympathy strikes, secondary actions and blockades, and the right to take out small 'key groups' in conflicts.

Most government policies discussed earlier tend to raise structural unemployment (including unemployment persistence). Of course, the other side of the coin is that a reversal of these policies is likely to reduce structural unemployment. But there are also well known examples of government policies directly aiming to lower structural unemployment. Competition policy, which accentuates competition in product markets, induces firms to increase production and employment at given real wages; in terms of Fig. 2, the *PS* curve shifts to the right. Increased competition in product markets also makes product demand more sensitive to changes in wage costs. This is likely to restrain the wage demands by insiders; the *WS* curve shifts down. The net effect would be lower equilibrium unemployment.

Active labor market policy is designed to keep workers out of open unemployment in the short term and to subsequently help them to get jobs. In particular, labor-exchange systems and retraining may improve matching between work applicants and vacancies. In terms of Fig. 2, the *PS* curve shifts up and the *WS* curve down with falling structural unemployment as a result. Moreover, subsidized education and training that raises labor productivity for (previously) low-skilled workers are likely to raise demand for them and reduce the upward wage pressure for skilled workers. This tends to generate similar shifts in the *PS* and *WS* curves as in the case of improved labor market exchanges. Unemployment persistence would also be expected to recede.

On balance, empirical studies suggest that labor-market exchange and properly conduced training programs, in fact, are useful for reducing structural unemployment (Layard et al. 1991); in the short term, also public works programs have such effects. But it is natural that the marginal return falls, possibly to zero, when the programs reach a large size (such as several percent of the labor force), and in particular when the programs are used largely to keep down statistically recorded figures on open unemployment.

Uneven Development, Geography of

'Uneven development' refers to the systematic processes by which social and economic change in capitalist societies enhances the wealth of some places at the expense of others. The resulting geographical differentiation in types and levels of development is not arbitrary but a systematic spatial expression of the social differences, inequalities, and processes that lie at the heart of capitalist societies. According to theories of uneven development, unevenness in space and time does not result simply from an accidental or statistical lack of evenness, nor does it result from local failures to adopt politically correct models of 'development' as might be suggested by contemporary doctrines of 'modernization' or 'globalization.' Rather, uneven development is a hallmark of capitalist societies, their geographical signature, a direct spatial translation of the logic of capital accumulation. The results of uneven development are easily understood in such contrasts as First World (centered on Europe, North America and Japan) vs. Third World (Africa, Asia, South America), city vs. suburb, and developed vs. underdeveloped regions. But processes and patterns of uneven development are highly dynamic and transform themselves as an integral expression of the ever-changing and evolving social relations of capitalism.

1. *Theories of Uneven Development*

Although a recognition of the unevenness of capitalist development can be found in various intellectual traditions, this notion is most fully developed in marxist and related critical traditions (see *Marxist Geography*). For Marx, the social relations of production and reproduction defined the specificity of any mode of production and the uneven geography of capitalist development emanates from the same source; uneven development is the elemental spatial form taken by the geography of capital accumulation. 'Capital grows in one place to a huge mass in a single hand because it has in another place been lost by many,' Marx famously argued (1987, p. 586). Marx displayed an evident sensitivity to the spatiality of social and economic change, indicating that specific geographies both facilitate and are produced by the accumulation and reproduction of capital, but he did not pursue the geography of capitalist expansion *per se* in any systematic way.

In the hands of later theorists, uneven development took a more political complexion. From his analysis of emerging capitalism in Russian industry and agriculture and its effects on the peasantry to his theories of imperialism, Lenin's work was infused with a sense of capitalism's systematically uneven geography (Lenin 1967, 1975), but it was Leon Trotsky who more than anyone crystallized the notion of 'uneven and combined development.' His focus was less on the economic geographic differentiation within and between societies than on the ways that such differentiation were bound up with and helped shape the possibilities for political change (Trotsky 1969, Löwy 1981). More specifically, what were the chances, he asked, of a transition to socialism directly from feudal relations of production. Accordingly, theories of uneven and combined development played a crucial role in Trotsky's rejection of Soviet aspirations for 'socialism in one country'—an oxymoron, he believed—but with Stalin's successful seizure of power and suppression of all opposition in the 1920s, any elaboration of the theory, now branded as counterrevolutionary, was blunted.

The question of uneven development re-emerged powerfully after the 1960s, this time in the West. Its recrudescence came with the need to develop critical analyses of the USSR and, in the context of the cold war, its relationship to global capitalism. Much more, however, it reflected a need to understand the intense geographical differentiations of global capitalism itself in the postwar world as Western social and political economies slouched toward crisis in the late 1960s and early 1970s (Mandel 1975) and as 'development' became the central means of relating to so-called Third World countries (see *Development Theory in Geography*). Decolonization, the Vietnam War, the precipitous decline of a previously hegemonic British economy, deindustrialization and the emergence of so-called newly industrializing countries, urban disinvestment and suburban expansion, and challenges by student, feminist, and civil rights movements, all put questions of uneven development on the political and economic agenda. In retrospect, this period from 1968 to 1991 initiated a significant transition from what some have called a Fordist to a post-Fordist regime of capital accumulation and regulation, but it simultaneously marked a crucial breakdown in established postwar geographies. Erstwhile differences between a First, Second, and Third World no longer made sense, deindustrialized regions retooled, and previously declining Western cities gentrified. Geographies that had previously been assumed as relatively fixed were now revealed as quite fluid and malleable, the products of

social, political, and economic change, and this cried out for explanation.

If the marxist political tradition was often indifferent or even hostile to geographical questions, treating them as displacements from the central issues of class struggle and the contradictions of capitalism, Western academic geography in the first seven decades of the twentieth century was equally immune not just to marxism but to social theory in general. It took a rapprochement between these separate political and academic traditions to make manifest the theories of uneven development that the transformations after the 1960s called out for (see *Space and Social Theory in Geography*).

2. *Sources of Uneven Development*

Uneven development is at root an expression of the contradictory tendencies toward differentiation and equalization of levels and conditions of social production (Smith 1991). On the one hand the stimulus toward differentiation stems directly from the creation and continual reproduction of the social division of labor. The logic of continued divisions of labor, whether at the scale of individual workplaces or transcontinental 'worlds' (First World, Third World), is inherently geographical. Thus Samir Amin (1976) distinguishes between a developed world which enjoys a balanced, self-centered mode of capital accumulation based on the preponderance of the world's industrial production and mass consumption, and an 'underdeveloped' world which specializes in the supply of raw materials and cheap labor and therefore experiences 'dependent development.'

Marx was equally explicit about the historico-geographical importance of the division of labor, albeit at a different scale: 'The foundation of every division of labour that is well developed, and brought about by the exchange of commodities, is the separation between town and country. It may be said, he continued rather enigmatically, 'that the whole economic history of society is summed up in the movement of this antithesis' (1987, p. 333). The development of the division of labor and attendant questions of social reproduction, consumption, and the differential power of nation-states and other political entities stimulates continuous social differentiation which is simultaneously spatial. The division of labor is the product of the competition between capitals which lies at the definitional heart of the capitalist mode of production, and it perpetually divides places as much as enterprises and people on the basis of their ability to differentiate their systems of production from those of neighbors and competitors.

But this powerful catalyst of social and spatial differentiation, enkindled by competition, does not go uncontested. There are powerful forces leading in the opposite direction, toward the equalization of conditions and levels of production, and these too emanate from the competitive impulse. 'Capital is by nature a leveller,' Marx once commented, exacting 'in every sphere of production equality in the conditions of the exploitation of labour' (1987, p. 375). Whatever its origins, this equalizing impulse is most intensely conveyed via the financial system where capital is most fluid, most mobile, and competition over decimal point differences in interest rates is most intense. It is precisely because the pressure of equalization is so intense in the financial sector that ideologies of 'globalization' and the 'end of geography' sprang from here in the later years of the twentieth century (Omae 1990, 1995, O'Brien 1992). Much writing about globalization (see *Globalization: Geographical Aspects*) at the end of the twentieth century captured very well the effects of this equalizing tendency in capitalist development while ignoring the equally profound counter-tendency toward differentiation.

These contradictory economic tendencies toward social differentiation and equalization find resolution in geographical space: a social problem is resolved, however temporarily, by fixing certain differences geographically in the form of discrete nation states, counties, regions, cities, and neighborhoods in such a way that the fluidity of commerce can continue with the least impediment. Uneven geographical development therefore represents a certain spatial fix (Harvey 1981) for the contradictions inherent in the capitalist mode of production. Far from being an ephemeral spatial result of capitalist growth and change, uneven development is integral to its constitution. Underdevelopment, therefore, is neither accidental nor simply a question of slower development along a pre-existing path. Rather, underdevelopment is an integral result of capitalist development.

At the same time, however much it represents a momentary fixing of social relations into specific spatial forms, uneven development is itself highly dynamic. The spatial fix is only ever temporary, and specific geographies that facilitate capital expansion and reproduction in one place in one period can become barriers to future development. To take an obvious example, the urban structure suitable for decentralized commercial and small-scale industrial activity in the seventeenth century is not only obsolete but was also an economic and political hindrance to the larger-scale industrial production of the nineteenth century. This might lead to wholesale urban 'renewal' as for example in Haussmann's Paris, or it may lead to a continued respecialization of activity leaving the old spaces largely intact, as for example in Venice where tourism is now the major industry.

A similar dynamism characterizes other spatial scales. Industrial regions owing their growth to nineteenth and twentieth century industrial expansion, such as New England or central Scotland, experienced economic decline in the second half of the twentieth

century as capital moved in search of cheaper and more pliant labor. But the very fact of disinvestment in those regions, the increase in unemployment, the cheapening of labor, and the breaking of previously powerful unions, also eventually made them attractive again for capital investment. There is a spatial correlate, therefore, to the classic characterization of capitalism as a system that lurches through cycles of expansion and crisis. Indeed, there is a powerful tendency for the cycles of investment and disinvestment inherent in capital accumulation to translate into a 'seesaw' geography of uneven development (Smith 1991). Capital concentrates in specific places but the fact of that investment continually erodes the attractiveness of these same places (higher labor costs, urban congestion, technological obsolescence, etc.) leading to disinvestment. Yet disinvestment itself creates the conditions and opportunities for new rounds of investment once sufficient devaluation has taken place. Over the long term, therefore, there is a powerful tendency toward a geographical seesaw.

Uneven development is every bit as fluid and dynamic as the logics of capital accumulation of which it is the spatial expression. A central theoretical issue here concerns the ways in which places come to be defined as discrete places vis-à-vis other places. Henri Lefebvre (1974) brilliantly taught us to see the world as a certain 'production of space' but there is little sense in his work of the specific social mechanisms and processes by which places and spaces become differentiated one from the other. This raises the question of geographical scale (see *Scale in Geography*) for not only is space 'produced' as an integral dimension of social change but the scaling of social activities is equally produced. Geographical scale, in fact, can be conceived as a metric—a vital sociospatial infrastructure—that organizes geographical differences into a coherence of different places. There is nothing in any way natural about the separation of different spatial scales: the scale of the global, the nation-state, regions and cities, the home and the body, all represent the ever-temporary spatial resolution of competing social forces.

This is easily illustrated with reference to the origin and functions of nation-states. Although nations and states separately preceded the flowering of nation-states in the eighteenth century, a good case can be made that the scale of nation-states emerged in response to contradictory impulses toward competition and cooperation that surfaced powerfully with the fruition of capitalism (Smith 1991). On the one hand, separate private capitals were driven by the necessity of competition, yet on the other it was imperative for them to find ways of cooperating in order to provide vital social and physical conditions for profit-making; the control of labor, a transportation infrastructure, the defense of private property, the provision of legal and financial institutions, systems of ideological mandate, all required a state apparatus—a structure of governance—to establish and regulate a modicum of self-interested cooperation among competing enterprises.

The territorial expression of this requirement was far from inevitable. From West Africa to South Asia to the Mediterranean, city states had previously performed this function, but the rapid expansion of capital accumulation in Europe by the seventeenth and eighteenth centuries now took place on a geographic scale that was less and less controllable from city states (Smith 1991, Arrighi 1994). The nation-state represented a very specific geographical compromise between capitalist competition and cooperation. Separate capitals cooperated within the nation-state over the provision of the vital collective conditions of production and reproduction while intensifying their competition in the market. Nor, of course, was this new territorial scale of governance uncontested or easily evinced (Tilly 1990). Rather it involved a dramatic mobilization of political as well as economic power, ideological persuasion establishing and expanding national identities, and military conflicts. The result was a system of national states and national economies which, while never entirely stable, represented a rescaling of the world such that national states for the first time became the basic building blocks of the global system.

3. *Recent History of Uneven Development*

The unevenness of the geographical landscape can therefore be read as a kind of palimpsest in which old social inscriptions are still quite evident in the landscape, albeit written in quite different registers—a kind of invisible socio-economic and political ink perceptible to the discerning geographical eye amidst later inscriptions. The decades spanning from postwar expansion (1950s and 1960s) to economic crisis (late 1960s to early 1980s) and the expansion of a restructured capitalism (1980s and 1990s) have witnessed a significant evolution in the patterns and processes of uneven development and although the tendency toward a seesaw motion of capital is far from complete, there are clear signs of it especially at lower scales.

At the urban scale, for example, the sustained disinvestment in many central cities throughout the Western world represented the geographical corollary of suburban expansion. Uneven urban development for most of the twentieth century was precisely about this differentiation of suburb from city, an expression of class as well as race and gender differences inscribed dramatically in the landscape. However, by the later decades of the century two new processes led a further evolution of urban unevenness. In the first place, suburbs became much more integrated functionally, adding retail, recreational, cultural, and service ac-

tivities to existing residential and industrial land uses, giving rise to what one commentator has called 'edge cities' (Garreau 1991). On the other hand, the widespread gentrification of central and inner city areas was spearheaded by reinvestment in previously disinvested neighborhoods, the seesaw of uneven development at the urban scale (Smith 1996). This reworking of the differences between suburb and city is driven by the continued geographical expansion of metropolitan areas and is mediated by the structure of ground rent within what is, effectively, a single (territorial) labor market.

At the regional scale we have already indicated a quite different if commensurate set of processes. Many major industrial regions that had been the economic backbone of national economies in Europe and North America—from the Midwest to the Rhine-Ruhr to the English Midlands—experienced disinvestment and deindustrialization after the 1950s as declining profit rates in traditional industrial sectors were matched by the expansion of new sectors. New regional agglomerations such as Silicon Valley, the Third Italy, or the high tech concentration around Taipei, emerged as the leading edge of regional change while by the 1980s some of the older deindustrialized regions (New England, central Scotland) experienced considerable reinvestment at the behest of the 'new economies.'

At the national scale, however, something rather different has been taking place. By the end of the postwar expansion in the early 1970s, the scale of capital accumulation had increasingly superceded the system of national states and economies that had, for two centuries, nurtured it. The pursuant 'globalization,' as it is misleadingly labeled, has eroded the rationale for discrete national economies and many systems of national state governance have, as a result, restructured themselves, significantly withdrawing from the support of social reproduction (the dismantling and/or privatization of social welfare and social services) while hewing more closely to the market logics of capital accumulation. If this 'hollowing out' of the state is only partial, it none the less has had the geographical effect of eroding the importance of national boundaries in economic terms. In general, both capital and laborers move more freely at the beginning of the twenty-first century than they did three decades earlier. There is a crucial caveat here, however. The increasing economic porosity of national boundaries does not in any way imply the end of the nation-state, and in fact the cultural and political responses to 'globalization' can equally lead to quite dramatic, even violent reassertions of national identity and difference (e.g., Serbia, Rwanda, various ex-Soviet states, or, in a softer vein, Scotland).

While previously hegemonic national powers—especially, perhaps, the UK—have clearly experienced comparative economic decline there is no real evidence of national economies undergoing a full 'seesaw' from developed to underdeveloped and back to developed economic status. The power of national boundaries over the last two centuries has entrenched highly resilient forms of inequality via colonialism, imperialism, and underdevelopment. Amidst the fluidity of capital and commodities in the global economy, a certain geographical fixity has prevailed at the national scale, accentuating patterns of unequal development.

This brings us to the global scale, where indeed we see that some regions and economies that were long underdeveloped have suddenly become major centers of global economic production. In other words, a 'new international division of labor' emerged in the wake of postwar reconstruction (Fröbel et al. 1980). Since the 1960s, the economies of South, South-east, and East Asia have experienced the most intense industrial revolution of all time, culminating in the momentous economic crisis between 1997 and 1999. Economies like South Korea, Singapore, or Taiwan, which in the 1960s were definitively consigned to Third World status, are now significant powers in the global economy. Together with the financial integration of European, North American, and Japanese economies after 1971, it was the inclusion of the industrial economies of Asia that spawned what is now known as globalization. Globalization is at root a recalibration of political economic power between transnational capital and national states. For apologists of globalization, it ushers in an equalization of conditions across the globe, while for critics it accentuates the differences. The theory of uneven development suggests that both visions are partially correct and that the contradiction between equalization and differentiation is resolved geographically. While much of Asia, even including China, which only nominally remains a socialist state, is drawn toward the capitalist core, Sub-Saharan Africa is increasingly distanced from any benefits of a new globalism. To borrow a language from the urban scale, Sub-Saharan Africa has, since the 1970s, been increasingly 'redlined' by global capital: a red line has been drawn around the region and international banks, governments, and aid organizations have minimized investments there, accentuating social poverty (see for example Bond 1998).

We have stressed that the geographical unevenness of capitalist development emanates from the structured social relations of capitalism itself, but this too is a historical result. Not until far flung economies were significantly interlinked through labor, finance, and commodity markets could uneven development evolve into the systematic expression of the inequalities at the heart of capitalism. While this was inevitably a gradual process, the years from the 1880s to 1919 marked a period of most intense transition. Radically divergent levels and types of economic development prior to this period may still have owed as much to divergent political economies, colonialism and imperialism notwithstanding. For the remainder of the twentieth century, however, such differentials in development were largely internal to a global capitalism that was

increasingly organized around US market dominance rather than around systems of European colonialism (Smith 1991).

Viewed this way, globalization after the 1980s represents not so much a wholly new phase of capitalist expansion but an accentuation of existing processes and patterns of uneven development. In this light it is important to stress that specific patterns of uneven development, while driven by powerful processes endemic to capital accumulation, also express the results of political struggles, social and cultural differences, and relict features and processes that have adapted to channel capitalist social and economic processes. Just as capitalism is a historically discrete mode of production, therefore, there is nothing inevitable about uneven development either in its broad outlines or specific details. Different modes of production make different kinds of social geographies.

Unfolding and Vector Models

1. Individual Differences in Preference

In this article a family of multidimensional models for preferential choice (or other 'dominance') data is considered, focussing on accounting for individual differences in relative preferences (or dominance judgments) of different subjects (or other data sources) for a number of stimuli (or other objects). The family of models involved comprise what is called the 'linear-quadratic hierarchy' of multidimensional preference models (Carroll 1972, 1980), beginning with the simplest case of the fundamentally linear 'vector model' first proposed by Ledyard Tucker, in which stimuli are represented as points in a multidimensional space, while subjects are represented by different vectors, or directed line segments, in the same multidimensional space—with the preference scale values (and thus the preference order) for a given subject being determined by projections of stimulus points onto that subject's vector. Next, in terms of complexity, is the 'simple' unfolding (or ideal point) model, originally proposed by Clyde Coombs. This inherently quadratic model assumes that each subject (or data source) is represented by a unique point, called the subject's 'ideal point,' representing the most preferred stimulus for that subject. That subject's preference scale values and orders (i.e., interval or ordinal scale values on what Coombs called the 'I scale' for that subject) for the stimuli are defined via a decreasing monotonic function of the (Euclidean) distances between the stimulus points and that subject's ideal point. Stated most simply, the closer a stimulus is to a subject's ideal point, the better that subject *likes* that stimulus. Other more complex models, generalizing the unfolding/ideal point model to include an idiosyncratic set of dimension weights for each subject, with distance being defined via weighted, rather than simple (unweighted) Euclidean distances, and another allowing each subject an idiosyncratic rotation of coordinate axes followed by differential weighting of the *rotated* axes, are also considered. The 'simple,' weighted, and generalized unfolding/ideal point models are all inherently quadratic models, entailing increasingly complex quadratic functions of the dimensions of the multidimensional space underlying the stimuli. These models, together with the vector model, comprise a hierarchy, since each simpler model is a special case of each of the more complex models—and is referred to as the linear-quadratic hierarchy of preferential choice models because they

all are either linear or quadratic, in the strongest (metric) case, or are *monotonically* related to linear or quadratic models in the weaker 'nonmetric' case.

Methods are discussed for fitting these models to appropriate individual differences preference data, including use of multidimensional scaling (MDS) methodology for 'internal' analyses—in which both stimulus *and* subject parameters are simultaneously estimated based on the preference data alone—as well as for 'external' analyses—in which stimulus parameters (e.g., coordinates of stimuli in a multidimensional perceptual space) are predefined, fixed *a priori* values (e.g., derived from MDS of proximity data), while subjects are 'mapped' into this *a priori* stimulus space by fitting subject parameters (vector termini, ideal points, and/or other parameters) to account optimally for the preference data *conditional* on the fixed dimensional coordinates of the stimuli.

2. Types of Preference Analysis

First we consider some important different types of analysis, beginning with internal vs. external analyses.

An *internal analysis* of preference data utilizes only the preference data to develop parameterization of both stimuli and subjects. An *external analysis* utilizes a stimulus space defined à priori; that is, *externally* to the preference data, for example, by multidimensional scaling (MDS) of independently defined proximity data, or from a physical, theoretical, or other 'rational' dimensionalization of the stimuli.

A mixed (ambiguous) case is that in which the stimulus space for an external analysis is defined via MDS or other structural analysis of the preference data.

Another important distinction is that between metric and nonmetric analyses. In a *metric analysis* the functions F_i (defined below) generally are assumed linear (or, at least of some well-defined parametric form) while in a nonmetric analysis they are assumed to be merely *monotonic*. It is important to keep in mind that this distinction between metric and nonmetric analysis has nothing to do with the metric (or distance function) defining distances between stimuli and ideal points, but with whether the basic data are ratio or interval scale (the 'metric' case) or merely ordinal scale data (the 'nonmetric' case).

In some cases the functions F_i may be assumed all to equal a single function F (so the subscript is dropped). This is a very strong assumption, since it assumes comparability among different individuals' preference data (thus assuming *unconditional* data). As will be seen below, this can lead to degenerate solutions in the nonmetric case. In most cases the data will be assumed to be noncomparable for different subjects, and thus to be *conditional* data.

3. Models for Multidimensional Preference Analysis

We now consider the '*linear-quadratic hierarchy*' of multidimensional preference models—ranging from the (linear) vector model through increasingly complex quadratic models corresponding to the 'unfolding' or ideal point model and its generalizations.

We begin with the vector model illustrated in Fig. 1, with an example due to Wish (see Carroll 1980 for details) shown in Fig. 2, from an intensive study of perception of and preferences for nations. This is a result of application of an *internal metric* analysis in terms of the vector model (via the MDPREF procedure, to be described below) to data on judgments of 'similarity to ideal' of 21 nations by 75 subjects, who were students selected from a wide range of nationalities at Columbia University's International House, in summer 1968 (at the height of the Vietnam war, and when, of course, the political and economic status of many of them was quite different than is now the case). The two dimensions can be interpreted as economic development (the first, or horizontal, dimension) and communist vs. noncommunist (or 'political alignment and ideology'), dimensions which were also found in independent MDS analyses of similarity data collected in this same or related studies. In the present case the subjects were given the labels 'dove,' 'hawk,' and 'moderate' based on responses to a one item questionnaire regarding US involvement in Vietnam; 'doves' being those preferring less US involvement in Vietnam, while 'hawks' wanted more involvement,

Figure 1
Vector model for preference illustrated. Projections of stimulus points onto a subject's vector are assumed to define preference scale for that subject

Figure 2
Two-dimensional solution from Wish's MDPREF analysis of 'Similarity to Ideal' judgments of 75 subjects on 21 nations

and 'moderates' preferred maintenance of the status quo. Since, however, many of these subjects were students from (then) communist countries, many of those classified as 'doves' on this basis might have been communist 'hawks,' that is, strong supporters of their own countries' positions opposing US involvement in Vietnam. For this reason we can see that many (but not all) of the 'doves' have vectors whose directions indicate preference for the communist countries, unlike what we might expect if these were 'doves' on the Vietnam issue from the US or other generally anti-Communist countries. On the other hand, all the 'moderates' and 'hawks' have vectors indicating either preference for the highly economically developed countries (as measured by judgments of 'similarity to ideal'), with relative indifference to political orientation, or preference for the noncommunist countries.

The vector model is mathematically of the form:

$$\pi_{ij} = F_i(p_{ij}) \cong \sum_{r=1}^{R} b_{ir}\, x_{jr} \qquad (1)$$

where R = number of dimensions, while $\cong$ means 'equals, except for (unspecified) error terms.' x_{jr} = value of the jth stimulus on r^{th} dimension ($j = 1 \ldots n$), b_{ir} = *importance* of dimension r for subject i (it is,

technically, a direction number, or is proportional to the direction cosine of the angle subject i's vector makes with the rth dimension or coordinate axis). p_{ij} = preference scale value of the jth stimulus for the ith subject ($i = 1 \ldots m$), π_{ij} = transformed preference scale value for subject i and stimulus j, F_i is a (monotonic, linear, or other) function transforming p_{ij} into π_{ij}.

In matrix form

$$\Pi \cong \mathbf{BX}' \tag{2}$$

where $\Pi \equiv (\pi_{ij})$ is the matrix of transformed preference values, π_{ij}, while $\mathbf{B}$ is the $m \times R$ matrix (b_{ir}) of importances, and $\mathbf{X}$ is the $n \times r$ matrix (x_{jr}) of coordinates of the stimulus space. Geometrically, we can think of this as *projecting* stimulus points onto a subject vector; the greater the projection the greater is that subject's (predicted) preference for the stimulus. These projections are multiplied by the *length* of the subject vector, which can be regarded simply as a scaling factor proportional to the square root of the variance accounted for in the transformed preference data for that subject.

In an *internal* analysis, both $\mathbf{B}$ and $\mathbf{X}$ are derived from data. A *metric internal* vector model analysis can be accomplished by a singular value decomposition (SVD) analysis—which amounts to a kind of 'direct' principal components analysis (PCA) in which both the components (corresponding to the vectors representing the subjects) and the component scores (corresponding to the *stimulus* dimensions) are derived directly from the Π matrix (which, in the metric case, is derived from the $\mathbf{P}$ matrix by simply normalizing rows/subjects—usually to zero mean and unit variance). This is the basis of the MDPREF method (see Carroll 1972, 1980)—perhaps the most widely used method of metric internal multidimensional analysis of preference data.

A *nonmetric internal* analysis can be accomplished by Kruskal and Shepard's *nonmetric* factor analysis of the $\mathbf{P}$ matrix (see Carroll 1972, 1980), which provides a nonmetric equivalent of MDPREF. Monte Carlo studies described by Kruskal and Shepard show that the parameters estimated using this approach are virtually indistinguishable from those fitted via the metric MDPREF approach—except in the case of the most extreme (but unrealistic) nonlinear, but order preserving, transformations of the data—so that they recommend using the metric procedure instead. For this reason, nonmetric factor/components analysis is never used in practice.

In an *external* analysis $\mathbf{X}$ is given and $\mathbf{B}$ is to be estimated. A *metric external* analysis can be accomplished by straightforward ordinary least squares (OLS) regression techniques—specifically multivariate multiple linear regression. The stimulus dimensions play the role of independent variables, while the preference scale values play that of dependent variables, while the regression coefficients predicting a subject's data estimate that subject's vector. This method is available in Carroll and Chang's PREFMAP (Carroll 1972) or PREFMAP-2 (Carroll 1980) procedures, or in PREFMAP-3 (Meulman et al. 1986).

A *nonmetric external* analysis would be accomplished by *nonmetric* multiple linear regression. Here one seeks a monotonic function of the dependent variable (the preference scale values) and the regression coefficients that *jointly* optimize an overall OLS criterion of fit. This method is available in all the PREFMAP procedures, as described in detail in Carroll (1972, 1980), or in Meulman et al. (1986).

An intuitively unattractive property of the vector model is that it assumes that preference changes monotonically with all dimensions. That is to say, it assumes that if a certain amount of a given attribute is good, even more is better (or, at least as good), which is unrealistic for most variables or attributes in the real world.

4. *The Unfolding or Ideal Point Model*

Coombs introduced the *one-dimensional unfolding* (or ideal point) *model*, which is illustrated in Fig. 3. Different subjects correspond to different '*ideal points*' representing their respective optimal values on the stimulus continuum. The farther a stimulus is from a subject's ideal point, the less the subject will like that stimulus. In Fig. 3, three hypothetical subjects are represented by ideal points, and the preference orders generated by these different ideal points are indicated. It is clear that, even in one dimension, quite different orders can be generated by this model. Coombs called this the 'unfolding' model because the preference order for a given individual can be generated by *folding* the stimulus scale at that individual's ideal point. To recover the stimulus scale from the preference data, it is necessary *simultaneously to unfold all these preference scales for individuals* (what Coombs calls the I scales) to find the common, or joint, stimulus scale (the J scale). The three curves drawn above the abscissa in Fig. 3 show *hypothetical preference functions* that go with the three individuals. Of major importance is that the curves are, to use Coombs's terminology, *symmetric* and *single peaked functions* (the latter meaning having a single maximum, corresponding to the ideal point). The particular shape is not important, so long as these two conditions are met, nor do they all have to have the same shape. Bennett and Hays generalized this model to the multidimensional case. The two-dimensional case of this *multidimensional unfolding* (*or ideal point*) *model* is illustrated in Fig. 4. As in the unidimensional case, the farther a given stimulus point is from an individual's ideal point in the multidimensional space the less that individual likes that

Figure 3
Unidimensional unfolding model illustrated. Distance of stimulus from subject's 'ideal point' (their optimal value on the unidimensional scale) is assumed to define (inversely) the preference scale for the subject

Figure 4
Multidimensional unfolding model illustrated. Distance from subject's 'ideal point' (inversely) defines that subject's preference scale. Isopreference contours are concentric circles centered at 'ideal points.' They would be spheres or hyperspheres in higher dimensions

stimulus. This, however, implies a metric on the space, which Bennett and Hays assumed to be Euclidean. This means the *isopreference contours* (or loci of equal preference) are, in two dimensions, a family of concentric circles centered at the individual's ideal point. They are concentric spheres in three dimensions and hyperspheres in higher dimensions. The basic algebraic structure of the (simple or unweighted) unfolding/ideal point model is defined in Eqns. (3) and (4) below

$$\pi_{ij} = F_i(p_{ij}) \cong d_{ij}^2 \tag{3}$$

$$d_{ij}^2 = \sum_{r-1}^{R} (y_{ir} - x_{jr})^2 \tag{4}$$

where $y_{ir} = r^{\text{th}}$ coordinate of the ideal point for the ith subject (and other parameters are as before).

While vector and unfolding models appear superficially to be quite different, the vector model can be shown to be a special case of the unfolding model. As the ideal point moves farther out in a fixed direction the preference orders are asymptotically identical to those for a vector in that direction. An algebraic and geometric proof is possible, but is beyond the scope of this article (see Carroll 1972, 1980). Thus, it follows that data appropriate for an R-dimensional vector model can always be fitted (arbitrarily closely) by an R-dimensional unfolding/ideal point model—with the preference orders for the ideal point model approaching those for the vector model as the ideal point moves toward infinity in the direction corresponding to that of the vector. This is also true for a *strong metric* version of the unfolding model, as described by Carroll (1972, 1980). Conversely, it can be shown that data

appropriate for either a *nonmetric* or *metric* unfolding/ideal point model can always be fit via a vector model with one extra dimension, as originally conjectured by Coombs and Kao and confirmed for the strong metric version of multidimensional unfolding by Ross and Cliff (see Carroll 1972, 1980). Thus, while an R-dimensional vector model is a special case of an R-dimensional ideal point model, an R-dimensional ideal point model is a special case of an $(R+1)$-dimensional vector model.

Any nonmetric or metric internal unfolding problem can be formulated as a nonmetric or metric multidimensional scaling problem of an $m \times n$ (e.g., subjects $\times$ stimuli) preference matrix (see *Multidimensional Scaling in Psychology*; Carroll and Arabie 1998). As first argued by Coombs the preference matrix **P** is interpretable as a *conditional off-diagonal proximity* matrix, that is, Coombs interpreted preference data as *proximities* between *stimuli* and subjects' *ideal points*, but *off-diagonal* since proximities among stimuli or among subjects are not provided, and *conditional* since data (e.g., preference orders or scale values) for one subject (row of the matrix) cannot be compared with those for a different subject/row.

Kruskal's MDSCAL-5, as well as various versions of KYST have options allowing a preference matrix (or another off-diagonal proximity matrix) to be treated as the above special form of proximity matrix and analyzed via either nonmetric or metric MDS. When doing this, for reasons discussed in Kruskal and Carroll (1969) and by Carroll (1972, 1980), it is essential to use the 'split-by-rows' option, that enables the preference data to be treated as conditional proximities, and an alternative measure of STRESS, called STRESS-2 (as contrasted to the earlier version of STRESS originally defined by Kruskal, now called STRESS-1). The details, and reasons for this, are discussed in Kruskal and Carroll (1969), or Carroll (1972, 1980). Suffice it to say that there are various totally meaningless *degenerate solutions* that are virtually guaranteed to occur, and which *appear* to yield perfect fit (STRESS = 0), yet recover essentially *no* information in the data, and are essentially totally *independent* of the data, if the guidelines stated in these papers are *not* followed. *Unfolding–External analysis* (*metric and nonmetric*).

Carroll and Chang's PREFMAP (for PREFerence MAPping) or PREFMAP-2, or, most appropriately, Meulman et al's. PREFMAP-3, accomplish an external unfolding analysis. Metric external unfolding analysis can be translated into a quadratic regression problem, while the nonmetric case can be treated as a nonmetric generalization of this special case of quadratic regression (Carroll 1972, 1980, Meulman et al. 1986). It is also possible to fit two generalizations of the unfolding/ideal point model via these programs—a weighted generalization in which a weighted Euclidean distance (analogous to that assumed in the INDSCAL approach to individual differences MDS) between stimuli and ideal points replaces the unweighted Euclidean distance assumed in the 'simple' unfolding/ideal point model, and a generalized model assuming a generalized Euclidean distance in which each subject is assumed to effect an idiosyncratic rotation of the coordinate system as well as having idiosyncratic weights for these (rotated) dimensions. At the other extreme, the simplest model in this class of models, called the *linear-quadratic hierarchy* of models; namely the *vector model*, can also be fit, by solving a metric or nonmetric least squares linear regression problem.

All four of these external models can be fit metrically or nonmetrically, while statistical tests based on the fact that these are, formally, nested models, can be used, at least in the metric case, to decide, for each subject, which model is most appropriate. In the nonmetric case, while not strictly valid statistically, the resulting 'pseudo-F's' can be useful in conjunction with other information (e.g., interpretability of the various representations) in deciding on the best model for each subject's preference data.

Other approaches to (internal or external) unfolding include a metric unfolding method proposed by Schöneman, and Srinivasan and Shocker's LINMAP, which fits an external weighted ideal point model, using linear programming techniques (minimizing a 'least absolute deviations' measure of fit) but with nonnegativity constraints on subject weights (see Carroll 1980). Other approaches include one based on 'homogeneity analysis' (closely related to correspondence analysis) proposed by Heiser, and DeSarbo and Carroll's three-way generalization of unfolding analysis (see Carroll and Arabie 1998). A general approach called GENFOLD is discussed by DeSarbo and Rao (1984).

In addition to spatial unfolding/ideal point models, tree-structure based unfolding models have been proposed by De Soete, DeSarbo, Furnas, and Carroll and generalized to the three-way case by De Soete and Carroll (see Carroll and Arabie 1998). Also, stochastic (or probabilistic) vector and (spatial) ideal point models as well as stochastic tree unfolding models have been fit to paired comparisons preference data (see Carroll and De Soete 1991, De Soete and Carroll 1992).

Unitary State

1. Definition

The nation state is the conventionally accepted form of territorial organization which originated in Western Europe. The term 'unitary state' is a black hole in the political science literature; a taken-for-granted notion for which it is rare to find a definition (an honorable exception is Rose 1982, pp. 51–2). It is all too often treated as a residual category, used to compare unitary with federal states to highlight the characteristics of the latter (Elazar 1997). It is used in this article to refer to the politically sovereign, centralized governments of unified nation states. It is an institutional and constitutional notion; politically sovereignty refers to international recognition that a government rules a specified territory. It is centralized because the decision to decentralize can be revoked by the central authority.

Following Rokkan and Urwin (1982, p. 11), I distinguish between the unitary state and the union state. The unitary state is 'built up around one unambiguous political centre which enjoys economic dominance and pursues a more or less undeviating policy of administrative standardisation. All areas of the state are treated alike, and all institutions are directly under the control of the centre.' In the union state 'integration is less than perfect … (and) … While administrative standardisation prevails over most of the territory … in some areas pre-union rights and institutional infrastructure … preserve some degree of regional autonomy and serve as agencies of elite recruitment.'

2. Types of Unitary State

There are at least three types of unitary state among liberal-democracies: the Anglo-Saxon, the Napoleonic, and the Scandinavian.

The Anglo-Saxon state draws a clearer boundary between state and civil society, there is no legal basis to the state, and 'the idea of the state as a thing in itself, an institution independent of and superior to members of society … is alien to British political thinking' (Rose 1982, p. 47). The Crown represents the sum of formal political authority. The classical example of a unitary state is the British Westminster model characterized by parliamentary sovereignty, strong cabinet government, accountability through elections, majority party control of the executive (i.e., prime minister, cabinet, and the civil service), elaborate conventions for the conduct of parliamentary business, institutionalized opposition, and the rules of debate (Gamble 1990, p. 407, Rhodes 1997, Chap. 1). Combining parliamentary sovereignty and a strong executive makes the British unitary state one of the most centralized in Western Europe.

Britain can also be seen as a union state. Scotland, Wales, and Northern Ireland have distinctive administrative arrangements because the English center chose an operating code which was flexible and accommodating, stressing indirect control of the periphery and representation of the periphery in the center (Bulpitt 1983). Constitutional reform in the 1990s reinforced functional decentralization by devolving political authority to the constituent territories of the United Kingdom.

The Jacobin–Napoleonic tradition sees the French state as 'the one and indivisible republic,' exercising strong central authority to contain the antagonistic relations between state and civil society (on French political traditions, see Hazareesingh 1994, Chaps. 2, 6) 'France is a unitary state superimposed on a multinational society.' Thus the Jacobin tradition stresses the need for a monolithic state apparatus to coerce the fragments of French society into a semblance of order. National uniformity lies at the heart of the link between state and citizen; there is 'a comprehensive system of central administrative control based on a hierarchical chain of command.' Regulations multiply. In debates about regional reform, fears are ever present that they will be 'a real threat to the unity of the state and nation.' The continuing challenge of government is to find unity out of chaos. So the state moulds society into a whole (all quotes from Hayward 1983, Chap. 2).

Knudsen (1991, p. 96) identifies homogeneity, continuity, a strong state tradition, a high integration between state and society through strong local governments, a tradition for consensual democracy, social democratic parties, and a public sector with universal bureaucracies, little corruption, and comparatively high efficiency as key characteristics of the Scandinavian model of the unitary state. Denmark owes its strong bureaucratic and legal tradition to the influence of its neighbor, Germany. The defining characteristic of a *Rechtsstaat* is that it is a legal state vested with exceptional authority but constrained by its own laws (Dyson 1980). Civil servants are not just public employees, but personifications of state authority. So Knudsen (1991, p. 37) describes the dominant tradition as 'a highly bureaucratic, rule-bound and hierarchic structure designed to promote objective decision making on the basis of appropriate laws or regulations in obedience to the current government, whatever its political complexion.' Denmark differs from the German *Rechtsstaat* in being decentralized with a strong participation ethic. So local authorities have the right 'to manage their own affairs under the control of the state.' They have a high degree of constitutional autonomy; described as 'spectacular' by Knudsen (1991, p. 74). The complexities of constitutional reform are an intimidating safeguard of devolution to local government. Denmark is a decentralized unitary state.

3. *Centralization*

No unitary state is wholly homogeneous. No unitary state is completely centralized. Decentralization is a common strategy for coping with diversity. There are types and degrees of decentralization: deconcentration (prefectoral and functional), delegation, and devolution to both regional and local governments (Rhodes 1992).

3.1 *Decentralization*

This refers to the distribution of power to lower levels in a territorial hierarchy whether the hierarchy is one of governments within a state or offices within a large-scale organization (Smith 1985, p. 1). Or, more briefly, it refers to the areal division of powers (Maass 1959). So defined, the terms encompasses both political and bureaucratic decentralization, federal and unitary states, and decentralization between levels of government and within units of government.

3.2 *Deconcentration*

Sometimes referred to as field administration, deconcentration involves 'the redistribution of administrative responsibilities … within the central government' (Rondinelli and Cheema 1983, p. 18). A broad distinction can be drawn between prefectoral and functional systems. In the prefectoral system, a representative of the center—or the prefect—located in the regions supervises both local governments and other field officers of the center. This person is the superior officer in the field, embodying 'the authority of all ministers as well as the government generally and is the main channel of communication between technical field officials and the capital' (Smith 1967, p. 45). The classical examples are the French prefect and the Collectors or District Commissioners of India. In the functional system, field officers belong to distinct functional hierarchies. The administration of the several policy areas is separate. There is no general, regional coordinator; coordination occurs at the center. This system of multifarious functional territories is typified by England (see Hogwood and Keating 1982).

3.3 *Delegation*

This term refers to 'the delegation of decision-making and management authority for specific functions to organisations that are not under the direct control of central government ministries' (Rondinelli and Cheema 1983, p. 20). Such organizations are referred to as parastatal organizations, nondepartmental public bodies, or quangos (quasi-autonomous non-governmental organizations). They include public corporations and regional development agencies. This category is also used to cover the transfer of functions to the private sector or voluntary bodies through marketization, privatization, or contracting-out, cumbersome neologisms which refer to the various ways of delivering 'public' services using markets or quasi-markets. Decentralization understood as managerial delegation and marketization fueled major reforms of the public sector throughout the world in 1980s and 1990s (Kickert 1997).

3.4 *Devolution*

Devolution refers to the exercise of political authority, by lay, mainly elected, institutions within areas defined by community characteristics (Smith 1985, p. 11). Thus, 'local units are autonomous, independent and clearly perceived as separate levels of government over which central authorities exercise little or no *direct* control' (Rondinelli and Cheema 1983, p. 22). Historically, the *locus classicus* of devolution is said to be British local government, but the most significant trend in the decentralization of political authority is the growth of regional government in Europe (Jones and Keating 1995).

4. *For and Against Centralization*

Centralization is the root of all evil for advocates of decentralization. The arguments for and against are clear even if there is no foreseeable end to the debate.

So centralization promotes territorial justice and equality. Central authorities uphold service standards, rationalize resource allocation, and coordinate local development. There is a need for national plans, especially when resources are scarce, and only the center can ensure territorial equality by the central provision of funds and supervising the uniform implementation of national policies. Centralization is encouraged by financial weakness, national elites, including the bureaucracy, eager to protect their interests, and political instability.

On the other hand, decentralization is often said to be the counterweight to central power. Liberal-democratic theory assumes that decentralization promotes democratic participation, especially local self-government. Nationally, decentralization is said to promote political education, training in political leadership, and political stability. In local government, it promotes the values of equality, accountability, and responsiveness (Smith 1985, p. 20, Sharpe 1970). It is also said to have many managerial or administrative advantages. First, it is seen as a way or surmounting the administrative incompetence of the center; that is, the limits of national planning, by getting closer to problems, cutting through red tape, and meeting local needs. Second, it improved central 'penetration' of rural areas, spreading knowledge of, and mobilizing support for, the plan and bypassing obstructive local elites. Third, it encouraged the involvement of various religious, ethnic, and tribal groups, promoting national unity. Fourth, it increased the speed and flexibility of decision-making, encouraging experimentation, and reducing central control and direction. Fifth, it increased the efficiency of the center by freeing top management from routine tasks and reducing the diseconomies of scale caused by congestion at the center. Sixth, it increased the administrative capacity of the localities and regions, and improved the coordination of service delivery. Finally, it institutionalized participation, provided opportunities for many interests to get a 'stake' in the system, trained citizens for democracy and politicians for government, and promoted political maturity and democratic stability (paraphrased from Rondinelli and Cheema 1983, pp. 14–16 and Smith 1985, pp. 186–8). Unfortunately, decentralization has not lived up to its promises. The strongest argument for centralization is the failure of decentralization, especially in developing countries, where the main outcome is chaotic inefficiency.

5. *Conclusion*

To raise the topic of centralization is to raise an emotive issue. Centralization is 'bad'; decentralization is 'good.' There is a clear implication that a federal state is a more decentralized form of government than a unitary state (see *Federalism*). Any such conclusion should be resisted. A federal state can devolve restricted powers to its constituent governments. The theory and practice of federalism can diverge markedly and, as the case of Denmark shows, a unitary state can devolve considerable powers to local and regional governments. The unitary state cannot remain a taken-for-granted notion. The degree of centralization, and its varied political and administrative consequences, must become matters of empirical inquiry.

United Nations: Political Aspects

The United Nations is an international organization of which almost every state in the world is a member. An international convention, the UN Charter, in force since 1945, constitutes its basic law. Its paramount purposes comprise the maintenance of international peace and security and the promotion of human welfare through international cooperation. As the UN agenda as well as its organizational design involves definition and resolution of issues of public policy, its establishment implies limited governance. Its decisional processes exhibit relative power among participants as well as attempts to change it. Shifting coalitions of members aggregate support or opposition for various ends, including allocation of resources. Some conclusions are converted into binding law. The United Nations maintains relationships with a variety of constituencies and other organizations.

1. *Conventional and Novel Capacities*

The organizational design, largely planned by American officials during World War II with some British and other contributions, owes much to the League of Nations, especially the concept of *collective security* that underlies enforcement against violation of the UN Charter. In promoting human welfare, the activist, reforming, government-led approach of the New Deal in the United States and the doctrine of *functionalism* offered important models.

The organization nevertheless rests on foundations of conventional diplomatic experience with the concept of *state sovereignty* as a backdrop. This heritage includes bargaining among diplomats to propose binding international law stated in agreements that governments ratify. The UN structure supports routine diplomatic, conciliatory, arbitrary, and judicial methods for the settlement of disputes. Such techniques set most boundaries to UN governing capacities.

The United Nations was endowed with some novel governing attributes. In interstate conflicts that breach the prohibition in the UN Charter on using force in international relations, the Security Council, as principal organ for international security, was empowered to coerce violators of the peace. This coercion included the use of a military force as well as diplomatic and economic sanctions. That coercive measures would both deter and arrest aggression was underpinned by the requirement that majority voting in the Security Council must include concurrence of the permanent members, the Great Powers of 1945. Moreover, arms control would bring the Security Council closer to a military monopoly.

Less directly coercive, but savoring of governmental functions, were broad duties in setting international standards. These included the novel, policy-pregnant topic of human rights. Related were supervisory functions pertaining to self-government or, in limited cases under the surveillance of the Trusteeship Council, independence of colonial territories. Less novel were recommendations related to international economic and social issues, put in the purview of the Economic and Social Council (ECOSOC) which was also to oversee other international organizations with technical agendas. The General Assembly, where all members had equal votes, would adopt overall policies.

Governments retained the main responsibility for executing policies adopted in the UN organs. Some central executive capacity, however, was given to the Secretary General, the head of an international secretariat. He carries out instructions of the intergovernmental organs, prepares documentation for meetings, and serves as the public representative. He thus acquires a role in decision-making. The Secretary General has the overtly political right to bring matters affecting peace and security to the attention of the Security Council.

2. *Political Processes and Outcomes*

The harmony of aims that planners assumed and acceptance of a formal process for deciding on policies, making recommendations, and reacting to crises never materialized. Instead, the organization has only partially functioned as a centralized policy source and provides an arena for competitive as well as cooperative policies among members.

2.1 *The Effects of the Cold War*

The lengthy antagonism between the United States and the Soviet Union and their respective allies made the United Nations an arena of confrontation and conflict. It soon crippled attempts to bring nuclear arsenals under international control. The planned armed force for the Security Council aborted amidst controversy. In a long line of disputes, e.g., the conflict between India and Pakistan over Kashmir, the Security Council operated more as sounding board than a settlement device. In the early years, the opposition of the Soviet Union to many proposed actions led it to much use of the veto. Led by Washington, the General Assembly tried to recompense the Security Council's lameness, but as the membership increased, the United States abandoned its position and emphasized the Security Council, where its opposition could

block action. Later the United States became a leading user of the veto.

Nevertheless, the Cold War neither canceled some use of the United Nations to maintain international security nor blocked organizational development. By reacting immediately to the attack on South Korea in 1950 by the Communist regime in the North, the United States gathered a coalition under UN auspices to check the invasion. But UN recommendations for the reunification of Korea remained unfulfilled during the next 45 years.

The UN organizational cluster was extended with the establishment of the World Health Organization, the Food and Agriculture Organization, the International Civil Aviation Organization, the UN Educational, Scientific and Cultural Organization, and the General Agreement on Tariffs and Trade. The Soviet Union and its allies opposed much of this construction and the programs that emerged.

2.2 Functionalism

This wave of organizational construction had its roots in functionalist doctrine (Mitrany 1966). It reflected the work of the League of Nations and the International Labor Organization to extend human welfare by international cooperation. Supporters of this organizational principle futilely hoped that technical agencies would have a nonpolitical character.

The use of ECOSOC as a policy leader and coordinator soon was frustrated in part by the Cold War antagonism and in greater part by resistance from the specialized agencies. These technical bodies had separate legal status, their own contact points with governments, and controlled their own budgets. Some of the organizations, especially the International Monetary Fund and World Bank, kept their relations with the council and other organizations at a distance. Yet the obvious need for coordination to prevent duplication and promote synergy led to a network of interorganizational relationships, alliances, and coalitions that became a standing feature of UN politics.

Charting interorganizational relationships was further complicated by the General Assembly's creation of agencies under its wing and by the notion of regionalism which was incorporated the in the UN Charter. To UN Children's Fund (UNICEF) and UN High Commissioner for Refugees (UNHCR), which by 1950 the General Assembly established as short-term agencies to which contributions were voluntary, were added the UN Population Fund; the large UN Development Program; the UN Conference on Trade and Development (UNCTAD); and more. It also created four regional economic and social commissions.

In matters of peace and security, both the Security Council and the General Assembly made sporadic and usually superficial use of independent regional organizations, such as the Organization of American States. Not until the disintegration of Yugoslavia and subsequent conflicts in Bosnia and Kosovo in the 1990s was a link forged between the United Nations and the North Atlantic Treaty Organization (NATO) and the European Union. NATO troops served for enforcement of policies given legitimacy by the Security Council.

Despite elaborate coordinating structures, reliance on *ad hoc* executing coalitions in both welfare and security activities hardly diminished. They reached new high points in the armed response to the Iraqi invasion of Kuwait and in several humanitarian disasters from the 1980s onwards.

2.3 Increasing Membership

Formation of new and shifting coalitions for both policy formation and execution connected directly to the near quadrupling of the original 51 UN members. First held in check by Cold War maneuvers, the membership greatly increased with the rapid collapse of the colonial system. Poor, weak, and small countries could coalesce in the General Assembly to restrict the powerful. Formal coalitions represented the views of the nonaligned states, which hoped to shun the Cold War; the developing countries organized as the UNCTAD group of 77; and several geographically-based groupings. While coalitions had no formal role in the Security Council, they conditioned its deliberations.

When security matters, including arms control, and such issues as human rights and development come before the General Assembly, the powerful governments necessarily seek support from a broad segment of the membership. This leads both to confrontation and broader cooperation. An always cumbersome decisional process, occasioning diplomatic bargaining, requires coalition formation. It offers a platform for nationalistic gestures and even for dissident ethnic minorities. It also impels some governments, especially the wealthy and powerful, to restrain UN involvement on certain security issues as well as on cooperation on development, trade, some arms control arrangements, and financial contributions.

2.4 Resource Allocation

Formally, the United Nations can only allocate resources put at its disposal by members who decide together on levies or offer voluntary contributions. Generally, financial constraints have pinched hard. They also reflect national policies such as when the Soviet Union and France declined to pay for some peacekeeping activities or the United States objected to the budgetary share assigned to it.

From early on, the General Assembly and ECOSOC sought to steer resources to governments seeking economic and social development. This effort included

various forms of technical assistance, capital grants which were very limited, and emergency relief. All of these found financial support in voluntary contributions, mainly from governments with highly developed economies. Together these efforts produced substantial programs that, however, failed to satisfy either needs or majority demands.

Broad approaches with a more compulsory tone emerged during the years of argument that led to creation of UNCTAD in 1964 as a global bargaining arena on terms of trade. This was followed by the General Assembly's attempt in the wake of the restriction of oil supplies during the Arab–Israeli war of 1973 to mandate a New International Economic Order. These stabs at resource reallocation fell well short of their high goals and were rejected by developed members. However, they affected various operations of the UN organizational cluster.

3. *Global Developments*

By its fifth decade, the United Nations had only a diminishing effect on international power relationships and warlike attempts to change them. Nevertheless, it assumed a central role in marking out and partially applying international cooperative agendas that reflected profound long-term global developments and in stimulating some popular opinion.

3.1 *Power Ranking*

The assumption of 1945 that the permanent membership of the Security Council—China, France, Soviet Union, United Kingdom, and United States—including the governments most able to muster effective force for UN missions would work harmoniously soon failed to match actuality. After 1948, China was represented by the exile government on Taiwan and stirred controversy and pressure from Beijing, which took over the place following a General Assembly action in 1971. France and the United Kingdom were by the 1980s challenged by the renaissance of Germany and Japan as well from large developing countries, including India, Nigeria, and Brazil. Yet finding a formula for reform that would be sustained by the existing permanent members, as is necessitated by the UN Charter, remained a paralyzing puzzle.

Even after the end of the Cold War and a newly cooperative spirit in Moscow, finding requisite majorities for enforcement and pacific settlement actions by the Security Council usually proved difficult. The weaker Russian successor to the Soviet Union and a China jealous of its national prerogatives implied use of the veto. The United States, obviously the most capable member, increasingly treated the Council with skepticism based on domestic developments and emphasized bilateral and alliance security arrangements. Elected members sometimes pursued national policies rather than cooperation.

The permanent members of the Security Council often ignored the General Assembly, dominated by lesser powers, and sometimes even its elected members. The Council accordingly was favored primarily for endorsing policies that had been negotiated independently of public debate and usually had little role in steering the resulting programs despite a UN stamp. This development was illustrated by the Council's activity in the 1990s in the Bosnia-Herzegovina and Kosovo as well as in its hesitant approach to the Rwanda genocide.

3.2 *Intrastate Conflicts*

Conflicts that originated in repressive governmental policies that ignored human rights standards, challenges to existing authorities that clung to power, and nationalistic movements that echoed the UN emphasis on independent nation-states increasingly came on the UN agenda, whether in the Security Council or the General Assembly. With rapid communications, the resulting human costs could not be hidden. Relief for victims of humanitarian disasters became a central and novel UN concern. Reconstruction of failed states as in Cambodia and Somalia included creation of democratic regimes. These aims expanded the scope of peacekeeping, even to include forceful intervention in such later cases as Kosovo and Bosnia-Herzegovina.

3.3 *New Global Issues*

Topical intergovernmental conferences, stimulated and prepared by the Secretariat and endorsed by ECOSOC, broadened the international agenda or sharpened attention to older items. Familiar agenda topics were population, arms control, food, and narcotic drugs control. Newly identified as global issues included the status of women; protection of the environment and climate change; refugees in Africa and from Cambodia; exploration of outer space; nuclear energy; development of the least developed countries and debt relief; human habitations; and an international criminal court.

While the form of topical intergovernmental conferences followed conventional diplomatic patterns and ended with communiqués that urged governments to act, those on human rights, women, and the environment attracted massive observation and some actual participation by nongovernmental organizations (NGOs). This added an unprecedented and controversial popular tinge to the otherwise formal conferences. The NGOs, some of which had consultative status with ECOSOC, claimed to voice the views of large groups. They effectively supported actions on human rights and the status of women

which many governments rejected as dilution of state authority. Some of the NGOs skillfully lobbied governments to apply the conclusions of the conferences and by using electronic communications acted as pressure groups undeterred by national jurisdictions. After the 1992 UN Conference on Environment and Development, a much larger number of NGOs were offered admission to ECOSOC consultancy. This suggested diminution of the governmental membership principle, but NGO participation remained controversial and fluid.

4. Scholarship and Research

Academic study of the United Nations and allied agencies has varied greatly in intensity and method (see *International Organization*). Realist and neorealist theorists of international relations generally ignore or give glancing attention to the UN system. Their concentration on national interest and foreign policies, moreover, fits with diplomatic rhetoric heard in UN fora. More specialized research that involves the formation of governmental policies has usually treated the UN system as one of many factors involved in international approaches to global topics, such as human rights, economic development, the environment, and chemical and biological weapons.

A cascade of theories seeking explanations for interstate cooperation have been employed as main tools or incidentally in studying the United Nations as an institution and as a locus of political processes. These include a variety of structural approaches, including Marxism and *dependencia*. Other intellectual paths that reflect nonstate as well as governmental actors comprise functionalism and derivatives; international regimes; organizational learning; neoinstitutionalism; and social networks. A few of these approaches have permitted statistical analysis and mathematical modeling.

On the whole, no single approach dominates research on the United Nations. The most detailed studies, which however aim at normative conclusions or the formal development of UN recommendations, generally come from legal or policy-oriented scholars. Publications of NGOs and interest groups focus on specific policy issues. Official documentation, e.g., topical reports, statistical collections, and records of deliberations, is voluminous and widely used in specific enquiries.

Universities and Science and Technology: Europe

The role of science and technology at European universities has been undergoing tremendous changes (Etzkowitz and Leydesdorff 1997, Zinberg 1991). Given the increased importance of information technology and the emerging global knowledge-based economy, scientific research and development, as well as academic training, form the basis of national policies and institutional strategies to promote economic growth. As a consequence, universities are expected to respond to the need for well-trained scientists and engineers, new knowledge, and applied science (Zinberg 1991). The industry and technology-oriented academic fields like engineering and business

management find it easier to combine science (as basic research) with technology (as a product of applied research) in order to meet the new requirements of the economy and to raise additional funds. Other disciplines in the social sciences or humanities may have greater difficulty in maintaining a key position within universities and obtaining necessary resources (Slaughter and Leslie 1997).

In order to understand the current trends in academic science and technology in Europe, it is important to describe the institutional varieties of universities. Trends in different European countries serve as a basis for analyzing new challenges for higher education systems. Consequences for the production and management of knowledge show the new imperative for the future, which emphasizes a redefinition of the relationship between universities, industry, and the state in Europe (Etzkowitz and Leydesdorff 1997, Neave and Van Vught 1991).

1. *Academic Science and Technology in Europe*

European systems of higher education consist of a variety of universities and colleges (Gellert 1993, Teichler 1996). On a very general level, two types of universities prevail: one of a comprehensive character and the other specializing in one field or area. The comprehensive university represents a conglomerate of different faculties, academic programs, and consequently a larger number of students. Specialized universities are focused on a particular academic discipline or field, such as business administration or engineering, with only one faculty and fewer students. Specialized universities tend to focus on applied research and professional training, thereby responding more easily to external needs of the labor market and private industry. Comprehensive universities are more likely to be dedicated to basic research and training (Teichler 1996).

The modern European university which combines research and teaching emerged in the early nineteenth century and went through a lively period of transitions up to the present. The proliferation of fields (e.g., biotechnology, telecommunications, electronic commerce) and new institutional types (e.g., business schools, vocational colleges) have been based on the increasingly diverse research and education needs of national economies. In retrospect, this differentiation of functions appears to have been a consequence of the new requirements of the labor market and changes in the knowledge infrastructure (Etzkowitz and Leydesdorff 1997). At the same time, the role of higher education shifted emphasis from social mobility to wealth creation (Nowotny 1995). In other words, universities had to find new forms to translate science into technology, moving away from earlier concerns with liberal education and curiosity-driven research (Slaughter and Leslie 1997). Many European governments and ministries have played a pivotal role in this shifting of emphasis in higher education systems by supporting universities through research money and other financial incentives (Etzkowitz and Leydesdorff 1997).

These new trends in the social and economic context of universities have also changed the role of knowledge (Gibbons et al. 1994). Traditionally, institutions of higher education across the world have performed core missions and functions: knowledge production (research), knowledge dissemination (teaching), and knowledge application (service–outreach). For universities operating in a social context of application, research has to accumulate not only disciplinary-based knowledge but also useful results for society. The reason for the increasing application–orientation of higher education systems, especially in Europe, has been mass higher education leading to new forms of knowledge production focusing more on a link between science and technology. As a consequence, the university has moved from an ideal model (i.e., social change) to a pragmatic model (i.e., wealth creation) (Gibbons et al. 1994, Trow 1973).

In Europe, mass higher education not only entails a sharp increase in students, faculty, and institutions. Generally, it also implies increasing institutional diversity, organizational complexity, and academic heterogeneity. Also, public pressure has challenged the ideal of autonomous universities as 'ivory towers' and has called for more accountable institutions (Dill and Sporn 1995). In the following section these challenges are analyzed more closely.

2. *New Challenges for European Systems of Higher Education*

Colleges and universities in Europe have become part of mass higher education systems because of expansion and diversification. Expansion refers to the large increases in student numbers in most European countries caused by public policies to provide education to a larger portion of the population. Diversification means mostly a binary system of higher and vocational education translating into different types of institutions for different target groups (Sporn 1999). In this process, knowledge production and dissemination have become very important. 'The driving force behind accelerated supply and demand of marketable knowledge lies in the intensification of international competition in business and industry. In many cases in-house research is no longer sufficient to meet competitive demands. In order to commercialize knowledge, firms have to look for new types of links with universities, government laboratories as well as with other firms' (Gibbons et al. 1994, p. 46).

An additional factor aggravating the socioeconomic challenges for higher education has to do with the trend to 'scientification' of employment and work

(Teichler 1996). The service and production industry has become increasingly dependent on the results of research. Additionally, a growing number of positions are labeled as 'knowledge work' and call for high skills and solid academic training. Management positions, especially in large companies with a wide reach, require a university degree (Teichler 1996).

As many observers of higher education have outlined, major challenges within European universities have occasioned the following changes (Gibbons 1994, Sporn 1999): diversification of functions, different social profiles of student population, more professional education, diverse funding of higher education, shifting power between academic and administrative roles, focus on efficiency and effectiveness, and new forms of knowledge production. In this realm, science and technology have gained importance by being more tightly linked with each other and with external constituencies. Scientific research has been translated into application-oriented results, thereby raising public credibility and legitimacy. For this amalgamation of science and technology, higher education scholars employ to the widely used term 'technoscience,' implying a combination of 'basic and applied research, discovery and innovation, science and product, knowledge and commodity' (Slaughter and Leslie 1997, p. 38).

As outlined earlier, these changes in university science and technology have been based on new economic conditions in many European countries caused by budgetary constraints and new patterns of public spending. Additionally, restructured job markets call for constant relearning of the workforce. These different areas display a general cross-national dynamic and include five major trends: scarce financial resources, changing role of the state, new technologies, continuing education, and increasing globalization (Sporn 1999).

State budgets for higher education have been restructured in many European countries. Although public funds for higher education are stable or even increasing in some European countries, they cannot respond to the rising number of students. As a consequence, new sources of funding are needed. Public spending is very often based on output measures like the number of graduates or publications. As a consequence, universities have acquired a more diversified public and private funding base and have concentrated their strategies on enhancing efficiency and effectiveness of teaching and research (Clark 1998, Williams 1995).

Closely linked to the problem of limited public funds are new mechanisms of coordination and control in higher education systems, especially regarding the role of the state. Many European systems formerly characterized by 'state control' have moved to a state 'supervising' model, with increased institutional self-regulation and autonomy while the state steers the system from a distance. In many cases like Sweden or The Netherlands, leadership structures have been strengthened and quality control is handled through external audits and evaluation (Neave and Van Vught 1991). As national economies in Europe have become more volatile and dynamic, the life-cycle of knowledge has shortened and employees need to refresh their expertise more frequently. Hence, continuing education and lifelong learning have become key elements of national policies for enhancing economic productivity. Universities responded by expanding their programs, offering adult education, interdisciplinary programs, and part-time studies with a more vocational orientation. This has expanded the number of continuing, postsecondary, and professional education programs. In Europe, this trend has been labeled as the 'professionalization' of general education (Gellert 1993, Teichler 1996).

The new knowledge economy is mainly based on the widespread use of technology. Information technology has also changed university teaching, research, and management. The expansion of the Internet and affordable hardware and software have led to computer literacy of large parts of the student population. The impacts on how students learn, professors teach and conduct research, and administrators manage the institution are complex. Recent trends like virtual universities and distance education programs, international research projects, and administrative information systems are a few examples of changes influenced by information technology (Sporn 1999). Globalization and international competition have put pressure on colleges and universities. The importance of research and development, the creation of common markets, rising mobility of students and staff, and the free movement of capital have increased the need for universities to contribute to national wealth by making the economy more competitive (Etzkowitz and Leydesdorff 1997). Consequently, market-oriented university practices and national policies have been pushing for university-industry research and development programs which aim at stimulating regional economic development (Slaughter and Leslie 1997).

These trends in European higher education systems have caused a process of restructuring of academic science and technology. Developments include new technology transfer strategies, shifting relations between applied and basic research, new funding patterns, and rising need for management capacity within universities.

3. *Consequences for Academic Science and Technology*

3.1 *Knowledge Transfer*

Government and universities have been designing strategies which should create and sustain competitive

advantage in industry. The critical role of knowledge transfer either through research or through teaching has triggered new alliances between industry, government, and academic institutions. Trends include partnerships between universities and businesses, technology transfer units, incentives for a combination of basic and applied research, and for professors contributing to spin-off or start-up companies (Etzkowitz and Leydesdorff 1997).

Knowledge transfer is often enhanced through funding for research that supports economic development. At the same time, industry relationships help universities to raise additional funds and support companies in their research and development. In this process, academic science and technology are increasingly linked to form the basis for this relationship. For example in The Netherlands, the University of Twente moved from a third-class technology-oriented institution to a successful university through the creation of new entrepreneurial practices focusing on transfer, research, and development (known as TRD activities) (Clark 1998).

International organizations like the European Union (EU) have a high interest in knowledge transfer as well. EU projects like EUREKA reflect new state interests by establishing large supranational networks of scientists and practitioners to stimulate technological innovations. EUREKA promotes 'market-driven' collaborative research and development through the use of advanced technologies thereby strengthening European competitiveness.

3.2 Problem Orientation

As higher education systems all over Europe have expanded, research and teaching have shifted their emphasis as well. Given the complex requirements of the job market, of knowledge-based industries, and of society at large, research and teaching have to be oriented more to problems than to disciplines. This orientation helps universities to better meet the expectations and needs of external constituencies and offer relevant programs to their students. Increasingly, universities define fields of competence (e.g., environmental economics, social medicine) which combine different disciplines and areas to provide solutions to problems like pollution or AIDS (Gibbons et al. 1994, Dill and Sporn 1995).

As a consequence, new forms of knowledge production have become necessary. Gibbons et al. (1994) coined the term 'Mode 2' knowledge production, ascribing five basic attributes to it: application context, transdisciplinarity, heterogeneity and organizational diversity, social accountability and reflexivity, and quality control. 'Mode 1' refers to the traditional discipline-oriented research of tenured faculty members. 'Mode 2' knowledge production includes a wider, more temporary, and heterogeneous set of researchers and practitioners collaborating on a problem defined in a specific and localized context (Gibbons et al. 1994).

3.3 Market-based Funding

In Europe, scarce resources for higher education have given rise to new claims for public accountability and performance-based funding of universities. These developments have increased the importance of market mechanisms for financing higher education (Williams 1995). Departments or groups which work in a field that is highly relevant to industry and society have more opportunities for raising additional funds and for gains in the process of resource allocation. They are also better able to contribute to the university budget through their share of overheads. These additional funds can then be used to cross-subsidize other less 'marketable' areas or programs (Clark 1998). Mechanisms of market-based funding have also created a more entrepreneurial culture within many European universities. Faculty members responsible for their own research institute or center at universities can form a periphery which obtains additional income and also serves the public need for applied research, teaching, and service (Clark 1998, Sporn 1999). Again, fields which can more easily combine science and technology, like telecommunications, are especially inclined to get involved in these activities. Conflicts arise if less successful areas which belong to the tradition of university research and teaching get scrutinized for downsizing or closure (Slaughter and Leslie 1997).

3.4 Managerial Capacity

The new relationship between universities, government, and industry requires institutional management capacity. Given the need to translate external demands into internal responses and strategies, faculty members in Europe—who have been steering universities for decades—have become overburdened. A new type of professional university manager is emerging, who is responsible for institutional efficiency and effectiveness (Gumport and Sporn 1999). Reforms in many countries like Austria, The Netherlands, Sweden, or Spain were aimed at strengthening the leadership structure of universities.

European universities historically were dominated by strong state control and little decision-making power. But with ongoing reforms in many European countries, professional administrators and university managers have gained importance and governments have delegated many tasks to the institutional level. Consequently, in countries like Norway or Sweden

(Gornitzka et al. 1998) an increase in the number of university administrators can be observed while the size of the faculty stagnates. The rising interest in knowledge transfer based on science and technology is adding to the need for management support for new activities.

Tensions arise from these trends as to the new status of employees and the relationship between basic and applied research. While in many continental European countries university professors have been state employees, new trends call for more flexible and decentralized forms of employment. Also, at the institutional level, basic and applied research will have to be redefined. Although the basic mission of the university includes basic research a more market-oriented system requires a larger amount of applied and problem-oriented research projects.

To summarize, the link between science and technology has played a critical role within universities in Europe. National policies have converged around increasing national economic competitiveness through product and process innovations, channeling students and resources into well-funded curricula that meet the needs of a global marketplace, preparing more students for the workplace at lower costs, and managing institutions more effectively and efficiently (Slaughter and Leslie 1997).

The expansion of European higher education systems will continue to aim at high participation rates. European economies will need more qualified specialists as well as valid research results in applied fields in order to stay abreast of major technological and scientific developments. Governments will move from a control to a supervising role, thereby trying to enhance new partnerships between higher education and industry to boost the economy. Universities have to emphasize their core commitment to a service function in order to meet these high expectations and needs. Science and technology will continue to play a pivotal role in this development.

Universities and Science and Technology: United States

The American research university's history is inseparable from the growing importance of science and technology to the state in the late nineteenth and twentieth centuries. From the passage of the 1862 Morrill Land Grant Act to the establishment of the National Science Foundation in 1950, government and university have established deep and long-lasting

connections, although the nature and character of those connections has changed profoundly over time. Once a ward of private contributions and philanthropic foundations, the American university, like American science and technology, became in some respects a ward of the state. By the beginning of the twenty-first century, the American research university was busy recasting its social relations and its position in the nation's institutional and intellectual ecology.

In many respects, this history repeats itself. At the beginning of the twentieth century a new kind of institution—the private research organization—emerged as a potential threat to the university as the primary site for the production of scientific and technical knowledge. Although such institutions survived, they were incapable of mounting a successful challenge to the university's intellectual hegemony. Research and teaching were powerful resources that other institutions could not match whatever their potential virtues to researchers. Today, universities and government-sponsored research are challenged by private corporations intent on capitalizing upon new discoveries, especially in the biomedical disciplines such as genomics. Ironically, the intellectual property issues that ruled out significant pre-World War II government patronage of academic science and technology have returned in a similar guise.

Equally important, the university's internal structure has altered profoundly over the past century, a change perhaps most visible in the shrinking role of university presidents. The presidents of the late nineteenth and early twentieth centuries were dynamic individuals willing to risk reputation and even wealth for their beliefs as they sought to shape and mold institutions. Charles Eliot at Harvard and Daniel Coit Gilman at Johns Hopkins invented the research university in the US, bringing German ideals to bear in a distinctly American fashion. Later, Harvard University president James Bryant Conant played a critical role in building the atomic bomb and developing postwar national security policy. Conant also led a vigorous public debate over the nature and character of the postwar American state. Presidents in the year 2000 have become largely fundraisers, anonymous even within their own institutions, let alone—with some exceptions—on the wider stages of national policy.

1. *The American College*

The antebellum American college was an institution devoted to the production of civic leaders, ministers, and schoolteachers. At heart, it was a character development institution complete with a psychological model of the mind legitimizing its pedagogical routines (Guralnick 1975, Veysey 1965). 'Faculty psychology,' the belief that distinct physical areas of the brains were the locations of different emotional and intellectual functions, was the early theory of cerebral localization undergirding the college's character-building program. Whether mandatory Latin or Greek memorization or mathematical reasoning, specific kinds of intellectual work were thought to strengthen the faculties to produce better, more capable citizens. The extent to which science and technology played a role in the antebellum college rested upon their ability to lay claim to this process of disciplining and shaping young minds. Social or economic utility was not yet an acceptable reason for the addition of science and technology to the college curriculum.

Passage of the 1862 Morrill Act granted each state federal lands for the establishment of a college dedicated to the mechanic and agricultural arts. These new institutions, including Cornell University, the University of Wisconsin, the University of Illinois, and others became sites for the development of new academic roles and new kinds of knowledge. Because graduate education in the sciences was largely unheard of in the US, the majority of instructors had studied abroad, mainly in Germany, and to a lesser extent in England and France. The land grant and its equally important sister institution, the agricultural experiment station, were hothouses for the production of a distinctive vision of American science. Utility had been the driving force in the creation of the new institutions, but many of the researchers hired at these new sites desired to transform these new domains into institutions resembling the laboratories of their German teachers, such as the famous chemist Justus Liebig. As Charles Rosenberg (1997, [1976]) argued, the agricultural experiment station yielded the first American hybrid, the scientist entrepreneur. Obtaining resources for research demanded that academics develop techniques and practices capable of satisfying multiple constituencies, ranging from the local farmer who wanted to know why crops would not grow in area soil, to the dean who wanted researchers to solve problems of interest to potential donors, and the politician who wanted results to justify re-election. Land grant colleges and agricultural experiment stations provided reasons for the support of scientific research so long as such research delivered useful results (Veysey 1965, Geiger 1986).

2. *Research*

The American research university was the product of two distinct intellectual trends—the increasing number of Americans travelling abroad for graduate education, and the problems posed by the rapidly industrializing US polity following the Civil War. First, American researchers who studied in Germany came to believe that the German university was the model of a research institution. This was an illusion fostered by the American's peculiar status in the

German university system—they were as much sophisticated tourists as students and few, if any, pursued the full course of study. American students in German laboratories worked with outstanding teachers, such as Carl Ludwig, but they failed to observe that the German university system trained more professionals—physicians, lawyers, and bureaucrats—than pure academic researchers. When American students returned to the US to take up academic posts they brought only part of the German university system back with them (Geiger 1986, Owens 1985).

The founding of the Johns Hopkins University in 1876 is often taken as the origin of the American research university. Although President Daniel Coit Gilman promoted the university as a center of '*wissenschaft*' in Baltimore, Hopkins represented less Göttingen on the Chesapeake than another form of hybridization: the meshing of research with the antebellum college's character-building function. Gilman benefited from the fact that Johns Hopkins had provided in his will for the foundation of a new university and medical school. However, the meaning of Gilman's innovations—laboratory- and seminar-based instruction—are often lost in the promotion of research. We should see Gilman and the staff he handpicked—including the physicist, Henry Rowland; the chemist, Ira Remsen; the mathematician, J. J. Sylvester; and the biologist, Henry Newell Martin—as men who brought new resources and practices to bear upon old problems. Gilman and other contemporaries such as Harvard University President Charles Eliot, believed that post Civil War America was a nation in crisis, suffering from effects of unprecedented technological change and the breakdown of local social orders in the building of a national culture. Education, that most universal remedy for social ills, was once again called upon to protect and reinvent social order. Research, manifested in the labors of the laboratory and the seminar room, was the perceived antidote for a hyperkinetic, market culture. It was in the laboratory, whether working on the cutting of diffraction gratings, as in Rowland's laboratory, or in the seminar room engaged in the philological study of classical texts, that the student would encounter a new form of discipline in which steady and methodical intellectual work would prepare the young mind for the task of living and working in a new social world. More importantly, such students would themselves work as teachers in the nation's colleges and secondary schools, transferring this new form of discipline and understanding to a wider populace (Kargon 1986, Hannaway 1976).

In the hands of educational reformers, the laboratory and the seminar room became new technologies for the (re)production of social order. They were also sites of intellectual innovation whose products might have value independent of their pedagogical origins. The *fin de siècle* saw the emergence of two new types of research institutions—the private, philanthropic research institution, such as the Carnegie Institution of Washington and the Rockefeller Institution for medical research (now the Rockefeller University), and the industrial research facility, such as those established at General Electric and AT&T. Both institutions sought to break the university's stranglehold on the production of knowledge and each was modestly successful. In the new organizations, research had a value for its own sake unknown in the university. Part of the problem was that many American academics were unable to understand why one would want to separate research and teaching. Andrew Carnegie charged his private research facility, the Carnegie Institution of Washington (CIW), with the mission of seeking out the 'exceptional man' and providing him with funds and resources to complete his work free of distractions. While the CIW consulted with academics on how to put Andrew Carnegie's generous gift to work, they were hard pressed to keep academics from applying for funds to relieve them of their teaching burden or pay for graduate research assistants. Neither was an acceptable use of CIW funds. Robert S. Woodward, the CIW's second president, established a variety of research divisions to insulate 'exceptional' men from both the university and other demands on their time (Reingold 1979).

Industrial research facilities were rather different and represented a wholesale transfer of the laboratory as a knowledge production site to the factory. Instead of students and theses, the new laboratories produced patents and processes necessary for corporate survival. Of the high-tech industries of the early twentieth century, electricity and communications led the way, integrating their corporate structures into the very manufacture of knowledge that might have industrial implications. Despite early press that these laboratories were universities in exile, later studies recognized that industrial research was always basic to corporate needs and goals. Successful laboratories integrated themselves into the firm's business; unsuccessful laboratories fought for independence that quickly evaporated when the firm suffered in the marketplace (Beer 1958, Reich 1985, Wise 1985, Noble 1977, Dennis 1987).

3. *The Visible Hand*

World War I brought about a fundamental reorganization of the university with respect to the production of technical knowledge. Although American academics made no great contributions to the development of weapons technology (save for the peripheral development of intelligence tests (Carson 1993), they organized themselves in new and powerful ways that allowed for the development of new forms of patronage. In particular, the National Research Council (NRC) established by Caltech president and astrophysicist George Ellery Hale, to resuscitate the

National Academy of Sciences, proved an invaluable mechanism for the support of university-based research. The early twentieth century had seen the emergence of incredibly wealthy private philanthropic foundations, including the gargantuan Rockefeller Foundation (RF), the Carnegie Corporation of New York, and the Guggenheim Foundation (Kohler 1991, Kay 1993). The RF easily dwarfed all its competitors and would forever alter the topography of American higher education. In the wake of World War I, the foundation supported a postdoctoral fellowship program administered by the NRC. As the historian Robert Kohler (1987) argued, the NRC was a 'trade association' for American science, providing philanthropies with a means of dispensing funds without having to support mundane university needs. That is, the foundations were not interested in supporting undergraduate education, or in building facilities; instead, the RF emphasized a policy of 'making the peaks higher.' Those who had excellent resources and professors became sites where NRC postdoctoral students clustered. In turn, those fellows left for jobs and attempted to build institutions capable of attracting such fellows.

We should note that the RF did not distribute its monies across the disciplines. The biomedical and social sciences were its primary targets of patronage; even during the Great Depression, the RF maintained its funding of these sciences, especially through efforts to import the techniques and instrumentation of the harder sciences into the biomedical and social sciences. It is to an RF officer, Warren Weaver, that we owe the term 'molecular biology;' and the RF's interest in genetics, human biology, and social engineering were to have lasting repercussions in another *fin de siècle*'s most public work, the Human Genome Project (Kohler 1976, Kay 1993).

Private support of the sciences was not matched by government support before World War II. Indeed, efforts to have the federal government pay for university-based research ran up against long-standing beliefs that government money invariably brought with it government control. Curiously, American academics did not seem to fear RF funds for analogous reasons. Various efforts to organize federal support of the sciences during the Great Depression foundered on this belief (Kargon & Hodes 1985, Genuth 1987). Equally important was a fundamental inability of university administrators and government bureaucrats to determine who would own the fruits of government-sponsored research (Owens 1990). Such disagreements made federal support of university-based research nearly impossible, save for research lacking any potential commercial value. Nor was industry a powerful patron of interwar academic science and technology. In large part, corporations sought such tight control over sponsored academic research that researchers almost welcomed the war and the possibility of relatively unconstrained government support (Galison et al. 1992). In postwar America, the state emerged for science as a patron of unprecedented wealth and power.

4. *Wards of the State*

World War II's effect upon the American university and American science and technology was profound. American researchers, organized by their leader, Vannevar Bush, of the Massachusetts Institute of Technology (MIT) and the Carnegie Institution of Washington, instituted a virtual revolution in warfare, bringing about a permanent revolution in munitions, whether it was the atomic bomb or attempts at the mathematization of strategic thinking through game theory and operations research. Scholars, especially David Noble (1984), Stuart W. Leslie (1993), and Rebecca Lowen (1997), have begun the task of examining how the war and postwar military patronage transformed specific universities. Others, such as Paul Forman (1987, 1992), have led an effort to understand how the very content of technical knowledge changed to meet the needs of new patrons. The rise of the military as the dominant patron of American university-based science had far-reaching effects upon the university, not the least of which was a strengthening of the faculty with respect to administrators. It was the faculty with whom military officers established relationships and it was the faculty that produced both the new technologies and the students that the military wanted. In turn, administrators attempted to reassert their authority through the development of new means of accounting, most notably the invention of indirect overhead as a means of capturing revenue from grants and contracts made to specific individuals (Dennis 1994).

Postwar military patronage focused upon four major research areas: guided missiles, continental defense, the managerial sciences, and intelligence-related research in areas as diverse as area studies and cryptography. These four domains capture the range of military interest and share a common tool, the digital computer. The development of the ballistic missile brought with it the development of miniature electronic components, including the integrated circuit and the ubiquitous microprocessor. Continental defense, the effort to develop a shield against a possible Soviet aerial attack, produced a range of technologies, including the modem and magnetic core memory. The US continental defense system, semi-automatic ground environment (SAGE), provided corporations like IBM with the technological experience to engage in massive commercial software developments, including the Semiautomatic Business Research Environment (SABRE), the airline reservation system. The managerial sciences encompass a multitude of fields, ranging from the quantitative social sciences, like operations research and systems analysis, to the

emergence of management science. In turn, interest in the managerial sciences, work which ranged from Simon and Ackoff's views on information processing and management to decision support systems, flourished in the reformed business school of the postwar era (Schlossman et al. 1994). That management might be taught as a science, in the most positivistic sense, was one reason for the growth and development of graduate business education, among the most notable stories of Cold War education. Finally, the effect of the US intelligence services—the CIA and the NSA—remains among the most secret effects of the Cold War on the American university. While it is clear that Area Studies and various departments of communications research were adjuncts to the Cold War effort, what remains unclear is the extent to which research on computers, artificial intelligence, and mathematics was driven by the ever increasing needs of national security. The digital computer and its associated academic departments—applied mathematics, linguistics, computer science, electrical and communications engineering, information theory, etc.—owe much to the nation's cryptographic needs for their development. Given that such work is still considered among the most sensitive, we may never know the depth of the state's penetration into the university.

What lies ahead for the American university and the technical research practiced there? The Cold War's end brought back fundamental issues related to commercial rights and production of knowledge, one reason among many for the enhanced visibility of intellectual property issues. At the same time, university administrators are eager to embrace the marketplace and its potential riches. In doing so, university presidents and faculty will continue to negotiate an increasingly fuzzy boundary separating students from consumers and research from commodities.

Universities, in the History of the Social Sciences

Since they first appeared in the twelfth century, universities have been the main if not exclusive setting for the development of the social sciences. No two universities are or have ever been absolutely alike, but all possess common features. A division of intellectual labor is foremost. The curriculum, composed of building blocks of knowledge called 'disciplines,' is organized into multiple teaching, training, or research structures called variously (depending upon time, place, and national language) 'faculties' (the oldest), 'institutes,' 'laboratories,' 'departments,' 'schools,' 'boards of studies,' 'colleges' (which can be freestanding), or, more recently, 'programs' and 'organized research units,' or 'centers.'

1. *The Problem of Knowledge*

Neither the absence of a universal measure of 'discipline' nor the variety of knowledge delivery systems alters the elementary cognitive principle that unclassified information is relatively useless. Knowledge and understanding are acquired through classification and specialization. According to the philosopher and logician Alfred North Whitehead, specialism is the 'natural' path to meaning. Specialism underlies all civilizations. Increasing specialism is a salient feature of modern life, an indispensable requirement for scientific investigation, intellectual discovery, and problem solving.

2. *Institutionalizing Knowledge*

Disciplinary specialization affects the primary internal structure of universities and their systems of teaching, examining, funding, staffing, and even the arrangement of buildings and spaces. Specialties seek what some scholars call 'autonomy,' consisting of control over their own destinies. Accordingly, specialties desire institutional guarantees of disciplinary self-regulation. But the opposite is equally true. The institutional forms themselves influence the content, development, and application of academic specialties. In turn, the missions of educational institutions such as universities are affected by outside pressures generated by governments, the judiciary, churches, the professions, public opinion, the media, and, increasingly, the commercial demands of industrial or high-technology economies. The 'modern' or 'nation-state' has been an important element in the formation of all contemporary disciplines but particularly in the sciences and social sciences. The story of the interrelationships between the social sciences, their host institutions, and all other disciplines, as well as society and government, is consequently complex, unstable, and unpredictable. The rate of knowledge change and production is however more rapid in some historical periods than in others. The resulting disjunctions between the generation and absorption of knowledge can produce social consequences.

2.1 *The Organization of Knowledge in the Medieval University*

In the universities of the Middle Ages, disciplines were incorporated into large divisions known as 'faculties.' Some faculties, as at Paris, were virtually quasi-independent corporations within a single university, but others were less settled in their administration. 'Nations,' groupings of students from European regions, homes away from homes, were often sub-administrative and teaching units too, with separate identities, as were colleges. The 'inferior' (or arts) faculty,' with its broad divisions into language and mathematical studies, was preparatory to the second, the 'superior' or 'higher faculties' in which the three great professional training programs were located—medicine, law (canon or civil), and theology.

Within the inferior faculty were the disciplines that contributed to the foundations of a general education. The seven liberal arts, inherited from Rome, were divided into two other general classifications. One was the language-based *trivium*—logic, grammar, and rhetoric. The second was the mathematically based *quadrivium*—music, astronomy, geometry, and arithmetic.

The basic organization of knowledge into binary arts and faculty teaching divisions was rendered more complicated by the teaching of the 'three philosophies'—natural, moral, and metaphysical—also derived from ancient classical sources. The analytical methods, as well as the substance of the philosophies, informed and interpenetrated all faculties and disciplines in a process of knowledge generation and debate that produced gradual and continuous revisions in the curriculum.

2.2 *The Relationship of Disciplines to One Another*

Therefore disciplinary taxonomy does not by itself adequately explain the uses or content of disciplines. The study of literature, for example texts such as Virgil's *Aeneid*, was included within grammar and thereby subordinated to the teaching of syntax.

Architecture could be found within the *quadrivium*, allied to the mathematical sciences. Rhetoric was a particularly elusive discipline. In some universities (or periods) it was subservient to grammar or logic and often limited to letter writing and religious preaching, but in other circumstances it was an important ingredient in the training of lawyers and public servants. The character of political science (based initially on Aristotle's *Politics*, translated into Latin in the mid-thirteenth century) changed significantly when it was later associated with law and employed in the task of building bureaucratic governments to replace medieval feudalities. Religious questions regarding the existence of the soul were not confined to the faculty of theology but were debated within logic, using such assigned texts as Cicero's or Aristotle's *Topics*.

Science, in the modern sense of the study of nature, and medicine were part of metaphysics. Methods and subjects commingled. In a scribal-based (and before the invention of printing, also oral) academic culture dominated by the writings of a relatively few classical authorities, with their Arabic and scholastic glossators and commentators, disciplinary crossover was readily achieved. The need to focus attention on a limited number of issues, notably those relating to the spread and administrative growth of the universal Church of Rome or the fiscal and legal problems of princely and imperial courts, contributed to a unity of academic purpose.

Yet the differences and principles of knowledge production between the medieval and modern university should not be exaggerated. The general rules about knowledge acquisition are similar. Disciplines absorb conceptions and methods from one another—content overlap—and the direction of investigation is influenced by the uses to which knowledge is put. The capacity of a discipline to describe its own trajectory is constrained (positively or negatively) by the faculty or disciplines (or professional associations) to which it might defer.

Today's universities have characteristics similar to earlier universities. The placement of contemporary disciplines like sociology, political science, ethical philosophy, or even cultural anthropology within a school of law determines the approaches and problems that receive primary attention. The study of economics, when situated within business schools, inclines more towards problem solving than towards the laws or principles underlying economic behavior viewed as a science. Historical inquiry, when located within departments of economics, political science or policy studies, music, or education, becomes the study of the evolution of those fields, or is oriented toward questions of interest to the supporting departments.

Anthropologists whose appointments lie within medical schools and hospitals address issues arising from the treatment and care of patients, as do ethical philosophers, psychologists, or social workers in the same environment. Architecture is affected differentially when associated with engineering, schools of urban planning, colleges of the environment, schools of design, or when viewed as a member of the liberal arts. The study of music in research universities favors composition or musicology or the history of music more than performance. Examples of disciplinary plasticity and allegiance are endless.

3. *Continuities and Discontinuities in Knowledge Acquisition*

The medieval university was not ideologically designed for intellectual discovery but for the dissemination of received knowledge. Nevertheless, significant knowledge growth and development transpired, if often unrecognized by practitioners or credited by polemicists. Change was advanced by the normal process of argument, by the discovery of new texts, by the reinterpretation of older sources, by the evaluation of existing systems of logic and proof, by theological controversies such as the Great Schism of the fourteenth century, and by issues concerning ecclesiastical reform eventually culminating in the Protestant heresies.

An essential difference between the medieval or later universities with respect to knowledge production is arguably the much higher degree of self-conscious disciplinary promotion within the latter as driven by professional and external imperatives. A second difference is the larger amount of ambiguity and relativism tolerated by modern cultures.

3.1 *Scholasticism and Humanism*

The period termed the 'Renaissance' (now usually called the 'early modern' period) or 'rebirth' of classical learning, beginning with fifteenth-century Italy and spreading northwards in Europe in the centuries following, has long occupied a central place in discussions concerning the differentiation of disciplines and the arrival of 'modern' conceptions of learning. Historians conventionally divide the learned into two groups: the medieval schoolmen and the early modern humanists. The issues dividing them were broadly three in number. First was the type and variety of classical sources later available when the Greek Byzantine empire collapsed in Asia Minor. Authors and texts unknown or known only by hearsay were brought into Western Europe. Sources could now be compared, stimulating an interest in variorum texts and the detection of forgeries. Historical criticism, whose place was hitherto minimal, developed as a cardinal feature of early modern scholarship and was applied relentlessly to canonical texts and the dogmatic foundations of Western Christianity. A second issue concerned the role of observation and experiment

in the conduct of scientific work. The humanists and practitioners of the 'new learning' charged that inductive reasoning was neglected in favor of deductive systems of logic derived from Aristotle and Arab scholars. A third issue was the purpose of the university itself. Detractors alleged that the medieval university was isolated from practical affairs, its members preoccupied with abstract knowledge and shopworn or irrelevant ideas. A corollary point involved personal style. Humanists stressed public speaking, appearance, and the *vita activa*, being interested in careers at the courts of state-building aristocracies in an age of conspicuous political symbols and ceremonies. They contrasted the philosopher-statesman style with the torpid and pedantic manner of university teachers.

Stereotypes, however plausible, are notoriously dangerous, especially when shaped by polemical intent. Not all humanists were outside the university system. Many remained within, attempting, with success, to alter scholastic habits. Some scientists—Galileo is the *ur*figure—borrowed heavily from scholastic methods of interrogating nature and were not as dependent on experiment and observation as they or encomiasts claimed. And some humanists, in their zeal to attract the patronage of rulers, became hired propagandists, sacrificing their integrity as scholars to hypocrisy and superficial elegance. Furthermore, whatever directions humanistic scholarship took, it is now evident that the world of new learning was first framed within the intellectual structures and methods created by the medieval universities.

3.2 Alternatives to Universities

Nevertheless, in the centuries that followed, criticisms of the university as hidebound and tied to an antiquated system of teaching were convincing enough to result in the introduction of different institutional forms and new sources of funding in which innovation, particularly of an applied nature, received a more immediate reception. In fifteenth-century England the teaching of the common law was given a home in institutions designated 'inns of court,' leaving Oxford and Cambridge universities with the teaching of canon law, Roman law, and jurisprudence. In the centuries following, academies, botanical gardens, royal libraries, observatories, museums, military schools, and new colleges were established outside university systems. In France in the course of the eighteenth century the state's need for experts resulted in the creation of specialized engineering schools,starting with the *École des Ponts et Chaussées* in 1747. The Jacobins of the French Revolution adopted this form for their own instrumental purposes. Their *École Polytechnique* of the 1790s was followed in the next century by other *grandes écoles*, institutions of high quality whose mission was to train specialists for appointments in government, industry, engineering occupations, or education. At the same time the French university system was dismantled by Napoleon as irrelevant to the tasks of a revolutionary and secular society. That system was only gradually rebuilt but never attained the prestige of the leading schools. Only recently has it acquired a few of the research functions typical of universities in other countries, high-level research in France being normally assigned to a different system.

The French *grandes écoles* are unique institutions in their patterns of student selection, purpose, and prestige. They are also unique because their prestige is not based on a research mission as in other countries (although now several research functions have been added). Few educational institutions anywhere have equivalent elite connections to government, bureaucracy, industry, and the leading professions. However, other countries have attempted to emulate some aspects of the French engineering model, most notably in the establishment of upper-level polytechnical establishments in European capitals such as London, Berlin, Vienna, Stockholm, and Copenhagen, and in major US cities such as Cambridge, Massachusetts. Many of these have been evolving towards a university form. Relevant social science departments, foreign language teaching and, in some cases, humanities courses were added, especially in the twentieth century.

In Germany and Austria other specialized universities were created: *Wirtschaftsuniversitäten*, for example—institutions where disciplines could be grouped and united with a focus on economic problems. In the UK regional universities and university colleges were established that combined applied with liberal arts studies but with special attention to the economic or social problems of their regions.

Medical schools and hospitals, freestanding or associated with universities, became umbrella or 'incubator' institutions for an astonishing range of clinical and scientific specialties. Also in the nineteenth century, geodetic surveys and sponsored explorations supported certain kinds of limited intellectual activity. Although professional education as contained in the 'superior faculties' was the featured curriculum of the medieval university, and especially law in the later centuries, the admission of other forms of vocational or occupational training was never guaranteed. Law, medicine, and theology were acceptable because they suited the needs of urban societies in which religion and secular life interpenetrated. Vocational latecomers had to fight for entry. Rivals for income and teaching appointments, for students, space, and a role in governance, they represented the interests of outsiders. Hence it was that newer professionalizing occupations of the later centuries, especially the nineteenth, such as engineering, commercial studies, schoolteaching, public administration, and social work, were associated with separate schools where they might develop an applied mission according to their own rules and methods. Several occupations—notably architecture,

accounting, and some legal and medical activities—were controlled by practitioners recruiting through guild apprenticeship methods. But guild and academic forms of education are not necessarily incompatible. The academic profession itself is the supreme example of guild-directed education. Early twenty-first-century universities tend to be comprehensive. Subjects or emphases once deemed unacceptable to universities built on the German research model or influenced by it are now more likely to be welcome. The general terms of inclusion have been mentioned. New recruits to the university community are normally expected to conform to its prevailing styles of intellectual achievement. However, the rapidly increasing fragmentation of the knowledge base everywhere evident suggests that the universities of the future will be less able than predecessors to impose uniform standards of work or a common scholarly ethos on their numerous departments, laboratories, and programs of instruction.

4. *The Transformation of the University*

Applied and experimental science owed more to medieval systems of logic and natural philosophy than critics granted, yet there was indeed a 'scientific revolution' of the seventeenth century that transformed the medieval worldview, produced a materialist conception of the cosmos, departures in physiology, and eventually the treatment of disease, and revised theological speculation concerning human understanding and potential. Mathematical measurement developed as a formidable scientific tool; for despite the medieval *quadrivium* with its mathematical base, the acceptance of Aristotle's physics by the schoolmen had produced a science that was heavily qualitative and metaphysical in character. Scientific instruments such as the microscope and the telescope, and later the Leyden jar, greatly enhanced the scope of intellectual achievement. Sophisticated machines have continued to be indispensable for science (and certain fields of social science), and never more than in the early twenty-first century.

4.1 *The 'Knowledge Revolution' of the Nineteenth Century*

Historical criticism, the development of the laboratory, and new systems of biological classification underlay the eventual adoption of a research ethic that completely reoriented the pantheon of disciplines inherited from the past.

Teaching and professional training were the two educational missions of the medieval university. Now there was a third, to be called 'research.' The ideas that knowledge could be created, that discovery was an aim of all scholarship, and that the new was preferable to the old were revolutionary assumptions that profoundly affected all educational institutions, and especially universities. The research spirit, while commencing in the scientific revolution and noticeable here and there in later Enlightenment Scottish, German, Dutch, or Swedish universities, did not dominate university culture itself until the nineteenth century. Historically, it is most closely associated with the German university model.

The general acceptance of an academic culture oriented towards original inquiry gave enormous impetus to the establishment of new or subdisciplinary fields. Pressures for the autonomous representation of those fields within universities increased. But two lasting versions of a research ethic emerged: one advocating discovery as an end in itself, the other advocating the use of research results to solve social, economic, or political problems, or to serve the needs of a democratic, consumer society. Proponents of the first feared that applied research funded mainly from commercial sources or results-minded governments would transfer direct and certainly indirect control over discipline formation and knowledge production to agencies outside the universities.

'Pure' research would suffer. Advocates of the second noted the disappearance of any useful distinction between 'pure' and 'applied' knowledge in the age of high technology. In any case, contemporary society, they maintain, requires applied knowledge as a condition of survival and prosperity. Arguments remain intense; and the available evidence suggests that both sides have a case.

4.2 *The Effect of the Social Sciences on Universities*

As observed, the 'social sciences' were embedded in the scholastic arts curriculum. The bureaucratizing states of the early modern period found a place for some forms of applied social science, notably *Kameralwissenschaft*, within the law faculties. The humanists, however, strengthened belles lettres within the faculty of arts (later, in the German university, to be called the faculty of philosophy). Accordingly, the maturation of the academic social sciences was a slow, two-stage affair. First came new methodologies for the study of social change and process developed by thinkers both inside and outside universities. Second was the emancipation of social science from domination by arts and professional curricula. Later Enlightenment Scottish university historians and philosophers developed 'conjectural history,' incorporating some of the insights of political economy and early theories of evolutionary change. Nineteenth-century French intellectuals such as the St. Simonians and Auguste Comte developed some of these beginnings into an overarching scheme of human development based on the 'march of mind,' the progress from primitive religion through metaphysics to 'positive science.' While the separation of subjects such as sociology or anthropology or economics, or psychology from such parent fields as law, history, religion,

and philosophy was a nineteenth-century development, the flowering of social science as a full-fledged set of university disciplines belonged to the twentieth century. The timing was not accidental. A focus on the comparative, normative (and deviant) behavior of groups, communities, and classes; on the functioning of institutions such as schools, bureaucracies, professions, religious organizations, trade unions, industrial firms, and family structures; and on the nature of belief and value systems of societies reflected the dominant features and problems of modern society with its mobile, plural populations and global reach.

Besides concentrating on issues and problems not conventionally incorporated into the inherited model of a university, the social science disciplines claimed the prestige gained by the physical sciences. As in the natural order, the human or social order could also be explained by scientific laws. And although in time some of the rigor and promise of words such as 'scientific laws' would be mitigated and exchanged for softer terms such as 'patterns' or 'regularities,' the claim to scientific objectivity served as a major legitimizing strategy. It was also the basis for an instrumental approach to the resolution of social problems and the means by which the social sciences secured access to external funding sources.

The number of social science disciplines and the different strategies pursued by social scientists to become citizens of the republics of letters and science in varying national contexts is a highly complex story. Yet some insight into the issues may be gained from a cursory look at the history of the London School of Economics and Political Science (LSE), founded in 1895 by socialists and left-wing liberals on the model of the *École Libre des Sciences Politiques* in Paris (the LSE was later incorporated into the federal structure of the University of London).

Two issues confronted the founders. The first was the independence of the LSE, solved initially by the creation of a wholly new establishment where the disciplines could function on their own terms. This conforms to the pattern indicated earlier, where alternative institutions provide the means of disciplinary entry into the knowledge universe. The second issue concerned the LSE's primary mission, and here the founders disagreed on basic aims and methods. Should the institution's mission be applied or scholarly? Should attention be focused mainly on metropolitan regions such as London or spread more widely? Were ideological commitments to social amelioration compatible with standards of objective research? These differences of purpose have never been completely resolved within the LSE's academic divisions.

Indeed, the differences cannot be resolved since they are inherent in the history of the social science subdisciplines. The structural flexibility of the modern research university has provided a practical solution. The applied social sciences have found homes in the professional schools, a number of which—social work, urban studies, education, public policy, and perhaps now journalism and media studies—are in fact based on the social sciences. But law, medicine, public health, and architecture all have room for social science subjects and methods. Elsewhere in the university the 'autonomous' social sciences are separated into distinct disciplines according to the history of each. They are either located in departments within 'colleges of letters and science' (the typical US case), traditional arts faculties or new faculties of social science (in some European universities). They are also to be found in crossover and multidisciplinary programs and research units.

Ideas, concepts, and problem-solving methods developed by the social sciences are now commonplace elements of any university curriculum. Historical research is greatly influenced by psychology, anthropology, economics, sociology, statistics, and political science; but history, as a 'universal recipient,' has often if not invariably demonstrated intellectual flexibility. Yet literary studies have also become social scientific as, *inter alia*, critics incorporate interpretations derived from the sociology of class relationships, the psychology of the individual, and the anthropologist's interest in symbol and ritual.

In concert with the technical and physical sciences (and the revolutionary biological sciences), the social sciences have played a prominent role in tying the university to social or national objectives, strengthening its place in the formulation of policies affecting the distribution of wealth, educational opportunities, the provision for social services, and other polemical issues that are the concern of modern, mass democratic societies. The entanglements with powerful and influential outside interests are not to everyone's liking, as they compromise the university's decision-making independence. However, the university has never been a wholly autonomous institution, not even within free and liberal societies. Such relative independence as it enjoys is the result of negotiation or 'social contracts' that each generation of university leaders, teachers, and researchers is destined to conduct.

5. *Controls over Disciplinary Formation*

The organization of the disciplines varies in different national and university settings, affecting the kinds of disciplinary emphases receiving attention.

5.1 *The Chairholder System*

The medieval faculties were the ultimate internal determinants of the curriculum, with alternative institutions such as colleges providing some opportunities for independent innovations. Centuries later, with the evolution of the professorial or 'chair' system of academic leadership, best known in its German form,

individual chairholders administered 'institutes' and laboratories and set the standard for teaching and research, especially at advanced levels. Although the institute structure was embedded in the traditional faculty structure, changes had occurred that made chairholders and deans the effective authorities, and they respected one another's independence.

This system, which became standard in continental Europe, Latin America, Israel, Japan, and wherever the German model of a university took hold before 1939, led the way in world scholarship and science. But an essential drawback was that younger academics with newer specialties could not easily find room within a structure dominated by seniors. Their career alternatives were to await chair vacancies at home or elsewhere, or to persuade institutions (and the government ministers who largely controlled financing, especially after the later nineteenth century) to establish new or different chairs in developing subdisciplines. Before unification in 1870, 'Germany' was a collection of independent *Länder* competing against one another for professorial talent. Thus intra-German rivalry itself was a variable in the formation of new fields of inquiry, along with the adoption of radical critical methods (the 'Higher Criticism'), and philosophical conceptions concerning intellectual objectives (*Bildung*) and research ('Humboldtianism').

5.2 Alternatives to Faculties and Institutes

Many of the features of the organization of knowledge that had evolved in Europe also existed in the USA, whose higher-education system, first established in the colonial period, reflected English and Scottish influences, then French and finally German ones. The chairholder system was much in evidence throughout the USA as well, but by the end of the nineteenth century it was losing its authority as the arbiter of the curriculum. It was gradually supplanted by the 'department,' the dominant US form of curricular organization. A century later its main features were being adopted in most university systems elsewhere. The essence of a department is that it is based on a discipline rather than a collection of disciplines (as in a faculty structure), is run by committees, and normally features a rotating head. Chairholders or their equivalents, while senior and influential, share authority with other teaching titles. The relatively 'democratic' decision-making apparatus of the department is broadly in keeping with medieval legacies of guild self-government.

Another US innovation, a credit-unit system of instruction that combines teaching and examining in a single person, was a departure from UK and continental European external examining practices, and underscored the intellectual freedom of individual instructors and researchers. In this context, subdisciplines were able to flourish. While it is still possible for an entire department to be built or rebuilt along narrow and exclusionary disciplinary lines, such solutions are generally short-lived given the independence of individual members and the variety of available funding sources.

One other US innovation of the twentieth-century deserves mention: the advent of the graduate school. The continental European chairholder system was suited to advanced instruction and the award of advanced degrees because it relied on a selective system of elite schooling—the *lycée* in France, the *gymnasium* in Germany and Scandinavia, their counterparts elsewhere—and gave the professoriate discretion in choosing the best candidates for creative work. The US university, which for historical reasons was not well supported by an excellent system of secondary school instruction, recruited undergraduates of mixed preparation. The solution to the problem of how to offer research-level instruction was found in the establishment of a wholly separate administrative division freed from the necessity of providing remedial and general teaching. This innovation contributed greatly to the building up of strong research traditions within the social sciences and other disciplines. Versions of the US graduate school appeared in Europe during the 1980s and 1990s in response or reaction to governmental policies encouraging the development of mass forms of secondary and higher education.

Before and during the introduction of departmental and credit-unit systems of instruction, the US pattern of disciplinary formation was similar to the European one. Subjects that did not find an immediate reception within traditional colleges and universities, especially subjects stigmatized as 'practical' (which could include modern languages), sought a more hospitable environment in alternative institutions. These had been springing up ever since the American Revolution.

By the end of the nineteenth century liberal arts colleges, comprehensive universities (combining professional and liberal education), specialized institutes (such as the West Point Military Academy), prestigious polytechnics (such as the Massachusetts Institute of Technology), a German-style 'research university' (the Johns Hopkins University), and state institutions with applied but also liberal education missions (the 'federal land grant' universities) were members of a differentiated system that had expanded in connection with national ambitions and market conditions.

Within the older US colleges and universities, internal reconfiguring took place alongside external differentiation. In the earlier nineteenth century, academic subjects such as the natural sciences or modern languages that were not necessarily applied but were regarded as inimical to prevailing teaching values were able to create alternate degree tracks, if not of equivalent prestige. Within the senior English universities of Oxford and Cambridge, subject-based 'schools' (Oxford) or 'boards of studies' (Cambridge)

representing specialties effectively replaced the medieval faculties structure. As in the German case, professorial chairholders controlled the university system of lecturing. However, as Oxford and Cambridge were collegiate universities or federations of relatively autonomous societies, the professorial system did not constrain the whole system of instruction. The collegiate structure with its small classes and tutorial arrangements in fact liberated the professors from routine or introductory teaching.

5.3 Criticisms of the Departmental Organization

The flexibility inherent in a departmental organization and its comparative openness to innovation reduce the temptation for subjects to migrate toward alternative institutional structures. Departments are therefore one of the factors that have brought the 'university' institutional form into the center of modern society as the principal source of knowledge generation and dissemination. Others—and they are outside the scope of this entry—are national imperatives, such as war and industrial competition, mass higher education requiring extensive private but especially public resources, professionalism, consumer economies, and the high division of labor so typical of contemporary society.

Yet it would be strange if the departmental organization did not have its critics. Discipline-based departments are said to be narrow in their own right, protective of privileges and unreceptive to cross-disciplinary fields of study. A similar criticism but with a different purpose arises from the defenders of US traditions of liberal education. Departments are attacked as the chief obstacles to the development of general education studies for undergraduates. In both instances the response has been the creation of interdisciplinary or multidisciplinary departments, or cooperative programs of teaching, as well as special appointments in broad fields such as 'Humanities' or 'Social Sciences.' Such experiments are now typical of newer European universities.

But an opposite kind of blame has also been voiced, most notably by two famous US *enfants terribles*: the maverick Thorstein Veblen at the turn of the twentieth century and the more establishment 1930s critic Abraham Flexner. Both excoriated US departments for being far too open to innovation, to fads, and to market demand and far too eager to attract the financial support of philistine parvenus. Flexner in particular admired the German university tradition with its high intellectual standards and *Kultur*. For him, the elite characteristics of the European higher-educational system—the alliance between government bureaucrats who decided educational budgets and chairholders who controlled institutes—meant that demands for the teaching of subjects unworthy of incorporation into the noble inheritance called a 'university' could be successfully resisted.

6. Universities of the Twenty-first Century

In the twentieth century the views of critics like Flexner proved to be shortsighted. Totalitarian governments in Nazi Germany and the communist states of Central and Eastern Europe, as well as their copies elsewhere, provided vivid lessons of how knowledge could be manipulated from above and turned from its natural channels of curiosity and negotiation to unimaginable and terrifying applications. The university systems of those countries had to be rebuilt after World War II, and the task remained unfinished as the twenty-first century commenced. While it is nearly an axiom of twenty-first-century higher-education policy in all democratic societies that universities must be flexible in providing access and instruction, disagreement exists on the institutional forms best suited to promote those ends. Technologies associated with the arrival of the 'virtual' or 'cyberspace' university and the possible competition of degree-granting 'corporate universities' have issued new and formidable challenges to all existing forms of higher education. Given numerous choices, it is safe to predict that the longstanding tensions between outside interests, institutional structures, and the formation of disciplines are certain to continue.

Unobtrusive Measures

1. Introduction

All measures must be considered to be subject to error. We would have no way of knowing if, perchance, a measure turned out to be absolutely accurate. For example, the National Bureau of Standards has a 10-gram weight which, because of a manufacturing error, weighs just less than 10 grams by about 400 micrograms (the weight of a grain or two of salt) (Freedman et al. 1991). Despite the most careful weighing, done on a weekly basis, the values actually obtained for the standard weight vary by about 15 micrograms (one microgram is about the weight of a speck of dust) either way from the mean. Presumably the mean of a long series of measures is the best *estimate* of the true weight of the standard, but there is no way of being sure of the true weight. Obviously, the way to deal with such errors, usually thought of as *random* errors, is to do the same measure several times. That is why careful carpenters measure their boards more than once before cutting them—especially if the wood is expensive. Random errors are associated with the concept of *reliability*—the expectation that if a measurement is performed twice under exactly the same conditions, very close agreement should be obtained if the measurement instrument and procedures for using it are dependable.

Another type of measurement error, though, is *bias*, i.e., consistent deviation from the 'true' value of the object or phenomenon of interest. For example, a recent news story recounted speculation that, in order to enhance the prospects of players for careers in professional football, some collegiate coaches might have arranged for the running tracks on which the players' speed is tested to be slightly downhill. If that is true, then the running speeds of players from some universities may be biased toward the fast end of the scale. If mothers are asked to estimate the intelligence (or good looks!) of their children, we might expect some bias to be evident, i.e., higher estimates than would be expected from other means of assessment. The bias is not reduced by replicating the measurement. Downhill is still downhill, and mother's love is constant.

The problem of bias has to be dealt with either by knowing the degree of bias so one can allow for it, or by using multiple measures that do not share sources of error, i.e., bias. A football scout who knows that a player has been tested on a track with a downhill slant can 'allow' for that in interpreting reported running speed. We may expect that mothers will exaggerate a bit in describing their children's skills or other virtues and discount the glowing adjectives in the descriptions by some amount. But an even better way to deal with bias is to use other measures that are less biased, or not biased at all in the same way as the original measure. Of course, if a scout knows that a track has a downhill bias, that scout may simply retest the athlete on a track known to be quite level and disregard the first, presumably biased, report. A scout might also use game films to arrive at a judgment of the speed of the player.

In social and behavioral sciences we usually have no absolute standard that can be applied, and we often should not assume that any one measure is less biased than another or unbiased altogether. The best solution is to use multiple measures of constructs and pick or devise those measures in such a way that they have minimally overlapping sources of error. A sports scout may not have any way of knowing that other running tracks are level, but if an athlete is tested on three different tracks, the average speed of those three runs is likely to be less biased (as well as having less random error) than any one of the runs. And, if all three tracks have a downhill slant, then maybe most tracks do, and the estimate of the athlete's speed is not biased with respect to estimates for other athletes.

2. Problems Associated with Single and Reactive Measures

Social science measures are susceptible to many sources of bias, but a few of those sources of bias are particularly important because they are common and may involve relatively large degrees of bias. Different sources of bias are inherent in every measurement procedure. The biases can pose threats to the valid

interpretation of a measure, in a manner akin to plausible rival hypotheses as threats to validity of experiments (Campbell and Stanley 1963).

3. Reactive Measurement Effects

A problem in measurement stems from the fact that the very act of measurement may produce a reaction on the part of the measured object that changes that object, whether temporarily or permanently. One cannot determine the tensile strength of a wire without breaking it, and one cannot determine whether a cake is as delicious as it looks without spoiling it to some degree. Asking to measure a person's height usually results in that person assuming a very erect posture that produces an estimate of height that is taller than their 'walking around' height. Similarly, giving a group of people a 'bigotry' scale is likely to result in an underestimate of the mean level of bigotry in the group, even if the scale is not explicitly labeled 'Bigotry Scale.' Some reactive measurement effects may be of limited duration or generalizability. The effect of bigotry measurement is unlikely to persist, but others may be long lasting, e.g., as when asking a person his or her opinion about something results in reflection leading to crystallization of an opinion that may have previously been ephemeral.

Scientists and others involved in measurement in social sciences often attempt to reduce reactivity in various ways, including telling respondents that their responses will be confidential, or even anonymous, or that their responses will be used only for scientific purposes. Often such generic efforts to reduce reactivity are not enough, or at least not enough to be completely reassuring, in which case the response of the investigator may be to try to identify and employ a nonreactive, or at least less reactive, measure. Although all measures must be considered reactive to some degree, they are not all reactive to the same measurement issues or to the same degree. Other measures may be thought to be relatively low in reactivity because the data on which they are based were collected in spatially and temporally remote ways that should have freed them from contemporary biases. One example would be the use by historians of personal letters in order to diagnose the state of mind of the letter writer at some earlier period in his or her life.

The most obvious and attractive way of reducing reactivity is to carry out measurement activities under conditions that do not require the subject to know that he or she is being measured. Such measures have come to be known as *unobtrusive measures* (Webb et al. 1966). A young businesswoman might, for example, be invited out for lunch without knowing that she was actually being 'sized up' for a promotion. Or, computers in a school might be programmed to record sign-ons by individual students so as to provide a check on students' reports of computer use and study time. Measures may be unobtrusive because they are embedded in or derived from ongoing activities that do not make measurement a salient feature of the activity or because they are concealed in some way. The term *unobtrusive* has come to be used generically for nonreactive measures, but it would be better used to refer specifically to measures obtained without the necessity for persons being measured to be aware of the fact of being measured. It is for that reason that the original publication, *Unobtrusive Measures: Nonreactive Measures in the Social Sciences* (Webb et al. 1966) was retitled *Nonreactive Measures in the Social Sciences* (Webb et al. 1981) in the revised version of the book. Some measures, e.g., many physiological measures, are not highly reactive (susceptible to bias) because they are not under voluntary control; other measures are not particularly reactive because the person being measured is mistaken about the purpose for which they are being measured; and still others because the measurement context is conducive to unbiased responding.

When people are aware of being measured, a frequent consequence is bias, even if the participant is cooperative and well intentioned. People being 'tested' often, very naturally, want to make a good impression, although in some specific instances, a person being measured may want to make what would ordinarily seem to be a bad impression, e.g., malingering. People being measured may adopt specialized roles that reflect their ideas about how they ought to behave, and those roles may not be characteristic of them when they are in other situations. Individuals will differ, of course, in the degree to which their characteristic responses are affected by knowledge of being measured. Bias may be limited in some instances because people believe their responses are completely appropriate. Criminals, for example, often believe that their behaviors are quite justified and therefore feel no need to disguise their statements about them.

Biases can be reduced with the implementation of multiple measures that do not share the same sources of bias. Unobtrusive measures are not free from their own sources of error, but they may not reflect the same type or degree of bias or reactivity as other measures. Unobtrusive measures, because they reflect different approaches to measurement, can often get around the limitations of reactive measures.

4. The Varieties of Unobtrusive Measures

Webb et al. (1966, 1981) provide an extensive review of unobtrusive or nonreactive measures in social science research and many fine examples can be found throughout the literature. Generally speaking, unobtrusive measures can be usefully categorized as follows:

(*a*) *Simple observations*. Many interesting behaviors can be directly observed, often without the necessity of the observed actor being aware of the fact. Observa-

tions may be made of individuals and groups. Targets of observation may include objects and events as well as persons. For example, the nature of ceremonial events may be of great interest. Also included here are observations of physical location and clustering of people, expressive movements, language behavior in the media or as overheard in public areas, the amount of time individuals spend gazing at public displays, or time sampling of observations to determine whether certain occurrences are linked temporally. A recent news story reported an observation that military dictators who begin to detect resistance and who desire to establish their legitimacy tend to abandon their military uniforms and don civilian attire, with recent appearances of Saddam Hussain of Iraq in regular business suits cited as an interesting example.

(*b*) *Contrived observations*. Simple observation can be tedious as one may need to wait a long while for behavior of interest to occur. Under such circumstances, researchers may contrive situations likely to produce relevant responses. The TV show 'You're on Candid Camera!' was based on responses of people to contrived situations. Social psychologists make extensive use of confederates in contrived situations in which the subject is unaware that he or she is a participant in an experiment. Also included in this category of contrived situations are the experiments in which unsuspecting individuals are deceived into doing things and studied in the process. Real estate companies are routinely tested for racially discriminatory practices by persons pretending to be clients. Bochner (1979) has made 'wrong number' phone calls and staged fake collapses on trains to assess individual's helpfulness in common situations. These types of investigations can be classified as nonreactive or unobtrusive because the participants are unaware that they are participating in an experiment. This lack of awareness implies that their reactions will be natural. Contrivances may include the use of hidden hardware such as audio- and videotapes.

(*c*) *Physical traces*. These include both erosion and accretion measures. Measures of erosion include measurements of floor tile or carpet wear in front of various museum exhibits to determine their popularity, or the wear and tear of library books to examine selective reader interest. Measures of accretion include indicators of inscriptions in public restrooms, the amount of debris left from a ticker-tape parade, or the number of cigarette packs that were thrown out with the trash in selected residential areas. Detectives regularly rely on physical traces of responses they have never seen to solve crimes.

(*d*) *Archives*. These include actuarial records. Materials supplied by the mass media, industrial and institutional records, sales records, and private written documents are archival records. Archival records are regularly used to track behaviors that might not otherwise be detected with reactive measures. Episodic personal and private records are in heavy use in hearings involving activities in the White House to check on the veracity of self-reports by those whose actions are in question.

It is important that unobtrusive measures not be regarded as substitutes for other kinds of reactive measures. That is the antithesis of the rationale behind unobtrusive measures. Unobtrusive measures are properly thought of as complementary to other measures such as questionnaires and interviews.

5. *The Uses of Unobtrusive Measures*

The countering of bias in measurement is of focal concern in considering the usefulness of unobtrusive measures, but such measures may actually be adopted for other purposes. That is in part because an investigator may follow different strategies for dealing with bias: verification, adjustment, and avoidance. An investigator may believe that measures being used are not greatly biased, but he or she may also believe that caution requires sensitivity to possible bias. That investigator may elect to use one or more nonreactive measures in order to probe for bias in case it exists. For example, in a workplace study of attempts to induce exercise, a researcher may ask respondents how often they walk up stairs rather than take an elevator, and reports of workers might be regarded as generally unbiased. Nonetheless, the investigator might still elect to probe the accuracy of those reports by using occasional observers to determine whether the proportion of people climbing stairs is consistent with self-reports. If it should appear that workers tend to exaggerate their reported use of stairs, the investigator might change the questionnaire to try to elicit better data or abandon self-reports in favor of reliance on observers. A prudent investigator would, at the very least, be cautious in interpreting self-report data. Probing might not require large numbers of observations or observations of all subjects of interest. A second strategy is to collect sufficient data by alternative means to make it possible to estimate by how much the numbers obtained by a primary measure (likely to be a questionnaire) are out so that estimates can be appropriately discounted. Observational data might indicate that reported use of stairs is exaggerated by 25 percent, in which case the researcher might deflate his estimates of total physical activity by an appropriate amount. Obviously, unobtrusive measures may be used in conjunction with other measures to arrive at a summary assessment that is likely to be less biased than would have been the case for a single measure. If trainees in a program claim to be spending 10 hours per week in a computer laboratory, but actual counts of people working in the laboratory are not consistent with the claimed level of use, a researcher might adjust downward estimates of exposure to the exercises involved.

It is not always easy, however, to obtain unobtrusive measures that can be used directly and exactly in order to adjust for biases in other measures. One major problem is that more common measures such as questionnaires and unobtrusive or other nonreactive measures are not in the same metrics, so that combining them is not easy. What would one do, for example, with questionnaire data indicating that people claim to eat four servings of vegetables every day and observational data indicating that many people fail to finish eating and discard portions of vegetables served to them? Such discrepant data may lead one to question the accuracy of one set of data or the other, but the discrepancies may not translate easily into quantitative adjustments.

Which data should one trust? Certainly our inclination would likely be to distrust questionnaire and other self-report data. Campbell (1969) suggested as much in discussing the role of qualitative data in program evaluation. Emily Dickinson once wrote the line in a poem 'I like a look of anguish because I know it's true.' That is likely to strike all of us as obviously true. Try to imagine the alternative statement 'I like a self-report of anguish because I know it's true.' And yet, there certainly must be times when self-reports are better assessments of underlying dispositions than overt behaviors. Think, for example, of the pressures toward conformity that lead people who may not be at all religious to bow their heads when other people pray, or the politeness that may prevail between politicians who dislike each other. The use of multiple and different measures cannot guarantee anything.

Under some circumstances, nonreactive measures may be available and be used alone. That may be because they are sometimes compelling, but also because they are sometimes inexpensive. In particular, archival records may be exploited, often at fairly low cost. If records are kept for reasons unrelated to any particular policy use, or at least for reasons unrelated to the purposes for which they are used in research, they may be of great value and characterized by very little bias. The identification by Dr. John Snow of a contaminated water supply as the cause of a cholera outbreak in London in the 1850s was facilitated by records kept of the location of individual cases of the infection, making it possible for Snow to map those cases onto alternate water systems (Freedman 1991). Barthel and Holmes (1968) were able to use information in high school yearbooks to show that persons who later became schizophrenic had low levels of social activity before the onset of their illness.

6. *Advantages of Unobtrusive Measures*

Aside from the possibility of reducing bias in measurement, several other advantages are often associated with unobtrusive measures (Rathje 1979, Babbie 1989). Typically, unobtrusive measures require little, if any, effort on the part of persons being assessed, and often no physical contact with, or even close proximity to participants is required. Unobtrusive measures tend to focus on behaviors and obviate the problems that may stem from inaccurate reporting on the part of respondents. Yet another advantage is that the employment of nonreactive measurement procedures is often relatively inexpensive, e.g., simple observations, physical traces, and archival records. They can be of great value in longitudinal studies.

7. *Limitations of Unobtrusive Measures*

Unobtrusive measures, like all other measures, have limitations. In the first place, it is not always easy to identify unobtrusive measures. Unobtrusive methods are typically limited in certain areas that can be open to interrogation with more reactive methods such as interviews and questionnaires. Methods that utilize verbal communication, such as structured and unstructured interviews, have 'an ability to reach into all content areas' (Webb et al. 1966, 1981). Webb et al. (1981) provided a 'generative taxonomy' for nonreactive measures in order to facilitate thinking about them, but very often coming up with good ones is more an act of creative thinking than of straightforward science. No rules govern the process, and hence, no limitations exist either. That means, however, that one cannot guarantee that an unobtrusive measure will be accepted by reviewers or readers of one's work. Unobtrusive measures are often novel and have no history of use in a field by means of which the case for them can be buttressed. Moreover, many unobtrusive measures do not readily fit the requirements of conventional psychometric analyses so that the usual indicators of difficulty level, variance, and so on are not available, and reliability cannot be directly computed. In the end, unobtrusive measures must have face validity, i.e., readers must see immediately and intuitively that they make sense. That is not always likely.

Unobtrusive measures may sometimes raise troubling ethical questions, for they may be obtained under conditions that at least appear to violate usual expectations about informed consent, confidentiality, and so on. Records may have been assembled with no expectation that they would ever be used for anything other than their original purposes, and even if confidentiality is protected at the public level, some people might feel that their personal confidence is breached when researchers gain access to their records. People may feel that even public behavior is in some sense private if they have no expectation of being systematically observed. In fact, some courts have ruled that people riding in automobiles have expectations of privacy that should protect them against at least some types of observation. Ethical concerns may not rule

out many unobtrusive measures, but at least they require careful consideration by researchers.

Furthermore, unobtrusive measures are not always inexpensive. Observers, for example, are expensive to train and support in the field, and unless they can produce information that is markedly better than what can be derived from questionnaires, they may not be affordable. Archives may be readily available, but the cost of mining them for usable data may be quite high. Many other types of unobtrusive measures may turn out to be surprisingly expensive. Questionnaires and interviews may be performed by mail, phone, or web sites, and the expenses associated with them, especially if multiple sites are involved, can prohibit them from being favorite in the array of methods potentially available. As noted earlier, however, unobtrusive measures may still be useful at modest cost when used as probes into the quality and bias of more traditional measures.

Ur

Urban Activity Patterns

1. Introduction

'Urban activity patterns' refer to spatial and temporal patterns of human activities in an urban area. Time and space are thus the most fundamental dimensions in the analysis of urban activity patterns. Studies have examined spatial movements of people and transitions of their activities over time. There are certain regularities in activity patterns due to physiological, cultural, institutional, and other reasons. There are, at the same time, substantial variations in activity patterns among individuals, or over time; while some activities are repeated with high regularities, some are pursued with irregular frequencies and intervals. Investigations into urban travel patterns have attempted to reveal their regularities and variations across individuals and over time.

Analyses of urban activity patterns may be traced back to Chapin (1974) and his colleagues, who attempted to explain differences in activity patterns using person and household characteristics, in particular, 'stage in the family life cycle.' Another important concept is Hägerstrand's space–time prism (Hägerstrand 1970). Jones et al. (1983) combined these two approaches and extended them to form an analytical framework, which incorporates both needs and desires that motivate engagement in activities, and constraints that govern activity engagement and travel.

Since engaging in activities implies using time in certain ways, activity patterns are synonymous with patterns of time use. Urban activity patterns have also been examined from time use perspectives. Studies have examined the allocation of time to different types of activities, activity duration, time-of-day characteristics of activity engagement, and sequencing of activities.

Additional elements are spatial aspects of activity patterns, which shall be termed 'travel patterns.' Travel patterns have been examined extensively in the field of transportation planning. Of particular interest is trip chaining, which refers to the linking of trips to visit a series of activity locations. (A trip refers to the movement from an activity location to the next activity location. In cases where movement itself is the activity (e.g., walking the dog), the entire movement is a trip.) Also of interest from both time use and travel perspectives are interpersonal linkages, day-to-day variations in activity patterns, and behavioral dynamics.

Characteristics of urban activity patterns are discussed below on each of the aforementioned subject areas. For other reviews of the field and additional references, see Damm (1983), Jones et al. (1983, 1990), Kitamura (1988), Axhausen and Gärling (1992), Hanson and Hanson (1993), Gärling et al. (1994), Pas (1997), Pas and Harvey (1997), and Bhat and Koppelman (1999).

2. Time Allocation

The total of 24 hours each individual has in a day is allocated to different types of activities. Some activities are mandatory due to prior social commitments (e.g., paid work), some are needed for physiological reasons (e.g., sleep) or for subsistence (e.g., grocery shopping), and some are discretionary (e.g., recreation). There are activities whose location, starting time, and ending time are predetermined, such as paid work. These activities constitute 'pegs' around which other activities are arranged.

The amounts of time allocated to sleeping, meals, or personal care are surprisingly similar across data from different regions and times (e.g., see Szalai 1972). Once the population is broken down into segments, data reveal meaningful differences that reflect the characteristics of respective subgroups and regions. For example, American women spend more time on paid work than Dutch women, simply because more American women are employed and more are full-time employees among those who are employed; working American women also spend more time on personal care than their Dutch counterparts.

Time allocation has been studied with theoretical microeconomic models and more descriptive structural equation models (SEMs). A microeconomic theoretic basis can be found in Becker (1965) on which many empirical studies have been based. Because the total amount of time available is fixed, the amounts of time allocated to different types of activities tend to be negatively correlated with each other. For example, as one might expect, those who work more hours spend less time on out-of-home maintenance activities or in-home recreation. A common finding of previous studies indicates that individuals with higher income tend to spend more time on out-of-home recreational activities. Effects of life cycle are evident; individuals

living alone and couples without children are more likely to pursue out-of-home recreational activities; single parents and those in extended families are least likely to do so.

3. Activity Duration

The time allocated to a type of activity may be divided into segments. Unfortunately, there seems to be no consensus on how such a segment should be defined. One candidate is the activity 'episode,' which shall be defined as a block of time during which none of the dimensions of activities (what is being done, where, with whom, for whom, etc.) change. Another construct is a 'project,' which shall be defined as a contiguous block of time in which a sequence of actions is taken to fulfill a purpose. Yet it is typical that the individual engages in multiple activities simultaneously, but not necessarily continuously, that serve a multitude of purposes, making the definition of projects difficult, or arbitrary, to a large extent.

Some projects have fixed durations while others have variable durations that are affected by a number of factors. For example, the project duration at an out-of-home location is positively correlated with the length of the trip to the location. Commute duration affects people's use of time; people with commutes longer than 60 minutes tend to spend most of their evenings indoors. Reductions in commute time induce more travel, i.e., a portion of travel time savings is invested in more travel. Consistent with the results of time allocation studies, older individuals and individuals with lower incomes tend to have longer home-stay durations.

4. Time of Day Characteristics of Activity Engagement

Many activities repeated daily have regular starting and ending times, for physiological and institutional reasons. Sleeping, eating meals, and work activities are repeated highly regularly. Californian and Dutch time-use datasets indicate that personal care has a peak in the morning, then distributed throughout the day, with another peak in the late evening. Activities such as childcare, on the other hand, have no peak. Running errands is distributed over a period between 8:00 a.m. and 10:00 p.m. with no clear peak. Social activities are distributed over a similar period, with higher intensities in the evening. Engagement in entertainment, reading, and TV viewing tends to increase toward the end of the day and peaks in the evening. These time-of-day characteristics of activity engagement have been examined with the concept of time-varying utilities of daily activities, and time-of-day effects have been quantified. Past studies have also found that characteristics of activity location choices differ by time of day.

5. Activity Sequencing

A set of multiple activities tends to be sequenced in certain ways by individuals. Those activities that are more mandatory appear to be pursued first as people tend to pursue out-of-home activities in a day in the following order: serve-passenger activities, personal business, shopping, then social/recreational. Similar tendencies are found within a trip chain. These sequencing patterns are correlated with the time-of-day characteristics of activity engagement discussed above.

Activities are engaged under a set of constraints. Most important constraints are work schedules, which typically define three space–time prisms for a worker. The intensity of constraints varies across individuals. For example, the concentration in time of commute trips is interpreted in a study as an indicator of how constrained trip making is, and it is noted that unmarried women with children have the least flexible, and singles have the most flexible, work trips. Several studies have attempted to explicitly incorporate constraints into models of activity engagement.

6. Activity and Travel

A trip is generated each time the activity location changes. Although the spatial and temporal characteristics of trips have been extensively studied, the mechanism of trip generation is not well understood. A theoretical model of shopping trip frequency has been developed by applying the inventory theory. This theoretical framework, however, is not applicable to all types of trips with nonwork purposes. The concept of time-dependent utility has been adopted to show when a trip will take place, and later some empirical evidence was offered in support of the model. These are among a very few examples in which the mechanism of trip generation is directly addressed.

From microeconomic viewpoints, more travel is done—by making more trips, traveling longer distances, or both—when the cost of travel is less. Then individuals residing in areas with higher accessibility to opportunities should be traveling more. Empirical evidence is not conclusive on this point, however. For example, a study found the 'degree of urbanization' is not associated with travel; another study reports that household location classification variables based on density measures are not significantly associated with the number of stops by nonworkers. On the other hand, very significant effects of GIS-based accessibility measures are reported in a study.

Attempts have been made to treat daily travel behavior in its entirety. Approaches taken in these studies include: applications of discrete choice models and applications of mathematical programming concepts. The former treats daily travel behavior as the choice of a travel pattern from among all possible alternative patterns. With the spatial and temporal dimensions, the number of alternative patterns can be astronomical, whose enumeration may impose computational difficulties. In addition, it is not compelling that the tasks of enumerating and evaluating numerous alternatives are manageable with human cognitive capacity. Likewise, treating the decision process underlying daily behavior as a mathematical programming problem does not appear to offer realism either. Furthermore, if viewed as an optimization problem, the decision process deals with an extremely complex problem of formulating and finding a solution for, leading to prohibitive computational requirements. An alternative approach is to decompose the decision associated with a daily travel pattern into a series of sequential decisions. Sequential approaches offer a better representation of cognitive processes underlying scheduling behavior. Yet they may not adequately depict individuals' responses to changes in the travel environment.

7. *Typologies of Activity–Travel Patterns*

Yet another approach to daily travel patterns is to develop typologies of travel patterns. An early work proposed a seven-group classification of travel patterns, obtained by applying a grouping procedure to factor scores that comprise measures of travel patterns, e.g., number of trips and total travel time. A later study developed 'geometrical similarity indices' based on a hierarchy of activity pattern attributes, and proposed travel pattern typologies that include five patterns of trip chaining. Application of pattern recognition theory and a variety of similarity measures can be found in the literature.

8. *Urban Travel Pattern Characteristics*

There is a substantial body of literature on urban travel patterns. A majority of individuals make 'simple' daily patterns of visiting one out-of-home location with two trips, i.e., a trip from home to the location, then a trip from the location back home. According to the 1990 National Personal Transportation Survey (NPTS) data, 30.4 percent of 48,385 respondents were reported to have made just two trips on the survey day, 8.6 percent three trips, 15.3 percent four trips, and 23.1 percent more than four trips. On the other hand, 21.2 percent of these respondents reported no trips at all. The average number of trips per person per day is 3.09; the average for those who made at least one trip is 3.92.

Gender roles and family life cycle are strongly associated with travel patterns. A number of studies have found that women engage in shopping more than men. An analysis of a 1990 dataset from the San Francisco Bay area indicates that women make about 75 percent more grocery trips than men, regardless of race/ethnicity, do more child chauffeuring, and make more household-serving trips.

The organization of nonwork travel, especially linking work and nonwork trips, varies with household structure. For example, singles tend to be away from home; two-person households have a positive propensity to conduct activities out of the home; and households with children tend to have more nonwork activity time, more nonwork trip chains, and more travel time to nonwork activities.

Household auto ownership is another factor that is strongly associated with household members' travel patterns. It is associated not only with the choice of the means of travel (or 'travel mode') but also with the number of trips itself. Study after study has shown a negative association between residential density and auto ownership, while household auto ownership is the principal explanatory variable of household trip generation that has traditionally been used in transportation planning studies.

9. *Trip Chaining*

Trip chaining is another subject area that has been extensively studied (e.g., see Hanson 1979, Golob and Golob 1981). Early models of trip chaining are Markovian that attempt to replicate linkages between activities pursued at successive out-of-home locations. This was later extended to include a continuous time dimension, and the stationarity and history dependence of activity transitions were statistically examined.

Many studies have indicated that individuals with higher incomes tend to chain trips more frequently and make complex trip chains. There are, however, results that income is not associated with forming complex commute chains, or indications that households with higher incomes have smaller propensities to chain trips.

Females appear to be more active than males, with more trips, more trip chains, and more trips per trip chain. On household structure and trip chaining, it has been observed that households of young working adults without children tend to have chains involving work trips; households with preschool children tend to make simple one-stop chains and simple commute trips; households with school-age children are inclined toward complex chains; while elderly households tend to have simple chaining patterns. Life cycle is also associated with the generation of serve-passenger trips,

and making more serve-passenger trips implies more trip chains.

A study of the 1983 NTPS data indicates that nonwork travel accounted for just over half of all person trips in the a.m. peak and two-thirds in the p.m. peak, and nonwork trips grew considerably faster than work trips between 1977 and 1983. This may be due to the linking of nonwork travel to commute trips. Importance of commute trips as a base to form trip chains has been noted by several researchers. Reductions in household size coupled with increases of multiworker households result in a greater tendency of linking nonwork trips to work trips.

10. Interpersonal Linkages

Most analyses of urban activity and travel patterns are concerned with the behavior of each individual. Although the focus on life cycle stage is in part based on the understanding that interactions among household members affect each member's activity and travel, characteristics of interpersonal interactions have been relatively unexplored. Subjects for investigation include how resources are allocated to household members, how tasks are assigned or performed on somebody else's behalf, and how activities are pursued jointly. Also of interest is how interpersonal interactions motivate the engagement in an activity, either jointly or separately. Such interactions are expected to take place through various social networks.

Inter-relationships among household members may be classified into substitutable relationships, complementary relationships, and companionship relationships. A study indicates that relations between household members are mostly complementary. Evening space–time paths of male–female couples have been examined and yielded findings that those with preschool or school-age children have higher propensities toward evening out-of-home activities, and young couples without children are oriented toward joint activities, often after meeting each other outside the home. Studies have shown that male travel demand is sensitive to female work and maintenance activities.

11. Day-to-day Variability

Another limitation of most of the studies is that they are concerned with activity and travel patterns for just one day, mostly a weekday. This reflects the fact that most datasets are based on survey periods of just one day. Such data contain patterns on a randomly sampled day, carrying no information on how typical or unusual that day might have been.

Examining day-to-day variability is important for several reasons. First, without information on day-to-day variability, it is impossible to determine exactly how much of the interperson variability in travel patterns is genuine, and how much is the artifact of intraperson, day-to-day variability. Likewise, it is not possible to detect how much behavior has changed over time. Second, statistical analysis of one-day data may not yield a correct depiction of behavioral change if it is history dependent. Third, one-day data do not indicate how many individuals exhibit certain behaviors over a span of time. For example, suppose one-day data indicate that 15 percent of commuters travel by public transit. This may mean a specific group of commuters, which comprises 15 percent of all commuters, travel by public transit every day, or every commuter commutes by public transit 15 percent of the time.

The level of repetition and variability in daily travel patterns has been studied using 35-day travel diary records, yielding findings that weekday and weekend patterns are different, and each individual has more than one typical weekday pattern. It is further shown that the level of repetition varies from population subgroup to subgroup. It has been reported that role-related constraints and commitments are associated with the variability in the individual's travel patterns. A study postulates a two-stage process: weekly behavior is selected first, then daily behavior is selected. Employed people with low incomes tend to select 'simple' weekly travel activity patterns. In another study, a two-stage model system is adopted in which a 'latent' daily pattern is selected, then travel time expenditure is determined.

12. Behavioral Dynamics

Most studies of urban activity patterns assume that patterns are stable or in equilibrium. Underlying this is the assumption that individuals adjust their activity patterns immediately and precisely whenever a change takes place in their travel environments or in their preferences (Goodwin et al. 1990). This of course is a very strong assumption. In fact, responses to changes often involve time 'lags.' Learning, or trial-and-error search for adaptation schemes, takes time, also producing lags. On the other hand, behavioral responses may precede changes in the environment because of individuals' planning actions, resulting in 'leads' in responses.

It is often the case that there are no responses to changes because of habit and behavioral inertia. Some of the issues addressed in day-to-day variability pertain to behavioral dynamics. The accumulation of empirical results is still in progress in this subject area, and it is premature to assess common dynamic characteristics of activity and travel behavior at this time. It is noted that there are pieces of empirical evidence which demonstrate the presence of behavioral intertia, show discrepancies between longitudinal elasticities and cross-sectionally evaluated elasticities,

and demonstrate dynamic properties in many aspects of activity and travel behavior.

Urban Anthropology

Urban anthropology attends to the social relations, symbols, and political economies that are most manifest in the city (Lynch 1994, Zenner 1994). In earlier overviews, Fox (1972, 1977), Jackson (1985), and Gulick (1989) advocate an anthropology *of* the city, rather than *in* the city, and argue that this distinction 'is not trivial or hairsplitting' (Gulick 1989, p. 14). Both approaches make important contributions: *in* studies focus on urban ethnography and foreground people, while *of* studies emphasize peoples' relationships to political and economic forces and the social and physical structure of the city. Urban anthropology as a subdiscipline combines the strengths of participant observation and intensive research with small groups with holism and political economy within a comparative framework.

Theorizing the city is a necessary part of understanding the changing postindustrial, advanced capitalist, postmodern world in which we live. The city as a site of everyday practice provides valuable insights into the linkages of these macroprocesses with the texture and fabric of human experience. The city is not the only place where these linkages can be studied, but the intensification of these processes—as well as their human outcomes—occurs and can be understood best in cities. Thus, the city is not a reification, but the focus of study of cultural and sociopolitical manifestations of urban lives and everyday practices.

1. Historical Overview

The historical trajectory begins with the Chicago School in the 1920s and 1930s and the development of an urban ecological perspective (Park and Burgess 1974). The city is theorized as made up of adjacent ecological niches occupied by human groups in a series of concentric rings surrounding the central core. Class, occupation, world view, and life experiences are coterminous with an inhabitant's location within this human ecology. Social change occurs through socioeconomic transitions of these areas in an ever downward spiral toward the inner city. Research strategies focus on participant observation as a method of uncovering and explaining the adaptations and accommodations of urban populations to these microenvironments. Urban ethnographies suggest that familiarity, avoidance, and surveillance play important roles in allaying fears that emerge from heterogeneity in the city. Sally Merry (1982) documents the interactions and perceptions of what she terms

'Black,' 'White,' and 'Chinese' residents in a high-rise, low-income housing project in a large Midwestern city, and concludes that lack of familiarity plays an important role in the perception of danger. Eli Anderson (1990) documents avoidance as a coping strategy in his study of 'streetwise' behavior of Philadelphians, in which residents cross the street when faced with oncoming young 'black' males. Wacquant (1994) portrays how institutional avoidance of young 'black' males can create a 'hyperghetto' of isolated families in Chicago's Black Belt, where the streets are deserted and no longer patroled by police; and Philippe Bourgois (1995) dramatizes the fear and sense of vulnerability experienced by residents of El Barrio and depicts their strategies of avoidance and surveillance used to deal with street crime. These studies describe how fear is spatially managed in urban contexts, and how avoidance and streetwise behavior are used by low- to middle-income people to mitigate their fears, while abandonment of the inner city by police and local institutions exacerbates these residents' feelings of fear and isolation.

A second major influence is a series of community studies undertaken as part of the Institute of Community Studies' program of policy and planning research on the slum clearance and replacement of housing in London, England and Lagos, Nigeria. These studies, beginning in the 1950s and continuing throughout the second half of the twentieth century (Young and Willmott 1957, Marris 1962, 1995), theorize the city as made up of a series of urban communities, based on extended family relations and kinship networks. Coincidentally, the Tavistock Institute of Human Relations published Bott's (1957) study of the social networks of middle class English families that drew upon discussions with anthropologists at the University of Manchester (Gluckman 1971). The methodological contribution of network analysis as the basis for studying the social organization of city residents is widely used to understand the rapidly urbanizing populations of Africa (Mitchell 1969) and Latin America (Lomnitz 1977), as well as by North American researchers interested in the interconnections and interdependencies of family and household relationships among the urban poor (Stack 1974, 1996). Network studies still provide an important methodological strategy and theoretical model for urban researchers (Laguerre 1994, Kadushin and Jones 1992, Liebow 1989).

Studies of planned physical and social change in Latin American low-income residential neighborhoods (Lobo 1983, Logan 1984), as well as studies of the planning and design of new towns such as Ciudad Guyana (Peattie 1972) and Brasilia (Epstein 1973) provide further ethnographic examples of local as well as national/international conflict over planning goals. These studies identify foreign capital investment (Peattie 1987) and the power/knowledge of the technologies of planning and architecture (Rabinow 1989) as antithetical to producing a humane environment for local populations and workers. Studies of urban renewal (Greenbaum 1992) and community rebuilding after natural disasters (Oliver-Smith 1986) further contribute to understanding how the dynamics of redevelopment processes often exclude the psychosocial needs of residents. Anthropological analyses of the conflicts that emerge among government institutions, planning experts, and local communities set the stage for contemporary poststructuralist studies of urban struggle for land tenure rights (Holston 1991) and adequate housing (Low 1988), as well as for studies of planning and architecture as instruments of social control (McDonogh 1991, Plotnicov 1987).

Another theoretical force has been the cumulative work of Leeds (1973) recently published in a posthumous volume (Sanjek 1994). Although Leeds' work concentrated on supralocal and local linkages and the nation/state level of analysis, the majority of his fieldwork dealt with the city as the point of articulation of these complex relationships. Anthropologists continue to utilize Leeds' theoretical model of the flow of goods, cash, labor, and services between metropolis and countryside in their analyses of the city (Guildin 1992).

The most important theoretical transition, however, occurred in the 1980s with the introduction of the study of the political economy of the city. Susser's (1982) landmark ethnography of a Brooklyn working class neighborhood, Hannerz's theoretical monographs (1980, 1992), and Mullings' (1987) critique of the study of cities in the USA ushered in a decade of critical studies of the structural forces that shape urban experience. The social organizational paradigm that dominated earlier studies was superseded by a political economy paradigm (Sanjek 1990). These studies theorize the city by examining the social effects of industrial capitalism and deconstructing the confusion of urbanism with inequality and alienation (Mullings 1987, Ong 1987).

The final development in this theoretical trajectory is what Jacobs (1993) has called representational cities—an approach in which messages encoded in the environment are read as texts. Jacobs argues that 'ethnographic studies were commonly prescribed the role of rendering more real the exotic and marginalized, but were seen to have little value in terms of the modern project of theory-building' (1993, p. 828). Radicalized urban ethnography, however, makes possible a link between everyday practices and the broader processes of class formation. According to Jacobs, new cities require new forms of analysis in which the urban built environment becomes a discursive realm. Within anthropology this representational approach is reflected in Holston's (1991) analysis of the planning and architecture of Brasilia, in which the city is read as an ideological tract of an imagined socialist utopia, and in Dorst's (1989) postmodern ethnography of the recreation of the history and landscape of Chadd's Ford.

The correspondence of academic training with the geographical area of study has also contributed to continuities of research and theory within culture regions. The tradition of British social anthropology in Africa has created a history of studies that focus on social relations in the city—exchanges, political alliances, market relationships, and network analyses that form the core of contemporary theoretical work (Barnes 1986, MacGaffey 1987, Peil 1991). Other continuities include studies of *favelas*, shantytowns, and *turgurios* in the urban periphery, and the informal economy in Latin America (Safa 1986); Japanese studies that focus on work organization (Hamabata 1990, Kondo 1990, Sumihara 1993, Bestor in press); and Chinese studies that emphasize urban hierarchies (Guldin 1993, Jankowiak 1993).

Thus, the historical development of the anthropological study of the city has produced a number of theoretical approaches that continue to be drawn upon by urban anthropologists. These approaches include: urban ecology models; community, family, and network analyses; studies of the power/knowledge of planning and architecture; supralocal/local linkage analyses; and political economic, representational, and discursive models of the city.

2. *Theorizing the City: Space, Knowledge, Time, and Aesthetics*

The view that contemporary cities not only pose problems that are intrinsic to the metropolitan experience, but also underscore and transform many of the most traditional concerns of the discipline—the social organization of space, the meanings of knowledge, group, and power, and the intricacies of commodity, exchange, and political economy—has been taken up by a group of scholars involved in the theoretical revitalization of the field (Low 1999). The concern is to articulate understandings of particular cities—Vienna, Barcelona, Valencia, Savannah, Atlanta, New York, Toronto, Lagos, Shanghai, Tokyo, Belize City, and San José (Costa Rica)—with broader anthropological concepts of space, knowledge, time, and identity. The inquiry begins not with imagining the city as a metaphorical object, but with imagining urbanites—residents, homeless people, planners, municipal bureaucrats, and architects—experiencing the city through the social relations, political economic, and planning processes.

Rotenberg and McDonogh's influential collection *The Cultural Meaning of Urban Space* reflects an attempt to understand 'the meaning of urban spaces through the knowledge of the people who live within them' (1993, p. 197, 11). The studies are characterized by the search for the underlying social and cultural values and power politics that give form and meaning to the cityscape and the urban built environment. McDonogh's (1993) exploration of 'emptiness' provides an evocative category that marks not an absence of urbanness, but a zone of intense competition that betrays the imposition of urban power. Low (1993, 1995) focuses on the historical emergence of spatial meanings of power relations in the Spanish American plaza, while others are concerned with the symbolic mapping of contested arenas of urban social interaction such as privacy (Pellow 1993), neighborhood (Bestor 1993), and schooling (Rutheiser 1993). Research on the design of housing (Cooper and Rodman 1992, Low and Chambers 1989) and place attachment to urban space (Altman and Low 1992) also contribute to this ongoing venture.

Pellow's work *Setting Boundaries* is more concerned with boundaries and perimeters, that is, the way in which 'physical and conceptual boundaries are integrally tied to the creation, maintenance, transformation and definition of social and societal relations—of sociocultural behavior and action' (Pellow 1996, p. 179, 3). The concept of boundary is dealt with both spatially and metaphorically, creating a link between the materialist and metaphorical analyses of social and spatial demarcation.

Many of the ideas have been elaborated by asking how meaning is created through both the social production of space and the social construction of space (Low 1996), and how power is represented in the history and evolution of the built forms (Leone 1995, Lawrence 1992). An ethnographic approach to the study of urban space includes four areas of spatial/cultural analysis—historical emergence, sociopolitical and economic structuring, patterns of social use, and experiential meanings—as a means of working out this theoretical agenda.

Rotenberg proposes a second project, that of identifying forms of metropolitan knowledge as a subset of the knowledge people gain from their lived experience and value socialization. City dwellers share the knowledge because they live in dense and specialized concentrations of people, information, built form, and economic activity. Rotenberg (1993) speaks of the 'salubrity of sites' as a way of understanding how metropolitan knowledge is made manifest on the urban landscape. In *Landscape and Power in Metropolitan Vienna* (1995), he traces the history of open spaces and gardens in Vienna and documents how these spaces have become a spatial template of urban symbolic communication.

An additional project, the study of time, directs urban researchers to consider the way in which schedules coordinate the circulation of people in the city as a means for studying ebedded power relations. Rutz argues that 'a *politics* of time is concerned with the *appropriation* of the time of others, the *institutionalization* of a dominant time, and the *legitimation* of power by means of the control of time' (1992, p. 7). Rotenberg's studies (1992) demonstrate the tyranny of urban schedules over individuals subject to their control. Issues of both time and space

emerge in the study of homeless people who live in urban public spaces (Hopper 1991).

The city also structures residents' urban experience, adding urban identity to place and time as universal sources of metropolitan knowledge (Rotenberg 1996). This proposal resonates with Sennett's (1994) interest in embodied urban experience. These universal characterizations bring us temptingly close to earlier essentializing discourses, but at the same time provide provocative material for perceiving how the city as a set of processes links experience and structure.

Another project that holds great promise is the study of ethnoaesthetics. Although much of this literature focuses on indigenous media and aesthetic and political sensibilities, the implications of this work transform our notions of the urban, global, transnational, and marginal. In the city, where culture-making often takes place, 'performing aboriginality' takes on new aesthetic and identity meanings (Ginsburg 1991). Bright and Bakewell (1995), in *Looking High and Low*, reposition art and ethnoaesthetics to redefine notions of cultural identity. Urban murals and low-rider cars provide examples of how the city constitutes an important dimension of the aesthetic. Although relatively undeveloped as part of the urban discourse, the study of ethnoaesthetics and cultural identity, and the demystification of art and artistic creation provide important insights for the analysis of the culture of cities (King 1996, Zukin 1995).

Contemporary anthropological studies of the city focus predominantly on the center, producing ethnographies of culturally significant places—such as markets, housing projects, gardens, plazas, convention centers, waterfront developments, and homeless shelters—that articulate macro and micro urban processes. These studies illuminate both the material and metaphorical power of spatial analysis for theorizing the city. Studies of the relationship of the urban to globalization, economic restructuring, and transnational migration have transformed traditional research concerns. The Society for Urban Anthropology responded to this transformation by changing its name in 1998 to the Society for Urban, National, and Transnational/Global Anthropology (SUNTA). As a subsection of the American Anthropological Association with a flourishing journal, *City and Society*, SUNTA provides a forum for the exchange of ideas within the subdiscipline and across the urban social studies.

3. Conclusion

The anthropology of the city incorporates a number of paradigms from other disciplines. The influence of political economy, architectural and planning theory, cultural studies, urban sociology, and cultural geography can be seen in the increasing attention to economic, political, and discursive models of the city. At the same time poststructural and postmodern perspectives have recast the kinds of questions and modes of inquiry used to study the city. The dominant research trends in urban anthropology are currently poststructural studies of race, class, and gender in the urban context; political economic studies of transnational culture; and studies of the symbolic and social production of urban space and planning.

Some areas of anthropological theory are more influential within the broader discourse of urban studies and urban policy. Many anthropologists contribute actively to theory and research on urban poverty, racism, globalization, and architecture and planning. (Stack 1996, Bourgois 1995, Susser 1991, Newman 1993.) The anthropological take on globalization is to focus attention on the transnational aspects of migration, culture-making, and identity management, and on the shifting cultural environments and meanings that contextualize and decontextualize behavior (Smart and Smart 1991, Pellow 1991). Urban anthropologists offer an experience-near critique of city life that provides a more complex understanding of the differences between cities' and residents' responses to racial segregation and class inequality (Gregory 1992, Susser 1991). Anthropological critiques of planning and design projects provide a methodology and theoretical framework for decoding the ideological intentions and material consequences of architectural plans and landscape designs (Holston 1989, Rabinow 1989, Rotenberg 1995, Rutheiser 1996). And anthropological studies link the macroprocesses of cultural hegemony with the microprocesses of resistance and social transformation within the context of deindustrialization and globalization demonstrating that these linkages can be made through a combination of sophisticated theorizing and empirical fieldwork. The contributions of anthropological fieldwork still retain the power to demonstrate the how, why, and when of urban processes, but are even more effective when linked to theoretical frameworks that provide a grounding for further study and discussion.

Urban Ethnography

Urban ethnography is the close and systematic study of urban life and culture, relying both on first-hand observation and careful interviews with informants, and on available records. Its roots can be traced to the early British social anthropologists. A peculiarly American variant emerged at the beginning of the twentieth century, most notably through the fieldwork of Jane Addams, W. E. B. DuBois, and Robert E. Park, all of whom wrote in the interest of social reform.

Their concern was to inform the wider citizenry of the conditions of the urban poor as well as the nature of racial relations. Concerned particularly with the social challenges of industrialism and urbanization, Park and his students conducted seminal ethnographic work on the city, effectively establishing the premier American school of urban sociology in the early part of the twentieth century. The urban world of the twenty-first century presents new challenges to the ethnographer, who must now deal with the social impact of de- and reindustrialization, increased urbanization, more complex immigration patterns, and the local manifestations of such global economic and cultural processes, including structural poverty.

1. *The Chicago Tradition*

At the University of Chicago, Park and his students produced a series of important and detailed ethnographic case studies of the cultural patterns of the peoples of Chicago. Prominent among these were Anderson (1923), Wirth (1928), Zorbaugh (1929), Thrasher (1927), Shaw (1966), and Drake and Cayton (1945). These studies tended to focus on immigrants, the poor, racial relations and the various social problems of the day, providing a treasure trove of local knowledge about the city, particularly its neighborhoods, creating a mosaic of social scientific work, and establishing effectively the field of urban ethnography.

After World War II, a new generation of Chicago ethnographers emerged, most notably Everett C. Hughes, whose most prominent students included Howard S. Becker and Erving Goffman. Jointly, they

shaped not only the field of urban ethnography but also American sociology more generally. Important examples of urban ethnography also appeared from other settings, such as Boston (Whyte 1943, Gans 1962), Newburyport, Mass. (W. Lloyd Warner's Yankee Studies Series), and Muncie, Indiana (Lynd and Lynd 1929). But as time passed, these efforts were overshadowed by quantitative methods of sociology.

By the late 1960s and early 1970s, the Chicago School was being reinvigorated by Park's students' students, with Morris Janowitz, Gerald D. Suttles, and Howard S. Becker as prominent new teachers. Short and Strodtbeck's (1965) classic study of gangs in Chicago was followed shortly after by influential works on the urban black ghetto. Though not of Chicago, Liebow (1967) and Hannerz (1968) conducted path-breaking ethnographic analyses on the black ghettoes of Washington DC. And Rainwater (1968) added to this work with his impressive study of a failed housing project in St. Louis.

In the mid-1960s, Suttles took up residence in the 'Addams area' of Chicago for three years as a 'participant–observer.' He analyzed and described the social worlds of four major local ethnic groups—blacks, Italians, Mexicans, and Puerto Ricans—and the ways they shared the social spaces of an area undergoing significant 'urban renewal' at the hands of the local government. The groups sorted themselves out in an 'ordered segmentation' created among themselves in a kind of territorial ballet. Residents distinguished their own values and social rules by knowing by whom they were opposed, and thus conflict was kept at a minimum.

During the late 1960s, William Kornblum took a job in a steel mill in South Chicago for two years and involved himself in the social world of the mill employees. They accepted him and his family in ways that became a profound learning experience for him. Among his chief findings was the surprising degree of comity and goodwill in the workplace in spite of the ethnic competition, much of it achieved through political sharing, which provided a certain meaning to the lives of the workers. Contrary to widely held assumptions, the people were quite conservative politically. Getting to know the workers through Kornblum's rich ethnographic experience makes such political views understandable.

In the early 1970s, Elijah Anderson spent three years studying black street-corner men at a Southside Chicago bar and liquor store. He socialized with them closely, drinking, hanging out, visiting their homes and places of work, and he came to know them very well. Contrary to the view of those who are inclined to see this world as monolithic, there were in fact three groups of men at this place. They called themselves 'regulars,' 'wineheads,' and 'hoodlums,' the latter two being somewhat residual, and subject to labeling or name calling. The study sought to understand the ways in which these men came together on this street corner to make and remake their local stratification system.

Around this time, Ruth Horowitz moved into a Mexican neighborhood in Chicago, and over three years affiliated herself with a male street gang, the young women who often spent time with them, and upwardly mobile youth, learning about the issues facing such groups at first hand. Her work represented an early document in the sociology of gender, but she also found that as gang members went about their daily lives in both the community and the wider society, they would experience tensions and conflicts between their efforts to pursue the American dream, and their commitment to a code of honor that demanded actions with a high risk of compromising these efforts.

2. *Ethnographic Fieldwork*

Like the recent Chicago researchers presented above, urban ethnographers typically involve themselves in a social setting or community with the express purpose of learning about the people residing there. Of particular interest is how residents meet the exigencies of life, group themselves socially, and arrive at their shared understandings of the rules of everyday life—conventions, prescriptions, and proscriptions of life peculiar to their world. The answers to the researcher's questions about solving immediate problems of living reveal much about the social order, or what Clifford Geertz labels 'local knowledge.' In particular, key events and people's reactions to them can alert the ethnographer to the subtle expectations and norms of the subjects, and so to their culture.

In penetrating such local cultures, the ethnographers must not only engage in intensive fieldwork, cultivating subjects, and experiencing their social world, but also keep copious field notes—a journal of the lived experience. In developing questions and hypotheses about the nature of the local setting, ethnographers must also deal with their own world view: their 'own story' or set of working conceptions about their own world as well as the world of the subjects. Depending on how the ethnographer treats them, such presuppositions can be problematic or advantageous. The subjectivity inherent in the process of fieldwork is often considered to be a strength, for with it can come profound sensitivity to the core concerns of the people being studied.

In this connection, a useful distinction may be drawn between the 'participant–observer' and the 'observing participant.' The former may be in an early, tentative process of negotiating a relationship with the group under study, and may be satisfied with this position, while the latter has become close to the subjects, effectively empathizing with them, and, it is hoped, able to articulate their point of view. Both positions have their drawbacks and strengths, re-

quiring the ethnographer to remember constantly the primary goal: to provide a truthful rendition and analysis of the social and cultural world of the subjects. To see the world from their point of view requires learning their vocabulary, their concerns, and even their prejudices. It is from such a position that the ethnographer may be able to raise the most penetrating questions, questions that focus on the subjects' core issues of social organization. In this respect, the most effective questions blend both the 'problems' confronted by the subjects in their everyday lives, and the conceptual 'problem'—the answers to which would presumably advance the field theoretically.

The ethnographer's formal response to such questions, once formulated, can be considered a hypothesis, which in turn may serve as the tentative organizing principle for the ethnographic representation and analysis to follow. Here, the critical task is to advance the hypothesis toward a tenable proposition, or a plausible argument. The ethnographer's accumulated field notes will likely include either positive or negative cases, requiring revision of hypotheses to take the case into account. Through this style of analytic induction, the goal is always to develop an accurate account of the world of the subjects, while at times knowingly generating ever more penetrating questions. Such questions, by provocation and stimulation, trial and error, help to advance the ethnographer's case to surer ground. In this sense, the questions can be, and often are, more important than the 'answers.'

In the effort to apprehend, understand, and ultimately represent the social setting, the researcher becomes a kind of vessel, a virtual agent of the subjects themselves, serving as a communication link to the uninformed. Such a task is not accomplished easily. Not only does it require a certain amount of empathy in addition to impressive conceptual and observational skills, but the audience, including other social scientists and the 'lay public' to whom the setting is represented may have such strong presuppositions that no amount of evidence will be convincing. This is one of the inherent difficulties and challenges of doing and presenting worthwhile ethnographic work, particularly in socially, politically, or racially charged environments.

3. *The Challenge for Urban Ethnography in the Twenty-first Century*

In recent years, deindustrialization, reindustrialization, increased urbanization, immigration, and economic globalization have made urban areas increasingly complex, both geographically and ethnically. Boundaries, including national ones, are, at the start of the twenty-first century, less important as a barrier to the movement of people, goods, capital, and culture. Los Angeles, for instance, with its ethnic diversity, sprawl, and lack of a single center may be an anticipation of the shape of future cities. So may 'edge cities' (Garreau 1991), such as the Valley Forge–King of Prussia area northwest of Philadelphia, Pennsylvania—urban centers that develop near, but not within, existing cities. And New York, as a global hub with an increasingly international population, epitomizes the tensions between 'local' and 'global' ways of life.

To understand the new global immigration, for instance, ethnographers must now come to appreciate and learn more about the lives of the British Sikhs of California who travel back and forth between New York and extended families in India, as well as Bombay elites and Punjabi farmers arriving in the United States at the same time, and low- and high-caste Indians in Chicago sharing utter confusion toward suburbanites. Also important is the manner in which such 'new' people impact established ethnic and racial populations. The black street vendor's story is important, as are the stories of the New York Haitian taxi driver, who finds his own identity by actively distancing himself from the African American, and who visits periodically his cousins who reside in suburban Paris (see Duneier 2000). Of no less importance is the social situation of the Taiwanese middle-class immigrants to Philadelphia who assimilate to 'get along,' but who are strongly ambivalent about 'losing' their Chinese heritage (Tsai 1998).

Moreover, the connections between urban poverty and culture become more acute and ever more complicated in these new environments. Park, DuBois, Addams, and other pioneers addressed the effects of industrialization, urbanization, and immigration early in the twentieth century. Modern ethnographers must come to terms with both positive and negative human consequences of deindustrialization, and cybernation of industry in the context of the new global realities, noting particularly the implications for living standards in the local urban environment often beset by ethnic competition. These socioeconomic forces have brought about increasing structural poverty, in which many people are unable to develop the human and social capital necessary to rise from destitution (see Wilson 1987, Anderson 1990). The process of reindustrialization in the areas of light industry, cybernetics, and service must be studied, with its attendant issues of hard and soft skills. 'Brown racism' (Washington 1990) must also be addressed, with its sources and its implications for local urban life and culture. The social world of illegal immigrants from China and from Mexico must be rendered, as well as that of the former peasant from the Ukraine who now makes his living brokering rental properties in New York. In many respects, Thomas and Znaniecki's (1918) early studies of Polish peasants in Europe and America anticipated the kind of ethnographic work on immigrant 'flows' being done at the start of the twenty-first century.

The shifts in social theory that accompany the growing complexity of the empirical world create new lenses with which to see, and therefore present new challenges for conducting a faithful ethnography. Increasingly, 'local' social processes are influenced by supra-local forces that must be studied to illuminate the connections among race, class, power, deindustrialization, and pluralism. To be effective, ethnography, then, must be holistic.

Ethnographers themselves, their audiences, and other consumers are also becoming increasingly diverse. The articulate voices of African-American, Native American, Asian-American, Latino, and gay and lesbian ethnographers as well as local residents who have become anthropologists and sociologists are being heard. Such diversity raises obvious questions about the politics of representation. Increasingly, as never before, ethnographers want to render their own stories, their own realities and local knowledge, and in doing so, make competitive claims on intellectual turf. In these circumstances, some stories get heard, others are silenced, and some interested parties want only the most flattering stories of their 'own' represented.

These are some of the more pressing challenges for urban ethnography today, and they are well worth the effort. As these challenges are met, urban ethnography will become more complex, meaningful, and it is hoped, effectual. David Riesman once likened worthwhile ethnography to a conversation between classes. In this sense, each ethnographic case study can be viewed as an important part of a dialogue for understanding between and among those of diverse backgrounds, a dialogue that becomes steadily more urgent.

Urban Geography

For the first time in human history, the majority of the world's population lives in cities. Metropolitan areas will soon become the immediate sphere of human existence and experiences, and this sphere is changing rapidly. The megacities of low-income countries are subject to stark urban population growth and as a result are increasingly difficult to command and to control. Urban/metropolitan areas of the highly industrialized nations are likewise undergoing a historical change: in the light of global trends in economics, society, and politics, they are facing challenges which require new and extensive economic and local policies in order to meet increasing intra-urban competition for investments and taxpayers.

Theoretically informed social science research is absolutely necessary to monitor trends of urban development, to provide basic information for the optimization of local strengths, to design urban development concepts which adequately provide for local needs and demands, and for urban planning which equally respects collective decisions, increased competition, modern urban structures, and the individual 'feeling' of the city. Social science research defines and analyzes control factors of urban development, brings to light basic data and information about urban structures, and processes, perceptions and the attractiveness of the cities. This is where urban geography has an important role to play.

1. *Urban Geography: Tasks and Approaches of a Social Science Discipline*

1.1 *The Scope of Urban Geography*

Urban geography is a specialized discipline within human geography. It deals with the analysis, explanation, and prognosis of urban forms, urban social fabric, and economic structures and functions. Urban geography addresses research questions from economic, political, social, and ecosystem geography in

their urban contexts at various scales. The scientific results of urban research increasingly serve as a basis for decisions on public investment, allocation of resources, and socioeconomic and urban development planning. Urban research can be broken down into interurban (system of cities) and intra-urban analyses, which address the processes going on within cities (see *Cities, Internal Organization of*).

1.2 Conceptual Approaches and Types of Research Areas in Urban Geography

A large number of conceptual approaches are utilized in urban geography. Each addresses different types of research questions that may contribute to the understanding of the complexity and complementarity of factors influencing the urban system. The approaches pertain to urban form and urban morphology, the urban social fabric and economic structures, urban development, and urban policy.

1.2.1 Urban form and urban morphology. This approach deals with the analysis of the built environment. The changing urban morphology, including historic/heritage preservation, the creative reuse of landmark buildings, the architectural and technological upgrading of dilapidated buildings and urban revitalization, have gained importance in recent years. These measures can improve a city's attractiveness for investors and high-income earners, hence the city's fiscal base, by increasing the emotional and intellectual attachment of the target population to the city.

Whereas revitalization has been shown to increase the attractiveness of the townscape and urban image, this form of urban redevelopment is not without social costs. Gentrification and urban sub-area revitalization, incumbent upgrading, and the dislocation/displacement of the lower-income population are all interrelated. The study of changes in urban form and the built environment and the effects on local population groups and businesses is but one aspect of understanding urban decline or urban fortunes, social restructuring, and population and neighborhood change.

In European countries, urban morphology is of particular relevance in historic cities, for example, in cities built during the medieval period. Here, the knowledge of the historic urban structure and design aids in finding and identifying historic sites that have either been buried by construction activities of later centuries, or that need to be preserved and protected from contemporary rezoning and/or construction activity.

Urban form and urban morphology have also been taken up by Neo-Marxian/Neo-Marxist urban geographers. The regulationist school, for example, tries to uncover the power structures and the functioning of urban regimes. According to this school of thought, urban form and the 'turning of skylines and CBD's is a means of accumulating capital at the cost of other urban sub-areas, a process accompanied by policies of neglect and disinvestment. Social and welfare disparities as are manifest in differing morphologies across urban space have thus become another major area of urban research.

1.2.2 Urban function and urban social structure. Analysis of urban land use development, urban functions, and specializations: specialized economic activities seek locations with the greatest competitive advantage. This approach helps to understand urban land use development and to determine those land use patterns that most competitively provide basic support for the city. The internal structures of specialized urban functions (wholesale, retail, service activity, etc.) within the city and their market orientation, i.e., urban locations that are best suited to meet the city's needs, are points of focus. On the micro scale of the city, the analysis of central business districts and neighborhood business/convenience centers have received priority. On the meso and macro scales of urban systems analysis, the degree of specialization in and between cities is considered the base for identifying a city's market potentials, strengths, and niches within a regional or national hierarchy of cities.

Empirical examination of factors organizing space and megalopolitan structure deals with the metropolis as a changing configuration and the processes by which metropolitan areas grow and expand beyond their rigid corporate limits. Studies of metropolitan patterning examine the functional differentiation of suburbs, the interrelation of the city and its surrounding area through economic linkages and commuting, and the way metropolitan communities reorganize themselves into supra-metropolitan areas. The development of megalopoles, the increasing functional specialization of metropolitan centers and communities, and their growing interdependency are key research issues.

Urban social geography and the factorial ecology of cities, social status differentiation, and segregation: urban areas are highly differentiated complex systems (see also *Cities, Internal Organization of* in this volume). These approaches deal with urban sub-areas, urban subpopulations, social and economic characteristics of urban neighborhoods, the social patterning of local residents by race, ethnicity, and class, and the behavior of subpopulations as a function of their social group, race, and class, or as mediated by the characteristics of the neighborhood, urban sub-area, and the urban system.

Urban sub-area characteristics and urban social and spatial differentiation are commonly analyzed

using factorial ecology. This term refers to various statistical approaches using factor analytic methods. Small area analyses with a limited set of variables grounded in social theory are common. Factor analysis, on the other hand, depends on a large number of variables that are then reduced in an exploratory way to essential properties of a particular phenomenon of urban sub-areas or urban space. It determines urban sub-areas according to common social characteristics or in terms of households or individuals with common characteristics.

The urban ecologist or social geographer does not focus on spatial differentiation *per se*. Rather, social and spatial patterns are regarded as the manifestation of a social process. Indeed, the urban social geographer or urban ecologist studies such patterns with a view to uncovering the social, political, economic, or cultural processes that may be responsible for these patterns. Residential segregation of different social status groups, for example, occurs in many different cultural settings and reveals the most residentially segregated social groups, for example, as those at the top and at the bottom of the social status hierarchy. In increasingly multicultural societies, patterns of differentiation among social groups and neighborhoods and their particular spatial geometry are becoming a growing problem. Factorial ecological investigations that use a variety of computational techniques help identify the differences between social, demographic, and economic characteristics in urban space. They help to monitor processes of social distance as reflected in the degree of physical distance and residential separation.

Perception of the urban environment: this approach sees age and social status-related perceptions of the urban environment, personal activity radius, and spatial behavior as related variables. Individual perceptions of reality affect spatial behavior, be it shopping trips or intra-urban migration. For example, characteristics of the automobile society, such as the monotonous urban landscape, can negatively affect an individual's identification with the physical urban environment and may induce him/her to move, thus contributing to the erosion of a city's tax base and concomitant inner city decline.

Differing social and age groups, for example, the elderly, the youth, the poor, have distinct ranges of activities and different patterns of spatial behavior in urban space. Market research utilizes the results of studies on the perception of the urban environment and spatial behavior. At the micro scale of individual urban geography, studies concentrate on activities that a person does regularly and urban places that are visited regularly, i.e., daily or weekly, as they form the basis of the personal contact field and average information field. These may be analyzed using the methods of time geography and indicate an individual's capabilities to overcome distance by means of mobility and communication. At the macro scale, the collective spatial behavior of social groups and the spatial geometries of social group behavior are focused upon. Decisions regarding distances between shopping centers and other central urban functions, for example, make use of empirical findings of collective spatial behaviors (see *Behavioral Geography*; *Urban Activity Patterns*).

Personal mental/cognitive pictures of space are also referred to as images. The analysis of these images focuses on the subjective evaluation of urban space by residents, visitors, business people, and potential investors. Perceptual geographic urban analysis upholds the theory that spatial behavior, like intra-urban migration or shopping and recreational activity, is often limited to a closed field of perception and reference, and it is affected by personal spatial evaluation. The overall image of a city from the point of view of a commercial interest is affected by the 'soft' locational factors (e.g., amenities, attractiveness of the urban environment, social and demographic processes in the city, or business climate). Image analysis can contribute significantly towards finding reasons for the exodus of population, companies, and enterprises, or disinvestment. Moreover, measures for the improvement of a negative city image or for instigating desired development can be recommended (see *Spatial Cognition*).

1.2.3 Urban development. The analysis of urban development as related to historical, political, and geographic peculiarities: this approach deals in particular with the development dynamics of the city and the determinants of that development. Different historical–political systems of society, socioeconomic factors and urban politics (see Sect. 1.2.4) fall into this category. Urban development analysis takes the positive consequences (e.g., concentration of social and economic performance, importance as center of innovation/innovation hub) and negative consequences of development (e.g., environmental problems or urban blight) into consideration. This approach can offer important impulses for the political, economic, and social components of urban development planning.

Urban cultural geography, intercultural comparison of cities and urbanism: this approach places the historical and cultural context of cities in the foreground. Processes of urbanization and the current physical urban structures of cities, including the inner differentiation, are assumed to be products of a series of sociopolitical systems. In cultural genetic urban geography, persistent historical urban structures are identified according to the appropriate historical social system and cultural sphere of influence. The understanding of current structures and processes that have evolved through construction, reproduction, renovations, and rebuilding during several cycles of social change, is easier if seen in the context of the past.

However, society changes faster than physical urban structures. Thus, the reflection of changes in society in old buildings and in the urban fabric, as well as the intercultural comparisons in society in old buildings and in the urban fabric, as well as the intercultural comparisons of these generation influences are amongst the most interesting topics of research in cultural genetic urban geography.

1.2.4 Urban policy. Globalization and urban policy: cities are social systems in space and as systems they react to any changes that result from both local and supralocal or global developments. Such supralocal trends include:

Increasing competition between metropolitan areas due to globalization of the economy and international competition.

Deregulation, separation of social politics from trade and industrial politics, leading to a decline of the welfare and possible intensification of social problems.

Economic and political integration, political change and crises that initiate migration flows. These result in increasing polarization of society and affect the perceived quality of the urban environment.

Change of societal values and pluralism of life styles. These encourage urban exodus and the concentration of marginal groups in the inner city.

Global economic restructuring, the increased competition between cities, and the decline of the welfare state force cities to pursue entrepreneurial urban development strategies. These may include economic incentives, the promotion of investments or megaprojects to increase urban attractiveness, and the decision to promote growth rather than redistributive urban development. Also, new entrepreneurial public–private partnerships or rigid urban regimes that place a great emphasis on private sector planning have emerged.

Urban regimes follow different approaches to development; some implicitly exclude or include social policies as part of their overall strategy, with different levels of impact on long-term development processes. On the micro scale of the individual city, the analysis of the interrelationships between urban policy, urban development, urban sub-area development, and the changing geometries of segregation helps to understand how and why planning may become unintentionally a determinant of social and spatial polarization. Given the adoption of Western urban policy and planning models in other countries, it is important to understand the social, spatial, and economic implications of each type of policy for urban development as such and in different cultural settings.

Government devolution, the state and local response: on the macro scale of the national urban systems, the relationship between national/federal urban policy and local policy and local urban development is of interest to urban geographers. Their main interest is what happens in cities when federal policies change. For several years now, one of the more noticeable national trends has been the shifting of financial responsibility away from the federal government toward state and local governments. This trend has been observed particularly in the US and Western European federal systems. Known as 'devolution,' it has led scientists and observers to believe that social problems may worsen if the federal/national role of counterbalancing unfavorable social and economic developments is restricted. To place theoretical concerns and real world developments under a policy of devolution into proper perspective, it is important to look at the actual situation and local responses. Federal/national policies may at first glance adversely affect inner city and other poverty areas, but one must also look at local policies and responses to federal/national policy in order to get a more balanced view of long-term adjustments and trends in societal development.

Policy-oriented urban geography deals with urban problems, such as social and economic disparities, caused by policies at various levels. In research on attempts at restoring run-down inner city neighborhoods in the US, one can find many examples of innovative community concern expressed by both the public and private sectors with the potential to counterbalance public sector devolvement to some extent. European nations, amongst others, have developed interesting local policy mechanisms to deal with the ills and imbalances of society manifest in urban areas. Policy-oriented urban geography thus studies and uncovers the problems and potentials of local planning responses to current problems of urbanism and federal and state polices.

2. *The Operational Methods of Urban Geography*

It is clear, then, that the differing conceptual approaches largely focus on two types of research issues:

those related to urban space and urban sub-area characteristics, the basic dimensions of city patterning, and the determinants and processes behind changing structural characteristics of urban space over time. The attributes may refer to physical, social, economic, or demographic phenomena and their differentiation (their concentration, densities, distribution, growth) in urban space;

those related to people in urban space, i.e., individual and collective spatial behavior (for example shopping trips, commuting, daily activity ranges), moreover, perceptions, images of urban space, and planning.

Concomitantly, there are two major methodological approaches: those of empirical regional/urban sub-area analysis, and those of empirical social science, here in particular the survey methods. These methodologies are, of course, not mutually exclusive, but

rather, complementary. Each sheds light on issues that would otherwise be impenetrable. Not only urban geography but also urban research in general makes use of these methodological approaches.

2.1 Methods of Empirical Regional/Urban Sub-area Analysis: 'Urban Social Monitoring'

Social and societal developments have their real world manifestations in urban space, and social and economic developments in urban areas are reflected in the structural characteristics of urban sub-areas. Urban geography is well suited to examine attributes and developments of structural characteristics by means of analytical techniques. These analyze the areal structure of urban communities in terms of attributes. Empirical urban research is both regional research specifically in urban areas and social or socio-spatial research. The methods correspond to those found in regional geography in so far as they are utilized for delineation and observation of structural change of agglomerations, city centers/cores, urban expansions, and suburban areas. Within the city itself, the research units are districts and neighborhoods as well as other 'official' spatial units of division, be they for planning, political, or statistical purposes (e.g., planning units), school and electoral districts, street rows and blocks. Urban sub-areas may be of any scale: census tracts are commonly used as statistical reference areas. Micro scale urban social geography also makes use of block level data to characterize the increasing differentiation of urban social milieus.

The methods of empirical urban sub-area analysis allow for urban social monitoring. This refers to the inventory, documentation and analysis of detailed socioeconomic structural patterns and processes of change. Complex spatial processes are broken down into individual components.

Statistical techniques aim to characterize and analyze urban space, urban sub-areas, and urban structural developments comprehensively. Three approaches are important:

(a) For descriptive purposes, methods include computer-assisted cartography and the refined cartographic and analytic methods enabled by Geographic Information Systems (GIS). These may produce unidimensional or multidimensional maps of social, demographic, or other phenomena as differentiated in urban space. GIS, of course, is also suited for the establishment of a long-term statistical cartographic database, which can be periodically updated. Such a database would simplify thematic longitudinal onsite analysis of the target urban region with regard to social, economic, and demographic processes and forecasts.

(b) In a more exploratory sense, factorial ecological investigations use a number of multivariate descriptive statistical techniques (the methods of factor analysis) to identify the essential dimensions that characterize and differentiate one urban sub-area from another in terms of social science variables. Underlying the concept of urban social areas is the assumption that societal processes reflect natural processes in that they have a competitive dimension that can lead to processes of selection. Social structures and social change in space are seen as the result of mutual adaptation of competing species. According to R. E. Park (1936), socio-ecological studies deal with processes that either uphold an existing social balance or that disturb the existing order in order to reach a new, relatively stable existence. One specific type of factorial ecology is social area analysis. Social area analysis is based on the theory of Shevky and Bell who understood urban social space as being primarily characterized by social rank, urbanism, and ethnicity. As such it only works with a limited set of input variables. Cluster analyses subsequently performed on factor analyzed urban sub-areas can help identify groups of sub-areas with common patterns of variability.

(c) In order to understand the determinants of and processes responsible for such patterns, one may combine descriptive and analytical statistical techniques. Factor scores from factorial analyses may, for example, be used as input data in multiple regression analyses that relate these aggregate characteristics to explanatory variables.

Social monitoring of urban sub-area characteristics over time enables a scientifically sound evaluation of the current structural change: urban geography falls back on existing statistical data collected by public and private institutions or public welfare organizations. As the data reflects institutional norms and goals, urban geography has no influence on either the exact questions, the survey method, or the aggregation and systematization of the indicators. Consequently, theoretically informed urban research is limited by the quality of these (secondary) data sources. However, the quality of official data banks and the methodology of secondary research in the field of spatial and thematic aggregation of data are improving continually.

2.2 Survey Methods—Empirical Social Science Research

Urban space is not only an attribute of space but also an area of activity. In order to analyze activity systems/patterns of individuals or households, as well as preferences, felt needs, perceived quality of the urban environment, locational/residential behavior, or general spatial behavior in a specific urban context, the urban geographer has to use survey methods.

Empirical social science research collects social data by means of survey methods, experiments, 'pure' observation, or 'participative' observation. In human geography, empirical social science research is applied to identify and investigate areas of perception and activity, as well as opinions and attitudes to values and

norms in society, as these form the framework of spatial behavior. Survey research methods in social geography concentrate on the interrelationship/correlation between spaces and social group behavioral patterns, designation and appraisal, group perception, and evaluation of spaces.

The advantages of incorporating surveys into the initial stages of research are that important issues can be identified at an early stage, and the survey allows for a differentiation and consolidation of research aspects. At the same time, preparation of standardized methods for covering the chosen topic continues unhindered or alternative and appropriate research methods (i.e., not from within empirical social science research) may be sought. Generally, the social surveys of empirical social science research open the door to a greater spectrum of human geographic research issues than would be possible with official statistics.

Research questions of urban geography thus deal with different sets of issues:

either the physical attributes of spaces or the indicators of their functional interconnection; or

immaterial aspects (spatial perception or space-related activity); or

both; or

those aspects of spatial change that result from the interaction between immaterial and physical elements (e.g., the physical results of political visions for the urban area and the consequent measures, or socio-spatial disparities caused by power relations in society).

The selected database depends on the research question. Studies of objective reality (e.g., socio-geographic structural analysis) use data that reflect numerically definable spatial characteristics (as opposed to subjectively perceived spatial attributes). This data is mostly found in official statistical material, published and unpublished, the basis of which is extensive censuses (e.g., of population) or surveys (e.g., of enterprises). Personal, small-scale, and tailored surveys are necessary if the time lapse between official censuses is too great or if certain details are missing (e.g., in order to incorporate structural, socio-spatial, and economic aspects, entrepreneur surveys or mappings of building conditions in different neighborhoods, of spatial use, or overall inner city differentiation may be necessary). However, if the research focus lies in the perceived surface and activity area of individuals and groups, then interviews are necessary if spatially related behavior, behavioral background, and possible consequences of behavioral patterns are to be dealt with.

Methodological procedures in urban geography stand out for their broad range. Some procedures overlap, thus hindering the exclusivity of subfield methodology. For this reason, it is not possible to refer to a particular methodology for economic geography, social geography or, for that matter, urban geography. However, within human geographic research of urban areas, the methodical–methodological approach of dealing with different issues is basically the same. Geographic scale, spatial delineation, and weighing of indices are the main differences. Between factorial ecology and survey methods, only the data sources and the scale of the evaluation differ. Even though the goals may vary, the basic principle of preparing and evaluating official or specifically collected social data from survey research in a descriptive and/or quantitative analytical manner stays the same.

3. *Outstanding Features of Urban Geography*

The standing of urban geography within the social sciences in general draws essentially on two things that the other disciplines dealing with urbanism do not share to the same extent.

3.1 The Combination of Cognitive and Methodical Capabilities

(a) Empirically and theoretically informed research from an integrational/holistic perspective.

(b) Relevance to society.

(c) Diversity of urban research topics in social, economic and environmental fields, amongst others. The range of urban research topics includes, for example:

(i) problems of increasing social differentiation in urban sub-areas and the development of an urban underclass, urban ethnic-cultural and lifestyle milieus, long-term urban unemployment, the welfare poor, the working poor;

(ii) population change (socio-demographic, socio-economic and socio-cultural), infrastructural, and policy adjustments;

(iii) housing and urban labor market developments;

(iv) urban environmental quality and urban sub-areas, questions of environmental racism;

(v) functional interrelatedness of cities and their suburban areas;

(vi) the territoriality of each context, the unique and unrepeatable set of social and economic relations, local networks in urban areas and development; the territorial embeddedness of global impacts;

(vii) local policy responses to supralocal trends;

(viii) entrepreneurial urban policy and micro-scale urban social development;

(ix) cross-cultural urban development; and

(x) urban systems development.

3.2 The Specific Methodological Competence and Diversity of Analytical Responses

(a) Empirical research: primary survey methods, such as monitoring, mapping, or field surveys;

(b) statistics: the scientific approach for drawing conclusions about research questions/hypotheses by means of processing spatial primary data and official-statistical secondary data;

(c) cartography: tool for working with and presenting spatially located and differentiated phenomena;

(d) remote sensing: interpretation of aerial photos and satellite photos as a further important source of information; and

(e) utilization of geographic information systems (GIS) to present and analyze data and developments in space.

4. Conclusions

Global economic restructuring, political change, government devolution, and social restructuring alter urban and regional fortunes and give rise to new socio-spatial patterns of development. Fragmentation, polarization, and new local spatial identities form new urban realities. Formerly prosperous cities may lose their comparative locational advantage. In order to retain competitiveness and build up local (endogenous) potentials, or to govern uncontrollable cities, new models, modes, and mechanisms of planning are being developed. In cities of the Western world, public–private partnerships—coalitions of major local economic and political players—have been outlining/developing and implementing grand visions of development. Megacities of low-income countries have yet to cope with the more basic infrastructural needs of their populations.

Thus increasingly, in cities worldwide, both urban planning and the prevailing urban regime, its orientation, and complex interaction with the regional, national, or supranational economic and political systems, have a significant effect on the development of a city. In order to deal with contemporary urbanism, decision makers will need to rethink urban processes, structures, and policies. What is needed is an understanding of the city from a systems perspective. This views urban developments, form, and social and economic structure as interrelated with the systems of society, economy, and politics. It also understands the city as an organism/entity with enormous local capacities and strengths that might successfully counteract the local or regional effects of globalization or other supralocal forces.

Urban geography is a systems-oriented social science discipline with great relevance to interdisciplinary solutions of problems of urbanism and urban areas. The systems perspective, the skills required, and the variety of research questions and applied research in urban geography make this discipline preeminently suited to understand and deal with problems of contemporary urbanism.

Urban Government: Europe

Urban governments are defined first as political arena and instrument for enhancing democracy, participation, and steering local societies and second in terms of services provision and public policy. They are back on the political agenda of Europe, not as the old medieval city, but as more autonomous political authorities within a European governance in the making. Urban governments usually are related to the nation–state in terms of democratization and legitimation of forms of territorial management.

1. Urban Government and the making of the Nation–State in Europe

Weber famously emphasized what he saw as the distinctive characteristics of European societies, that is, the medieval occidental city defined in terms of 'sworn confraternisation' based upon a fortress, a market, bourgeois associations, specific rules in terms of land ownership and tax, and sometimes courts and armies (Weber 1978). The importance of the urban government was stressed as the city developed upon the movement of medieval 'communalisation' (i.e., communes being formed through acquiring a *charter*). Cities became institutionalized associations, autonomous and autocephalous, active territorial corporation characterized by autonomy and capacity for action towards the outside (the lord, the prince, the state, the emperor, rival cities) and led by urban officials. Medieval urban governments developed democratic institutions, and commerce left its mark through the edification of monuments symbolizing this power: squares, town halls, belfries or bell-towers.

In due course, 'voracious states' consolidated with or against 'obstructing cities' (Tilly and Blockmans 1994). The making of the modern state and the coming age of the second (industrial capitalism) marked the end of the golden age and autonomy of occidental cities.

Later, in industrial cities, for instance in the UK but also in Germany, France, and Scandinavia, the scope of social problems became such that elites in urban government pioneered policy programs in housing, planning, basic elements of welfare, education (De Swaan 1988) and hygienist concerns led to the 'Haussmanisation' movement of city rebuilding, that is, the emergence of local public goods. Urban governments played a key role in providing basic utilities and services such as water, sewage, street lighting, and, later, gas and electricity, firemen, and transport, not to mention slaughterhouses. This development was diverse, fragmented, contested between a conservative petty bourgeoisie and the municipal socialism movement, and more consistent in the North of Europe than in the South. Most local government in Europe gained legal recognition in the second part of the nineteenth century. Gradually, a professional local bureaucracy emerged to deal with those developments. The rise of urban government was not just a local or national phenomenon. Exchanges of experiences of ideas, for instance in planning and social housing, were crucial.

Later, in most of the post-1945 period, the category 'European urban government' did not make much sense, and was not an issue. Within the social democratic compromise of most European states, the role of urban government was understood within the center-periphery paradigm (Mény and Wright 1985), that is, in national terms and as part of local government. Urban governments differed in Europe because each country had a different constitutional setting, different rules, different public finances systems, different political systems and traditions, and different organizations to provide services. Sometimes, variations within a country were also important (Germany or Italy).

Urban governments were understood either as a functional entity to deliver services, in particular welfare services (hence the long-lasting debate on size and amalgamation), or as a political unit. In their classic comparative research, Goldsmith and Page (1987) have suggested that local government autonomy in Europe should be analyzed in terms of autonomy through two major criteria which encompass or are closely related to other dimensions: legal status and political status).

That analysis clearly stressed the differences between the welfarist northern European urban governments and the more political (sometimes clientelistic) southern European urban governments.

2. A New Pattern of Constraints and Opportunities for European Urban Governments

These classic distinctions are now under question because a common set of pressures and opportunities (Europe, fragmentation, state reorganization, economic restructuring, social tensions) tends to blur the frontiers between existing national models of urban governments and to reinforce differences within nation–states. Several pressures for changes are put forward.

Urban governments were contested in the 1970s and 1980s by urban social movements. The bureaucratization, hierarchies, urban regeneration projects, com-

plex and fragmented decision-making process of urban government were attacked in cities all over Europe. Conflicts entered the realm of urban politics in relation to housing, planning, large infrastructures projects, economic crisis, and cultural issues. New groups, beyond class basis, organized to raise new issues (quality of life, democracy and participation, economic development, and culture) to promote urban change against elected urban leaders. New middle classes gradually were incorporated within political parties (social democratic and green) and played an important role in many European cities to promote a new set of urban policies to deal with those issues. In the most radical cases, squatters in Amsterdam or Berlin for instance, urban government officials have learned to cooperate, to provide sources of funding, and to incorporate those groups in more loosely-defined structures of governance (Mayer 2001). Preventing large social conflicts and including various groups has become the norm for urban governments.

Those movements and changing patterns of governing elites led both to structural changes and experiences in urban governments all over Europe such as the 'free communes' in Scandinavia. More significantly, most urban governments have initiated management reforms including neighborhood councils and the decentralization of services management, that is, new mechanisms for citizen participation in decisions despite the twofold difficulty of giving up power and budgets (uneasy for councillors) and of sustaining citizen interests in running day-to-day business. Beyond the UK, market friendly ideas associated to 'new public management' (Dunleavy 1994) are having an impact in urban government, in particular in the north of Europe (Baldersheim and Stählberg 1995). Issues of citizen participation in urban governments are associated with growing issues of management efficiency in the delivery of services to customers. The restructuring of the public sector leads to increased confusion in public policies and the fragmentation of urban governments (Pierre 1998); hence the growing interests for issues of leadership, management, coordination, and governance (Borraz et al. 1994, Stoker 2000).

The fragmentation of urban government was also accelerated by the large privatization movement which is slowly making its way in western Europe. Lorrain and Stoker (1997) suggest that variation depends upon the intensity of political ambition and the public/private dimension with, for instance: (i) the UK (reform of urban government plus the privatizing of a large part of social housing, major utilities, not to mention the introduction of competitive tendering for most social services); (ii) Scandinavia where municipal public bodies are still dominant (gradual change) despite the pressure of competition; (iii) France where, in the post decentralization process, urban mayors wanted to increase their autonomy vis-à-vis the state by privatizing a large amount of services but remaining active in their regulation, and (iv) slow change in the south of Europe and in oriental Europe because of uncertain changing institutional patterns. Different models of regulations and contracts of those privatized or semiprivatized services emerge in Europe and are in competition both in Brussels and in former Eastern European cities. Large utilities firms are now competing all over Europe and beyond to provide new services.

Urban governments in Europe are also facing political pressure related both to the restructuring of the state and to questions about representative democracy and changes of political culture (Clark and Hoffman-Martinot 1998). First, there is a transnational movement to raise issues of urban democracy and accountability (King and Stoker 1996). This has translated, most importantly in Germany and in Italy, but even in the UK to a limited extent, in the direct election of urban mayors. Mayors have often gained a higher political profile in most European countries, most notably in Italy but even in small centralized countries such as Portugal, Sweden, or Finland. Second, relatively small green parties are now established in most continental countries and have an impact on urban politics. Since the mid-1980s onwards, they have pushed two kinds of issues: direct consultation (local referendum, experiences of deliberative jury) to go beyond the elected representative on major issues (for instance, the choice of public transport) and procedural democracy. They also benefited from the move against corruption in Italy, France, or Germany. Third, at a time when some urban government elites have espoused the discourse and less often the policies of urban entrepreneurialism, thus building sorts of growth coalitions, new urban social movements have appeared specifically opposing flagship urban projects supposedly crucial to enhance cities' image. Fourth, the relative erosion of national parties' capacity to mobilize and increase resources at the disposal of urban government, gives more prominence to the urban leaders and apparatus of parties which are, in some cases, also the aggregation of local parties. Fifth, the complexity of public policies together with the perceived needs to organize at a larger scale than old cities has led to a resurgence of attempts ('*trompe l'œil* renaissance of metropolitan governments' Lefevre 1998, p. 16) to move from urban governments to metropolitan governments for instance in Italy, Rotterdam, or London; hence the salience of the governance issue again and the role of urban governments. Sixth, the restructuring of the economy also had some direct impact on urban governments and planning. In the postwar period, most urban governments had little to do with economic development beyond planning, land, and infrastructures provision. All that was to change in the 1970s. Rising unemployment, state retreat, and gradually more firms' internationalization have put urban governments at risk (tax, social groups, social problems). In the early 1980s, a large movement of

creation of urban economic policy was noticed in particular in the UK, the Netherlands, Germany, France, Belgium, and also in the most dynamic Italian and Spanish cities, but less so in northern Europe (Judd and Parkinson 1990). Supporting firms and, above all, attracting outside capital became standard policies in most European cities; hence strengthened forms of cooperation between private interests and urban governments, but rarely American-like urban regimes or growth coalitions. Seventh, the decentralization of social policy and the European integration are also leading towards specific social and political urban rights (Garcia 1996). Differentiated patterns of political participation (elections, procedural democracy, associations) are leading towards more diverse forms of urban citizenship already obvious in the case of quasifederal states. Eighth, most European countries are still involved in some reform of the legal and tax powers of various levels of subnational government, regions here, cities there, quasifederal state or provinces. The rise of meso-government in Europe can be seen within investment figures. The share of local (but massively urban) government in the national public investment now amounts to around 50 percent in small centralized countries (Portugal, Finland) to around 60 percent (UK, Italy, Germany, Spain, Denmark), or even beyond 70 percent (The Netherlands, France).

3. *Conclusion: Urban Government and Governance in the European Polity in the Making*

Urban governments are part of wider social and political processes such as the making of Europe or the restructuring of the economy. Urban governments in Europe reflect both well-established institutional arrangements and more strategic behaviors with the European governance.

The making of Europe goes together with a vast movement of reallocation of authority. The changing scale does not suppress the narrow legal and financial relations between urban government and nation–states but includes them within a wider set of intergovernmental relations, networks, interdependent bodies. Urban governments have to deal with an increasing amount of actors and policy tools (contracts and partnership, for instance) together with more diverse networks and actors. The making of a European polity implies not just a more complex structure of vertical intergovernmental relations but also horizontal ones. Networks of cities are flourishing in Europe, including policy best practices exchanges financed by the European Commission, or old twinning arrangements modified in multidimensional cooperation between cities in Europe. In this multilevel governance in the making, the constraints imposed by the state are often lessened, urban governments tend to get more discretion (not always) but also a different set of constraints.

The institutionalization of the European Union has also concrete implications for urban governments: access to funding for specific programs (from structural funds to the environment) goes together with the learning of norms, new methods, buzz words (partnership), accounting rules, evaluation. The gradual institutionalization of different policy domains gives more and more importance to EU rules. Urban governments, all over Europe, gradually are developing strategies to cope with those opportunities and constraints, sometimes to influence them, for instance, in the case of structural funds (Goldsmith and Klausen 1997).

Rather than looking for convergence or divergence in urban governments, one can first notice the blurring of national frontiers to identify common modes of governance in groups of cities, usually articulated in part by national patterns. What is interesting in the European case is the attempt made by urban government elites to deal with increased fragmentation, to balance the politics of growth with social issues, and to strengthen governments and processes of governance. Urban governments in most European countries have become more complex organizations, more fragmented, and to some extent, more responsive to the demands of local groups and neighborhood but also more dependent upon firms, and utility firms, in particular.

In other words, the issue of articulating urban government and urban governance in different ways is central. That attempt to bridge the gap between politics and policies and to define some collective urban interest is at heart a political process. The erosion of the nation–state does not mean the end of politics in Europe—it reappears at every floor of the multilevel government—but urban politics may be less defined in terms of domination and more in terms of coalition and institution building, or even identity formation. Cities (together with regions) have returned to the central stage of European politics and urban governments are key actors within the emerging pattern of European governance.

Urban Growth Models

An urban model is a statement about the interrelationships between parts of an urban system, which not only describes these interactions, but makes possible the prediction of the effects of some kinds of changes in the system or in its environment. This is the essence of any scientific theory.

Viewed as a part of a scientific discipline, urban models provide an organizing framework for bringing together many aspects of knowledge about urban life, for testing subsidiary theories, and for identifying gaps in knowledge and guiding future research. Viewed as an aid to professional practice in urban planning or engineering, a model which is operational at a relevant level of detail can provide insights into the future results of new policies, and guidance in their formulation and improvement. To serve these two divergent purposes, a model must be understandable and acceptable to both the scientist and the professional.

Prior to the mid-1950s, many disciplines and professions engaged in disjointed efforts to analyze urban affairs. In Geography and Sociology, there were efforts to achieve an overall view in largely descriptive terms. Examples include Burgess (1927), Hoyt (1939), and Harris and Ullman (1945). Starting in a period of optimism about scientific management, the last 50 years have seen substantial growth in urban modeling, but there are still many imperfections in current models, and obstacles to their filling their dual role. We will try to expose the bare bones of both the progress and the difficulties as they have developed over five decades.

1. Basic Considerations

An urban metropolitan area comprises a set of organized activities and residential spaces, occupying land and buildings, and using infrastructure. These activities and their containers are at higher densities than their nonurban surroundings, and are more closely connected with each other than with their ambient environment. Their existence and development require the proper functioning of markets or allocation methods for land, for housing, offices, and factories, for labor, and for public and private services, including those of the transport and communications systems which knit these other functions together.

Because of the paramount importance of resource allocation, and the role of real or artificial markets, these interrelationships are largely governed by economic considerations—but with many differences from received economic dogma. There is a division of decision-making between the private and public sectors, necessitated in part by economies of scale and indivisibilities. In the ultimate political sense, economic efficiency is only one of several means to a bundle of humanistic ends. In analyzing behavior, especially that of households and their members, economic forces are greatly influenced and modified by social and psychological ones. Economic analysis depending on equilibrium tendencies ignores or belittles the lags in personal and organizational adjustment to change,

and the durability of investment in infrastructure, buildings, and human capital.

There is another and fundamental schism between economic descriptions of 'rational' behavior and the realities of urban life. This divergence has led to two trends in urban modeling which are only now being resolved. In economics, similar actors in similar conditions make similar decisions—people shop at the nearest center, traffic follows the shortest route, and employees seek out the nearest jobs. In reality, some actors make long trips, and roundabout ones (but with diminishing frequency) for the same purposes which might be pursued using shorter and more direct trips. The 'rational' behavior is defined in economic models of optimizing choices, while diverse behavior is described, but not explained, in a number of ways by 'gravity models', 'entropy maximization', and 'discrete choice'—three very similar approaches.

By far the most important issue in model development has been this antinomy between an economic view that posits uniform behavior and a humanistic view which posits diversity. These two views underlie different lines of model development, and we will follow their reconciliation, though a recognition of ignorance—a reconciliation which clears the way for the resolution of other but less important difficulties.

2. *Inventing a Paradigmatic Model*

In the early 1950s a number of factors favoring the discovery of a new paradigm in urban modeling came together: on the ground, through the suburban redirection of American urbanism, and planning and building urban expressways; in technique, through the optimism of instrumental rationalism, seen in Operations Research and Management Science and buttressed by the commercial availability of computers; and in planning, through the widespread influence of the University of Chicago Program. In the middle of the decade, urban land planning began a slow movement in the direction of modeling (see Voorhees 1959), and the Chicago Area Transportation Study (CATS 1959) developed an innovative approach, drawing on many sources, which in retrospect must be considered a new paradigm for urban modeling.

A new paradigm in scientific or professional matters involves a framework for studying phenomena and defining their relationships. The importance of such innovation does not imply perfection; implementing and extending the paradigm and overcoming its imperfections may require decades. The essential novelty of this paradigm for analyzing the critical aspects of urban settlement systems extends far beyond transportation itself, and embodies the following elements:

(a) Examine the system in all relevant detail, with massive data collection and thorough analysis of user behavior and system responses. (This was done in transportation studies by large-scale sampling of travel behavior and traffic conditions.)

(b) Simulate user behavior over the entire system or subsystem, together with the system response, and with feedback in which the system response influences the user behavior. (The simulations in CATS were inventive and completely novel.)

(c) Draw heavily on other disciplines that can contribute to the accuracy and realism of the simulations; use exact formulations wherever possible, and implement data management and simulation through computers where this is necessary and relevant. (CATS employed sociologists, planners, economists, engineers, and computer experts—and used computers for its most advanced innovations.)

Similar simulations could be imagined, and indeed have been undertaken, for the housing market, the labor market, the location of economic activity and public services, and the environment. Clearly, these subsystems are mutually interdependent, and in the final analysis their simulations would have to interact.

Despite its seminal influence, the CATS study has often been denied its paradigmatic role because of its shortcomings, most obviously inadequate attention to transit and failure to take into account the reaction of land uses to transportation. It shares many other problems with land-use modeling, as we will see in exploring them. It also embodied the schism between economics and behavior: in connecting residences and workplaces by trips it used a gravity model of dispersed behavior, but in assigning trips to the highway system it used the deterministic idea of taking only shortest routes. As a paradigm for transport analysis, it has been and is being reworked; in principle its methods can be traced even in divergent but related urban models.

3. *Residential Models: Two Directions and Their Linkages*

The major steps in land-use modeling are easily summarized. A series of theoretical models, initially of residential location, were generated by Wingo (1961), Alonso (1964), and Mills (1972)—with other contributions. These models all assumed a monocentric city (having a single employment center), which produced rings of settlement, each occupied by a single residential income class. Density declined and income rose with distance from the center. Residents were trading off commuting costs against space, under the constraints of their income. Mills's model dealt with zones in a linear programming framework, while the other models used continuous space.

The rigor and simplicity of these models inspired efforts to make them operational, hindered by their restrictive assumptions. Herbert and Stevens (1960) developed very early the idea of bid-rents (i.e., speci-

fications of willingness to pay for various types of housing in various locations), and postulated a multicentered city with competition for land in a linear programming format. They did not operationalize the measures of preferences that would underlie a bidding process, or the connection between place of residence and place of work. The National Bureau of Economic Research (Ingram et al. 1972) extended this work in a larger operational form, with actual employment centers, a diversity of choice of spatially distributed housing submarkets, and a final determination of residency by linear programming based on the cost of work-to-home travel. Building, remodeling, and redeveloping housing was in a separate supply model.

The alternative route of replicating consumer choice in housing and shopping through the use of a gravity model (that specified a declining probability of choice with increasing distance) was more realistic and more appealing to planning practitioners, but was initiated at the cost of disregarding some economic realities. The Lowry Model (Lowry 1964) thus gave the appearance of modeling the behavior of all locators (including residents and their choices), and gave room for diversity through a gravity model. The same approach was widely adopted; for a review, see Goldner (1971). It was popularized by Putman (1982) in the USA, and in structure planning and by Echenique in the UK (reviewed in Echenique and Owers 1994). Most of these efforts went beyond modeling residential choice to consider other locational trends, and other improvements were introduced to make the Lowry Model still more realistic. This model was thus a major contribution to the paradigm shift, by its introduction of a partially unified system of activity location.

The stage was set for a new type of advance that tended to bring these two trends much closer together. The necessity for multicentered models in applied analysis was firmly established. The NBER had introduced a certain amount of diversity through a probabilistic choice of housing markets. Echenique had realized the necessity for constraints on residential location, and began to introduce rents as an incentive for supply and a brake on choice in the face of income limitations. Three important events in the 1970s solidified these advances. In Geography, Wilson (1970) explained the gravity model by analogy with entropy (or constrained randomness) in physics. In Economics, MacFadden (1973) formalized the idea of 'discrete choice', which made diverse behavior acceptable to economists; the gravity model became a special case of this accepted theory. Independently, Anas (1975) showed in a seminal paper that interaction under a gravity model could be constrained by ability to pay in a competitive housing market, leading to an economic equilibrium solution, with market clearing.

All three models—gravity, discrete choice, and maximum entropy—can produce mathematically identical results. There is a common recognition that there are aspects of behavior which are not represented in models, and which contribute to a kind of statistical error in any deterministic explanation. The degree of error varies, and may or may not be susceptible to resolution by further analysis.

4. *Complete Models*

While residential choice models are the most important and perhaps the most interesting, a complete model as described at the outset would be a model suite containing numerous submodels. First, land development and its uses are determined by way of locational decisions that in turn are strongly influenced by transport considerations. Putman and Echenique have taken the lead over the last three decades in driving this lesson home—at least to the transport planning community. We will assume that any complete land-use model will embody or interface with an appropriate transportation model and use a forecast of transportation system changes. Second, even the most advanced residential models suffer from some of the general difficulties discussed below, and in particular, models of residential housing supply are weaker than those of demand. Third, models are needed for all land uses, most particularly manufacturing industry and trade and services. With the increasing shift in the overall economy toward business and consumer services, these sectors and their representation in models need thorough review.

There is a modest number of complete model suites publicly available worldwide (see Wegener 1994 for a review). Putman's ITLUP and EMPAL models have been extended to METROPOLIS, which is widely used, and maintains the Lowry tradition of noneconomic constraints. Its employment location is somewhat descriptive in style. Echenique has developed an elaborate input–output framework to generate goods traffic as well as personal trips, with extensive economic constraints. Anas (1987) is continuing to develop a range of economically rigorous and ambitious models, most recently for the New York Metropolitan Transportation Commission (in progress). New work is being undertaken which we cannot elaborate here, but special mention must be made of de la Barra, who follows Echenique in the Americas, and Waddell (2000), who is approaching residential location from a microeconomic viewpoint in direct collaboration with state planning and transportation studies. Most model sets are provided on a made-to-order basis, which raises their cost and severely limits their availability.

In our judgment, the characteristic nonresidential models have various weaknesses in almost all model sets. The manufacturing sector is undergoing changes that are not yet fully understood and which may upset conventional wisdom. Business services have barely begun to be studied in the locational literature, let

alone embodied in models. Retail trade is the best understood of these three fields, but inadequate use is being made of existing knowledge.

5. *Comments on the State of the Art*

It is apparent that considerable advances have been made in urban models, but that results are still short of what might be desired. There are still no established scholarly standards in the field, nor is there a clear link between research and practice. Limited tests of models on the same or similar data sets show little unanimity in their conclusions.

There are many social and equity issues being newly faced in planning of all sorts. Some of these have appeared in the USA in the implementation of the clean air act and its amendments, and related issues in transport planning have been litigated. It appears that there is inadequate disaggregation in most models, so that the behavior of minority groups and their reactions to policy inputs could be studied, while some aspects of disaggregation affect the evaluation of transport and planning policy. These needs conflict with the needs for simplicity, transparency, and speedy computation which arise in public discourse.

With increased computer capabilities, microsimulation is appearing as a possible approach to the disaggregation problem, but its relation to the speed of computation must be studied. Indications in the transportation planning field are that it will extend greatly the time required for analysis—and even today transportation models are the biggest bottleneck in operational land-use models.

The growth of urban modeling is linked closely with the expansion of computational power through both mainframe and personal computers. The first steps in modeling were conceptual, and computationally limited in their demands. Growing computer power has made it possible to develop and implement more accurate and more elaborate models. Computing for planning has been decentralized to the desks of planners and administrators. Computer users have readier access to large data sets, now organized in Geographic Information Systems. Research workers of all types have greatly increased power to investigate localized and sectoral phenomena, having better access to computation, data, and modeling methods. All of these investigations contribute to a web of knowledge that expands understanding of urban phenomena, and undergirds improved modeling. Examples include, the work of Anas and Waddell discussed above, as well as of specialists like Landis, Cevero et al. (1999), and Shen (2000).

Urban History

Urban history started as early as the nineteenth century in Western Europe. Italian scholars had a deep concern with the Commune, the governing body of the medieval city–state in connection with the unification process of the country. French historians had a similar concern with the commune movement

which, over the centuries, had developed into town autonomy against the rule of a feudal lord, and also with freedom of citizens of medieval towns. German scholars showed interest in freedom and equality of townspeople of the medieval towns as a forerunner of democracy. In England during the modernizing process of local government, especially in connection with the reform of municipal corporations, historians had some interest in historical privileges of citizens given in the charters granted either by the King or by feudal lords, lay or ecclesiastical. From the nineteenth century to the early twentieth century, the historians' main interests were in political, legal, and/or constitutional problems.

1. Regional Studies

The new trends of urban historians' concern after World War II are more social, economic, physical, or topographic. There were two opposing opinions as to how to reconstruct historic towns which suffered serious damage by bombing during the War, either rebuilding them exactly as they were before or rebuilding them entirely anew according to new town planning and a new scheme. Moreover, as built-up areas are impossible to excavate, this offered great possibilities for archaeological excavation in areas destroyed by the bombing, especially in German and English towns and cities. Archaeological investigation explored not only medieval towns but also the deeper stratum of ancient Roman cities.

During the 1960s, either construction of new towns or redevelopment of the slum areas of nineteenth century industrial towns became urgent matters, and urban historians were concerned with the problems of new towns or the process of building towns during the Middle Ages, as clearly observed in Maurice Beresford's *New Towns of the Middle Ages, Town Plantation in England, Wales, and Gascony*, published in 1967.

Organized research in urban history began in Germany at the end of the 1950s, in England during the 1960s, and in Japan and the USA in the early 1970s.

In West Germany, two Study Groups were organized: *Arbeitskreis für landschaftliche deutsche Städteforschung* as a national organization and *Arbeitskreis für südwestdeutsche Stadtgeschichtsforschung* as a local organization. They were started in 1959 and 1960, respectively. In Münster, *Institut für vergleichende Stätdegeschichte* was established by H. Stoob, and began to publish its journal, *Städteforschung*, in 1970.

In England, the 'Urban History Group' was organized in 1963 at the General Meeting of the Economic History Society, and H. J. Dyos issued the *Urban History Newsletter* until 1973. From 1974 to 1991, 18 volumes of the *Urban History Yearbook* were published by Leicester University Press. Since 1991, as the continuation of the *Urban History Yearbook*, *Urban History* has been published semi-annually by the Cambridge University Press.

In 1986, The Centre for Urban History was established at Leicester University and the new second series of the *Urban History Newsletter* was published until 1999. The third series of the *Urban History Newsletter* started in Autumn 1999, when Richard Rodger was appointed Professor of Urban History at Leicester University.

In London, in 1975, the Metropolitan Society was founded and a new Journal, *The London Journal, The Review of Metropolitan Society Past and Present*, was launched. This journal was 'planned to combine the work of historians and of scholars in other fields, for the first time presenting a more complete study of the whole region in its historical, its societal, and its cultural framework.' Two years later, at the Institute of Historical Research, University of London, the Centre for Metropolitan History was founded by Derek Keene and *The Newsletter of the Centre for Metropolitan History* was issued in 1992.

In 1987, The Urban Morphology Research Group was founded at the Department of Geography, University of Birmingham, and the *Urban Morphology Newsletter* was issued until 1997 when it was succeeded by *Urban Morphology, Journal of the International Seminar on Urban Form*.

In Japan, The Tokyo Study Group in Comparative Urban History was formed with six charter members in 1971, and issued *Urban History Newsletter* from 1975 to 1981. Since 1982, *The Comparative Urban History Review* has been published semi-annually. In 1991, the Study Group published two volumes of essays entitled *Toshi to Kyodotai [Stadt und Gemeinde]* in commemorating its twentieth anniversary, and also *Edo and Paris, Urban Life and the State in the Early Modern Era* was published by Cornell University Press in 1994, and *Edo and Paris*, the Japanese edition, was also published in 1995. These publications were outcomes of the Symposium held in Tokyo in 1990 to commemorate 400 years of the beginning of *Edo*. In 1978, the Society of Hokuriku Urban Historians was launched as a local organization by the initiative of T. Toyoda, and the Society holds annual meetings at three historic towns; that is, Kanazawa, Toyama, and Fukui, alternately. *The Hokuriku Urban History Review* appeared from 1979 to 1989, and *The Journal of the Society of Hokuriku Urban Historians* has been published since 1990.

In September 1974, the *Journal of Urban History* was established 'to provide urban scholars in the USA with a forum for interpretation and new research.'

2. Urbanization

There are four types of cities in history.

The first historical type of city appeared in the ancient Orient, namely in Mesopotamia and Egypt, in

ancient India, and China. Walled towns with the surrounding territories were the center of theocratic rule of oriental despots. Officials of despots, clergy of temples, and wealthy merchants lived in those cities, which usually were located near palaces or temples, and were surrounded by quarters of subordinating poor tribes. They flourished with long-distance trade. However, there were no citizens as such.

The second type of city appeared in the ancient Greek and Roman worlds. They were city–states called either *polis* or *civitas*. Cities were formed by land-owning warriors settling in militarily defensible places, that is, acropolis. Rome was founded on seven hills, and by conquering the neighboring *civitas* became finally the Roman Empire ruling the Mediterranean World. Colonial cities were founded at strategic points in various provinces with a similar city plan. Agricultural estates or mines organized with slave labor, supported by long-distance trade, brought prosperity and peace, that is, *Pax Romana* to the Empire.

The third type of city, the medieval city, appeared in the area beyond the Alps; namely, Germany, France, the Low Countries, and England. Max Weber characterized ancient cities as consumers' towns, and medieval towns as producers' towns, because citizens of medieval towns consisted mainly of tradesmen and craftsmen. They were enjoying the privileges of freedom of citizenship, and they were enabled by feudal lords to form guilds and to constitute a self-governing body; that is, a mayor and the town council. These medieval cities located in areas that had facilities for water transportation, such as ports on estuaries or river banks. Emperors, kings, and feudal magnates, lay or ecclesiastical, granted these towns privileges of holding weekly markets and yearly fairs, as nexuses of long-distance trade as well as local trade.

The fourth type of city is called a modern or industrial town. As the result of the Industrial Revolution, a new type of city appeared. In England, at the earlier stage of industrialization, factories with machine systems were set up in dales where water power was available. However, after the steam engine was invented, factories were established at places near coal and iron mines, and/or near cities which could serve for the domestic market as well as overseas trade. The earliest of factories were abandoned very quickly, but remained as objects for industrial archaeologists' research. Around the new type of factories, developers constructed cheap houses which accomodated wage laborers and their families. These houses were called 'back to back,' with poor sanitation systems, and later became poor slum areas. On the other hand, in the West End of London, in the suburbs of provincial towns, and in the resort towns such as Bath, new developments of landed estates started during the latter half of the eighteenth century, and constituted fashionable town houses not only for nobilities but also for the new middle-class. Although the size of these new type towns were limited by the system of transport within them, the population of cities increased significantly. This process was called the first stage of urbanization, and lasted until World War I.

After World War II, the so-called second urbanization process started not only in the highly industrialized countries but also in 'developing countries.' As the result of the rapid motorization and efficient communication systems, not only the size of cities expanded, but also the population of cities increased enormously. Huge cities appeared connected with satellite cities constituting a megalopolis.

Thus, urbanized society offered people amenities. However, the rapid urbanization brought pollution problems as well as poverty and misery, causing urban historians deep concerns.

3. *International Cooperation*

One of the distinct characteristics of recent research in urban history is international cooperation. In 1955, when the International Congress of Historical Sciences was held in Rome, European urban historians established *La Commission Internationale pour l'Histoire de Villes*. The first president of the Commission, Hermann Aubin [1955–8] was succeeded by Hektor Amman [1958–67], Phillipp Wolff [1967–81], and Sergi Vilfan [1981–91]. Adriaan Verhulst has been the president since 1991.

The Commission presents a report to the Congress as the result of five years' preparation by the members of the Commission. The overall theme at the XIIIth Congress in Moscow, 1970 was 'Urban Autonomy,' at the XIVth Congress in San Francisco, 1975, 'Social Structure and Urban Morphology,' at the XVth Congress in Bucharest, 1980, 'Central Government and the Towns in Europe,' at the XVIth Congress in Stuttgart, 1985, 'Town and Country,' at the XVIIth Congress in Madrid, 1990, 'New Towns in Europe (XII–XX century),' at the XVIIIth Congress in Montreal, 1995, 'Markets and Fairs,' and at the XIXth Congress in Oslo, 2000, 'Destruction and Reconstruction of Towns.' The list of the themes shows not only the results of international cooperation but also the trends of historians' interest. Along with internationally organized common research and reports, the Commission has undertaken three joint projects—the compilation and publication of urban bibliographies by country, of selected urban history texts (*Elenchuses*), and historical atlases of towns.

The urban bibliographies were published during the late 1960s and early 1970s. The earliest bibliography was by French historians Philippe Dollinger, Philippe Wolff, and Simon Guenée, *Bibliographie d'histoire des villes de France* in 1967. It was followed by German historians Erich Keyser's *Bibliographie zur Städtegeschichte Deutschlands (Acta Collegii historiae urbanae Societatis historicorum internationalis)* in

1969. The last one was by English historians G. H. Martin and Sylvia C. McIntyre, *A Bibliography of British and Irish Municipal History*, Vol. I in 1972.

Elenchus is a collecion of selected sources to illuminate the history of towns. The first volume was published in 1967, *Elenchus fontium historiae urbanae, Volumen primum, quem edendum curaverunt C. Van de Kieft et J. F. Niermeijer (Acta Collegii historiae urbanae Societatis historicorum internationalis)*. In 1977 a guide book was published, *Guide international d'histoire urbaine, I Europe, préparé par la Commission sour la direction de Philippe Wolff, Membre de l'Institute de France*.

Publication of a historical atlas has become a more enterprising and widespread project. Although there was fundamental agreement on a unified concept, the actual outcome has been very diverse, and is unique country by country.

The earliest of the atlases to reach fruition was the British one, with a first volume of *Historic Towns. Maps and Plans of Towns and Cities in the British Isles, with Historical Commentaries, from the Earliest Times to 1800* in 1969. This was the outcome of very close collaboration of M. D. Lobel, urban historian, and Colonel W. H. Johns, cartographer of the Ordnance Survey. The first volume consisted of historical atlases of seven British historic towns bound in one volume of folio size.

The fundamental process of drawing historic town maps is as follows: on the contemporary map of scale 1:2500, modern buildings and constructions were eliminated piece by piece from a map and the town map reconstructed as it was in 1800; that is, the state of the town before industrialization. Then demolished buildings and perished constructions are added on a map based on archaeological findings as well as other information obtained from the old cadastre maps and other literary sources. As a result of these painstaking processes, medieval towns and even Roman towns were shown on large-scale colored maps, with commentaries by historians.

In the preface to this masterpiece (*Historic Towns*), Professor Wolf, as the president of the Commission, made the comment:

> The legitimate curiosities of scholars are not, however, the only interests to be involved. Nor is it only lovers of the past who will be glad to get a faithful picture of the ancient 'heart' of towns. Ours is an era of extraordinary town development. Tomorrow's 'urban textures' run a great risk of losing in charm and in human value what they gain in expansion. Our children run a great risk … of growing up joyless in soulless cities. The old centres of our towns, where the most precious of the ancient buildings cluster, make up the element peculiar to each town, by which it is differentiated from every other. This is a touristic treasure-house, … What is more, it is a human treasure-house, and one which any concern for the future bids us reconstitute and save: atlases of urban history provide an indispensable tool for this work—and only an exceedingly short-sighted realism could prevent us from appreciating the work's importance.

The second volume was published in 1975 with the same format for four more English towns. The third volume was published in 1989 for the City of London from prehistoric times to c.1520.

The second winner of the international competition of publication of atlases of historic towns was German. Four series of historic town atlases were organized in Germany: (a) *Deutscher Städteatlas* published five volumes to 1993; (b) *Hessicher Städteatlas* published one volume in 1998; (c) *Rheinischer Ständteatlas* published 12 volumes until 1996; and (d) *Westfälischer Städteatlas* published five volumes to 1997. Each set consisted of a reconstructed color map on a scale of 1:2500, an old map of the nineteenth century, an air photograph of the present day towns, old prints and historic photographs of towns with present photographs from the air, and a leaflet of the commentaries by historians, making the atlases more attractive to general as well as local readers.

In Austria, the *Österreichischer Städteatlas*, five volumes [1982–97] and *Historischer Atlas von Wien*, five volumes [1981–94] have been published under joint editorship of *Wiener Stadt und Landesarchiv* and the *Ludwig-Boltzmann Institut für Stadtgeschichtsforschung*.

In France, the *Atlas historique des villes de France* has been published under the editorship of Centre Charles Higounet, *Centre de recherches sur l'occupation du sol et du peuplement*, at the Université Michel de Montaigne, Bordeaux since 1982 containing 42 towns in various provinces.

In Italy, two titles of historic atlases of towns have been published; that is, *Atlante storico della cittá italinae (Italia settentrionale et Sardegna)* and *Atlante storico della città italiane (Italia centrale e meridionale)* since 1986, containing four and 14 towns, respectively.

Other European countries are also editing and publishing atlases of historic towns of their countries, so that more than 300 towns in Europe had an atlas by the end of the millennium.

In 1989, the European Association of Urban Historians was organized and the Association is holding biennial conferences. The first conference was held in Amsterdam in 1992, the second conference in Strasbourg in 1994, and the third conference in Budapest; the overall theme was Cities in Eastern and Western Europe. The fourth conference was in Venice in 1998 when the theme was Cities in Europe: Places and Institutions. In 2000, the fifth conference was held in Berlin and the theme was European Cities: Networks and Crossroads. The sixth conference will be held in Edinburgh in 2002.

4. *Multidisciplinary Research*

Another feature of recent trends of urban history is inter- or multidisciplinary research. The Society for Medieval Archaeology was founded in 1957, and publishes a Journal, *Medieval Archaeology*, annually.

In 1969, a small number of British historical geographers formed a group in order to collect material for an International Glossary of Agrarian Terminology, and in 1973 the name of the Historical Geography Research Group was adapted and formally recognized by the Institute of British Geographers. Since 1975, the *Journal of Historical Geography* has been published by the Academic Press, London, under the joint editorship of John Patten (Oxford) and Andrew Clark (for the Americas).

A Planning History Group was established in the Centre for Urban and Regional Studies at the University of Birmingham in 1974, and issued the *Planning History Bulletin* from 1979 to 1987, but when the editorial team changed, the title of the Bulletin changed to *Planning History, Bulletin of the Planning History Group*. Then, from 1993, *Planning History* became the *Bulletin of the International Planning History*.

In 1989, Gordon E. Cherry and Anthony R. Sutcliffe launched a new journal, *Planning Perspectives, An International Journal of History, Planning and the Environment*.

In Italy, since 1976, *Storia Città, Rivista Internationale di storia urbana e territoriae* [International Review of Town Planning History] has been published irregularly.

Another discipline is architectural history. It is deeply connected with town planning and also townscapes of different periods. In Japan, the Society of Architectual Historians of Japan was established in 1983, and is publishing the *Journal of the Society* semi-annually.

Interdisplinary research is organized between different disciplines and is flourishing. However, the most remarkable contribution to urban history has been medeival archaeology. Not only in European countries but also in Japan, excavations of ancient and medieval towns have been carried out extensively.

In Japan, not only Kyoto and Nara, ancient capitals, but also Ichijo-dani, a medieval castle town constructed in 1472 and destroyed by war in 1573, and so-called One Thousand Houses in Kusado, an ancient market town lost by flood in 1673, are distinguished examples of excavation by medieval archaeologists. Archaeological findings were examined with contemporary literary sources, and clarified the details of town plan, economic activities, social life of the day, and even the mentality of townfolks.

In Europe, Germany, England, France, and Scandinavian countries, the results of research on medieval archaeology are remarkable. However, the most distinguished case of cooperation between archaeologists and historians must be the investigation of Anglo-Saxon and medieval Winchester. *Winchester Studies 1*, the first volume of the series of publications was published in 1976 entitled *Winchester in the Early Middle Ages: An Edition and Discussion of the Winton Domesday* [surveyed in 1148]. Two volumes of *Winchester Studies 2, Survey of Medieval Winchester* were published in 1985 and part two of *Winchester Studies 3, Pre-Roman and Roman Winchester* was published in 1979. Still more volumes are to be published.

5. Conclusion

Research into urban history has tended to be concentrated on Western or European countries. China has a long and unique history of towns and cities. However, these never were given any autonomy of their own, and therefore they remained as mere centers of central or local administration. So it makes comparison with European towns difficult. As to other Asian countries, the processes of building new towns under colonial rule such as New Delhi, Rangoon, or Bangkok have been much clarified. However, the urban history of their predecessors, Old Delhi, the Mogul city, Yangon, a port town of Burma, or Ayuttha, the old capital of Siam, should be further explored. The other unexplored field of urban history is towns and cities within the Islamic world.

K. Ugawa

Urban Life and Health

In Western countries where tabulations have been made, such as the USA and the UK, city residents face shorter life expectancies than their rural cousins. The differential was great in the early days of urbanization, when the leading causes of death were infectious diseases that spread readily in densely crowded environments (Wiehl 1948). In 1900, death rates exceeded birth rates in many cities, with urban population growth occurring only as a result of migration from rural areas (Fox et al. 1970). By the mid-twentieth century, with sanitary and public health measures in place, antibiotic treatments and vaccines averting deaths from infectious disease, and financial prosperity far-reaching, the urban mortality disadvantage ran at about 5 percent, after adjustment for differences in the age, race, and gender composition of urban compared to rural populations (Kitigawa and Hauser 1973). However, by the late twentieth century, a sizeable urban mortality disadvantage re-emerged, especially in high-poverty areas, with urban mortality rates running about one-and-a-half to three times those in rural areas or small towns, even after adjustment for age, race, gender, and socioeconomic status (House et al. 2000, Geronimus et al. 1999). Currently, urban residents have higher prevalence rates of many health problems, among them preterm birth, asthma, infectious disease, cancer, cardiovascular disease, and lead poisoning. City residents also suffer disproportionately from pervasive ambient stressors such as noise, traffic, pollution, and crowding, as well as social problems such as homelessness, suicide, and violence. Ironically, urban areas have also been the place of origin for major medical and public health initiatives, including great advances in public sanitation, clean water systems, and medical technology (Freudenberg 1998).

1. *Understanding Urban Health Disadvantages*

1.1 *Methodological Limitations*

Social scientific consensus on the underlying reasons for apparent urban health disadvantages remains elusive. Part of the ambiguity stems from methodological issues. Empirical estimates generally suggest urban residents are worse off than others, at least in terms of mortality, yet the body of research is largely descriptive. Most research on this topic has been cross-sectional, much of it ecological, and investigators have had to make unfortunate trade-offs between analyzing samples with national scope and focusing on important subgroups of the urban population. This data limitation along with another—the inability to control for many potential confounders of the association between urban life and health—severely restrict causal inference making.

1.2 *Early Theories*

Conceptually, the study of urban life and health has changed markedly over the past century. Initially, rapid urbanization in the early twentieth century stimulated theories reflecting broader societal concern that city life was dangerous and unhealthy compared to pastoral country life. Wirth (1938), posited that characteristics of cities—such as their size and population density, their fast pace, their heterogeneity—were negative influences on psychological well-being and group life. The requirements of urban industrial organization and technology were also viewed as deleterious. In these theoretical perspectives, urban life alienated individuals from one another, their roots in nature, their labor, and their core values; it promoted superficial and transitory relationships; and it provoked anomie, alienation, and insecurity. These influences devalued community, threatened social cohesion, and placed individuals in peril.

Empirical studies often found weak endorsement for the working hypotheses that followed from this conceptual emphasis (Fischer 1976). Researchers continuing in the sociopsychological tradition in the mid- to late twentieth century saw urban characteristics in a new light. Milgram (1970) reasoned that brusque behavior and anonymity might demonstrate an adaptive response to the sensory overload produced by urban population density and a fast-paced life, rather than imply that urban residents were without intimate, supportive relationships within their personal social networks. Studies documented the existence and salience of local social bonds within cities among 'urban villagers' (Gans 1962) embedded in kin 'networks' (Stack 1974). Cities were reinterpreted more positively as mosaics of individual and cultural differences, even a refuge for individuals who faced stigma or persecution in small parochial towns (Fischer 1976). House and Wolf (1978) observed that the effects of urban residential environments on behavior grew out of particular social settings at different historical times, not necessarily urbanism, *per se*. This observation was consistent with their empirical findings and with the variation in magnitude of urban health disadvantages in different time periods.

1.3 Recent Developments

In the 1980s, as urban homicide rates increased and were highly publicized, urban life again became viewed as unhealthy and dangerous. By this time, poverty was concentrated in central cities, urban decay left poor neighborhoods as staging grounds for drug trafficking and related homicide deaths, while infectious diseases such as tuberculosis, and in specific cities HIV/AIDS, re-emerged as important causes of death (Geronimus 2000). Though less publicized, some environmentally induced and stress-related diseases also were increasing, such as asthma, reproductive disorders, some cancers, and cardiovascular disease. Variations on early sociopsychological theories took shape in scholarship on urban life and health. For example, the 1990s witnessed renewed interest in the effects of depleted social cohesion or social capital on health, with social epidemiologists joining social psychologists in studying these topics, particularly among urban residents. The actual significance of social capital to health disparities is currently subject to debate (Lynch et al. 2000) and agreement has grown that it alone cannot explain the severely disproportionate ill health and early mortality experienced by some segments of the post-industrial urban populace. In addition, as the growth of edge cities and globalization has shrunk the urban labor market, the notion that the impersonal nature of industrial organization is a key cause of urban health disadvantages has been superseded by new concerns about the health effects of unemployment, segregation, poverty, ambient psychosocial stresses, and the physical environmental hazards of urban life.

1.4 Social Inequality

Evidence suggests that urban areas confer some disadvantages, at least in terms of mortality, on all of their residents, but this penalty is inequitably divided among the haves and have-nots within cities (Geronimus et al. 1996, Shaw et al. 1998). This is unsurprising since the social and psychosocial factors that have been linked to morbidity and mortality, including material hardships, acute and chronic stress, and overburdened or disrupted social supports, are suffered disproportionately by those in poverty (Williams and Collins 1995). Those living in poverty also have more difficulty accessing information, services, medical care or technologies that could abate health risks (Link and Phelan 1996). Much current research is informed by this social patterning of the distribution of health risks or protective factors. Even the ambient stressors to which all residents of major cities are exposed are not equitably distributed among urban neighborhoods. Household crowding and environmental toxicity are more severe in poor, ethnic enclaves than in affluent segments of cities, for example (Mohai and Bryant 1992). Such findings signal the need to broaden the intellectual context for the study of urban life and health by looking at the socioeconomic and demographic landscape of modern cities, and coming to understand the historical and structural underpinnings of that landscape. For example, some investigators now seek to describe how economic restructuring combined with the segregation of ethnic minority groups into urban enclaves served to concentrate poverty in neighborhoods characterized by urban decay, with housing stock, municipal services, and public spaces all substandard (Massey and Denton 1993, Kelley 1997). This new context will permit examinations of how social and economic policies affect the physical, social, and built environment in ways that impact health.

In the USA, low-income African Americans segregated into central cities suffer the worst health disadvantages of any identifiable group (Hart et al. 1998). African American residents of high-poverty urban areas suffer rates of early mortality that are staggering. For example, male youths in Harlem or Chicago's South Side face a lower chance of survival to age 45 than their counterparts nationwide enjoy of surviving to age 65 (Geronimus et al. 1999). Such mortality profiles are similar to those found in less developed nations (McCord and Freeman 1990). In European cities, minority and low-income populations are often fragmented and dispersed along city peripheries where they, too, suffer demonstrable health disadvantages compared to the more affluent who reside in vital urban centers (Shaw et al. 1998). These observations suggest that any theory that hopes to illuminate the association between urban life and health in the post industrial period must explicate the historical and structural factors that produced modern ghettos with predominantly minority populations (Thompson 1998).

Moreover, although homicide deaths account for an important share of deaths among urban African American men, chronic disease deaths have been the primary influence on these rates for urban African American men and women. Indeed, homicide rates declined in the 1990s for this population, yet the influence of chronic disease on excess urban mortality appears to be growing. No one understands why. However, these findings place new emphasis on understanding the particular stresses faced by and the coping strategies available to ethnic minority residents of high-poverty urban areas. They also suggest the prospect of intensifying environmental hazards. Inequitable distribution of environmental hazards among neighborhoods may contribute to increasingly excessive rates of cancer, asthma, and reproductive disorders in high-poverty urban areas. Another possibility under consideration is that the adverse health effects of an ambient stressor or environmental toxin may be increased in interaction with other insults to health, as most often occurs in the poorest urban

communities where residents face multiple, pervasive, and cumulative exposures, with few mitigating resources.

2. Future Directions of Theory and Research

As the study of urban life and health progresses, investigators are likely to continue their examinations of social inequality, augmenting research on material conditions and poverty with improved research on the role of race/ethnicity in two fundamental aspects: (1) the role of racial discrimination (in housing, medical care, employment, and environmental exposures, for example); and (2) the ability of ethnic networks and cultures to mitigate adversarial health impacts. The 1990s witnessed the greatest influx of immigrants to the USA in almost 100 years, many into high-poverty urban areas. Documentation that the extent of ill health among low-income urban residents varies by ethnic group and nativity status has stimulated interest in developing dynamic understandings of the potential for ethnic culture to preserve health. James (1993) speculates that as a group's economic strength diminishes, its ability to supply the protection conferred by mutual aid, social support, and identity-affirming cultural frameworks may be especially critical to preserving the health of its members. According to this model, current urban health problems may derive from a combination of significant material adversity (the result of joblessness, and skyrocketing housing and medical care costs, for example) that is, at least in part associated with racial discrimination, and the concomitant overloading and weakening of protective networks (Geronimus 2000). These remain empirical questions.

More broadly, the question of what exactly it is about living in cities that may adversely affect health remains unanswered. Toward addressing this basic question, several additional empirical directions are anticipated. These include understanding how urban residence affects health across the life course both in terms of its effects on people at different life stages and also the net effect of the accumulation of health insults over time, particularly among those segments of the urban population who are further disadvantaged by race/ethnicity or low income. Another is distinguishing the effects of urban residence on morbidity and life quality separately from mortality, while developing full models of how social background factors and social experience work through physiological processes to exert an impact on morbidity and mortality. Also likely is increased attention to applied research, including demonstration projects, participatory action research, and community-based public health approaches (Freudenberg 1998). The motivations for this are diverse. Current policy interest in the labor force participation of the urban poor prompts an interest in their health and disability status. Similarly, policymakers and citizens concerned about urban sprawl may invite input on the anticipated health impact of social, economic, and urban planning policies meant to revitalize urban centers. The broader environmental movement has become concerned with environmental justice for urban populations. The appeal of applied research in the academic public health community stems from the mandate to reduce as well as understand urban health disadvantages.

Urban Life: Future Developments

The future of urban settlements and the lives lived therein will depend on a mix of predictable trends and human contingencies. History is the best guide to those future trends, and three are discussed here: technology, the limits to growth at urban peripheries, and the attractive power of urban centers. Caution is perhaps the best guide to discussing future contingencies, but three major issues are so apparent that they will likely confront urban decision makers in the coming generation: large versus dense settlement structures, local versus regional decision-making processes, and automobiles versus other means of mobility and access to urban resources.

1. *Three Determinants of Urban Futures*

Since the beginning of the urban era, technologies in various forms and the relative 'gravitational' pull of urban centers and rural hinterlands have been powerful determinants of urban life. These fundamental mechanisms are surely the product of human action and are never completely beyond a human capacity to intervene (Mumford 1961). Yet, the power of such mechanisms (for example, the technology of production and the related attractiveness of center versus peripheral locations) often exerts a defining influence on urban settlements in ways that can overwhelm individual or collective action in a given time or place. Introduced below are three such large trends that may be expected to influence the future of urban life.

Waves of innovation in communications and transportation technologies occurred throughout the twentieth century. At present, these roiling changes are understood and discussed in a summary way as the emergence of an Economy (Mitchell 1995). A new digital geography will reshape the possibilities of urban life over the next generation (Kotkin and Siegel 2000). In particular, the Economy changes many of the incentives (e.g., economies of scale and various costs that increase with distance) that led to concentration in urban centers in the nineteenth and twentieth centuries. By weakening and sometimes inverting such incentives, the New Economy is characterized by much more footloose (or non-location-specific) production and consumption. It is now both possible and increasingly common to participate in employment, education and many other daily activities well beyond the commuting radius of a daily urban system. Under such conditions, the nineteenth and twentieth century comparative advantages of specific locations (e.g., entrepot for commodities, large physical agglomerations of workers and consumers) are being eclipsed by locational amenities such as weather and natural beauty as well as cumulative advantages that accrue to particular locations that happened to innovate first in some industry or activity.

Second, the limits of post-1945 development patterns, especially the low density suburban form prevalent in the United States for 50 years, will be tested and some expect those limits to be reached. Technological changes (with, in the United States, the full support and encouragement of several national policies) have maximized the opportunity for low-density choices and this has led to a half-century of suburbanization in urban settlements, in which the increase in built-up land area has far exceeded the increase in population or employment. The resulting development patterns have been associated with a long list of social costs, including increased traffic congestion and lengthening commutes, loss of both open space and agricultural land uses, a rise in social and ethnic segregation as well as in aggregate housing costs, and the decline of communal participation and social capital (Downs 1995, Kunstler 1996, Duany et al. 2000). These critiques have sought to portray as unsustainable the current low-density development regime, often labeled sprawl. Policy recommendations range from government controls on new peripheral growth to the modification of cultural and aesthetic values related to suburbanization.

Third, the attractive power of centers will wax or wane; given the diminished power and autonomy of large industrial urban centers over the preceding century, this third mechanism is likely to be closely related to changes in the first two. Paradoxically, the decentralizing trends of both the digital economy and a low-density development regime have created a

powerful role for centralized command and control exploited by a select group of 'global cities' (Sassen 1991). This centralizing function is also present on a smaller scale within regional systems, somewhat reviving a role played for smaller urban centers. In addition to this emerging economic function, urban centers may also gain a new importance derived from the limits on further growth at the urban periphery (Rusk 1999), whether those limits are imposed by technology or by governments.

2. Three Issues Facing Future Urban Decision Makers

The multiple contingencies of these and other mechanisms will likely frame the important issues facing decision makers over the coming decades. Without knowing how the possibilities will turn out (a placeless city of bits or not? More growth on the undeveloped urban edge or less? A sustained re-centering of urban settlements or their permanent de-centering?), it is imprudent to list specific issues to be grappled with. But three critical issues are already apparent in the foreseeable (or more seeable) future.

First, if largeness is a consequence of a passing industrial era, then how will the more fundamentally urban quality of density be manifest in the coming decades? While the emergence of a New Economy is neither fully understood nor even universally accepted, the technological framework within which urban settlements are constructed and maintained seems to have changed profoundly. While industrialism's appetite for physical agglomeration has weakened if not collapsed, there appears to be a powerful revival of demand for density on a very large scale in a select set of global cities and on a smaller scale in centers throughout the urban system. This demand for density appears to be related less to production and distribution, unlike during the industrial era, and more toward lifestyle amenities. Breaking the link between density and largeness in the minds of urban dwellers and decision makers, which seems fundamental to the suburban reform agenda discussed above, will be a major challenge in coming decades. In many ways, of course, this leads back to the future and to a revival of Ebenezer Howard and Garden City and New Town ideas.

Second, if the well known mismatch between formal and informal organization (local–state–national versus neighborhood–regional–global, respectively) is accurate, then how resistant or malleable will formal structures be in the service of informal imperatives? Many of the changes demanded in the preceding paragraph require collective action and governmental capacity. That the ideas being debated are neither new nor complex suggests the difficulties of actually implementing a desirable future. Whether or not the public apparatus of decision–making related to urban life can be adapted to match the new and emerging scales at which urban life is being lived through new technologies and relationships is perhaps the single most important issue framed by observable trends.

Third, urban life will continue to confront the issue of automobiles versus every other form of mobility. While epitomized by US settlements, this tension is rapidly becoming global in both its prevalence and its consequences. Regardless of the scale and governance issues outlined above, physical access to some resources (perhaps a different set than those of today) will continue to be a fundamental rationale for urban settlements. The access problem is solved through mobility of some form. The worldwide trend toward individual automobile mobility (whether that trend moves from the large base of car use in the United States or the smaller but rapidly growing base found in the developing world) will likely join if not eclipse other specific critical priorities facing urban decision makers. Ironically, the negative environmental impact of increasing automobile use is as global an urban issue as the positive relationships of the New Economy. The intersection of combustion engines, urban settlement patterns, and cross-national environmental degradation will challenge urban life in powerful and perhaps decisive ways.

Urban Places, Planning for the Use of: Design Guide

'Life Takes Place on Foot,' is the aphorism of Jan Gehl, a Danish architect who is an acute and sympathetic observer of the way that people interact with each other and with their surroundings. Gehl's theory is that, no matter what technical innovations are taking place, human beings have not changed. They still need the casual contact with other human beings that used to be built into daily life, but is becoming more and more unusual in countries with advanced industrial economies. Gehl has concluded that this complicated concept can be reduced to a relatively simple mechanism. People pursue necessary activities that take them through public spaces. If the spaces are a poor physical environment, people will get through them as quickly as possible. If the environment is attractive, people will linger and engage in what Gehl calls optional activities, like sitting down for a few minutes in a cool place in summer, or a sheltered, sunny spot in winter, or just slowing down and enjoying life, stopping for a cup of coffee or tea, or looking at a statue or a fountain. The more optional activities there are in a public place, the more likely that there will be what Gehl calls 'resultant activities,' that is, sociability, people meeting accidentally or striking up a conversation with strangers (Gehl 1980).

Gehl argues for the sociability created by traditional streets and squares, as opposed to the open spaces in most of Denmark's modern housing projects or the big institutional parking lots where there are trafficways but few streets next to buildings. He believes that designers can make new groups of buildings that have similar characteristics to the traditional townscapes that his research finds are still successful in fostering sociability.

Gehl's contemporary, the late William H. Whyte, makes comparable arguments about streets and public spaces in New York and other big American cities, mapping the places where people congregate and interact, and comparing them to public places that are empty and sterile (Whyte 1980, 1988). He also argues that design can make a big difference in behavior in public places, comparing spots that are taken over by antisocial activities with those that are safe and popular. Whyte adds two elements to Gehl's conclusions: one is the usefulness of providing movable chairs in public places, so that people can create temporary environments for themselves; the second is the importance of animation: multiple activities fronting on the public space and programmed for the space. The more that is going on in and around a space, the more likelihood that people will be attracted, their paths will cross, and Gehl's 'resultant activities' will take place.

1. *The Origins of Modern Public Spaces*

Traditional public spaces were not designed for leisure, so the issue of whether they were inviting or not did not arise. Market streets and squares were crowded, functional places, and other separate plazas in front of palaces or religious buildings were intended for ceremonies. Public fountains, became a meeting place as people went there to draw water. In large parts of the world these functional aspects of public space continue as they always have.

During the Renaissance period in Europe, public spaces began to be embellished to create compositions in perspective; comparable to those already created in paintings, gardens, and stage scenery. Buildings were designed to be symmetrical around a central axis, arcades and colonnades modulated the facades, and often the same design system was applied to the frontages around a square. Long, straight streets were designed to terminate at the center of a public building, or at a plaza with a monument. Most of these design innovations were about ceremony: an enhanced street environment for the carriages of the aristocracy, a place where the arrival of important people and their entrance into a palatial building would be appropriately stately and impressive.

The opening of Vauxhall Gardens and other pleasure gardens in London in the eighteenth century and the conversion of the Palais Royal in Paris during the 1780s into what we might today call a shopping and entertainment center, were some of the earliest public places dedicated to leisure-time activities. The Tivoli Gardens in Copenhagen is a descendant of this type of public space whose most recent evolution is the theme park. Public parks open to everyone, like Central Park in New York, are a nineteenth century innovation, so are village greens with a public bandstand. The New England common in the seventeenth and eighteenth century was a staging area for cattle, overgrazed, dirty, and full of manure—not a green oasis with a while-painted pavilion in the center. The street as a place for a leisurely public promenade is also a mid-nineteenth century invention, the Parisian boulevards being the archetype. The European café with tables on the sidewalk or in the public square is a relatively recent innovation. The pedestrian street or pedestrian district is mostly a new phenomenon since around 1950, the Stroget in Copenhagen, Denmark, being one of the

first shopping streets that were closed to all but pedestrians. In US cities many of the pedestrian malls have been taken out again, as closing the streets to vehicles caused them to disappear from the mental maps of the people who once used them. In the historic centers of European cities, where public transit is much more a part of everyday life, the pedestrian street and plaza remains successful.

2. *Making Public Space Inviting*

The idea that cities should have many urban outdoor spaces, open to all, without an admission charge or the need to patronize a café, owes something to the modern movement in architecture. Tall buildings need space around them, and architects began designing plazas to provide an appropriate setting for towers. These plazas were not always intended to encourage people to spend time there. The idea was to create an impressive approach to the building. The owners often placed spikes on ledges so that people would not sit or lie on them, and the microclimate was frequently unfriendly, with strong downdrafts from the building when it was windy, blinding sunlight on hot days, and large unsheltered expanses in winter.

Uninviting spaces in highly accessible locations became places for 'anti-social elements' to hang out, they attracted drug dealing, they detracted from the atmosphere of corporate dignity that the owners and architects had hoped to create. In addition, some of these public spaces had been built in response to government incentives; they were supposed to be a public benefit, not a public nuisance.

Research by William H. Whyte, Jan Gehl and others has now given us some simple principles for the design of these new kinds of public spaces, which can be summarized under the following seven headings.

2.1 *Legibility*

Savvy pedestrians are not going to enter a public space if they cannot see how they can get out of it again. Sunken and raised plazas are usually not attractive for this reason, neither is any kind of enclosed dead end. A successful public space needs several clearly visible entrances and exits. The same considerations apply to sub-components of the public space. There should not be any secluded pockets or inaccessible corners.

Interior public spaces need openings to the outdoors so that people can figure out where they are. Bridges in skyway systems generally have windows that provide orientation. Underground concourse systems should look out on occasional sunken courtyards. Works of art and distinctive storefronts can help people find their way, but they do not provide any reference to familiar landmarks outside of the building.

2.2 *Microclimate*

As the public open space is sometimes a residual element in the design of the building, it can end up having an unfavorable orientation. A north-facing plaza, which gets almost no sunlight, is not likely to be attractive, even in a warm climate. New York City's plaza regulations require a southern exposure whenever possible. Wind tunnel tests are usually done for tall buildings to evaluate special conditions on the exterior walls that might cause windows to pop out or other structural failures. At the same time, tests could be done to see if there are any unusual wind conditions created on the plaza. The shape of the tower can interact with winds from a certain direction to create augmented air currents across plazas. These locally created winds can be strong enough to knock people over.

People like to sit in the sun on a cold day and be protected from the wind. On hot days they look for shade and a cool breeze. Good public-space design should be able to create both conditions. Well-placed trees and a fountain can create a pleasantly cool microclimate on hot days; chairs or benches in front of a south facing wall that stores heat and blocks wind can produce a favorable environment when the weather is cooler.

2.3 *Seating*

The essence of an inviting space is the ability to sit down and linger as long as you wish. The seating does not have to be benches or chairs. Ledges on buildings or the edges of planting boxes—without spikes—will do very well if they are placed at three feet or less (but more than a foot) above the plaza, a height where sitting is easy and comfortable. Flights of wide shallow stairs lend themselves to all kinds of impromptu seating arrangements.

Whyte recommends individual movable chairs, such as are rented out for a small sum in French parks, over fixed arrangements of benches. The chairs can be moved about to create all kinds of groups, pulled into the sun or shade, and just generally rearranged to give individuals a feeling of comfort. If fixed, backless benches are used, Whyte suggests making them wide enough that strangers can sit on either side without making each other uncomfortable.

Furnishing a public space with movable chairs means that there must be a guard or attendant present, which is desirable for other reasons: even the best designed spaces need someone to keep order and deal with emergencies.

2.4 *People Watching*

One of the principal attractions of being in a public space is the opportunity to watch other people. Seating

areas should face out over circulation paths. Studies have shown that benches or other fixed seating oriented away from traffic flow will go unused, or will be used in what Jan Gehl calls 'untraditional ways.' He illustrates his point with a photograph of two Danish matrons seated back to front on a park bench, with their legs through the gap between the seat and the backrest, watching the crowds walk by.

2.5 Food

A concession that sells sandwiches, salads, soft drinks, and desserts enhances a public space and is an economical way of making sure that there are responsible people around to keep an eye on what is going on. The only problem is if the concession is permitted to take over the space and make it uncomfortable for anyone who has not bought food or drink.

2.6 Lighting

Even cities that have given a zoning bonus for a public plaza should allow it to be closed from the late evening to the early morning. However, lighting is still an important factor in extending the use of the space and making sure it is not misused at night. Floodlights glaring down on the plaza from tall poles or surrounding buildings are efficient, but can create a penitentiary atmosphere. Although harder to maintain, some of the light should be reflected off trees, come from built-in fixtures near ground level, and from street lamps in scale for pedestrians, with light sources that give a pleasant illumination.

2.7 Surrounding Activities

The most important factor in the design of an urban plaza is what happens around it. New York City's regulations governing plazas that qualify for a zoning bonus require that 50 percent of the building frontage on the plaza be devoted to retail—defined as not including banks, brokerages, airline offices, and travel agencies. This is a shrewd requirement as the typical New York zoning plaza, before these regulations were written, belonged to an office building. If the office tower had any ground-floor uses at all, they were likely to be a bank, a brokerage, or a travel agency, dignified activities that were useful for office tenants but did not do much to enliven a plaza, compared to a restaurant, a shop selling take-out food, or a book store.

Jan Gehl goes farther, saying that tall buildings should not directly adjoin a public space or even, if at all possible, a sidewalk. His reasons have to do with keeping buildings and their activities in scale with pedestrians. Someone leaning out a third-floor window is still recognizably a human being to a person walking by at ground level. Of course, most modern office towers are sealed buildings, even on the lower floors, but that is exactly the point Gehl is making. A street or a public square is a three dimensional place, for it to be at its best it should relate to activities on the second floor and perhaps above. Shopping malls are now designed this way, so that, if you are walking along on level one, you can see that there is a food court on level three. On the same principle, retail streets and public places should be designed with a liner of buildings of low buildings with active uses, with the taller buildings set back within this matrix of traditional relationships.

In residential neighborhoods, the same principle suggests that houses be designed in relation to streets and public spaces. This is the basis for the front porches and small front yards characteristic of many 'new urbanist' communities.

2.8 Walking

According to Whyte's observations, the distance that people were likely to walk in New York City was five north–south blocks, which adds up to about 1250 feet, or a little less than a quarter of a mile. This finding agrees with the experience of shopping center developers who have found that 1200 feet is about the practical limit to the distance between major destinations, like department stores, in a shopping mall.

It also agrees with the diagram published by Clarence Perry in his famous article, *The Neighborhood Unit*, showing a residential neighborhood lying within a circle a half-mile in diameter—that is no more than a five-minute walk from a central point (Perry 1929). At the center of the circle were an elementary school and other neighborhood institutions.

These are modern figures applying to people who are used to driving a car or taking public transit. The five-minute threshold is not about physical stamina but about the onset of boredom, and the fact that people today feel that they need to use time efficiently. According to Whyte, New Yorkers, living in a transit-rich environment, will start thinking about taking a bus, the subway, or a taxi if a trip is going to take more than five minutes on foot. In a more typical city, someone leaving the office to go to lunch will start thinking about getting the car out of the garage if the distance is more than a short walk.

Whyte found that to get people to walk for even five minutes meant that you had to keep them interested. In environments where buildings flanking the sidewalk had long stretches of blank walls, Whyte found that pedestrian traffic was low. Again, this confirms the experience of shopping-center owners that even a few vacant storefronts near a prominent corner could be enough to discourage shoppers from entering a whole section of a mall. The interest factor turns out to be far more important than ease of pedestrian movement.

For years city planners and designers believed that the best way to promote pedestrian movement was to remove 'conflict' between pedestrians and vehicles and to protect pedestrians from the weather. This is the theory behind the skyway systems in Calgary, Minneapolis, St Paul, Charlotte and other cities in the USA and Canada, and also the underground pedestrian concourses in Montreal, at Rockefeller Center in New York, and in downtown Dallas and Houston. Whyte measured the pedestrian traffic in skyways and concourses and found that the numbers of people dropped off sharply as he went farther from the center of the system. Not only did a skyway or concourse system not overcome the five-minute limit, but also, unless there were shops along the way, people did not even walk that far.

The weather protection provided by the concourse and skyway system is clearly useful. In Canada, Calgary has sub-zero winter temperatures, although even in Calgary Whyte found that people prefer the streets when the weather is good. On a winter day in Montreal that was so cold that his camera froze, William H. Whyte found as many pedestrians on Ste. Catherine Street as in the nearby underground concourse of Place Ville Marie.

Separating people from cars is more useful for drivers, by getting rid of delays at crosswalks, than it is for pedestrians, who generally prefer a direct route at street level to the bridges or underpasses placed for their safety at busy urban intersections.

The effect of a skyway or underground concourse system is to divide the pedestrians into numbers that are too small to support retail at both street level and the skyway or concourse. Except in very busy cities the protected level will become dominant, leaving the street level without much in the way of shopping, which means it is too boring to attract pedestrians, and does not look safe enough.

Whyte's studies left him much impressed by the efficiency of walking and the instinctive skill with which people avoid collisions on busy sidewalks. He was also bemused to note that the places where people stopped to talk were generally at street corners, right in the middle of the pedestrian traffic stream.

3. *The Empty Square*

Both Gehl and Whyte, working in the 1970s, present these issues as questions of design, a follow up to Jane Jacobs' famous comparison of the deserted and dangerous lawns in a public housing project with the active social life on her street in Greenwich Village in the 1950s (Jacobs 1961).

Today in some parts of the world this kind of livability has become a larger design issue than the configuration of individual streets and public spaces. An article, 'The Empty Square' by Alan Ehrenhalt in a recent *Preservation*, asks the question: 'If casual social encounters are at the heart of civic life, where did everybody go?' (Ehrenhalt 2000). In most US cities and towns necessary activities take place using a car, and the opportunities for any kind of casual interaction are much diminished. The commuter goes from the garage at home to the garage or parking lot at work. Only the journey from the car space to the lobby takes place on foot. Shopping and errands are done by car to individual destinations. Schools, churches, country clubs, restaurants, movies—each are a separate destination reachable only by car. The Court-House Square is empty. People drive to the health club and do their walking on a treadmill.

Architects, landscape architects, and city planners are currently debating whether it is still important to create public places that permit the face-to-face contact found in traditional cities and towns, or whether life today requires something completely different. One side, which includes the people who call themselves New Urbanists, believes that traditional streets, squares, promenades, and parks are still the essence of city design (Charter of the New Urbanism 1996, 2000). Their opponents, among whom the Dutch architect, Rem Koolhaas, is perhaps the most articulate, believe that the idea that cities can be designed at all is based on unexamined philosophical assumptions, and that modern transportation and communication, particularly the Internet, have made traditional urban spaces obsolete. One of Koolhaas's characteristic statements: [we need] 'to accept what exists. We were making sandcastles. Now we swim in the sea that swept them away' (Koolhaas and Mau 1995).

An expert on computer technology, William J. Mitchell, has written a book, *e-topia: 'Urban Life, Jim—But Not as We Know It,'* which observes that the interactions of technology and behavior are much too complex to allow simple apocalyptic conclusions (Mitchell 2000). Mitchell points out that you have to look at the totality of people's work and personal lives if you want to make good estimates about where new technology is taking us. Most of the people who have chosen to leave cities and suburbs because the computer has freed them to work where they choose are not living on mountain-tops but in smaller, rural communities, precisely because of the face-to-face communication possible in such places. Many email messages are about establishing face-to-face meetings. The demand for hotel rooms and convention centers seems to be going up. Mitchell notes the rising interest in living in or near places that are rich in social interaction: older urban centers and suburban downtowns, older mixed-use neighborhoods and their modern imitations, as well as resorts. He concludes that the power of place will still prevail, that people will still gravitate to settings that offer particular cultural, scenic, and climatic attractions—'those unique qualities that cannot be pumped through a wire'—and will continue to care about face-to-face interactions.

Assuming that William Mitchell is correct, and the design of urban public places will continue to matter, how can such spaces be incorporated into new development?

4. *Designing Livable Communities as well as Public Spaces*

Planning workplaces and residences so that they relate more closely to each other, designing retail as park-once districts, following economic development policies to create self-reinforcing clusters of businesses and related activities, building neighborhoods of diverse housing types instead of instead of housing tracts, and integrating school buildings back into their communities would go a long way towards creating more livable communities where personal interaction is easier and more meaningful.

The amount of time spent commuting is clearly one of the most important livability issues, because excessive commuting time takes up the part of the day that could otherwise be used for more leisurely activities or spent at home with children. Attempts to solve this problem by building new roads are seldom successful because the roads induce new traffic. New patterns of working at home and commuting electronically will diminish the problem. But the real answers will come from creating places where home and work are more closely related.

What made the traditional main street a place where people could meet unexpectedly was that they were walking from one destination to another. Now, designers of retail development are trying once again to create park-once districts, partly to foster interaction and communication, but also to create synergy among the different retail tenants. This is another trend that will make the design of public spaces more important, as people walk from one destination to another.

5. *Bryant Park*

How some of the design principles discussed in this article work out in practice can be understood from the example of once derelict Bryant Park, a public space behind the New York City Public Library between 40th and 42nd Streets. William H. Whyte was consulted about the redesign of the park. A restaurant was built on the Library's back terrace, in keeping with Whyte's prescription for animating public spaces, but against the instincts of people who do not believe that public spaces should be used for commercial purposes. Landscape architect Laurie Olin also followed Whyte's precepts in making subtle adjustments to the terracing in the park, making it easier for people to see into the park, and getting rid of dead-end locations. Lush gardens, good maintenance, a constant security presence, and lots of movable chairs completely transformed the park, which is now a popular place during the day and well into the evening.

The story of Bryant Park and similar successes elsewhere demonstrate that derelict places can be made livable by following a few simple principles, which can also be applied to the design of new neighborhoods, workplaces, and shopping districts.

Urban Places: Statistical Definitions

Almost a century ago, Walter Lippmann observed that a great gap exists between 'the world outside and the pictures in our heads.' The gathering of facts through the creation of governmental censuses and statistical reporting represents a major attempt to remedy this condition. Statistical information provides important data that are critical to understanding

and planning for the economic and social development of society. It aids in the assessment of local and national patterns of development and the allocation of resources to reflect changing needs. It supports the articulation and coordination of goals for national, local, and regional development. A major obstacle to the ability to accomplish this is the presence of dynamic societal change and the emergence of new facts that challenge the accuracy of existing concepts and statistical definitions. Faced with conceptual obsolescence, governmental statistical agencies often resist change uncertain about how to accommodate to it and concerned about the integrity and comparability data. Conflict emerges between the need for stability in concepts and definitions and the desire for relevance. Attempts to develop information about a society's urban population, which changes so rapidly that it quickly renders obsolete the conceptual underpinnings of data definitions, especially susceptible to this dilemma.

All developing societies create some model of an information-gathering national census, albeit with great differences in quality and extensiveness of coverage. The impetus for statistical definitions and data stems from a variety of factors, such as the need for knowledge about a nation's development patterns, the desire to support local and national planning functions, the projection of future development, and the planning and managing of an allocation of resources responsive to the changing location distribution of population need. In addition, in many societies there is a desire to determine the ways in which racial and ethnic differences relate to patterns of settlement and place.

This article focuses on ways in which nations have developed urban statistical definitions. It emphasizes the United States experience, the historical evolution of the urban definition, the current assessment of statistical practices and the prospects for change in the statistical definition of urban. But first, it will consider contrasting practices throughout the world in order to develop an understanding and perspective of how different nations have responded to the need to develop urban statistical definitions.

1. *Contrasting International Definitions for Urban*

No one statistical definition captures the entire story about urban definitions in countries around the world. In fact, the collection of data regarding urban population is perhaps the least standardized and comparable of worldwide census activities. Individual national approaches are highly differentiated and particular in terms of data collection systems and analysis, thereby rendering difficult attempts at cross-national comparisons. These differences stem from contrasting levels of development, diverse cultures, and changing societal needs. They also reflect differing historical traditions, practices inherited from colonial regimes, fiscal and human resources available for census activities, and levels of national integration. The resulting variety of urban definitions rely on such factors as minimum population size, levels of population density, the distinctiveness of a governmental or administrative political unit, the percent of agricultural and nonagricultural working population, and other political, social, and economic factors distinct to particular societies and nations. For example, the meaning of a governmental jurisdiction, such as town or village, is often very different among nations. Or, the difference between *de facto* and *de jure* population has a great effect on the classification of urban and rural populations, especially at times of turmoil and instability which result in large movements of population.

A survey of national census practices reveals widely varied definitions of 'urban'. The Swedish define it as those built-up areas with less than 200 m between houses. Bulgaria uses the term to refer to localities legally established as urban, regardless of size. Denmark employs a minimum population requirement of 200 while Japan has a minimum population requirement of 30,000. France, Nigeria, Iran, and Turkey have definitions of a minimum population of 2,000, 5,000, 5,000, and 10,000 respectively. Many countries, largely concentrated in Africa and Asia, have either not yet developed or made available estimates of urban population in their national censuses.

India presents an interesting example of the complexities involved in urban definitions. It includes towns (places with municipal incorporation, municipal area committee, town committee, notified area committee, or cantonment board), as well as all places having 5,000 or more inhabitants, a density of not less than 1,000 persons per square mile, or 390 persons km^{-2}, pronounced urban characteristics, and at least three-quarters of the male population employed in pursuits other than agriculture. Clearly Indian demographers have recognized the difficulties in developing accurate terminology that reflects the complexity of their country's economic and social development.

Once established, statistical categories and definitions are increasingly codified and difficult to modify or change. While the goal of consistent comparability of data among different nations is a distant vision, nations are continually expending resources to develop refined population data reflecting their unique patterns of development. We shall now turn our attention to the example of the United States, a nation that has tried to adapt its definitions of urban to dynamic economic and social change.

2. *The American Quest for an Urban Definition*

The American quest for a statistical definition of urban reflects a tortuous pattern of adaptation to

changes in the structure of society over this last century. Demographers of an earlier period could not foresee the dynamic changes that were to affect how Americans live and work. They differentiated between urban and rural by contrasting the preponderance of agriculture or manufacturing, the size and density of the population, and the concentration of commercial activity. These characteristics informed their assessment of urban and rural places. In practice, the distinctions between urban and rural were easily made because the concept urban was applied only to a few large cities that were easily considered as an urban population.

This approach is described with great detail by Adna Weber (Weber 1899) in his statistical study of nineteenth-century cities. He classified rural and urban populations by size of place, specifying rural as 'scattered' or 'agglomerated' (hamlets and villages with fewer than 2,000 population and towns with from 2,000 to 10,000 population) and urban as 'cities' (more than 10,000 population) and 'great cities' (more than 100,000 population). The Census Bureau's current urban and rural classification consists of two different urban categories. One is any area that is part of an Urbanized Area (UA) and those places outside the UA that have a population greater than 2,500. Territory not included in these two categories is classified in the residual category of rural.

The US Bureau of the Census officially adopted the 2,500 level for the 1910 Census, a figure that survives till this very day, but now has a more limited application. Between 1910 and 1940 the decennial censuses had an additional requirement that the urban place be part of an incorporated territory. The Bureau made some allowances for minor civil divisions (MCDs) having large population size and density. The place size definition of urban was soon considered to be inadequate because of its exclusion of many population concentrations located in unincorporated places, resulting in their inappropriate rural classification. To remedy this problem, census demographers continued to grapple with the challenge of modifying the concept to reflect the changing realities of urbanism, especially the increasing spread of the population to new areas. There was a need to create a concept that would be based on additional criteria other than place size and MCD status. This led to the development of the idea of an 'urbanized area' (UA) in 1950, a concept that exists, albeit in a modified form, till this very day.

Although first defined in 1950, the Census Bureau has modified the UA concept over time. A UA is a continuously built-up area with a population of 50,000 or more, comprised of one or more places and the adjacent settled surrounding area, the urban fringe. The UA includes only urban populations, consisting of a central city and incorporated places with a minimum population size of 2,500, or unincorporated places with a population density of at least 1,000/mile^2. Since 1990, there has been no minimum size stipulated for a central place and the requirement of central city has been changed to central place. A Census Designated Place (CDP) that contains a densely settled unincorporated area of 2,500 or more is now classified as urban, thereby correcting a major gap in previous urban definitions.

3. *The Emergence of the Metropolitan Idea*

Even at the time of its formulation, the UA concept failed to provide an accurate measure of contemporary developments. Its focus was on the contiguous connection between the central place and the urban fringe excluded population residing in noncontiguous urban enclaves that were economically and socially related to the center. Demographers searched for a concept to reflect urban relationships in the new era of metropolitan dominance. They developed new terms to refer to the metropolitan concept, beginning with the Standard Metropolitan Area (SMA) in 1950, the Standard Metropolitan Statistical Area (SMSA) in 1959, the Metropolitan Statistical Area (MSA) in 1983, and most recently the Metropolitan Area (MA) in 1990.

Their work paralleled what Hans Blumenfeld described with great insight in 1967 as a new stage in the 'urban revolution,' the transition from the 'modern city' to the 'modern metropolis.' He stated that 'this change of name reflects the fact that from its long, slow evolution the city has emerged into a revolutionary stage. It has undergone a qualitative change, so that it is no longer merely a larger version of the traditional city but a new and different form of human settlement' (Blumenfeld 1967). While Blumenfeld's view of the metropolis was in some ways similar to the 'conurbation' idea originally described by Patrick Geddes at the turn of the nineteenth century, and later elaborated by Lewis Mumford, it was distinctly different from the 'megalopolis' of Jean Gottmann 1961, and the 'ecumenopolis' of Constantinos Doxiadis 1967, which were also conceived in the 1960s. Attempts to portray the realities of contemporary urbanization by referring to an urban settlement that is 'neither city nor country but a complex of urban districts and open areas' have much precedence in the development of urban ideas.

The need for a concept that better reflected the spread of the urban population beyond city boundaries dates back to before the Civil War. This perception is evidenced in the New England Gazetteer's entry on Boston which noted that

> owing to the almost insular situation of Boston, and its limited extent, its population appears small. But it must be considered that the neighboring towns of Quincy, Dorchester, Milton, Roxbury, Brookline, Brighton, Watertown, Cambridge, Charlestown, Medford, Malden, and Chelsea, although not included in the city charter, are component parts

> of the city, and are as much associated with it in all its commercial, manufacturing, literary, and social relations and feelings, as Greenwich, Manhattanville, and Harlem are with the city of New York; or Southwark and the Northern Liberties with Philadelphia (United States Department of Commerce 1994).

By 1905, the Census of Manufacturers utilized a metropolitan concept when it replaced its 'industrial district' classification with a 'metropolitan district' concept, retaining it with modifications through 1940. Metropolitan districts were defined in terms of minor civil divisions (MCDs), with their boundaries based primarily on population density. In 1950, the Bureau of the Census incorporated the metropolitan concept in its term Standard Metropolitan Area (SMA). The journey to work as measured by commutation patterns is the major characteristic defining the boundaries of the metropolitan area. The SMA includes at its center a city, (or in a few instances a census-designated place or county subdivision with a minimum population of 50,000), and its county and those contiguous counties that meet specified requirements such as the 15 percent commutation rate to the central county. Other characteristics relate to population density, percent of the population classified as urban, percentage of growth in the population between the two previous decennial censuses, and percentage of, or absolute number of, inhabitants within the UA that qualifies for inclusion in the metropolitan area. A contiguous county is included in its entirety or it is not included. This can result in a significant number of rural persons being included in a metropolitan count.

The Metropolitan Area (MA) is meant to capture the high degree of economic and social interdependence among a central city and its surrounding counties. It contrasts with the urbanized area that focuses on the densely settled agglomerations surrounding large cities. The MA concept provides a means of defining a functional area based on the activities of the population while the UA measures the extent of urban agglomeration around a central core. The census demographers viewed metropolitan areas and urbanized areas as complementary. Together they present an accurate depiction of the urbanization process.

Dynamic and new forms of growth often render both the MSA and UA ineffective as measures of the new realities. Population decentralization away from the central city to new centers in outlying areas has resulted in a form of urbanization far different from that envisaged in the original metropolitan concept. As metropolitan areas grow, their boundaries expand to and often overlap the boundaries of other adjacent urban areas. In 1983, the Bureau of the Census responded to these developments by introducing two new designations, the Primary Metropolitan Statistical Area (PMSA) and the Consolidated Metropolitan Statistical Area (CMSA). An area with a population of one million or more is recognized as a CMSA if it has component parts that are eligible to be PMSAs. These component parts must meet certain statistical criteria that demonstrate strong internal economic and social links as well as ties with the center of the larger area. The support of local public opinion is an additional criterion for inclusion. The boundaries of the CMSA are defined as the area resulting from the aggregation of all of the PMSAs.

After a century of classifying urban data, the Bureau of the Census has formulated a number of statistical definitions, each relevant to different aspects of the urbanization process. Their development reflects the efforts of government statisticians and demographers to describe and understand different patterns of urban development resulting from the dynamics of technological and social change. Together these definitions form a conceptual framework that accounts for population size, density, economic and social interdependence, and jurisdictional units of government in portraying urbanization and metropolitan growth.

This framework incorporates minimum place size, density characteristics, core–periphery relationships involving cities, suburbs, and metropolitan regions, and monitors the increasing decentralization and deconcentration of urban areas. By moving beyond the more limited notion of urban place they provide an accurate picture of a complex and continually evolving reality. Nonetheless, a gap remains between how American urbanization is currently developing and how it is portrayed in statistical concepts. Attempts to remedy this situation are discussed in the final section of this article.

4. *Prospects for the Future*

Cities are no longer the dominant form and entity of urbanization, and suburbs are generally considered to be that part of the urban population residing outside the central city, referred to as the 'urban fringe.' While there is no formal census statistical definition of a suburb, there is recognition of the fact that suburbs have been the most rapidly growing part of the urban population. A half a century ago, 60 percent of the residents of metropolitan areas lived in central cities. At the current time, 60 percent live outside the central cities, that is, for the most part in suburbs.

This dramatic change in American life styles led the historian Jon C. Teaford (Teaford 1993) to conclude that traditional concepts of urban have become so outdated that:

> at the close of the twentieth century, then, the age of urbanization in the United States had come to a close. The concept was no longer relevant for a nation that was metropolitan but not urban. Unimaginative data collectors in the Bureau of the Census still embraced the outdated concepts of urban and rural, but such concepts masked rather than

> illuminated reality. The urban frontier had closed, and the term *urbanization* should have been retired to that conceptual attic frequented primarily by students of the past.

Similarly, Robert Fishman (Fishman 1990) stated that:

> for most Americans, the real center of their lives is neither an urban nor a rural nor even a suburban area, as these entities have been traditionally conceived, but rather the 'technoburb,' the boundaries of which they can conveniently reach in their own cars. The true center of this new city is not in some downtown business district but in each residential unit. The old central cities have become increasingly marginal, while the technoburb has emerged as the focus of American life.

While in the past dissatisfaction with existing urban definitions led to the introduction of such new statistical measures as the Urbanized Area, and the Metropolitan Statistical Area, many, like Teaford and Fishman, believe that they are not fully adequate in their depiction of contemporary America. The question remains as to what will be the next stage of conceptual change in the statistical definition of urban.

Today's urban statistical definitions have a strong bias towards interpreting urbanization within the framework of a core-periphery model emphasizing the central city. Critics argue that the emphasis on central city-suburban relationships ignores what is going on in the rest of the metropolitan region, especially the increasing decentralization of population and job location that results in an increase of suburb-to-suburb journeys to work and other functional relationships. They also maintain that dependence on the county as a building block results in the inclusion of non-urban population in the metropolitan count and the neglect of numerous and varied subcounty interrelationships.

Further, advances in computer technology allow for data collection and analysis disaggregated at levels far smaller than the county. This phenomenon allows for additional change, never before contemplated, in the statistical definition of urban. The Bureau of the Census is currently reviewing proposals involving utilization of such alternative geographic building blocks, including the Minor Civil Division (MCD), Census County Division (CCD), Census Tract, Zip Code, and Grid Cell. All involve different levels of consistency, stability across boundaries, accuracy of depiction over time and space, data availability and familiarity, and identifiability. It is expected that the current review will result in a number of modifications in existing practices, but it is as of yet uncertain how extensive these recommendations will be.

The center-core orientation of the definition of urban had great validity in the past, but is inadequate at a time when the percentage of the nation's urban population living in suburban area continues to increase. Structural factors (such as population size and density) combined with functional factors (patterns of economic and social linkages such as the journey to work) still remain the best indicators for metropolitan inclusion. In addition, the emergence of less expensive telecommunications, and the increasing pervasiveness of the information superhighway associated with the use of the Internet, are changing functional relationships in ways that will lead to the increasing decentralization of the urban population.

To appreciate the significance of these changes, it is not necessary to agree with the views of Adna Ferrin Weber who forecast in the late nineteenth century that suburbanization 'furnishes the solid basis of a hope that the evils of city life, so far as they result from overcrowding, may be in large part removed. If concentration of population seems destined to continue, it will be a modified concentration which offers the advantages of both city and country life' (Weber 1968). Much has transpired since Weber predicted the growth of the suburbs and its impact upon cities. Today, urbanists focus on the dynamics of urbanization. Flow and movement and the 'space of flows' (Castells 1996) have become a dominant distinguishing urban characteristic of our time. This is true whether one emphasizes the influences of technology upon transportation and production or is more concerned with the impacts of new communications technology on forms of urban development.

Speculations about the future of the city, involving concepts such as 'edge city,' 'technoburb,' 'transactional city,' 'informational city,' megalopolis,' global city,' or 'post-suburbia,' represent attempts to understand how the concept of 'urban' is changing. Nevertheless, while these new forms involve an important and broad range of conjecture and imagination, there still remains the central importance of space as human beings construct their lives primarily in relation to where they live and work. While statistical definitions of urban have undergone a complex and changing history, it remains clear that much is yet still to come, as the dynamic facts of economic and social change intrude themselves upon established statistical categories of urban definition. The search for new concepts and definitions continues. The outcome of this struggle will be clearer to the readers of the fourth edition of the *International Encyclopedia for the Social Sciences*.

Urban Planning: Central City Revitalization

1. Definition

As cities age, their physical features gradually deteriorate. Buildings, public facilities, vegetation, open spaces, and other elements may be involved. Careful maintenance and preservation can minimize this process, but with the passage of time, nearly all structures, spaces, and other features will have to be restored, rebuilt, or replaced. This process, usually accompanied by negative economic and social conditions, is termed central city (or urban) decline. Ameliorative responses to these forces are known as central city revitalization. While improving the condition and appearance of buildings, parks, streets, and the other elements of the urban environment is the most obvious goal, closely linked are desires to improve economic and social circumstances for those who live in, work in, or visit the city.

2. Historical Evolution

From the very earliest human settlements to modern world metropolises, the revitalization of cities is an enduring theme in world history. Cities have been rebuilt in response to the depredations of warring invaders and the destruction from volcanic eruptions, hurricanes, and earthquakes. More commonly, the forces of urban decline act less dramatically and over many decades. For example, during the Renaissance the medieval sections of several European cities were replanned. The clergy or nobility demolished ancient walls, straightened and widened streets, removed aged buildings, and added parks, monuments, and aesthetically pleasing visual features. The rebuilding of Rome under a sixteenth-century plan prepared by Pope Sixtus V and his assistant Domenico Fontana is a most notable example. In the early nineteenth century, royal architect John Nash redesigned a series of narrow London streets into today's Regent Street, which connects Piccadilly Circus to Regent's Park (also designed by Nash). Napoleon III's Prefect of the Seine, Baron Georges-Eugene Haussmann, tore out thousands of Parisian slum buildings and built wide boulevards with landscaping, arches, and statuary in the mid-nineteenth century (Barnett 1986). The City Beautiful movement in the USA brought plans to revitalize San Francisco, Chicago, Denver, Cleveland, Indianapolis, Minneapolis, Washington, DC, and other central cities in the early twentieth century.

3. Contemporary Central City Revitalization

Central city revitalization is associated here with a more modern expression of this idea. A central city is generally thought to be a more densely populated urban core surrounded by a metropolitan area of lower density but larger land area. Many central cities in the advanced industrial nations of Europe, Australia, New Zealand, and Canada have experienced decline, primarily since the middle of the twentieth century. There is little question however that of these, the USA has suffered the most severe and widespread central city deterioration. There is general agreement among social scientists and urban planners that suburbanization (the relocation of businesses and predominantly middle- and upper-income households from central cities to suburbs) has been the primary dynamic influencing these outcomes. While experts

disagree on precisely how and why rapid suburbanization occurred, most concur that it was a combination of the attractiveness of suburban life and the desire to escape the noise, congestion, crime, declining schools, and changing racial, ethnic, and social profiles of city residents.

As urban decline progressed in the USA, once middle-class city neighborhoods became lower-income enclaves. Landlords reduced maintenance due to diminished income and city agencies cut public services in response to lower tax receipts. In most cases, overcrowding occurred, crime increased, tensions arose between older and newer residents, and more households departed for the suburbs. Downtown department stores and shops followed their customers outward, establishing suburban outlets at shopping centers and regional malls. Corporations sought more modern factory and office space in the suburbs. Maritime industries such as fishing and shipping relocated their operations away from the historic city waterfronts due to higher costs, eroding dockage, and the introduction of new cargo-handling technologies. National and state government programs built more highways connecting cities to outlying areas, making it easier for more affluent families to live in the suburbs and commute to central city employment. By the latter half of the twentieth century other advanced industrial nations experienced many of these urban forces, though generally with less severity than the USA. Cities such as London, Paris, Amsterdam, Munich, Buenos Aires, Sydney, Melbourne, Auckland, and Toronto began to experience demographic shifts in their centers, rising suburbanization, and disinvestment in their downtowns, some neighborhoods, industrial areas, and waterfronts. In most cases private market interests were insufficient to reverse these trends and it was necessary for national, state, and local governments to step in.

The first era of central city revitalization was under way by the 1950s and is generally termed 'urban renewal.' While the details varied from nation to nation and city to city, urban renewal usually involved financing and rules provided by the national government, with program implementation by the municipal and/or state governments. Real property in declining central city enclaves was acquired, occupants were moved to other locations in the city, decaying structures were demolished, large areas were cleared and master plans for redevelopment were prepared. Land was sold cheaply, supportive public facilities were upgraded, and other incentives were provided. In the USA in many cases, hospitals and universities expanded into these areas. In downtowns, pedestrian walkways, parking garages and office buildings were constructed. Often, public or social housing for low- and moderate-income households was erected, although fewer units were built to replace the number destroyed, lowering population densities. By the 1970s a combination of the high public costs of urban renewal, the politically and legally contentious issues of land acquisition through condemnation and eminent domain, and the social disruption of compulsory household relocation brought urban renewal to a halt in several nations.

Gradually, national governments replaced urban renewal with a more selective approach. This process, never known by a singular identifying phrase, could be called 'urban conservation.' The emphasis in urban conservation was the rehabilitation and restoration of older buildings, their re-use for new purposes, isolated or 'spot' land clearance and relocation, and greater efforts to involve indigenous residents, businesses, and institutions in planning for the future of their communities. Instead of erasing older neighborhoods, concern was for extending their utility and, where necessary, adapting them to new uses. Closely allied with this trend was the growing popularity of historic preservation and an awakened interest (primarily among young adults) in architecture of the nineteenth and early twentieth centuries. These urban 'gentry' fed a process now known as 'gentrification.' While some of the gentry were the beneficiaries of government subsidies designed to spur urban conservation, most received no public assistance for renovating their own homes (Davies 1980, Gale 1984).

Urban conservation sought to revitalize other central city sections as well. Downtown storefronts were rehabilitated, streets were repaved and new lighting, vegetation, signage, and other features were added. Public spaces were built or expanded and new or upgraded mass transit systems were installed. Rotting piers and dilapidated factories and fish processing operations were removed from waterfronts and replaced by marinas, parks, pedestrian ways, restaurants, housing, hotels, and entertainment facilities (Breen and Rigby 1994).

Obviously, central city revitalization is a complex process, unfolding over several years, even decades, with multiple participants, complicated financing mechanisms, and a multiplicity of people who are affected in various ways. It may be understood from several disciplinary perspectives.

3.1 Physical Dimensions

Nothing conveys the impression of decline more readily than the sheer visual impact of deteriorating architecture, bridges, streets, street furniture, parks, playgrounds, schools, public transit systems, and the other physical manifestations of urban life. These many signs of deterioration contribute to an ethos of disrespect among residents, often resulting in poor maintenance, vandalism, and destruction. Those forced to live in slums, dispirited by their surroundings, are left to measure their personal worth in terms of the sights and sounds that greet them each day. Visitors to the city avoid these enclaves, if possible,

further isolating their residents and limiting their economic opportunities. Another impact of decline is the sheer ineffectiveness with which such conditions serve their residents and others. Uninhabitable dwellings and apartments offer no shelter, vacant factories and offices provide no jobs, empty shops offer no goods or services, deteriorating schools undermine educational processes, and broken playground equipment provides no recreation. The physical dimensions of urban decline usually result in a lack of confidence among property owners, banks, and developers which contributes to further disinvestment, thus compounding the dilemma.

3.2 Economic Dimensions

Closely related to these conditions are the economic dimensions of central city decline. Until the last quarter of the twentieth century, central city decline was blamed mainly on rising suburbanization in Western societies and the attendant devaluation of urban locations. Since then, the world has undergone increased economic restructuring, resulting in firms relocating business activity not merely to the suburbs but to other regions and nations altogether. As traditional employment in manufacturing industries declined, especially in central cities, employment in fields requiring higher education accelerated. Some cities 'captured' more of these jobs than others. Aggressive investment followed and in cities such as San Francisco, Boston, Sydney, Singapore, Hong Kong, Vancouver, London, Frankfurt, Geneva, Brussels, Madrid, and Paris, downtown, waterfront, and neighborhood revitalization has been widespread.

Questions have been raised of cities that have been less successful regarding how much financial support governments should supply to prop up urban economies. While nearly all cities advance revitalization programs and projects with government incentives such as loan, grant, and tax relief schemes, some have been more effective at attracting private sector investment than others. Should billions of dollars of scarce government resources continue to be invested in these less promising communities? Or, should they be spent on other social needs such as health care or environmental protection? Does it make more sense economically to help needy people in city centers to move to the suburbs, where job, housing, and education opportunities are often better? Economic issues such as these have accompanied the late twentieth-century phenomenon of central city revitalization.

3.3 Social Dimensions

The primary social cost associated with revitalization is the displacement or dislocation of low-income households, often racial or ethnic minorities, as the prices of housing appreciate due to increased investment activity. Rents and property taxes may be raised in response to these forces and tenants are forced to make way for more affluent successors. The socioeconomic composition of a residential neighborhood is likely to change as a result of these dynamics, and religious, ethnic, and cultural organizations may lose members. Small businesses in downtowns and neighborhoods may lose their lease and vacate their premises, leaving low-skilled employees jobless. In short, the positive economic outcomes of revitalization do not redound equally to the benefit of all who live or work in the city (Sanders 1980).

3.4 Political Dimensions

Whenever there are threats to the existing social and demographic composition of central cities, there are political implications, as well. While city administrators may promote revitalization activities, some elected officials with constituents in the affected areas are likely to resist. This is especially true in ethnic and racial minority voting districts that have elected a city councilperson, for example, from their own ranks. Fearful that the councilperson will not be re-elected if the composition of the neighborhood electorate changes significantly, they may promote organized resistance to reinvestment and displacement activities.

On the other hand, pro-growth political administrations in city governments, keen to attract revitalization activity, may overlook or disregard the negative externalities (i.e., unintended outcomes), such as household displacement, which result. Collaborating with developers, banks, corporations, and investment firms, so-called 'growth machines' or 'regimes' result, which foster economic growth with little regard for the negative effects on low-income and minority households, as well as their businesses and institutions (Logan and Swanstrom 1990, Teaford 1990).

3.5 Historic/Cultural Dimensions

As central city urban renewal and highway construction removed thousands of older structures during the 1950s and 1960s, a growing appreciation arose for the historic and cultural legacies being destroyed. Historic preservationists organized and local governments enacted historic landmark and district ordinances to protect older neighborhoods and sections of downtowns and waterfronts. Urban conservation replaced urban renewal as government officials and business interests recognized that a community's historic identification could enhance the local tourism economy. Railroad stations, public schools, warehouses, factories, hotels, office buildings, movie theaters, churches, and other structures, depending on their age and

stylistic identity, qualified for special protective measures. Revitalization schemes often adapted the older structures to new uses. In other cases only the street-facing facades of aged buildings were preserved, while the interiors were demolished and replaced with modern spaces. Notable examples of historic districts include the Vieux Carré in New Orleans, the Old City of Quebec, the Altstadt in Bonn, the Lace District of Nottingham, the Marais in Paris, and Gamla Stan in Stockholm.

3.6 Design Dimensions

Closely related to the historic significance of urban spaces are the challenges to architects and designers of integrating modern structures into historic settings. New office buildings and hotels, for example, can tower over cathedrals or public libraries built in the last century, casting shadows. Newer materials such as glass, concrete, and steel do not necessarily blend in with the brownstone, brick, or granite surfaces of another century. Larger structures generate more vehicular and pedestrian traffic, causing access and parking problems. Some successful design projects have created ensembles of existing and new buildings, joining them in complexes linked by glass-covered atria, pedestrian walkways, bridges, and other devices. In other cases, new spaces have been placed partially below-ground under and adjacent to historic buildings, thus presenting a less obtrusive profile at street level. A second challenge is the alteration of historic buildings for new uses. Sometimes called adaptive use, these conversions tax architects' design skills as they try to accommodate modern demands for elevators, access for the handicapped, heating and cooling equipment, fiber optic cable, and office devices such as computers, photocopiers, facsimile machines, and other communication tools. Equally challenging are the constraints imposed on older buildings by local building codes, especially in settings where earthquakes, cyclones, and hurricanes occur.

3.7 Behavioral Dimensions

At least since the late nineteenth century, questions have arisen about the effects of urban environments on human behavior. Leaders of social reform movements often cited the pernicious effects of crowding, inadequate sunlight, and poor air circulation on immigrants. Alcohol abuse, mental illness, prostitution, street violence, and other forms of social deviance were sometimes linked to the debilitating effects of the slums in which they occurred. Later, urban renewal advocates implied that tearing down these blighted areas and relocating their inhabitants to newly built public or social housing would substantially reduce the incidence of social deviance. Thus, a connection—still unsupported by empirical research—was suggested between urban revitalization and behavioral change. If there is a consensus among social and behavioral scientists, it is that urban environments have moderate impacts on human behavior but that other conditions such as poverty, racial prejudice, and crime have greater explanatory power. Ironically, studies of those who were forced to move due to urban renewal or revitalization processes found that some people experienced greater personal hardships, at least over the short run, when taken out of their earlier neighborhood (Gans 1982, Nasar 1988, Schill and Nathan 1983).

3.8 Environmental Dimensions

The notion of environmental sustainability has achieved prominence since the 1970s. It argues that there are certain natural limits on the capacity of individual ecosystems to support human life without significant environmental degradation. Suburban sprawl is viewed as unsustainable, due to its extravagant consumption of space, prime agricultural soils, water supplies, water pollution, and other effects. Urban decline is seen as a consequence of suburbanization and sprawl. Central city revitalization has been advocated as a means to redirect growth from suburbs to central cities. Environmentalists and some urban planners have argued that older city centers should be revitalized and reused to meet continued human needs for urban space, rather than allowed to become underutilized, decaying slums.

4. Methodological Issues and Future Research

As a public policy issue, central city revitalization raises questions that are generic to public policy research. Are the costs of revitalization outweighed by the benefits accruing to the public? Or, in a somewhat different frame of reference, how effective are revitalization expenditures in achieving designated social objectives such as increasing property tax receipts, lowering unemployment rates, and increasing household income? Are there less expensive options for achieving the same level of effectiveness? Given the complexities of revitalization programs and the duration of time over which they must unfold to show measurable effects, these questions are difficult to answer with certainty.

Another difficult methodological issue is sometimes termed 'the substitution dilemma.' It asks, to what extent do public expenditures in revitalization programs engender benefits that would have been forthcoming even in the absence of those expenditures? For example, if a city government offers tax incentives to developers to invest in downtown rebuilding projects, would they have made those investments without the incentives? If market conditions were quite negative

prior to commencement of the downtown program, the incentives may have been necessary. However, as conditions improve (especially after the first few developer projects have been completed), continued tax incentives for subsequent projects may not be necessary. Yet, the city government may continue to 'substitute' public subsidies (e.g., tax incentives) for private investment when, in fact, the investment climate has improved to the point that developers would be willing to undertake projects even without those subsidies.

A third research issue questions the impact of new technology, especially telecommunications, on the physical, economic, and social character of central city life. Suburbanization and global economic restructuring have reduced the importance of many central cities as centers of culture, religion, and commerce. With the introduction of telephones, radios, televisions, and automobiles within the past century, the necessity for central places began to unravel. Today, with the internet, computer networks, facsimile machines, cellular and digital telephones, and other devices, businesses and individuals have more locational freedom than at any time in the past. Large headquarters buildings in downtowns may become less important, especially among global industries with facilities and clients in several nations. As retail sales increasingly take place over the Internet, the need for downtown (and suburban) department stores and speciality outlets will probably diminish. With newer telecommunications equipment, white-collar workers in many fields are able to carry out their duties from their homes or other remote locations. Thus, research will be needed to understand the evolving purposes of central cities for meeting residential, commercial, cultural, and entertainment needs in the future. To be sure, there will always be human need for contact with others. Whether those needs will be sufficient to sustain large central cities into the twenty-first century, especially in their present configurations and organizational structures, remains to be seen. Urban revitalization initiatives sympathetic to the evolving future of central cities must be carefully examined.

Urban Planning (Chinese), History of

The principles of Chinese urban planning grew out of the heartland of Chinese history and culture. In broad historical perspective, Chinese city planning can be divided into millennia-old imperial planning and twentieth century modern planning. Chinese urban planning history ultimately reflected Chinese cultural visions, political ideologies, and power relations. Chinese imperial urban planning, characterized by its basic design principles of centrality, axiality, and rectilinearity, was based on a syncretic world view which emphasized the centrality of the emperor as the pivot of the four quarters of the universe, and combined traditional Chinese cosmology, the *yin* and *yang* and five-element theories, and *fengshui* geomancy. Modern city planning is a product of the interaction and fusion between Western concepts of city development and Chinese indigenous urban traditions, which reflects tensions, conflicts, and accommodations between impulses of global forces or ideological and political monuments to reduce Chinese cities into decontextualized uniformity and the heightened appreciation for Chinese cultural roots and local sensibilities in spatial arrangements. The future of Chinese urban planning is destined to transcend both modernism driven by the pursuit of rationality and

functionality and rigidified socialist politics and be based on a pluralistic and multidimensional sense of Chinese history and culture.

1. *Imperial Urban Planning*

The depths of the planning and design principles of traditional cities have been explored by scholars such as Paul Wheatley, Arthur Wright, and Sen-dou Chang. In a comparative study, Wheatley analyzed the origins and nature of ancient Chinese urban planning, arguing that the ceremonial center represented the earliest stage of Chinese urban development and the cosmo-magical symbolism played a decisive role in defining the functionality of the ancient Chinese city (Wheatley 1971). While some scholars, based on new archaeological data, have recently challenged the ceremonial-theocratic or 'city as temple' thesis of urban genesis, the cosmic symbolism in the design of cities that perhaps found a more explicit expression in China than in many other civilizations was further emphasized. The symbolic and cosmological elements associated with the design and location of ancient Chinese cities, which included early cosmological traditions, Taoist principles, *yin* and *yang* and Five Elements schools, and the geomantic (or *fengshui*) considerations were idealized and systematized as general urban planning principles by Confucianist philosophers in the Han dynasty (206 BC–AD 222) (Wright 1977). At the same time, these rules were appropriated to symbolize and sanctify the centrality of the emperor and Confucian social order that emphasized power, authority, and hierarchy.

Consequently, the uniqueness of premodern Chinese city planning lies in the fact that the buildings and their locations within the city were pre-established by age-old traditions set forth in revered literature or documents of the classical age (Steinhardt 1990). These ritual and divination texts include *Zhou Li* (*The Rites of Zhou*) and *Yi Jing* (*The Books of Changes*). According to *Zhou Li Kaogongji*, a planning and construction text, a city should be built in a square with three gates on each side. Preferably surrounded by hills in the distance with a river system running through, the wall- and moat-enclosed city should have an area of about seven square miles, a good size for a pedestrian city. Inside the city, there should be thoroughfares running north–south intersecting with other east–west thoroughfares. Major buildings in the city should face south, the best of the four cardinal directions. On the east side of city an ancestral temple should be built, while on the west side there should be a state shrine. The market place is usually situated in the north, while the imperial palaces lie in the southern part of the city. Built in the fifteenth century, Beijing, with its layout and structure epitomized by a seemingly endless maze of walled compounds within walled compounds, best exemplifies a highly regimented city conditioned by the prescriptions of the imperial cosmology and its geomantic modularity (Wu 1986, Meyer 1991).

Traditional city plans were almost always square or rectangular rather than circular or irregular, reflecting Chinese cosmological belief that heavens were round while the earth was square. Nearly all cities were walled to protect imperial palaces, temples, granaries, and residences from barbarian invasions, tribal uprisings, and peasant rebellions. Huge wall-gates were usually constructed, connecting between different parts of the walled city and between the city and the outside world. Walls were so important to Chinese cities that the characters for city and wall are in fact identical (Chang 1977). Another distinctive feature of traditional city planning was the axial balance and interdependence of urban spaces. Compared with the European Renaissance palace, as at Versailles, where the open vista is concentrated upon a single building and the palace itself was detached from the city, the Chinese conception was much grander and more complex. The central axis of Beijing, for example, was composed of hundreds of buildings, and the palace itself was only part of the larger organism of the whole city. Although so strongly axial, there was no single dominating center or climax, but rather a series of architectural experiences. This Chinese form of the great architectural ensemble, 'combined a meditative humility attuned to nature with a poetic grandeur to form organic patterns unsurpassed by any other culture' (Needham 1975).

Traditional Chinese cities were planned and designed to reinforce important power relations, especially the cultural hegemony and political dominance of imperial monarchs. City planners were determined to uphold imperial power through shaping the design and configuration of the built environment. The urban spatial hierarchy represented powerful testimony to and physical proof of the imperial order. Maintaining a highly structured and carefully planned city form was an important means through which Chinese emperors legitimized their position as both rulers and guardians of tradition. The alteration of an accepted design was therefore considered a challenge to the imperial order.

2. *Modernist Urban Planning*

China's modern planning experience is primarily a twentieth century phenomenon; it has undergone three important phases of development: the modernist (1900–50), socialist (1950–84), and global capitalist (1984–2000).

The principles of imperial urban planning came under attack in the nineteenth century, when Western industrial countries transformed a number of coastal Chinese cities into treaty ports, which became enclaves of foreign political domination as well as Western

trade and commerce. Chinese cities elsewhere were also pressured to adopt Western ways (Dong 1989). Westerners brought along a host of entrepreneurial, technical, and modernist ideas about urban life and industrial prosperity, as well as a body of political, social, and economic values. In addition, the urban transformation was a direct result of domestic political changes in early twentieth century China. Modern urban planning reflected a shift in indigenous ideological discourse from emphasizing the supremacy of the imperial power to one that stressed the primacy of a civil society and people's rights. Both Western and modern Chinese ideology confronted the integrity of the Imperial-Confucian world system and its cosmology with a series of powerful secular trends: modernization, Westernization, and later on, revolutionary nationalism.

As a result, the early twentieth century witnessed a significant change in planning principles and the transformation of Chinese urban landscape. A variety of political, intellectual, and commercial leaders sought to 'modernize' their cities according to their understanding of what modernity meant. The quest for modernization took a number of different forms, but there was also a number of common elements. The newly created Chinese republic required new types of public spaces—parks, public squares, and meeting halls. Municipal governments sought to improve public health, with such measures as building modern waterworks and sewer systems. Many cities sought to improve urban transportation with streetcars and railroads. Through both public and private efforts, the architecture of Chinese cities was transformed, with new-classical Western architecture in such treaty ports as Shanghai and Canton and a variety of attempts to blend modern materials and covenience with distinct Chinese styles. One striking aspect of this effort at urban renewal was the extent to which the old Chinese cities, often viewed as the prototype of the pre-industrial city, were now subjected to a new generation of planning and new attempt to discipline the urban population.

The Republican government was bent on tearing down city walls, remodeling city gates, and constructing or widening roads to allow passage of railroads, streetcars, and general traffic. Proponents for dismantling city walls argued that since the introduction of modern warfare, the ancient city walls and gates became useless. Moreover, the walls blocked mobility and the flow of traffic, and prevented cities from growing spatially to meet the needs of population increase and economic development. Based on the modernist ideology of rationality, the republican government demolished city walls in many Chinese cities. Opponents of modern city planning, however, emphasized the role monumental architecture such as the walls and gates had played in Chinese culture. They argued that the walls and gates served to anchor the collective memory of Chinese cityscape, reminding residents and visitors alike of the enduring power of culture and tradition. They were skeptical of the modernist government's effort to replace traditional monumental legacy with monuments that intentionally express a 'modern' society. Some even evoked the traditional ideas of *fengshui* to resist the modernists' attempts to introduce modern technology to reconfigure the urban order. In short, they opposed modern reconstruction not as defendants of the *ancien regime*, but as advocates of cultural sciences and in the secular effort to preserve and draw inspiration from the one heritage that was uniquely their own.

3. *Socialist Urban Planning*

The second phase of modern Chinese urban planning covers roughly the first 30 years of the history of the People's Republic of China. Shortly after taking over power in China in 1949, the Chinese Communists embarked on a course of urban reconstruction based on a socialist agenda. Swayed by radicalism and the utopian revolutionary ideology of Mao Zedong, Soviet-style planning and design dominated Chinese cities. During this period, Chinese urban planning focused on industrial production and socialist reconstruction. Many Chinese cities were transformed into industrial centers, and capitalist consumer cities like Shanghai were criticized as being exploitative and parasitic (Kirkby 1985). The government cleaned out old teahouses and pleasure zones, and lined major streets with official monuments, government offices, standardized state-run stores, and utilitarian apartment buildings. Mao envisioned Beijing to be a symbol of the Chinese socialist state, a role to be enforced with the buildings of Soviet-style public structures. In a symbolic break with the past, Tiananmen Square replaced the former embodiment of imperial power—the Forbidden City—to become the new political center of the nation. The socialist monuments of this period tossed together ingredients of Soviet, classical Chinese, and modernist architecture to create a new socialist identity for revolutionary China.

Ideas of cultural conservation were not completely ignored during this period. Liang Sicheng represented a group of architectural experts and city planners who became cultural advocates during the radical years of Maoism. Liang himself was an architectural historian who had been trained at the University of Pennsylvania in the 1920s. As early as 1950, he drafted a plan to keep all of old Beijing enclosed in city walls, turning it into a great museum and cultural center, and to build a new, modern city next to it. He insisted that the large structures of Beijing's street grid, its system of enclosures and its axial symmetry—all landmarks in the world's history of urban planning—must all be preserved to maintain the historical and cultural identity of Beijing. As for the city walls, he had an idea of lining the route atop the walls with flowers, benches,

transforming the ring of walls into an elevated park. This plan, he believed, would allow Beijing to leapfrog through time while avoiding all the mistakes Western cities had made: a modernization that would contain the explosive effects of rapid development and keep an ancient masterpiece for aesthetic appreciation (Fairbank 1994). Liang's proposal bore a striking parallel to what Eric Hobsbawm calls 'the invention of tradition' (Hobsbawm and Ranger 1983). Sensitive to both the homogenizing force of modernity and the deep-rooted sophistication of Chinese culture, Liang sought to restore and recreate an older urban fabric and rehabilitate it to new uses and attempted to repackage the old infrastructure of urban space for new style recreation and entertainment. To him, tradition and modernity could go together, and modern transformation and cultural conservation caused no apparent conflict. However, Liang's alternative planning vision was ignored by the government in favor of demolition and other radical urban planning principles.

4. *Contemporary Urban Planning*

In China today, people are no longer concerned with the revolutionary and political ideology of Maoist urban planning, but become preoccupied with modernization along Western lines. While urban planning is still largely controlled by the government what is increasingly evident is the participation of global, profit-driven, capitalist and market forces from Hong Kong, Taiwan, and the Western countries. Modernism returned with a vengeance. Global capitalistic forces are competing with localized cultural traditions, giving rise to an identity crisis in contemporary Chinese cities. Many old cities are being quickly stripped of their character as ancient buildings are torn down for office buildings, apartment blocks, freeways, and shopping centers, edifices which are seen by city officials and real estate developers as a symbol of modernization but which have alarmed culturally sensitive citizens.

Conflict between global and local cultures and the problems of modern economic development vis-à-vis cultural conservation are at the heart of the debate over the future of Chinese urban planning. In the feverish race to transform Chinese cities into world-class metropolises, many urban planners are also struggling to come to terms with China's rich urban heritage. The major urban planning question has become how to excel in the global community without losing China's national identity. Some began to lament the loss of the old urban fabric of walls and gates, alleyways, and courtyard-style residential houses, and especially the close-knit community atmosphere and neighborly connectedness. There is growing complexity in Chinese popular attitudes toward cultural heritage and local identity. Many people realize that in the face of ever-stronger global forces for homogenization through technological change, increased mobility, and improved communication, a primary goal of Chinese urban planning policy must be to retain culturally essential features of China's urban past and to ensure the continuity of Chinese history and culture.

Urban Planning: Competitions and Exhibitions

Competitions and exhibitions are means of stimulating the production and exchange of ideas and techniques in urban planning. Competitions aim to elicit ideas

from various people on a defined topic, exhibitions permit the comparison of projects and realizations from several locations. Both are aimed at enhancing good design and prompting public discussion and awareness, possibly consensus.

1. Competitions

Competition is one of several options available for the choice of an urban plan and a planner. Others include: direct commissioning, holding of workshops or planning seminars, the appointment of an accompanying committee or a consultant. Competitions are good ways to find solutions, if the program and the constraints are clearly defined, so that the participants can make meaningful statements within a limited period of time. Competitions allow a selection from a variety of proposals, even if no project is realized as such, and may help to stimulate further insights into the planning problem and ideas for realization.

Competitions can take several forms. They can be open to the general public or to members of the relevant professional institute, or they can be restricted to a limited number of participants, appointed by the organizer or chosen after an application process. These procedures may also follow upon each other. Restricted competitions, which include a payment for all participants, have been criticized for being limited to famous names or big companies. Anonymous, open competitions allow unknown and young planners to participate and present their ideas, and may result in new concepts. This can, however, bring about large numbers of participants, or lead to the choice of an author who lacks the means and experience to realize the proposal. As only prizewinners are paid, much unpaid work is done, particularly in the case of complex urban competitions, which therefore are sometimes considered to be unproductive. However, even unbuilt contributions are part of the architectural culture and history of a city and a period. In some cases unrealized competition projects have had a stronger impact on planning history and theory than built ones.

Competitions are often seen as particularly democratic, and are used in democratic societies where the governments have to justify their expenses and choices and where they try to include citizens in the decision-making process. The democratic character of a competition depends primarily on whether its preparation and the ensuing realization are part of a public and open discussion. Competitions can also be used in a dictatorial situation. Thus, the outcome of a competition depends on the participants and is strongly influenced by the aims and quality of the competition brief and the organizers. Their character—public institutions, private sponsors, professional organizations, architectural schools or magazines—and concrete power over the competition site determine whether the competition leads to realization or is limited to creating ideas, whether it is supposed to adapt to the existing context or provide a long-term vision for the future.

1.1 History of Major Large-scale Competitions

Architectural competitions have been held for many centuries, particularly for the design of religious and public buildings. City planning competitions are more recent. Early examples are the international idea competitions for urban embellishment opened by the Russian empress Catherine II for the city of Saint Petersburg (1763) or the contests for the Place Louis XV (today's Place de la Concorde) in Paris (1748). Urban planning was usually seen as a part of architecture, and the competitions held by professional and educational architectural institutes included urban design projects, such as for a 'Seaside resort for a sovereign on the Mediterranean coast' a topic at the Paris Ecole des Beaux Arts in 1872. Competitions were used at educational institutes for grading and awards such as the 'Rome prize' which included travel and a several year stay in Rome. These projects were not made for realization, but nevertheless reflected the design spirit of their time. The 'Rome prize' winners were assured an honored part in public building projects on their return.

The history of urban competitions reflects the development of the planning profession: Following industrialization and rapid city growth, early competitions tackled large areas on the outskirts or even the whole city. With the growing scale and complexity of cities, their compounds became the main topic of later competitions. A comprehensive and international analysis of urban planning competitions is still lacking and the number of competitions is too large to be analyzed here: analysis of the late 1920s, for example, shows between 15 and 30 urban planning competitions annually in Germany alone (Becker 1992). Only some major examples can be presented here. In spite of the large number of competitions held over the last century, major transformations and extensions of cities, including the work of Eugène Haussmann in Paris (1850s–70s) or the extension of Berlin under James Hobrecht (1862), were and are based on direct commissions or procedures other than competitions.

One of the most interesting examples of nineteenth-century urban planning, the transformation of the Vienna fortification zone, did result from an international urban competition in 1857/1858 (Albers 1997, Hall 1997); it requested ideas for traffic planning, plot division and urban beauty for a zone both sides of which were already built. None of the prize-winning or recommended designs was realized, but they were taken as references for a basic urban plan—a pro-

cedure often used in urban competitions which is not faithful to the original ideas. In 1892, Vienna was once again the site for a major urban competition that, like the competition for Munich in the same year, was aimed at obtaining ideas for a master plan of the whole city. As such, they can be seen as a milestone in urban planning. What is more, both competitions showed the impact of major urban planning theoreticians of that time, such as Reinhard Baumeister, Camillo Sitte, and Josef Stübben.

Another landmark in urban planning history was the Berlin competition of 1908/1910. Initiated by architects' associations and organized by several independent municipalities, it concerned a large urbanized area of more than 5 million inhabitants. Although this competition was not followed by immediate realization, it helped clarify major problems and led to several competitions for city parts. Its results were used for promoting general awareness of urban problems and educating the public through a large urban planning exhibition which also featured foreign examples. Through exhibitions, publications in magazines and private brochures the competition formula and its results were disseminated and became major references, stimulating other large-scale competitions in major and minor European cities in the late nineteenth and early twentieth century including Göteborg, Strasbourg, Paris, Barcelona, and Zagreb (Albers 1997).

The early European competitions concentrated on remodeling and extending existing cities. Meanwhile, new nations around the world had a strong desire for cultural representation. This led to the planning and construction of new capital cities. Competitions held for Canberra in 1911/1912 or for Brasilia in 1956/1957 were means to obtain a state-of-the-art urban plan ready to impress the nation and foreign countries. The competitions gave the authorities the opportunity to consult with leading planners and, as in the case of Canberra, eventually appoint a foreigner for the realization of the plan, albeit over a long period. For the evaluation of competitions it is particularly interesting to analyze the process from the competition design to the actual city.

In Europe, competitions for a completely new city are rare, although some proposals have been put forward following private initiatives. The few exceptions were characterized by a utopian touch from the very beginning. The search for a capital of Europe, in particular, led to several city competitions and projects for new cities. Due to the lack of large tracts of land, and the dominance of nationalist thought, most proposals were located close to existing cities. Thus, they could profit from existing infrastructures, but were not free to develop an independent identity. These competitions were, generally, flawed by the lack of political and financial power, as well as by the unclear future of the new European communities. What is more, the largely academic design concepts reflect the lack of conviction of the organizers, they include few innovative solutions (Hein 1996).

Reconstruction after World War II stimulated urban competitions of various scales in several countries, particularly Germany, leading to intense and often controversial discussions. The most political of the large-scale competitions was probably the international urban idea competition 'capital Berlin' of 1957/58 (Hein 1991). Organized by the governments of West Germany and West Berlin it covered an area which was largely under East German administration. A preparatory committee including practitioners from major Western cities outlined a plan for inner-city development that guided urban development for the Western part for many years and served as the basis for the competition. The competition itself was a political statement to the world that West Germany had developed into a democratic and modest nation, and also that the West German government was not abandoning West Berlin. The East German government reacted to this provocation with a competition of its own for the city center, another extension of the Cold War into planning.

1.2 Competitions for Limited Areas and Special Functions

Projecting an entire city area brings with it numerous difficulties and demands extensive knowledge that cannot be expected from competition participants. The twentieth century therefore concentrated on public and private competitions for limited areas and clearly defined tasks such as campuses, government centers, commercial or recreational centers or urban parks. Examples can be found worldwide and include the privately sponsored competition for the University of California (1897/1899), the city-held competitions for educational districts in Tokyo (1940s), the design competitions for civic centers in the USA, or the urban design competition for the government districts in the Spreebogen and Spreeinsel areas in Berlin (1993/94), as well as the competitions for the Volkspark in Hamburg (1906) or the Peace Park in Hiroshima (1949) (Zwuch 1993, 1994). Recent attempts at recreating a multifunctional city have led to competitions combining office, commercial and housing functions as in the case of the Potsdamer Platz or Alexanderplatz competitions in Berlin (1991/1993).

The largest number of competitions, however, has probably been organized for residential layouts. Examples can be found in various countries; examples from Germany are given here for illustration. The country has been a major organizer of competitions over the last century and their topics and results reflect the main concerns of housing over this period. Thus, early competitions focused on small-city and company housing such as for the Krupp colony Altenhof in Essen (1892). Metropolitan housing, economic land

use and the creation of a rational block structure became central topics in the competitions of 1911 for Tempelhofer Feld and Schöneberg South which followed on the Greater Berlin competition of 1910. Convinced that competitions led to the best solutions for metropolitan housing, the city of Hamburg promoted several competitions for social housing areas through the 1920s. The search for an economical solution for residential areas found its climax in the competitions for the experimental district Berlin-Haselhorst (1928) and the Dammerstock-Siedlung in Karlsruhe (1929), both of which featured strict parallel housing blocks. Competitions for new towns dominated the 1950s and 1960s, while the return of housing functions to the city centers has become a major topic since the 1980s.

2. *Exhibitions*

Exhibitions are an important means to present urban planning theories and concepts to the specialists and the general public. They can follow on competitions or accompany conferences but can also be events on their own. In the early years of the profession, topics of urban planning were addressed by various specialists, ranging from the hygienists, to architects and the garden city organizations. These issues were also featured in exhibitions accompanying major conferences. Two forms of exhibitions can be distinguished: the exhibition of projects and plans, or the realization of an urban district.

Major exhibitions on urban planning have been held since the turn of the century, reflecting the ongoing debate. In 1903, Dresden was the site of the first German Municipal Exhibition, presenting the achievements in engineering and urban planning of several German cities. In 1911, an exhibition on hygiene was held in the same city, which included a large display of urban planning. Other exhibitions were held in parallel with congresses of the International Garden City and Town Planning Association or with international architectural congresses, such as that of London in 1906 which displayed works of major planners including Raymond Unwin, Josef Stübben, Charles Buls, and Eugène Hénard.

Key events in urban planning history were the exhibitions held in Berlin and London in 1910, which featured projects from numerous countries. They aimed to transmit political, cultural and esthetic statements. The London exhibition was held in parallel with an international conference on town planning which had an impact as far away as Japan. This effect was further promoted by major publications by Werner Hegemann based on the exhibitions of Berlin (1910), Düsseldorf (1912), and Göteborg (1923) (Hegemann 1913, 1925). The interest in urban planning at that time is revealed by the fact that three major urban planning exhibitions were held in 1913 alone: in Nancy, Ghent and New York. Others followed, often inspired by local planning problems as was the case for the 'Coventry of Tomorrow' exhibition in 1939 or the reconstruction exhibitions 'Berlin Morgen' of 1946.

Planning exhibitions today fall into two major categories. They can have practical tasks, such as the public presentation of concrete proposals. As such, they are part of the planning process of many countries which aim at promoting democratic participation. They can also be primarily cultural events, displaying the history, present or future of planning. These exhibitions have increased over the last decades together with the proliferation of unbuildable projects and the creation of architectural archives and museums. These institutions' exhibitions present historic, present and future planning, and are instruments for the promotion of particular concepts or styles. They may even intervene in planning as was the case with the 'Berlin Morgen' exhibition in Frankfurt am Main in 1991 where proposals were presented that later reappeared as competition entries (Lampugnani and Mönninger 1991).

Exhibitions can also take built form, provisional or permanent. Built exhibitions are a means to try out visions and promote urban concepts. Thus, the American world fairs in Chicago (1893) or in St. Louis (1904) were manifestations of City Beautiful concepts and helped to promote the new style. Several international building exhibitions were held, the most famous of them in Germany, where each epoch was represented through its own exhibition on the function and form of residential design. They include such diverse examples as the artists' colony at Mathildenhöhe near Darmstadt (1901), modernist projects such as the Dammerstock mentioned above or 'traditionalist' examples illustrated by the Stuttgart-Kochenhof Siedlung (1933). Building exhibitions with an urban concept can be found also after World War II. Well-known examples are the reconstruction of an inner-city district as a high-rise housing area, the Hansaviertel of the Interbau (1957), the International Building Exhibition (IBA) in Berlin of the 1980s, which aimed at a critical reconstruction of the city (Faskel and Barth 1988), or the International Building Exhibition Emscher-Park in the Ruhr region (1990s).

3. *A Cultural Phenomenon*

Competitions and exhibitions have furthered the development of modern planning through the promotion of exchange, particularly between European countries and North America at a time when there were no examples to follow. They were helpful tools in the search for the best functional and esthetic solution.

There are, however, cultural differences in the use of these instruments. Germany, for example, has a long tradition of competitions and exhibitions, while other countries with different planning traditions and aims, Japan, for example, has realized only a limited number of competitions with limited impact. The country favors instead the invitation of foreign experts, study trips, the presentation of foreign projects in magazines or book translations for the introduction of foreign ideas.

Urban Planning: Growth Management

'Growth management' aims to influence the location, magnitude, and timing of urban development through land use and capital facility planning, and development permitting. Unlike conventional planning whereby land is designated for particular land uses and facilities are extended when market demand dictates, growth management is a more conscious effort to shape development patterns during discrete intervals of time based on explicit urban form objectives.

1. Historical Context

The earliest growth management effort might have been recorded in the Old Testament:

> *The Lord said to Moses … Command the people of Israel, that they give to the Levites … cities to dwell in; and pasture lands round about the cities … . The pasture lands of the cities … shall reach from the wall of the city outward a thousand cubits all around* (*Numbers* 35: 1–4)

This command is clearly aimed at containing urban development within a boundary so that farming can occur around it. Britain's 1947 Planning Act extended this concept nationally by nationalizing greenbelt land combined and directing local government to contain urban development within stoplines.

American experience is less draconian. The earliest growth management effort appears to have came out of Milford, Connecticut in the early 1950s, which mapped high and low priority development areas. Development in low priority areas needed to demonstrate that adequate public facilities existed to serve it without prematurely directing development away from existing urban areas. Moreover, approved projects could only be constructed in increments of 20 percent annually.

More famous is the plan devised by Ramapo township, New York, in the mid-1960s. It provided for township buildout over an 18-year period. A capital improvements program helped to pace buildout during that period. Developers had to demonstrate that their project was consistent with the buildout plan (through a point system) and, if not, either wait for infrastructure to reach their site or install it themselves at their own cost.

A version of growth management, called 'growth control,' came from Petaluma, California, in the early 1970s which capped development at 500 dwelling units annually. The cap was suballocated to different housing types to assure reasonable diversity of housing opportunities.

2. Statewide Efforts

Only a few American states engage in growth management on a statewide level, although that number is rising.

Hawaii, the nation's newest state, has the nation's oldest statewide growth management and for good reason: it is composed of islands for which there are very few alternatives to sharing development needs with agricultural and environmental needs. Through efforts by a state planning agency pursuant to the Hawaiian Land-Use Law of 1961, all land on major islands is designated for urban, agriculture, low density rural, and conservation land uses. Counties (individual islands) have very little say about those allocations.

The state with the longest history of statewide growth management among the contiguous 48 states is Oregon. The Land Conservation and Development Act of 1973 established a state commission and an administrative department. The commission's primary role is articulating statewide planning goals (the original 15 goals have grown to 20) and deciding whether locally prepared land use and facility plans meet them. Like Hawaii, land in the state is designated essentially for urban, agriculture/forestry, low density rural, and conservation uses. Unlike Hawaii, local governments have a significant say in how those allocations are made. Communities devising plans that provide more land for urban and low density rural development than needed are instructed to eliminate excess supply or face suspension of development permitting authority. Today, Oregon's land use pattern is a system of urban centers contained within urban growth boundaries (UGBs) surrounded by open space.

In the early 1990s, Washington state adopted its Growth Management Act which has many of the same features as Oregon, including UGBs and open space preservation. In the late 1990s, Tennessee adopted similar legislation.

Florida's growth management efforts, stemming from the 1970s and revamped in the mid-1980s, are relatively weak in containing urban development or preserving open space from low density rural development. Its 'concurrency' provisions, however, which limits new development to only those areas where adequate public facilities exist or are planned, appears to have shifted development away from many open spaces to infill and redevelopment sites.

Maryland's 'smart-growth' initiative, launched in the late 1990s, provides state infrastructure funds for only those projects that redirect development to infill and redevelopment sites and away from open spaces.

3. Regional Efforts

There are very few regional growth management efforts, mostly because they require state-level legislation and commitment among competing local governments to cooperate. The most notable regional growth management effort is that of the Twin Cities Metropolitan Council, coordinating planning, infrastructure investment, and development permitting among the 187 municipalities and seven counties composing the Minneapolis–St. Paul metropolitan area. The Council works to contain urban growth within 10-year urban service limits that are adjusted about every 5 years. The Council was formed in 1967 but not until the late 1990s did it have the authority to manage the region's water, sewer, and transportation operations.

4. Local Efforts

Local government growth management efforts are quite numerous. Early efforts include Milford, Ramapo, and Petaluma reviewed above. Other notable areas include Sacramento, California, Boulder, Colorado, Sarasota, Florida, and Lincoln, Nebraska, all of which employ UGBs with open space preservation. It is possible that every state has at least one example of a local municipal or county growth management program. The primary limitation of all such programs is that unless neighboring jurisdictions also engage in growth management, there is confusion on long-term development and investment expectations.

5. Primary Elements

Growth management is composed of six elements: (a) overall form; (b) growth guidance; (c) infrastructure provision; (d) protecting open spaces; (e) enhancing community life; and (f) coordination between governments.

5.1 Overall Form

A common feature of growth management programs is the containment of urban development within American-style urban growth boundaries, British-style development stoplines, or more flexible urban service limits. Collectively they can be called 'urban containment boundaries' or UCBs. UCBs are complemented by urban facility service area plans that control

the timing of utility extensions and infrastructure improvements. Land within the UCB may be subdivided into different categories for the phasing of services, depending on development suitability, proximity to existing public facilities, contiguity with existing development, and other factors. Sufficient land must be included within a UCB to accommodate market demand within the planning horizon. If too little land is included, land prices may increase beyond the ability of the market to accommodate development needs. Too much land defeats the purposes of encouraging compact, contiguous development and usually results in excessive and premature capital outlays for public services.

5.2 Growth Guidance

Growth guidance relates to the timing, phasing, and dimensioning of development within UCBs. Within UCBs may be intermediate containment boundaries (ICBs) which, as their name suggests, are short-term development boundaries within the long-term UCB. In contrast, outside UCBs, there may be urban development reserves (UDRs) where future urban development will be targeted once the UCB is filled in.

Growth management usually results in 'upzoning' land within UCBs and 'downzoning' land outside. The reason is simple. Land intended for urban development should accommodate more intense activity and land not intended for urban development should be prevented from urban development.

The 'upzoning/downzoning' requirement permeates through other land use policies. For example, conventional planning uses transitional zoning to buffer land-use activities from each other and to facilitate a concentric-ring urban form wherein uses farther away are at lower densities than closer in. Transitional zoning is not generally compatible with growth management, however. The result of transitional zoning is that low- and very-low-density land uses expand into rural areas and into resource lands, thereby perpetuating urban sprawl and undermining the long-term economic viability of resource production. Instead, growth management programs use nontransitional zoning strategies which, among other things (a) establish moderate to high-density and -intensity land-use categories throughout much of the urban area, (b) facilitate nodal and corridor development especially along transit routes and major multimodal intersections that are themselves surrounded by moderate to high-density-zoning, (c) reduce the scale of low and very low urban densities within urban areas, (d) eliminate low- and very-low-density development in areas that are predominantly resource lands or other environmentally sensitive lands, and (e) restrict the size and location of low- and very-low-density development outside urban containment boundaries and away from resource or environmentally sensitive lands.

Growth management also challenges conventional 'Euclidian' zoning—so called after the US Supreme Court's decision upholding zoning of the sort challenged in *City of Euclid, Ohio, vs. Ambler Realty Company*. Euclidian zoning is a pyramid of allowable land uses. At the top is residential land use; land zoned for residential is restricted to residential uses. Commercial zoning allows commercial and residential uses. Industrial zoning allows industrial, commercial, and residential land uses. Agricultural zoning allows all land uses. The problem is that many land uses allowed in some zones are incompatible with the primary purpose of that zone, such as a residential development in an industrial zone. The trend is now towards exclusive use zoning of open spaces and inclusionary zoning allowing the mixing of land uses in urban areas. Growth management thus reshapes Euclidian zoning.

Growth management also aims to eliminate exclusivity. Many communities use zoning strategies to exclude certain classes of people, especially those occupying low-income housing. A typical strategy is to zone the community for large lot sizes and large minimum floor areas. Low-income households will, thus, be unable to afford to live in the community. Growth management recognizes the need to provide housing to all income levels. Many growth management communities have 'inclusionary zoning' policies that require large-scale projects have housing opportunities affordable to a wide range of households.

Finally, it is one thing to designate land for moderate to high density and give developers the impression that they have flexibility in meeting market demands but it is quite another to actually allow such densities. Unwary developers who propose high-density developments can get stalled in decision-making, often because existing residents oppose such developments. Housing density usually is reduced but this defeats the purpose of growth management. The solution is 'minimum density zoning.' For example, if the maximum residential density allowed is 8.0 units per acre of land, the minimum may be 5.0 and the community average target for this category of zoning may be 6.5 units.

5.3 Infrastructure Provision

Growth management cannot succeed without infrastructure planning and financing that makes urban development more attractive than development in the countryside. On the other hand, development must not exceed the ability of existing infrastructure to accommodate it. 'Adequate public facilities' standards assure that, in addition to meeting applicable zoning and subdivision standards, facilities and services are able to serve it. 'Concurrency', whereby facilities needed to serve new development are in place or committed concurrent with the impacts of new development, is another version of the same principle.

Under growth management, infrastructure is a shared responsibility between government and developers. One form of shared responsibility is 'development exactions' in which the developer provides a certain range of infrastructure at their cost. Infrastructure within the development is normally the developer's responsibility but the responsibility for financing offsite roads, water, sewer, schools, parks, and other facilities is complex.

'Special taxing or assessment districts' are one way in which onsite and offsite infrastructure costs can be absorbed via long-term, below-market interest rates financed by new development. 'Impact fees,' which are one-time assessments on new development to pay for new or expanded facilities needed to serve new development, help cover a share of the offsite costs.

5.4 *Protecting Open Spaces*

What happens outside UCBs? Growth management is not effective unless it preserves open spaces and manages rural density development. Some states, such as Hawaii and Oregon, are very aggressive in preventing any development of open spaces. In those states, 'exclusive farm/forest use' regulations require owners of such land to manage it for farming and forestry if they wish to live on it.

Economic mechanisms can be used to encourage development inside UCBs and prevent development outside. 'Purchase of development right' programs involve public acquisition of the development rights of open spaces. 'Transfer of development right' programs involve developers acquiring development rights from open space owners in rural areas for transfer to areas within UCBs at higher density.

Not all land outside UCBs is appropriate for farming, forestry, or other open space uses. Indeed, there is some demand for rural living that if not accommodated would result in urban households acquiring farms and then maintaining only the yard they wish, typically one-quarter to one-half acre. 'Clustered' development in rural areas is one solution. For example, a 100-acre farm may be subdivided into 10 parcels of which nine are one-acre and one is 91 acres, which in many parts of the country is sufficiently large to accommodate reasonable commercial farming operations.

5.5 *Enhancing Community Life*

Growth management changes existing neighborhoods. Oddly, many neighborhoods view growth management anathema to their quality of life, especially if infill and redevelopment activities locate there. 'Design review processes' help assure that new development in stable neighborhoods enhances neighborhood character. 'Supplemental housing' such as mother-in-law, over-garage, basement, or attic living units allowed in established neighborhoods improve property values, increase safety (more 'eyes-on-the-street'), make more efficient use of infrastructure, and generally assure neighborhood stability thereby increasing neighborhood vitality.

5.6 *Coordination Between Governments*

Growth management is not effective in isolation. Because a number of governmental units interact with each other at various levels, effective growth management results in all relevant governmental units sharing the same vision for a preferred built and natural environment given the need to accommodate projected development. Cross-acceptance is one way in which this is achieved. Conceptually, cross-acceptance means that all units of government affecting a particular community—including state, regional, local, and special district governments (such as school districts, water districts, fire protection districts and the like)—agree to each other's plans and they all agree to share the vision of the region's future built and natural environment.

6. *Benefits*

For a long time, the benefits of growth management in the United States seemed illusory. Recent studies indicate, however, that growth management of the kind described here reduces tax burdens, reduces air and water pollution, reduces vehicle-miles-traveled per household, increases incomes, and improves quality of life across many measurable dimensions.

7. *Challenges*

Growth management is not without challenges. Growth management policies *per se* do not solve problems associated with rapid growth or urban sprawl. Growth management requires that development be encouraged in urban areas and discouraged in rural areas. This can engender opposition from stable neighborhoods because of potential threats. It also requires patience. The positive effects of growth management take about 20 years to realise. Unless there is political will to sustain growth management efforts, benefits will remain illusory.

Urban Planning: Methods and Technologies

The collection, interpretation, and dissemination of the information needed to improve public and private decision making is one of the major justifications for urban planning. As a result, planning methods and technologies have played a central role in planning practice and education since the profession's inception. This article reviews the evolution of planning methods and techniques, considers the methods and technologies that are most widely used in contemporary planning practice, and speculates on the future of planning methods and technologies.

1. Evolution of Planning Methods and Technologies

Three relatively distinct eras can be traced in the evolution of planning practice, methods and techniques. The first era, 'planning as design,' characterized planning from its inception until the decade of the 1960s. The second, 'planning as applied science,' characterized the profession in the 1960s and 1970s. The third, 'planning as communication and reasoning together,' characterized the profession during the 1980s and 1990s. The following sections examine each of these eras and their corresponding methods and techniques in turn.

1.1 The Early Profession

The planning profession emerged in the USA at the beginning of the twentieth century in response to the unregulated urban growth and inadequate public facilities of the new industrial cities. Guided by a rather naive form of environmental determinism, the early planners assumed a professional responsibility for improving society through changes in the physical environment and protecting an overarching public interest from the presumably self-interested and uninformed actions of elected officials and private citizens. Planners' methods were largely intuitive methods of manual design adapted from the profession's institutional homes in architecture and landscape architecture, taught primarily by planning practitioners in the ubiquitous studio workshop.

By the 1950s these largely intuitive methods had evolved into a standard land use planning approach codified in and F. Stuart Chapin's *Urban Land Use Planning* (1957) and T. J. Kent's *The Urban General Plan* (1964). This model defined planning as the preparation of a formal document laying out a long-term, comprehensive, but general, vision for a community's future physical development, including public and private uses of land and related public facilities. These plans included a summary of existing and emerging conditions and needs, a statement of planning goals, a 20- or 30-year development plan expressed in map form, and policies for implementing the plan. Variations on this general approach are reflected in contemporary land use planning practice (Kaiser and Godschalk 1995).

1.2 The 1960s and 1970s

The planning profession's attention turned in the 1960s from the design of the physical city to new concerns with improving transportation access, reducing urban blight, and improving social and economic conditions on both the urban and regional scales. The dominant perception of the field changed from an image of 'planning as design' to 'planning as an applied science' as new students, faculties, and departments joined the profession from outside the traditional schools of design. An increased emphasis on quantitative methods and social science theory led to the abandonment of the once ubiquitous design studio for new courses in research design, statistics, and quantitative techniques represented by Isard et al.'s

monumental *Methods of Regional Analysis* (1960) and Krueckeberg and Silvers' widely used *Urban Planning Analysis* (1974). Planners' professional role was now seen as delivering unbiased, 'objective,' and politically neutral advice to elected officials and the public and collecting and disseminating more and better information that could inform and improve the policy-making process.

Computers were first used in planning in the 1960s, as part of a general faith in science and technology and the emergence of new academic fields such as operations research, urban economics, and regional science. The most notable early attempts to use computers in planning were the extremely ambitious and highly visible federally-funded efforts to build large-scale metropolitan land use–transportation models and integrated municipal information systems. These efforts were seen as providing the foundations for a new 'science' of planning by helping to understand and guide the urban development process and improve the information base for public and private decision making (Harris 1965, Webber 1965).

Planners' optimistic faith in computer technology was severely tested in the 1970s. The pioneering efforts to develop large-scale urban models and municipal information systems failed spectacularly, largely as a result of their overly ambitious goals, the limitations of available computer equipment, the lack of required data, and an inadequate understanding of the urban development process. Sophisticated analytic tools such as mathematical programming, which were once assumed to provide the foundations for 'scientific planning,' were found to be largely inappropriate for most planning applications which are hard to define or solve, have outcomes that are difficult to predict, and involve considerable judgement (Lee 1973, Brewer 1973, Laudon 1974).

The practical failure of the early computer-based urban models reflected a more fundamental rejection of the 'rational planning' model that was assumed to underlie all attempts to use computers in planning. Planning methods and technologies that were once assumed to be 'objective' and politically neutral were found inevitably to increase the power of administrators and technical experts at the expense of those who lacked the expertise to use them effectively. Information that once appeared to be more accurate, credible, and objective, simply because it has been generated by a computer, was found to reflect fundamental choices in the selection of data, the application of computational procedures, and the distribution of results that helped answer the fundamental political questions of 'who gets what, when, and how' (Wachs 1982). By the decade's end, most planners had no access to—or perceived need for—the expensive, fragile, and hard-to-use mainframe computers of the era and continued to rely on manual computational techniques that had changed little since the 1950s.

1.3 The 1980s and 1990s

Planners' faith in computing technology was reborn in the 1980s with the emergence of microcomputers that made computer-based methods and techniques readily available to planners the world over. By the end of the century, nearly all planning agencies used computers for general-purpose office functions such as processing documents, monitoring budgets, and maintaining records. Many of the larger planning agencies routinely used geographic information systems (GIS) (see Sect. 2.2) for planning management tasks such as processing permits, collecting and maintaining land-related information, and preparing thematic maps. The maturation of municipal GIS and the dramatic growth of the internet allowed planners to access vast quantities of spatially related information that could only have been dreamed of by earlier planners.

Underlying these developments were new images of 'planning as communication and reasoning together.' Planners increasingly realized that planning involves not only the collection and distribution of information but, more importantly, face-to-face communication with colleagues and clients involving other nontraditional types of 'information': stories, advice, and personal experiences. As a result, planners increasingly realized that the *ways* in which they transmit information is often more important than *what* they say.

For example, planning forecasts could be described either as the result of sophisticated computer-based modeling efforts too complex for laymen to understand, or as implementing a few easy-to-understand assumptions. The same analysis techniques and results could be employed in both cases. However, in the first case planners' communications are likely to mystify their audience and exclude nonexperts from the planning process. In the second, they will invite the public to participate by critically examining the assumptions that underlie the forecasts.

The 1990s also witnessed the emergence of new professional models which suggested that planners should develop and guide interactive and ongoing processes of community learning and debate that allow, public officials, stakeholders, and planners to jointly define issues, collect information, and share their ideas, perspectives, and interests. These strategies not only help promote public participation and understanding, increase public support for the proposals that are developed, but often help resolve issues before the formal decision-making processes begin (Innes 1998).

2. Current Planning Methods and Technologies

Before the advent of computers, planning data were available only in voluminous printed volumes and paper maps that were incomplete, inconsistent, and

could only be updated manually. Planning analysis and communication required manually copying the relevant information, laborious and error-prone hand computations, typing text and tables, and drafting maps and graphs.

Today all of this has changed. An almost overwhelming array of data are readily available in digital form from national, regional, and local databases. Planners' computer-based tools allow them to analyze these facts quickly and use them to produce attractive documents, charts, and maps. As a result, it is almost impossible to conceive of planning *without* computers and related advanced information technologies. The following section briefly reviews the most methods and technologies that are most widely used by contemporary planners.

2.1 Spreadsheets

An electronic spreadsheet (or simply a 'spreadsheet') is an electronic version of the accountant's traditional paper spreadsheet, which stores numeric data in two-dimensional tables that display the results of calculations performed on these data. They have been called, with some justification, 'God's gift to planners.' They are easy to learn, forgiving of errors, and provide an intuitively logical structure for examining any quantitative problem that can be formulated as a two-dimensional table. They are easily adaptable, allowing users to copy data and computational formulas easily from one location to another and develop predefined 'spreadsheet models' that for many years provided the most widely used software tools designed specifically for planning applications (see, e.g., Klosterman et al. 1993). And, most importantly, spreadsheets are ideal for examining the 'what if' questions that permeate planning by allowing planners quickly and easily to determine the effects of alternative policy choices and different assumptions about the future.

2.2 Geographic Information Systems

GIS are computer-based systems for capturing, storing, analyzing, and displaying spatially related data. GIS combine: (a) sophisticated mapping capabilities which allow attractive and informative maps to be prepared quickly and easily; (b) highly developed data base management tools for storing, modifying, and manipulating descriptive data describing the features displayed on a map; (d) topological data structures which explicitly describe the spatial relationships between map features; and (e) extensive data describing anything that can be displayed on a map.

GIS has proven extremely useful for a full range of planning applications such as:

(a) displaying spatially related information;

(b) maintaining land-based inventories and organizing spatial data previously maintained by different organizations;

(c) identifying the best (or worst site) for locating facilities and activities;

(d) conducting spatial analysis tasks such as defining buffers around selected map features; and

(e) dealing with network-related transportation and infrastructure issues.

2.3 Planning Support Systems (PSS)

The popularity of GIS is due largely to its ability to serve as a 'chameleon technology' which provides basic functions that are extremely useful for a wide range of public- and private-sector applications. However, this general applicability comes at the expense of the particular needs of specialized fields such as planning. In response to these limitations, at the end of the twentieth century, planners began to develop PSS that adapted the concept of decision support systems to planning. PSS combined (a) an array of spatial and nonspatial data with (b) a broad range of models and methods for determining the implications of alternative policy choices; and (c) visualization tools for displaying model results in easily understandable formats, ideally over the Internet. More importantly, PSS provided interactive and participatory processes for group interaction and decision making for dealing with non-routine and poorly structured decisions (Brail and Klosterman 2001).

2.4 Visualization and Multimedia Systems

Planners use not only printed reports, charts, and maps to describe and understand neighborhoods, cities, and regions, and relate their descriptions, analyses, and plans to others. They also use computer-based visualization and multimedia systems to combine these traditional types of information with aerial and eye-level photographs and video and audio clips to provide a more comprehensive understanding of an area and alternative plans for its future.

For example, all types of information—statistical, textual, mapped, audio, video, and computer-generated—on a vacant industrial site and alternative proposals for developing it could be compiled in digital form and made available for face-to-face group meetings or 'virtual' meetings held over the web. These different types of information can help provide the foundation for collaborative processes of collective design by allowing meeting participants to explore current and past conditions, review issues and concerns raised by community residents, and jointly explore alternative development possibilities and their impacts. Computer-aided visualization can also help

promote community participation by rendering information more understandable, credible, and usable to different segments of the public, particularly to those who have not had experience with more traditional forms of information (Shiffer 1992).

2.5 The Internet and the Worldwide Web

The internet and the worldwide web (or 'web') provide a 'network of networks' that connects millions of computer users around the world into a seamless web of electronic communication and information dissemination. The internet has been extremely useful by providing planners and the public with 'anytime, anyplace' access to large databases such as the entire contents of the national census, local property information, and interactive audio and video displays. It also allows plans and proposals—along with their supporting documents, information, and analytical models—to be distributed at very little cost, allowing people with different skills, viewpoints, and objectives to contribute to the collective decision-making process, independent of time and/or place.

3. Future of Planning Methods and Technologies

Planning methods and technologies have changed dramatically, due largely to the tremendous advances in information technology that occurred during the 1980s and 1990s. Future technological advances promise to be even more dramatic, making it extremely difficult to forecast what the future will hold. However, some trends are relatively clear. Computers and related advanced information technologies will continue to get faster, more powerful, cheaper, and easier to use. Nearly universal, high-speed access to the internet will allow planners to retrieve, analyze, and distribute vast quantities of spatially referenced information quickly and easily. Planners' software tools for processing and analyzing all types of information—numerical, textual, graphic, audio, and video—and for conveying it to others in readily understandable ways, will become increasingly powerful, available, and easy to use.

The effects that these advances will have on planning practice are much less clear. The increased availability of spatially referenced information, improved data dissemination and visualization technologies, and the ability to conduct meetings unconstrained by location or time, will facilitate increased public access to government information. Continually improving technology and the increased sophistication of planners and the public they serve will allow computer-based planning, analysis, and evaluation models to take their place at the center of planning practice. Together they will provide the foundations for new modes of planning which more directly involve the public in the fundamental public policy choices that help shape their communities. Only time and professional practice will tell whether this potential is achieved.

Urban Planning (Western), History of

The evolution of urban planning is inextricably linked with the processes of modernization and the nature of modernity. The emergence of planning was the most

literal way in which the role of government expanded in response to the problems of accelerated urbanization from the end of the nineteenth century. The agenda and scope of urban planning have expanded and changed dramatically. At the start of the twenty-first century, urban planning is a multifaceted set of policy and administrative processes which resists easy categorization. Its forms have ebbed and flowed in concert with myriad social crises, economic changes, environmental and demographic pressures, political opportunism, and technological innovation, notably new forms of transportation and communication.

While an early focus on reforming the physical framework for urban life has braided in various social, economic, and legalistic directions, some common threads have characterized the mainstream history of planning theory and practice. These include a pervasive ideology of holism and the benefit of the 'birds eye view' in directing urban development; a practical commitment to reconciling the diverse interests of stakeholder groups; an emphasis on order, scientific analysis, and rationality in public policy decision making; belief in the power of environmental improvement to invoke social change; and an ongoing faith in the potency of enlightened state intervention to secure the 'public interest' in the face of market failure.

1. *Antecedents and Beginnings*

For such a quintessential twentieth-century activity, urban planning has a remarkably long history. But this premodern planning invariably meant a rudimentary form of spatial layout or architectural set-pieces disengaged from the broader policy vectors of the state. Indeed, planning was all too frequently coopted as a mere technical device for the imposition of authoritarian will. Planning as civic design stretches back to antiquity—to ancient Egypt, Greece, and Rome—with the organization of urban spaces manipulated to reflect the dominant political and social order. This thread continues through the grand public squares and piazzas of the renaissance city and into the planning templates for imperial expansion, notably the Vitruvian-inspired Spanish Laws of the Indies of the sixteenth century.

Planned towns were centers for government, displays of autocratic power, military footholds, and central places for land settlement schemes. Rectilinear, gridiron or chessboard street plans were the most time-honored morphology, but by the start of the nineteenth century these were studded with open spaces and enveloped by distinctive parkland belts. Back to antiquity, ideal cities assumed a variety of alternative geometries. Radial plans would decisively influence the first generation of early modern planners. Dating from the beginning of the eighteenth century, Karlsruhe in Germany became an enduring icon with its rigidly-ordered street pattern fanning out from a central palace.

A more modern urban planning emerged in the late nineteenth century to address challenges unleashed by industrial urbanization. Existing narrowly focused administrative procedures and primitive building regulations were ill-equipped to address unprecedented rates of urban population growth, new forms of economic enterprise, and accompanying housing demands and environmental pollution, a new geography of accessibility producing a chaotic competition for urban space, and a transition toward new social structures.

An amazing array of modes of thought and practical innovations was tapped to help shape the new discourse of planning. At the theoretical end of the spectrum, for example, a nexus was forged between a longer tradition of social and economic utopian thought and the notion of better cities through classic works like James Silk Buckingham's *National Evils and Practical Remedies* (1849) and Edward Bellamy's *Looking Backward* (1887). Other thinkers, like the influential anarchist Peter Kropotkin, looked toward a more decentralized society aligning village life with new modes of production. The most substantial experiments in industrial decentralization were more socially conservative. These were the planned industrial villages expressing an emergent form of welfare capitalism geared to educating and disciplining a productive labor force. What Walter Creese in *The Search for Environment*(Yale University Press, 1966) called the 'Bradford–Halifax' School of model village builders in the English Midlands developed into full-blown community building in places like Bournville, Port Sunlight and George Pullman's eponymous suburb near Chicago. More romantic were planned low-density suburbs for the elite (also fleeing the city) such as Riverside (1869) near Chicago.

More utilitarian issues consumed reformers within the cities proper, as the management of established infrastructure (transport, water supply, sewerage) showed the strain. Poor housing conditions in the form of high density slum and tenement dwellings became a major concern. Exposes by reformers like Jacob Riis in New York City in *How the Other Half Lives*(Scribner's Sons, 1890), shocked middle-class sensibilities. Philanthropic model lodging houses and stricter regulations over space standards for rooms, dwellings, allotments, and, in turn, streets ensued. Provision of parks and open spaces was another preoccupation. Utilizing the organic metaphor so prevalent in early planning propaganda, parks were the 'lungs of the city' and needed to be secured in advance of development. Citizens improvement associations, the precursor to civic art and 'tidy towns' movements, provided a 'bottom up' chorus of concern. A major theme through all of this was the need to secure higher standards of public health and hygiene,

a crusade which extended to cognate missions of social, moral and cultural cleansing.

The crucial intellectual breakthrough made simultaneously around the Western world in the 1880s and 1890s was a recognition of the limitations of piecemeal improvement, the interconnectedness of urban life, and the necessity for more coordinated intervention to avoid the undermining of the social order through outbreaks of disease, community dissent, and loss of economic competitiveness. The coining of the terms 'town' and 'city planning' reflected the emergence of the new approach.

Synthesizing ideas then in the air, the basic precepts of planning were expressed through a rich palette of modernist thought. An American contribution was the park system, the concept of interlinked networks of open spaces mixing formal and informal elements and parkways developed by Frederick Law Olmsted Sr., which has given cities like Boston, Denver, and Kansas City a green legacy enjoyed by many generations. The enormously influential garden city idea was similarly associated with an individual, British shorthand reporter Ebenezer Howard, and advanced in his book *To-morrow: A Peaceful Path to Real Reform* (1898), reprinted as *Garden Cities of Tomorrow* (1902). At its most visionary, the manifesto called for clusters of new, self-contained 'slumless, smokeless cities' of limited size on community-owned land as an alternative to the sprawling urban-industrial city. Alternative new urban structures were mooted in the same era. In 1892, Spanish engineer Arturo Soria y Maya invented the idea of the linear city (*La Cuidad Lineal*) which resurfaced in twentieth-century forms such as Edgar Chambless' Roadtown (1910), the ideas of the Soviet deurbanists in the 1930s, and corridor city planning in the 1960–70s.

A string of seminal contributions signposting ways ahead emerged in Europe in the late nineteenth century. Town extension planning and land-use zoning were already accepted municipal practices in Germany before the turn of the century. Important texts were Reinhard Baumeister's *Stadterweiterungen in technischer, baupolizeilicher und wirtschaftlicher Beziehung* (Town Expansions Considered with Respect to Technology Building Code, and Economy, 1876) and Joseph Stubben's *Der Stadtebau* (1890). Baron Haussmann's extraordinary transformation of Paris under the patronage of Napoleon III from a largely medieval city into a modern masterpiece of boulevards, star-points, and strategically located public buildings had begun in the 1870s. A competing aesthetic was that of Viennese architect Camillo Sitte whose *Der Städtebau* (1889) helped codify more artistic, intimate, and historically sensitive techniques for the modern 'art of designing cities and suburbs.'

International exhibitions provided unique opportunities to showcase new urban planning ideas as planned cities in microcosm. The most sensational synthesis was the 1893 World's Columbian Exposition in Chicago. This collaborative integration of grand architecture, landscape design, public art and early amusement park was overseen by local architect Daniel Burnham, who was to emerge as the leading American architect-planner of the early 1900s.

2. *The First Half of the Twentieth Century*

At the turn of the last century, modern planning goals crystallized around recurrent themes of convenience, efficiency, healthfulness, beauty, and order. The actual means to these ends were quite diverse, from totally planned landscapes through selective interventions in the urban fabric to new regulatory frameworks for private development. Certain kinds of planning assumed a cultural distinctiveness. House-and-garden were at the center of British concerns, France was known for its monumentalism, planning advocates looked to Germany for its innovative land management, and to the United States for the business-minded aestheticism of city beautiful thought. The planning movement had become genuinely international. Even a relatively closed Asian country like Japan, in acknowledging the importance of modernization in economic and political advancement, had discovered Western planning ideas through study tours and private visits. The colonial ties of European powers saw many ideas imposed abroad as much as imported.

Major conferences were important agents in the diffusion of knowledge. An arm of Howard's Garden City Association (1899, and renamed the Town and Country Planning Association in the early 1940s) was the International Garden Cities Association (1913) which would evolve into the International Federation for Housing and Town Planning. Information sharing would be damaged by World War I, and never again capture the early excitement, but planning was well established as a global movement with astonishing commonalities of purpose and method in diverse settings. With that came moves to institutionalize the activity as a genuine profession occupying the interstices between the traditional built environment professions of architecture, surveying, and engineering. Urban planning was also developing its own methodology, with the accent on scientific civic surveys, an extension of settlement worker investigations. Scottish polymath Patrick Geddes supplied the requisite mantra: 'survey-analysis-plan.'

In the English-speaking world, several interconnected events in Britain at the end of the first decade of the twentieth century would have reverberations around the world, and especially in the British Empire. In 1909, the first formal town planning course started with establishment of the William Lever-endowed Department of Civic Design at the University of Liverpool, and Raymond Unwin's classic *Town Plan-*

*ning in Practice*appeared. In 1910, the Royal Institute of British Architects organized an international conference which attracted the leading names in world planning, and the first planning legislation was passed in the form of the *Town Planning, Housing etc Act*. The British Parliament was told of the government's intention to realize 'the home healthy, the house beautiful, the town pleasant, the city dignified, and the suburb salubrious.'

The British law was initially restricted to zoning for new development but was later applied comprehensively. Land-use zoning also eventually established itself as the standard form of microregulation in the United States and elsewhere. A popular early mode of zoning was the residential district, a concept which was grafted readily onto existing local government regulations and widely invoked as a tool of social exclusion. A 1916 New York City zoning ordinance introduced novel controls on building height and shape that led to the Manhattan 'wedding cake' skyscraper form. It was not until the historic 1926 US Supreme Court case *Euclid, Ohio vs. Ambler Realty Co*. that the legal validity of planning was finally confirmed in America. British and continental models interconnected planning and zoning, but in the United States city planning commissions and zoning boards could pursue independent agendas.

The early twentieth century is distinguished by some landmark plans which codified modernist planning ideas. The 1901 plan for Washington DC by the Senate Park Commission headed by Daniel Burnham reconfigured Pierre L'Enfant's eighteenth-century plan into a monumental triumph for city beautiful ideas. Many plans for American cities would follow, but the most impressive was the privately sponsored *Plan of Chicago* (1909) by Burnham and Edward Bennett. Artistic in presentation and regional in scope, it set a new standard for comprehensive planning. Edward Lutyens' New Delhi (1912) transplanted grand manner planning to an imperial context. The 1911–12 international competition for the new federal capital of Australia produced a unique survey of early modern planning thought. The winning scheme by Walter Burley and Marion Mahony Griffin, both former associates of Frank Lloyd Wright, was a brilliant landscape synthesis of garden city, city beautiful, and deeper democratic ideals. The most idealistic plan of its day was the footloose *World City for Peace* (1912) by American sculptor Hendrik Anderson and French architect Ernest Hebrard. The multivolume Regional Plan of New York masterminded by Thomas Adams in the late 1920s was the archetypal pragmatic, professional, growth-oriented plan of the interwar period. A celebrated critique by urbanist Lewis Mumford branded the scheme as dinosauric in entrenching rather than curbing trends toward megalopolitan development.

Mumford was deeply influenced by the garden city movement and advocated a more organic, environmentally sensitive variant of regional planning. While stopping short of Howard's dream of a 'better, brighter civilization,' garden city advocates campaigned tirelessly for new towns. Their successes were modest in the overall scheme of things but resulted in impressive showpieces of planning in practice. Two British garden cities were built: Letchworth (1904) designed by Raymond Unwin and Barry Parker, and Welwyn Garden City (1919) by Louis de Soissons. Welwyn was conceived as an overspill satellite community for London, and this concept was readily exported. An early German response was the fringe *grossiedlung* with apartment blocks of social housing. In the United States, echoes of the garden city notion can be read into 1920s speculative sunbelt 'new towns' such as those designed by John Nolen in Florida; the New Deal towns of the late 1930s such as Greenbelt, Maryland sponsored by Rexford Guy Tugwell's Resettlement Administration; and Clarence Stein and Henry Wright's Radburn, New Jersey, with its cul-de-sacs and 'superblocks' representing an experimental 'garden city for the motor age' stifled by the Depression.

The 'garden city' label and concept was translated to many countries: *cite-jardin*, *gartenstadt*, *cuidad jardin*. The most ubiquitous application was to suburban rather than new town settings, becoming more popular and prolific through the prosperous 1920s with privately master-planned elite communities leading the way. These ventures refined further an enduring amalgam of site planning ideas revolving around house-and-garden living, hierarchical street systems, provision of open space and public facilities, and attention to landscaping and streetscape qualities. The low density suburban ideal reached its zenith in Frank Lloyd Wright's *Broadacre City*dream of the early 1930s.

Other expressions of modernism were more vertiginous. New York City's Rockefeller Centre in the 1930s foreshadowed the penchant for large-scale urban redevelopment. The most startling theoretical schemes were those of European theorists like Auguste Perret, Ludwig Hilbersheimer, and most famously the messianic Swiss architect Le Corbusier. Through the 1920s, Le Corbusier worked his way through a succession of urban utopias—'La Ville Contemporaine,' 'City of Three Million Inhabitants,' and the 'La Ville Radieuse'—to perfect a design vocabulary of towers-in-parkland, multilevel transportation systems, and functional land-use segregation. His *Plan Voisin* applied these ideas to a portion of central Paris, sweeping away narrow streets and 'diseased quarters' for a forest of cruciform high-rise tower blocks. The legacy of these ideas can be seen in large-scale state housing programs and planned capital cities such as Chandigarh and Brasilia. The guiding spirit here was architectural modernism, and emerging out of the deliberations of CIAM (*Congress International d'Architecture*) was the 'Athens Charter,' the definitive town

planning manifesto of the 1930s for 'the functional city' distinguished by specialized transportation and freeway systems, high rise buildings, extensive open spaces, and planned dormitory communities.

3. *Post-war Master Planning*

World War II delayed implementation of this blueprint but unleashed a universally strong planning impulse under the banner of 'postwar reconstruction.' In many European cities, the necessary reconstruction was as much physical as ideological. But in most Western nations cross-political agreement on the relevance of at least some state involvement in urban development processes moved planning decisively beyond the rhetoric, experimentation and broad theoretical acceptance attained by the 1930s into the realm of implementation. Through the 1950s the scale of planning activity grew significantly as planning settled comfortably into the policy machinery of the welfare state. The bureaucratization of planning was underpinned by a steady professionalization and growth in tertiary education to train the larger numbers of experts required.

The dominant discourse was of urban planning as an unambiguously beneficent activity of government: comprehensive, technocratic, scientific, and socially progressive. More was better if cities were to remain healthy, efficient, prosperous, and beautiful. The major focus was on land-use planning. The elements of modernist planning had surfaced before the war and were now synthesized into a total package embracing master plans; comprehensive redevelopment of the innercity; mono-functional land-use zoning; high rise social housing towers, low density middle-class suburbs; planning and replanning of residential areas as neighborhood units; freeways, ring roads and pedestrianized town centres; green webs of open space, industrial decentralization, and new towns. From mid-century, these planning ideas, variously interpreted and combined, but broadly accepted by architects, developers and government, made decisive impacts on the urban landscape.

All-encompassing metropolitan blueprints assumed a central status. Three early master plans from the mid-1940s which set moulds for many which followed were those for London, Stockholm, and Copenhagen. Patrick Abercrombie's definitive plans for the city and county of London 1943–44 were built around a cellular community structure, an encircling green belt to contain suburban sprawl, and a ring of new towns. Sven Markelius' general plan for Stockholm 1945–46 skillfully integrated transportation, land use and environmental planning, with new subcenters developed around railway stations. And the first Copenhagen finger plan of 1947 also anticipated the transportation corridor planning which would gain popularity from the 1960s when the *cordon sanitaire* of the green belt concept was doomed by escalating suburbanization.

Postwar city strategies targeted both 'obsolete' inner areas and planning opportunities on 'greenfields' sites. Urban renewal schemes involving high-rise housing, upgraded transportation infrastructure, private and public sector offices, and other new uses sought to modernize the late industrial city, frequently doing so at the expense of existing community structure and historic building fabric. The garden city dream was kept alive in new towns. The most heroic program was in the United Kingdom, with the *New Towns Act* 1946 facilitating construction of over 30 new towns by public corporations between 1947 (Stevenage) and 1970 (Milton Keynes). This model of growth management also found favor in the Third World, while private sector new towns (such as Reston, Virginia and Columbia, Maryland) were more common in the USA. Everywhere, however, and even if it did not look like it, considerable planning energy was devoted to the processes of suburban development.

4. *Postconsensus Urban Planning*

The highpoint of technocratic master planning allied to 'scientific' methodologies and modernist architectural solutions was the late 1960s. But the new world order which emerged in the 1970s constituted a markedly different context. The notion of the centralised, benevolent state crumbled. Economic policy was forced to look beyond the industrial fordism which had been the touchstone of social progress in the first half of the twentieth century. Dissent about unpopular wars and civil rights spilled onto the streets. More frequent calls were heard for greater community participation and self-help. The environmental movement awakened. In the face of these challenges, even if planning seemed to be realizing prewar dreams in physical terms, it was not always delivering attractive, equitable, and environmentally sound outcomes.

As the world changed, urban planning came under attack on many fronts: for standardized formulaic solutions, freeway proposals slicing through established neighborhoods, destruction of historic buildings, minimal attention to social issues, facilitation of suburban spread, and so on. A famous critique of mainstream planning ideology was Jane Jacobs' *The Death and Life of Great American Cities* (Random House, 1961). Robert Goodman portrayed planners as the 'soft cops' in *After The Planners* (Simon and Schuster, 1972). If the demolition of the award-winning planned housing project Pruitt-Igoe (1972) in St Louis was symbolic of the end of architectural modernism, it also represented the loss of faith in the 'brave new world' international-style planned landscapes of the postwar era. Many unpopular grand redevelopment plans for Western cities were scuttled by citizen action during these years.

The political consensus which had been the platform for the rise of urban planning after the World War II had broken down. This did not so much destroy planning as fragment it into many specialties: advocacy planning, participatory planning, cultural planning, economic development planning, transportation planning, historic preservation, urban design, etc. A growing complexity and uncertainty about planning's mission mirrored wider social tensions and crises. In recent decades, the contours of urban planning have shifted still more, as cities have become more competitive, socially fragmented, and unmanageable. It is surely not coincidental that the scholarly pursuit of urban planning history burgeoned in the last quarter of the twentieth century, with an International Planning History Society formed in England in 1974.

5. *The Achievements and Legacy of Urban Planning*

Urban planning ranks as a significant social movement which came of age in the twentieth century. Its modern history is a complex and ongoing story of achievement, failure, resilience, and redemption. Over time, chameleon-like, its role has been constantly adapted to place, culture, and circumstance. It is a history of both continuities (the quests for health, justice, efficiency, environment, amenity) and discontinuities (in response to global technological, economic, and political shifts).

Planning thought has experienced its greatest periods of innovation in response to periodic social crises—explosive population growth, war, global economic shifts. Planning's aspirations have always soared above the practicality of their comprehensive realization, being buffeted and reshaped continually by broader social constraints. At times, planning has been a deeply flawed practice, with outcomes often the reverse of those intended (destruction rather than enhancement of community, promotion of segregation rather than social cohesion, dreary townscapes rather than inspired urban design). This is planning's *noir* side. Always more political than mere technical, it has been exploited as a tool of social control to pursue policies of exclusion, segregation, and marginalization.

At the same time, there is a raft of value-adding achievements in such areas as open space provision, affordable housing, mass transit, public infrastructure, the development of liveable, new communities, the injection of sanity into myriad land use determinations, and the protection of natural and cultural resources. There is general community acceptance that constraints on individual freedoms and property rights may be warranted for collective benefits. On balance, urban planning initiatives have meant that a significant proportion of humanity on every continent found itself living in better circumstances at the end of the twentieth century than at the beginning. World Town Planning Day, an initiative launched in the late 1940s, is now celebrated worldwide every November.

Urban Policy: Europe

1. *Introduction*

The first question to be addressed here is: is there such a thing as a European urban policy? There is clearly a wide variety of urban policies in the different countries of Europe, so many that it is beyond the scope of this entry to review them all in any insightful way. It is also true that there are a number of European urban policies, in the sense of policies of the European Union that address urban problems. During the 1990s there have been significant moves towards the establishment of a European Urban Policy although it is not yet possible to say that this has been achieved in a comprehensive manner. It is possible, however, to identify the emergence of certain common policy themes and priorities.

The unifying theme of this entry, therefore, is the emergence of a European Urban Policy during the 1990s, the establishment of urban policy instruments in early 2000, and the broad policy objectives that this is designed to achieve. This is related to the broadly parallel development of European spatial policy over the same period, the focus of which will in the early years of the current century be on the development of a balanced and polycentric city system and the forging of a new rural-urban relationship.

The concept of a European policy is applicable specifically to the European Union (EU), which is a jurisdiction whose laws are superior to those of the 15 member states. Of course the EU does not include the whole of Europe but it does cover a sufficiently large number of member states to be representative, particularly taking into consideration the association agreements with certain Western non-members and the expectation that 11 countries in Central, Eastern, and Southern Europe will join and adopt the same policies by 2005–2010.

This entry will begin by discussing the dimensions and variety of urban policies and cultures to be found in Europe and the extent to which certain overall policy objectives are generally accepted. It will then go on to outline the development of urban policy in the 1990s and the state that policy development has reached at the time of writing. The place of urban policy within the wider structure of the EU and of related policy sectors, and the extent to which a European policy community can be identified is then explored. Finally some directions in which policy development may be expected in the next few years are indicated.

2. *Common Themes within Urban Policy in Europe*

Although the urban form and cultures vary greatly between different parts of Europe (Newman and Thornley 1996), there are a number of policy themes that can be discerned very widely, if not universally. It is the exception in Europe for cities to be still growing in the traditional manner as a result of migration from surrounding rural areas. This was the dominant form of urban population growth in the nineteenth century in countries that industrialized early (e.g., Britain, Germany, and Belgium) and in much of the twentieth century in most of Southern Europe. Urban change in the last quarter of the twentieth century was often associated with factors such as migration into Europe of ethnic minority populations from former colonies, economic restructuring and the loss of large numbers of traditional manufacturing jobs, extensive suburbanization, longer distance commuting, and new home–work relationships. Many cities are, of course, attracting substantial population growth. This is especially true of those with the most favorable economic structure or position within Europe's territory. A major concern in recent years has been the extent to which growth is concentrated in cities in the core of Western Europe, the so called 'blue banana' or 'pentagon' (CSD 1999). Many other cities are experiencing growth in the number of households and of the area of urbanized land associated with them without experiencing overall population growth.

National urban policies were widely adopted to address the social and economic consequences of migration, unemployment, and poverty and to promote urban economic development and regeneration. This period of urban policy was also characterized by considerable growth in acceptance of the idea of competition between cities. Several cities that were undergoing economic and social decline adopted policies of image promotion as a significant element in their regeneration strategy. Competition could take different forms. At times it was directed at potential visitors or inward investors for whom a very positive and attractive image was essential. At other times, the competition took the form of seeking to qualify for some form of assistance under national or European policy, for which it was necessary to assert a degree of need greater than that of the competition.

Concern for the urban environment has grown dramatically in the same period. One aspect of this relates to the growth in the use of private car transport and policy towards the construction of urban motorways. Growth in car ownership has been a universal phenomenon in Europe as elsewhere but the 1980s and 1990s have seen significant growth in investment in rail-based urban transit systems and in acceptability of policies to restrain or even prevent the use of cars in urban centres. This latter dimension shows very distinct North–South variations. The Nordic countries accept a very high level of restriction on the use of cars in urban areas while in more Southern countries, such policies are politically very difficult to introduce. Nevertheless several major cities including Athens, Paris, and Rome have suffered such extremes of atmospheric pollution that they have experimented with no-car days and other means of restricting car access.

Cities in the former communist countries of Central and Eastern Europe present a distinct set of urban policy issues. Their existing urban structure is often heavily influenced by the experience of central planning and the lack of any urban land market. Substantial investment and transformation has occurred during the 1990s but, in the context of European urban policy, they will continue to present a distinct set of issues for some years to come, especially in the context of the enlargement of the EU.

A number of identifiable policy themes are widely adopted throughout Europe or are being promoted specifically as European policies. These include policies for urban regeneration, directing development on brownfield, rather than greenfield, locations, urban

economic development, property-led development, policies to combat social exclusion and the problems of peripheral social housing estates, policies to accommodate the growth in household numbers without population growth due to the greater number of one and two person households, policies to counteract urban sprawl and promote the concept of the compact city, and policies to minimize private car commuting and promote the use of energy efficient transit systems. Core–periphery issues are recognized at the European level as well as within several member states and the concept of a balanced and polycentric urban structure has been developed as a central objective of European spatial policy to counteract this.

3. *The Place of an Urban Policy in the EU*

Since the EU originated as an economic community, it is by no means generally accepted that it should play a role in urban policy. Constitutionally, the EU cannot engage in activities for which there is no provision made in the founding treaties, i.e., for which there is no legal competence. Strictly speaking, this limits the scope of EU legislation but is not so restrictive in respect of funding and networking programmes and policy advocacy. In practice, the European Commission, as the main policy-making institution, regularly pushes beyond the strict limits of existing competences, often in anticipation of future treaty revisions. The latest revision, the Treaty of Amsterdam, entered into force in May 1999 (SO 1997).

Many aspects of urban policy have been introduced within the framework of programs for which a treaty basis previously existed, such as regional and environment policies, which are specifically intended to address urban problems although they may not be labelled urban policy. During the 1990s, there was growing political support for the idea that an urban policy should be added to EU competence as part of one of the periodic revisions of the treaties. The overall basis for this is the argument that over 80 percent of Europe's population is urban, and that there is no specific channelling of funding in this direction although a substantial proportion of EU funding is directed at agriculture.

To date the objective of adding an urban title to the treaties has not been achieved. The latest revision, the Treaty of Amsterdam, amended the statement of overall duties and objectives of the Union by including *inter alia*, the phrases 'to achieve balanced and sustainable development ... strengthening of economic and social cohesion,' and 'promoting social and territorial cohesion' (Articles 2 and 7D, Treaty of Amsterdam). These indirectly provide a treaty basis for urban policy, which can be conceived as policies to promote social cohesion. It is a common feature of EU policy development that significant policy initiatives take place before any explicit treaty competence is agreed by the member states. This was true of both regional and environment policies, both now and well established with a clear treaty basis, and it is reasonable to expect that the same trajectory is being followed by urban policy. Meanwhile it is possible to identify several distinct elements of urban policy derived from existing EU policy sectors.

4. *The Evolution of EU Urban Policy*

European urban policy took distinct shape during the 1990s but the foundations in respect of both research studies and innovative policy initiatives were laid during the 1980s. Studies were undertaken into urban problems and into the comparability of urban data from different member states. One of the most meticulous attempts at overcoming data comparability problems and arriving at a consistent analysis was that undertaken by Cheshire and Hay (1989) who developed a concept of the functional urban region for which data was adjusted to eliminate the distorting effects of different administrative boundaries and definitions. Policy initiative during the 1980s included development of the concept of urban black spots, designed to focus the attention of the regional and social funds (European Social Fund [ESF] and the European Regional Development Fund [ERDF]), on what were essentially inner city problems. Up to this time, it was not considered appropriate for EU policy to focus on spatial designations below the regional level. However, the widespread recognition of inner city problems led to political pressure to incorporate policy measures within the structural funds that could address them.

Another element of urban policy thinking that came to the fore by the late 1980s was concern for the urban environment. This moved to the top of the political agenda following the 1989 European Parliament elections where a historically high vote for green parties was recorded in a number of member states and a significant if small green party group was elected.

4.1 *Structural Funds*

Before discussing the outcome of these initiatives, it may be helpful to explain the term structural funds. This term came in to use during the 1980s to refer to three major funding programmes, ESF, ERDF, and the guidance section of the European Agricultural Guidance and Guarantee Fund (EAGGF). The latter, part of the Common Agricultural Policy, is not of further concern here. ESF and ERDF, on the other hand, are very important in the context of European urban policy. The ESF is not a social fund in the welfare sense, but in the sense of providing for the so-called social partners, i.e., employers and those employed. It is a fund designed to promote and steer

Objective 1	Economic adjustment of regions whose development is lagging behind
Objective 2	Economic conversion of declining industrial areas
Objective 3	Combating long-term unemployment and facilitating the integration into working life of young people and of persons exposed to exclusion from the labour market
Objective 4	Facilitating the adaptation of workers to industrial changes and to changes in production systems
Objective 5a	Adjustment of the processing and marketing structures for agricultural and fisheries products
Objective 5b	Economic diversification of rural areas

Figure 1
Structural fund objectives 1994–1999

employment policy. During the 1980s, reforms of the ESF allowed it to focus very directly on the type of job creation and wage subsidy schemes that were being developed in the UK and some other member states as an integral part of inner city policy. The ERDF originated in the 1970s as an augmentation to national regional policies and it was only during the 1980s that it began to operate according to policy objectives set at the European level (Williams 1996).

During the later 1980s agreement was reached on the coordination of the structural funds. This came into operation in 1989. In simple terms, the basis on which it operated was that five overall objectives were set (see Fig. 1). In the case of those with a primarily regional or spatial purpose, the area of benefit was designated. Thus the poorest areas, broadly speaking those with under 75 percent of the EU average per capita GDP, were designated Objective 1 areas and received maximum funding. Objective 2, which focused on areas undergoing industrial restructuring, was also subject to territorial designation and substantial funding. The majority of urban areas suffering economic or social problems were to be found within Objective 1 or Objective 2 areas. There were exceptions, generally whenever poor districts occur within economically successful city regions, such as Hamburg, the assumption being that the necessary resources were available locally.

4.2 Urban Environment

Building upon these foundations, the first major initiative of the 1990s was in respect of the urban environment. This was the preparation of the *'Green Paper on the Urban Environment'* (CEC 1990), known as the Green Book, by the environment directorate of the Commission. This attempted firstly to establish the place of the city in European culture and to argue in a continent where approximately 80 percent of the population lives in urban or sub-urban areas, the quality of urban life and cultural identity are crucially dependent on the quality of the urban environment. More specific urban policy themes were developed, including the link between urban social cohesion and rural poverty as a result of rural–urban migration, the connection between urban development and air pollution, concern for conservation of the cultural heritage and the need to introduce traffic calming, to counteract pressures of urban sprawl and unrestricted tourist development. The Green Book went on to develop more specific policy proposals that could be implemented within the framework of EU powers as they then existed, particularly in respect of urban transport and planning, energy management, management of urban waste, promotion of industry, and heritage conservation.

The Green Book did not lead directly to the development of a European urban policy although it did capture the imagination of many urban planners and have an influence on policy thinking during the following years. One specific outcome was the establishment of the European Academy for the Urban Environment in Berlin (Williams 1996, pp. 204–10). Another was the adoption in 1994 of the Charter of European Sustainable Cities and Towns, whose signatories pledged themselves to work towards sustainable urban development, and establishment of the Car Free Cities Club, whose members were cities prepared to make a political commitment to the promotion of traffic reduction policies and the exchange of experience.

4.3 Urban Pilot Projects

Within the ERDF, provision is made for innovative or pilot projects and for community initiatives, funding programs targeted at specific problems often of an urban policy nature. An important step forward in the development of urban policy was the program of Urban Pilot Projects. This was a series of projects designed to test out new ideas for the delivery of urban policy. The intention of this program was to identify new policy measures and demonstrate the potential they had, not only in the context in which they were developed, but also in respect of transferability to cities in other parts of Europe. Projects were grouped around four major themes:

(a) economic development projects in areas with social problems, such as peripheral and some inner city residential areas with high unemployment levels and limited access to skills and training,

(b) areas where environmental actions can be linked to economic goals,

(c) projects for the revitalization of historic centres to restore economic and commercial activity,

(d) exploitation of the technological assets of cities.

As this was a pilot program, normally only two or three cities in each member state were designated for assistance.

A key feature of the Urban Pilot Programme was the requirement to publicize and disseminate the experience of each participating city. Many conferences and exhibitions were held with this in mind, but it is nevertheless very difficult to identify the extent to which lessons were transferred and applied to non-participating cities with comparable problems. An evaluation of the whole program was carried out in order to identify good practice and inform the development of a more substantial program known as URBAN, funded as a community initiative of the ERDF.

4.4 URBAN Community Initiative

URBAN was launched in 1994, before the pilot projects had finished or been evaluated, as part of the 1994–1999 agreement on the structural funds. This is perhaps an indication of the strength of the political coalition between the Commission and city authorities supporting greater intervention at the urban scale. It was designed to overcome serious urban social problems by supporting schemes for economic and social regeneration, renewal of infrastructure, and environmental improvement. It supports schemes to overcome serious social problems in inner areas of designated cities of over 100,000 population through economic revitalization, job creation, renovation of infrastructure, and environmental improvement. This program had a substantial budget, two-thirds of which went to cities within Objective 1 regions, most of the rest going to Objective 2 areas. One subtext for both these initiatives was to support moves to add an urban competence to the EU treaties at the Amsterdam summit in 1997. Although this was not achieved, the new emphasis on tackling unemployment will have a strong urban dimension, and urban policy development is continuing within existing competences. At the 1998 Urban Forum (see Sect. 4.5), Commissioner Wulf-Mathies emphasized that urban policies would be 'mainstreamed' within the structural funds.

Individual projects normally run for four years, must have a demonstrative character and potential to offer lessons to other cities, and form part of a long-term strategy for urban regeneration. The original intention was to designate around 50 projects, for which a funding partnership between the European Commission and the national authorities was proposed. The pressure for designation from cities was such that a total of 85 projects were approved by January 1997, many of which did not actually start until August 1998 (CEC 1998a), so evaluation has not yet been possible. By the end of the decade, approximately 120 projects had been designated. URBAN has thus proved to be a very popular program, so much so that it was maintained in the post-2000 funding period, contrary to the wishes of the European Commission, due to very strong political support form local and regional politicians throughout Europe.

4.5 Urban Agenda and the Urban Forum

Although the European Commission had initiated these various components of a European urban policy, it was politically necessary for the Commission to proceed with great caution in respect of any suggestion that it was proposing a new role for itself, thus the title it gave to an official communication was 'Towards an Urban Agenda' (CEC 1997). The stated purpose of this document was therefore to assess the extent to which existing policies affected urban areas and to examine the possibility of bringing these together to form a more coherent body of urban policies. It was also designed to stimulate debate among the urban policy professionals and, to some extent, generate pressure on the Commission itself in the form of advocacy of a more coherent EU urban policy from this group. Stimulating pressure from external lobbying groups in this way is not an unusual method of seeking to generate momentum for a particular policy direction. The focus of this pressure was twofold: firstly, to seek to influence governments participating in the discussions concerning the proposed amendments to the European treaties in preparation for the Treaty of Amsterdam; secondly, to contribute to preparations for the Urban Forum in 1998.

There was considerable pressure, especially from political representatives of major cities and urban policy experts, to add a so-called Urban Title to the European treaties in the Treaty of Amsterdam. In the event, this proved unsuccessful in that no Urban Title was incorporated in the Treaty, although the lobby did achieve some indirect success. The phrase 'territorial and social cohesion' was added to the section dealing with overall objectives and duties (Article 7D). This phrase can be taken to refer to the need for coherent spatial and urban social policies. Additionally, the Amsterdam Treaty added an Employment Title, which also provided a basis for intervening in issues of urban economic development and social exclusion.

The Urban Forum was an event held on the initiative of the then Commissioner, Dr. Monika Wulf-Mathies, in Vienna in November 1998. This meeting was attended by over 800 representatives of major cities and urban policy professionals at which a major document outlining the direction in which European Urban policy might go was launched. This was entitled *Sustainable Urban Development in the European Union: A Framework for Action* (CEC 1998b). This document aimed to create the foundation for a more highly developed and targeted European urban policy. The first part set out the general principles, political context, and rationale for the

policy, noting also the applicability of the principal of subsidiarity. The key policy development takes the form of a set of 24 Actions grouped under four broad policy aims:

(a) strengthening economic prosperity and employment in towns and cities,

(b) promoting equality, social inclusion, and regeneration in urban areas,

(c) protecting and improving the urban environment: towards local and global sustainability,

(d) contributing to good urban governance and local empowerment (CEC 1998b, p. 11).

Some of the Actions propose the use of existing policy instruments to meet urban policy objectives more explicitly. For example, Action 8 makes proposals for Structural Fund support for urban regeneration. In order to be implemented, it is necessary for the Structural Funds' operational guidelines to incorporate similar principles and this is being negotiated where appropriate. Other Actions anticipated the new powers, especially in respect of social exclusion and employment promotion, available following ratification of the Treaty of Amsterdam. Certain Actions are directed towards matters within the responsibility of urban authorities, for example, Action 11 on implementation of existing environmental legislation, while others seek to apply to the urban context international agreements, such as the Kyoto strategy on climate change.

5. *The Urban Dimension of European Spatial Policy*

The policy framework for the network of cities and urbanized areas in Europe is not to be found in the urban policy instruments discussed above. Instead it is to be found within the framework of European spatial policy. Spatial policy has been developed over a similar period, reaching a degree of coherence with the adoption of the European Spatial Development Perspective in 1999 (CSD 1999, Williams 1999, 2000). Although this is better understood as a separate field of policy development, concerned with the territorial cohesion of urban and rural areas, it does incorporate certain guiding principles which provide a framework for urban development.

The ESDP was based on certain principles by the ministers responsible for spatial planning in 1994: development of a balanced and polycentric urban system and a new urban/rural relationship; securing parity of access to infrastructure and knowledge; sustainable development, prudent management and protection of nature, and cultural heritage. These principles have no mandatory effect: there is no European spatial plan that must be adhered to. However, these are intended to provide a framework for policy thinking at national, regional, and local levels.

In several member states, most notably France and the UK, the national urban system is dominated by one primate city (Paris and London), and in some others, such as Spain and Italy, two cities jointly dominate the urban structure (Madrid and Barcelona, Rome and Milan). There were fears that, at the European level, a similar situation may come about especially after the creation of the single market in 1992. More specifically the fear was that a core region of Western Europe, from London through Brussels and Amsterdam, including Bonn and Frankfurt and ending with the Milan region of Italy, would become so intensely developed and become so dominant both politically and economically that it would unbalance the overall spatial structure of Europe and consign cities and regions in the periphery to a perpetual state of relative underdevelopment. An influential French study into the spatial structure of Europe gave the term 'Blue Banana' to this core region (Brunet 1989), and the image remains in use.

The principal exception among the major member states to this core–periphery model of urban development was Germany. The pre-1990 German Federal Republic was an especially good example of a polycentric urban structure. Several cities had major national or international functions (e.g., Frankfurt and Bonn) or were internationally significant commercial centres (e.g., Hamburg, Düsseldorf, and Munich). This was perceived to be a more appropriate model for application at the continental scale, and has been incorporated in EU spatial policy as a guiding principle.

6. *The State of EU Urban Policy Development in 2000*

In 2001, EU policy towards cities and urbanized areas can, for the most part, be found in two particular bodies of policy-making. One is the funding program for urban projects and initiatives designed to combat social exclusion, the other is the spatial policy framework for the network of cities and city regions. Policies directed at urban areas can of course also be found within the context of energy, transport, and environment policies, for instance in respect of pilot schemes for energy-efficient transit systems and policies for landfill and waste disposal.

At the Urban Forum in 1998, the Commissioner was advocating that urban policies and their associated funding should be 'mainstreamed' within the overall structural funding program when this was renewed for the funding period 2000–2006. The intention was that cities would not be regarded as dependent upon one relatively small fund for any special initiatives. In fact this proposal was strongly opposed by the representatives of the cities, and it proved necessary to propose the continuation of a dedicated funding program, known as URBAN, in

order to satisfy these objections. This is one of only four Community Instruments, compared with 14 in the earlier funding period and is substantially better funded than its predecessor. It is not possible at the time of writing to comment on what this program may achieve, since the guidelines have only recently been negotiated and have not yet received final approval.

The spatial policy framework is now established in the form of the European Spatial Development Perspective (ESDP), adopted by the Ministers at Potsdam in May 1999. Although this is in no sense a legally binding policy statement, it is anticipated that it will form significant guidance for urban development, especially in respect of networks of cities and links between them, and in respect of the need to minimize urban sprawl and maximize sustainability through compact urban development and efficient transit systems. An action program to follow up the ESDP was agreed in October 1999, which included further study programs designed to develop and operationalize concepts such as a balanced polycentric urban structure.

7. *Urban Networking and the Development of a Policy Community*

A noteworthy feature of urban policy-making during the 1990s has been the extent to which cities have attached importance to networking activities. The term 'policy community' is sometimes applied to the entire group of people and organizations that play a role in any given sector of policy-making. This is readily recognizable phenomenon within the national context. What is new is the extent to which it is becoming possible to identify a European policy community in a number of sectors including urban policy.

The European Commission has sought to stimulate networking and partnership activities through a number of programmes requiring participant cities to form partnerships with cities in other member states in order to qualify for funding. Some partnerships were fairly short-lived but several small networks were established which have since grown into quite substantial organizations. One of the most significant is a body called 'Eurocities,' whose members are all regional cities of over 250,000 population. The original core group was formed by certain 'second cities,' Birmingham, Barcelona, Lyons, and Frankfurt, which were seeking to support each other in their efforts to achieve a higher European profile, outside the shadow of their respective national capitals. Eurocities has members from throughout the EU, and now includes capital cities. It is the major non-government organization currently active in the field of European urban policy and has a wide range of working parties concerned with different policy sectors—urban environment, transit systems, telecommunications, economic development, social exclusion, etc.—which not only react to proposals and consultations from the Commission but also prepare and submit their own policy proposals. The URBAN Community Instrument is itself to some extent the product of this process. Eurocities has also been instrumental in promoting its own specific networks, for example the Car Free Cities Club, a network of cities that have committed themselves to implement measures to reduce the impact of cars in city centers.

There are a number of other networks representing smaller cities, or cities with particular functions or situations, such as historic cities that have difficulty reconciling heritage conservation and tourism pressure, or cities sharing a particular manufacturing industry.

8. *New Policy Concepts and Agendas*

At the beginning of the twenty-first century, very substantial progress has been made, compared with the situation a decade earlier, in developing a coherent body of European urban policy. The principle that the EU should contribute substantially to meeting urban policy objectives is now accepted and for urban policymakers in city administrations, this is a major factor in their daily professional lives. On the other hand, the ambitions of several of those who were actively seeking the incorporation of urban policy within EU competences have by no means been fulfilled. There is still no Urban Title in the treaties, and therefore there are only weak powers to legislate, and only on the basis of unanimous political support.

The present situation is not likely to remain static. The spatial policy aspect is continuing to evolve, associated with study programs which will seek to develop policy instruments to promote a polycentric urban structure and more integrated urban–rural relationships. It is anticipated that the link between the European Spatial Development Perspective and the Structural Funds will be made explicit for the 2006 revision of the Funds. Urban environment and transport initiatives can be expected to continue, with strong political support especially from Northern Europe. It was always envisaged that the Urban Forum should become a regular event. Although this has not yet happened, it would be inconceivable for this not to happen, given the political strength of the cities of the EU. Finally, the next round of enlargement of the EU, to incorporate former communist countries of Central Europe, will take place during the period 2005–2010. The impact of this is yet to be fully appreciated among existing EU members, in spite of many studies and technical assistance programs that have taken place. However, the urban regeneration and social cohesion problems that these will bring will have a more profound influence than

anything hitherto experienced on the future development of EU urban policy.

Urban Policy: North America

In general usage, 'urban policy' takes on two closely related meanings. The word 'policy' may denote a definite course of action selected from among alternatives and intended to guide specific decisions. In that case, 'urban policy' refers to such courses of action in relation to urban areas and issues, especially in the public realm. 'Policy' may also indicate a more general and high level guide to decision and action, particularly by governmental or other public entities. In this case, urban policy should be seen as comprising general principles that guide public action in urban areas and on the issues associated with them. In practice, it is difficult to disentangle the two, especially in advanced societies, such as those in North America, where most of the population lives in urban areas. Furthermore, the diversity of urban areas within a national political system, no matter whether they are metropolitan regions, cities, or smaller urban places, engenders specific forms of complexity that are reflected in public policy. Thus, to understand urban policy, it is necessary to see how public decisions are formulated, as well as to examine the character of urban policies in both their specific and general senses.

1. *Public Action in Relation to Urban Areas*

The organization of public action reflects a profound dilemma associated with geographically differentiated places whose populations have political power. Metropolitan areas, cities, and other urban entities are the most dominant such places in our time. Considerations of technical efficiency often suggest that public action should be shaped by functional requirements, rather than in accord with governmental structure (examples are transportation, public utilities, and public safety). Such function-based structures might be seen as a 'vertical' form of organization, in which a particular function is managed coherently to take advantage of economies of scale. Most national states have ministries that reflect such a functional division, as do lower levels of government. In strongly unitary states, such national ministries extend their reach to virtually all aspects of life, even at the most local or individual level.

Society, however, comprises much more than the nation state, being a vastly complex structure of social, economic, and political relationships among individuals and groups. The reality of everyday life engenders strong relationships in a 'horizontal' form, crosscutting functional concerns and focusing on place itself. Such 'place based' concerns are accentuated where people in subnational communities have the political power to express their collective desires, even though they may run counter to national concerns expressed through vertical forms of organization. Democratic societies in which legislatures are elected on a geographic basis are particularly likely to express such horizontal pressures. However, the fundamental social organizational forces that create subnational communities are present everywhere, with concomitant tensions between the vertical and horizontal, the functional and the communal, at all levels of government.

One solution to this dilemma is a federal system, in which both legislative and executive responsibilities are allocated explicitly to different levels of government, usually associated with accompanying geographic disaggregation of the national space. This is so in all three countries in North America. Conventionally, systems of this type exhibit at least three formal levels of government: national, state (also called regional or provincial), and local, with the latter often further subdivided. Urban areas are rarely national in scale or

scope, though Singapore provides an important exception. Singapore is, of course, a unitary state, albeit with local forms of administration within itself. Urban areas at the first level below the national in a federal system are also relatively infrequent, though Mexico City and Washington DC are principal examples. Even there, the capital is a unique political entity rather than a state within the federal system. Thus, most urban areas in explicitly federal systems fall under the jurisdiction of local governments.

Although urban places are geographically local in nature, urban policy is not also essentially local. To the contrary, cities are intricately involved in national politics in urbanized societies. Many strands of national policy affect urban areas or are intended to respond to the concerns of their inhabitants. The formation and execution of urban policy occurs at all levels of government. In addition, many policies that affect urban areas and their inhabitants deeply are couched in terms of other policy domains. Major governmental ministries or agencies whose explicit mission is to shape urban policy are rare. Nonetheless, urban places are the targets of many explicit policies, while also being the recipients of the consequences of others. It is often difficult to distill the urban policy implications of policies formulated in other fields.

2. *Urban Policy in North America*

North America is a continent comprising three separate nation states, each with a distinctive history, its cultural and demographic makeup, and its own economic, social, and political system. Nonetheless, Canada, Mexico, and the United States do have much that is common in their forms of urbanism, their governance, and the policies they have evolved. All three countries are highly urbanized, although Mexico has a somewhat lower proportion of its population living in urban areas, reflecting its status as a less-developed economy. In each country, market forces drive urbanization, though the extent to which they are regulated varies substantially. Cities in each are shaped by the dominant technologies of our time, especially by the automobile as the primary means of transportation. Demographic changes, especially immigration and aging, are affecting urban areas in each country. Nonetheless, there are important themes of urban policy in each. Critical to understanding those themes are the categories of public policy involved and the governments that address them.

Although 'public policy' is a widely used term, which now drives graduate and professional education and research, it is seldom voiced in governmental decrees. In relation to urban policy, it is especially important to differentiate the ways in which public policy may be understood. In the first meaning noted above, it is the expression of a particular public course of action that has been decided or is in the process of debate. More generally, in line with the second definition above, public policy also expresses a higher level of generality in the principles that guide public, especially governmental, action. This second sense, however, opens some important distinctions of its own. Much public policy, in fact, may be settled, broadly accepted, and challenged only when conditions change sufficiently to lead to questions being raised about its validity. Urban policy, in this view, is something like an iceberg, much of which is virtually invisible.

2.1 *Urban Policy as Land Use and Development*

Consider the fundamental question of how urban areas in most of North America are designed and built. Current policy debates concerning land use planning, urban sprawl, and transportation infrastructure investment are shaped by long-agreed public policy that urban development should be carried out by private investors, regulated by government and, in part, supported by public investment. Europeans established this policy in the early years of settlement of North America, even though the first settlements were far from pure capitalist enterprises. As colonies of Britain, the Netherlands, France, and Spain, they were intended to benefit their parent countries, and to varying degrees they were rigorously regulated and their forms prescribed. Nonetheless, in the United States, especially, there had emerged by the early nineteenth century a distinctive form of settlement that was to define the American form of urbanism, namely the grid-plan.

The urban grid, a rectilinear structure of streets, was the physical expression of a fundamental policy that urbanization would be market driven, privately organized, and minimally regulated. It enabled two key elements necessary for such a process to work. The first was the creation of easily laid out and marketable lots that could be sold speculatively to buyers at a distance. The second was the easy expandability of the urban structure, simply by adding further streets and subdivisions as the market expanded. Thus, a distinct and recognizable form of American city emerged, speculative in its origins, highly adaptable to changes in growth and technology, and based on the conception of land as a marketable commodity. Even when the grid was replaced in the twentieth century by the curvilinear streets of the suburbs, development remained a function of the private market. The suburbs, with their stronger appeal to the consumer's sense of aesthetic quality and lifestyle choice, necessarily expanded the realm of public or quasi-public regulation, but they were equally the product of private, speculative development. With this shift, however, came major public policies that have supported this form of urbanization, notably the federal funding of major highways, and the deductibility of

mortgage interest, the latter justified by an explicit policy of encouraging home ownership rather than rental tenure. The most recent challenge to suburban forms of urbanism, by neo-traditional or 'New Urbanist' critics, calls only for a change in the way in which urbanization is treated by regulation and taxation. Only relatively rarely in modern American history has government attempted directly to create urban places, even though national, state, and local laws have fundamentally shaped urban settlement patterns. US efforts to build new towns during the Great Depression of the 1930s were unusual in this respect and they failed.

Clearly, this account simplifies a complex, continental-scale reality. The legacy of Spain in Mexico was one of a much more centralized, class defined, and bureaucratic society. Mexican urban development reflected those facts in its slower growth and more constrained forms of urbanism. Similarly, development in Canada reflected both the earlier French centralizing influence and the British legacy of unitary parliamentary government, albeit grafted onto a federal system in which the provinces were relatively strong. It is no accident that public control of urban development in both Mexico and Canada remained historically much stronger than in the United States, yet in both countries cities are not built by governments.

The idea that urbanization is market driven has been powerfully consequential. Paradoxically, the market itself implies public constraints. No market functions without some prior structure of behavior or public order; some constraints must be established for markets to function at all. For urban policy, this implies public regulation of the urban development process. The nature and locus of that regulation has defined many of the key urban policy issues in North America during the twentieth century. In the United States, control of public policy is ultimately vested either at the level of the states or of the federal government, depending on the Constitution and its interpretation by the Supreme Court. With respect to land use, control is generally agreed to rest legally at the state level, although the basic legal doctrines that support land use regulation rest on constitutional decisions that are national. In fact, states have delegated land use regulation to local governments under a variety of names. California, for example, delegates the power under the doctrine of 'Home Rule.' On this legal basis, aided by a long history of piecemeal settlement and independent formation of urban places, US urban policy toward development and change is played out at the most local level.

This situation contrasts sharply with that in many other advanced countries, notably in Europe and Asia, where state or central governments play more centralized roles in land use planning, regulation, and development. Canada and Mexico also present substantially more centrally regulated versions of urban development. In Canada, cities in the central and western provinces tend to look more like those in the USA. The eastern provinces have a stronger tradition of central control, though always empowered at the provincial level. Toronto's ability to control its suburban development contrasts markedly with any US city, but a change in political complexion at the Ontario provincial level has had substantial implications for the city's policy. In Mexico, until very recently, with a single-party state, local control of development was limited. Although state or central governments did not always have the capacity to enforce their will more than intermittently over economically or politically powerful local groups, the tradition of central government finance and fiat remained powerful. How this will evolve in the first decade of the twenty-first century, as the political monopoly of the PRI ends, remains to be seen.

2.2 Urban Policy as Functional Management

Local power over development has major implications for urban development, particularly when viewed from a functional perspective. For decades now US observers and advocates have argued that urban problems of transportation, energy, utilities, and environmental quality require the political ability to act at a regional level. Again and again, such arguments have been turned back as localities have refused to form larger regional governments or to cooperate in accepting land uses that they deem undesirable. That refusal has been encapsulated in the term 'NIMBY' ('Not in my back yard'), which has become both a rallying cry for control by local neighborhoods in the face of larger economic and political forces, and a term of opprobrium conveying selfishness and exclusion. Nonetheless, metropolitan areas cannot be built and cannot operate at a high level of amenity and income without necessary functional efficiency. One widely employed means around the problem has been the creation of single purpose special districts; for example, to handle water supply. These are typically limited in their range of action and their ability to override local decision-making. They are established by state law, but with the clear requirement that local political representatives support their formation. In recent decades, some entities of this type have also emanated from federal governments in all three countries.

Management of air quality is a good example of such urban policy, illustrating both its urban character and its placement within another organizational realm. Awareness of the dangers of air pollution has a long history in urban areas, but its modern manifestation in the USA may be dated from the passage of clean air legislation by the city of Pittsburgh in the 1950s and the enactment of state and federal air quality standards and legislation in the 1970s. At first, efforts to improve urban air quality focused on

stationary sources of pollution, especially industrial sources such as steel mills and oil refineries. As they were controlled, however, it became apparent that the single greatest source of air pollution was from mobile sources, especially private automobiles. In metropolitan areas and cities such as Los Angeles, dirty air was identified as a contributing cause of serious public health problems and reduced quality of life associated with smog. Clearly, these were regional and in some cases inter-state problems. The federal government's response was to treat environmental quality by regulatory legislation and the formation of the US Environmental Protection Agency in 1970. State governments reinforced the effort with similar legislation.

Air quality degradation by automobiles can be countered in many ways, including regulating the emissions permitted, increasing the cost of driving, providing incentives for use of cleaner vehicles, and changing the way in which urban areas are structured so as to reduce the number of miles driven. Any of these policies are conceivable, but the specifics of implementation differ among them. Furthermore, the mode of intervention might have a great deal or very little relationship to urban areas themselves. Regulation of automobile emissions through national specification of permissible technologies is only indirectly urban in character, and its effectiveness will vary with the standards applied from place to place. On the other hand, consider the problem of regulating development as a means to control emissions in metropolitan Los Angeles. Although both federal and state agencies have regional offices, neither would typically be able to carry out such a policy effectively at the local level. To do so for the metropolitan area required also a regional agency, in this case, the South Coast Air Quality Management District. This agency, established directly by the state, legally has the power to override local development decisions. However, in the face of overwhelming political opposition to such actions, which would violate home rule, it has been reluctant to do so, preferring to employ its regulatory powers in other directions. Alternative air quality policies may have similar goals, but their urban manifestation may be quite dissimilar.

This story of policy directed towards urban problems, defined on a functional basis, and legislated and implemented at multiple levels of government can be found again and again in North America, as it can everywhere in the urbanized and urbanizing world. Apart from being much worse than in Los Angeles, air pollution in Mexico City presents much the same set of problems. In transportation, public health, housing, water supply, wastewater disposal, garbage removal, and public safety, governments have been attempting to find solutions within their own financial and political situations. It is not a new phenomenon. From the beginning of the Industrial Revolution, much of what we recognize as urban policy has been driven by attempts to deal with the dysfunctions of the industrial process. This process occurred a little earlier in Britain than in most of Europe and North America, but once on course it has barely slackened. Some urban concerns, of course, are much older. For example, laws to prevent disastrous fires by prohibiting wooden buildings may be found in the very earliest records of urbanization. However, the emergence of systematic urban policies really dates from the nineteenth century.

For early industrial cities in North America, the most urgent issues were public health, public safety, and transportation. The previous section indicated how the use of a planned grid permitted both a functioning land market and lines of transportation. Although the cores of cities were often congested, especially where, as in Boston, their cores were essentially unplanned, they could function with pedestrian and horse-drawn transportation before the advent of the railroads. However, such cities were necessarily densely built, outran their water supplies, and had primitive sewage disposal. Frequently, they endured epidemics, notably of cholera and yellow fever. As epidemiology evolved, the importance of clean water and sewerage became evident and the first great modern age of urban policy began. Although the delivery of pure water was, at first, a privately financed and run form of enterprise, it soon became a municipal monopoly, as did sewerage. Provision of electric power and gas, on the other hand, primarily remained private enterprises in North America, with a few minor exceptions. These utilities were regulated after the turn of the twentieth century in order to limit their monopoly power. Public safety became a key municipal function with the creation of police and fire forces in the nineteenth century and has generally remained so.

Beginning with the development of urban trolley lines and railroads in the nineteenth century, transportation investments have played an especially critical role in urban policy over the past 200 years. Although streets and street maintenance have primarily been managed by local governments, the provision and regulation of transportation has involved both private markets and public entities and governments. In the United States, most public policy in this realm was enacted by state and local governments throughout the nineteenth and early twentieth centuries. The ability of dense but growing cities to expand depended on fast and reliable forms of transportation so long as employment remained centralized. Privately run trolley lines, buses, subways, and commuter railroads, operating under local or state charters, provided a workable, if often uncoordinated solution. Later, many were consolidated under public ownership. Together, they enabled development of the suburbanized city of the early twentieth century, brought to full flower by the automobile. With the advent of automobiles, the focus of public

policy shifted from private investment in infrastructure to public investment in highways, funded in large part by taxes on the sale of gasoline. National government engagement in transportation within cities remained minor until the 1950s. By that time, the invention of the freeway had raised the cost of new investment beyond the capacity of both local and state governments.

Large-scale federal entry into the process began with the creation of the Interstate Highway Program in the 1950s. Despite its formal purpose of enhancing national defense by providing high-speed, controlled-entry highways linking the entire country, the Interstate system played a substantial role in urban development through the second half of the twentieth century. By the year 2000, urban freeways ran both through and circumferentially around every major urban area in the USA, fostering suburban decentralization of cities across the continent. Similar freeway development took place in Canada and, more recently, has been occurring in Mexico. Although there has been much debate about the precise intent and impact of the Interstate system on US cities, there can be little doubt that the availability of federal funds has enhanced suburban development significantly since the 1960s. Whether these were conscious policy choices and whether this was the primary cause of the decline of central cities, discussed below, cannot be demonstrated. Given the rapid growth of population, productivity, and income, together with consumers' desires for single-family housing and automobile transportation, it seems likely that economic and political pressures would have had similar effects, whether or not the federal government were involved. Nonetheless, this period saw the entry of federal policy into urban transportation in a major way. It remains there today, although the nexus has shifted. Since the 1980s there has been a resurgence of political support for urban mass transportation, driven by the perception that the freeway solution is either too costly or too destructive of environmental quality to be sustained. This perspective parallels the critique of the suburb and urban sprawl discussed above. As a result, federal transportation funds now include substantial subventions to mass transportation—buses, light rail, and commuter rail in metropolitan areas. While the effectiveness of this shift is being debated, it now appears to be an entrenched element of national policy towards urban areas.

2.3 Urban Policy as Social Policy

Since the 1960s, urban policy in the United States has not been associated in the media and public debate primarily with the issues discussed so far, though the recent resurgence of concern about urban sprawl has shifted attention back to the effects of urban growth. Rather, for several decades, urban policy has been identified primarily with problems of poverty, racial discrimination, segregation, and the decline of central cities. As is true in so many other instances, such a definition of urban policy is not new. It emerged in tandem with the industrial city in the nineteenth century, when low wages, intense overcrowding, dilapidated housing, crime, social disorganization, and disease combined to generate a new form of urban slum. The public health effects of industrial urbanism first engendered policy responses that were engineering solutions, especially in the form of potable water supplies and waste disposal. Epidemics and infectious diseases, such as tuberculosis, also required medical responses, which took the form of public hospitals and health services. Crime problems engendered police forces and prisons.

However, by the late nineteenth century, the fact that so many of the new urban populations in the United States and Canada were immigrants, led to concerns for public safety in a larger sense, namely the stability of the society itself. Public education became a key element of local urban policy, its intent being both to provide a literate and capable labor force for the expanding economy, and to ensure that children were able to speak English and become acculturated into society at large. Fears that immigrants would bring with them European socialist ideas and form labor parties were not unjustified, for all that they were not realized. The momentum for these policies was certainly national in scope and linked to the prevailing sense of the United States as an emergent imperial power on a world scale. However, their realization was almost entirely at the state and local levels, where governments and influential voluntary groups were at times almost indistinguishable.

Poverty presented not only a risk to the health and social position of the affluent in American cities; it also affronted their belief in the United States as a place of freedom and opportunity. Efforts to help the 'worthy poor' raise themselves out of poverty took many forms, of which the Settlement House movement is the best known, evolving into forms of assistance associated with the social work profession. This movement also provided an early means for women of higher social status to become active in professional and social realms. Thus, by the early twentieth century, many believed that urban poverty called for effective governmental and voluntary actions.

A key realm of response was housing, and it is here that the largest challenge to the idea of urban development through the market emerged. The slum was perceived in many ways, but the vision of grossly overcrowded, unhealthy, dilapidated housing was intrinsic to all of them. Observers and critics of capitalism had noted the inability of markets to provide adequate urban housing from early in the Industrial Revolution. Public efforts to regulate construction or management were largely ineffectual, however. By the end of the nineteenth century in the

USA, as in Britain and Europe, there had emerged two competing policy responses. Public regulation of housing quality took the form of building and housing codes, enforced by local bureaucracies. Those who saw regulation as insufficient or ineffective called for direct public or non-profit ownership and rental of housing for low-income families. Market advocates opposed both.

The twentieth century saw the parallel evolution of these approaches to low-income housing policy in all three countries of North America. Mexico, which was undergoing a revolution and installation of a one-party state, probably exemplifies the highest level of commitment to public provision. However, the lack of resources due to underdevelopment, and the mistaken effort to adhere to unrealistic standards, ultimately ensured that public housing would become only a very limited part of its mass urbanization. In common with other developing countries, urbanization for the poor primarily meant informal housing on the margins of major cities. Canada, with a stronger tradition of government intervention, though varying greatly across the provinces, has also adhered to policies that give greater weight to provision of low-income housing. In both the United States and Canada, the tradition of local regulation continues, with rising standards and incorporation of new areas of oversight. In the United States, a determined effort to create a public housing program in the 1930s saw its culmination in the Housing Act of 1949, which led to construction of federally funded rental housing for the poor in most cities. However, the program became discredited, in part because of social problems emanating from its increasing racial segregation and focus on the very poorest populations, and in part because of insufficient funding to maintain and control high-rise housing that was ill-designed for its purpose. In a major shift of federal policy affecting cities, the program was largely replaced after 1974 by a low-income rental subsidy, which remains the basis of federal policy in this area. As a result, direct provision of new housing for the poor has switched towards the nonprofit sector.

Entangled with housing and poverty policy, especially in the United States, is the issue of race. American cities have long been segregated, both by race and income. African-Americans were confined by economics and social pressure to limited residential areas within cities. This phenomenon was exacerbated by major migration from the rural South to northern cities throughout the first half of the twentieth century. While that migration resulted at first in opportunity and rising incomes, by the 1950s there had also emerged ghettoes of African-American and other minority groups in poverty, in which serious social problems persisted. This process was exacerbated by the out-migration from older cities of white middle- and working-class populations seeking a suburban lifestyle and impelled also by race-based fear and prejudice. As a result, cities' financial capacity to address the needs of their populations declined. Education and public service quality diminished, which reinforced the migration. With improvements in civil rights during the 1960s, yet with racial discrimination still widespread, the contrasts between racial groups' aspirations and achievement burst out into urban civil disorder on a massive scale. Large areas of cities including Detroit, Los Angeles, and Washington DC were devastated.

The question of appropriately responsive policy is almost paradigmatic of urban policy in general. On the one hand, efforts were made to improve incomes and opportunity through broad programs, such as those for education and job training. On the other, were efforts to empower local communities through a variety of supports and incentives for the formation of community organizations. The so-called 'War on Poverty' of the 1970s exemplified both kinds of policy. It certainly led to the formation of new political networks and organizations among the urban poor, with long-term results on the racial and ethnic makeup of local politics. However, the position of the poorest and most socially disadvantaged populations improved little, if at all, in the face of a widening gap in the income distribution at large and a decline in the demand for unskilled labor. Increasing crime and social disorganization associated with rising drug use also contributed to the problem. In the face of falling national rates of economic growth, budget stringency led to the withering away of urban poverty programs. In the mid-1990s, these issues were once more addressed by national policy, operating this time through the medium of the welfare program, and especially its support for unmarried parents. Insistence on entry into the labor market has reduced the level of dependency substantially, but the results have yet to be tested outside a boom economy.

3. *Conclusion*

Urban policy in North America remains something of an anomaly. National governments have few policies that are identified explicitly as urban, yet most of their people live in urban areas and most national domestic policies have powerful urban implications. Urban areas contain their own local governments within larger federal and state structures, and those governments pursue the welfare of their inhabitants and other organizations within their boundaries. States and provinces occupy an intermediate role within the federal structure of each nation state, establishing the ground rules for much that urban governments may do while intervening directly. Although urban policy has come to be identified particularly with some sets of issues, notably those to do with poverty and racial segregation, in fact it is much broader than this. Indeed, it may be argued that many of the most

important components of urban policy in the countries comprising North America are scarcely visible. Cities are the most dynamic form of human social organization. Urban policies reflect fundamental social agreements about how cities and towns will continue to be built and transformed and how their inhabitants will relate to each other. Only when those understandings are challenged does the visible portion of urban policy emerge, usually in the context of political and social conflict. Resolution of those conflicts has been a part of urban life throughout history and it will continue to be so.

Urban Politics: United States

By the time Banfield and Wilson's major text, *City Politics*, was published in 1965 the book and its title already seemed inadequate to describe the processes of conflict, competition, and negotiation taking shape in the public sphere of America's large metropolitan centers (Banfield and Wilson 1965). According to Banfield and Wilson, 'city politics,' which 'rarely occupy the serious attention of practical men,' simply concerned who got elected to office, how to apportion the local tax burden, and where to locate various public facilities in the city's ethnic checkerboard (p. 18). But American cities in the 1960s had begun to change since the immediate postwar decade, as blacks and other racial minorities began to assert themselves at the ballot box and in the streets, as population and economic activity migrated to suburban locales, and as neighborhoods suffered under the destructive onslaught of drugs, crime, and family disintegration. Hence the emergence in common use of the term 'urban politics,' a more resonant, grittier description of the processes by which people and groups in big cities sought to mobilize and allocate public resources to deal with these new developments.

If the term 'urban politics' was originally meant to dramatize the emergence in metropolitan centers in the 1960s of an altered civic landscape, it has now come to conventionally refer more simply to patterns of politics in large cities. These patterns are in fact constantly evolving. The texture and scope of urban politics in the US are best understood by examining three closely intertwined patterns: the shifting nature of political conflict in big metropolitan centers, the changing preoccupations of local politics, and the functional evolution of city government as the institutional center of the urban political process.

1. Shifting Patterns of Political Conflict

In the first half of the twentieth century, politics in big American cities was typically defined by the conflict between working class European immigrant groups and middle class native Protestant interests. This was a period of Irish Catholic ascendance in cities as diverse as Boston, Chicago, and San Francisco, but other ethnic and religious minority groups also emerged in local politics in these decades, including Eastern Europeans, Italians, and Jews. The charac-

teristic vehicle for promoting ethnic political interests was the 'political machine' a disciplined, hierarchical organization designed to capture local elective office for the purpose of distributing city jobs and spending to coethnics and allies. As the power of ethnic machines took shape, Protestant political and business elites responded to the threat of displacement by promoting municipal reform, an agenda of structural changes, such as city manager government and the nonpartisan ballot, designed both to make city government more businesslike and to undercut machine dominance of electoral competition.

By the 1960s the last vestiges of machine organization had crumbled in most cities, in no small part because of their inability to reconcile the demands of newly militant African American voters, who the machines had historically exploited, and their traditional white ethnic base, fearful of housing and school integration (Grimshaw 1992). It was in this context that urban political conflict evolved from class and ethnic divisions within the white community to competition based predominantly on race.

In the two decades after 1967 black mayors came to power in more than 300 towns and cities in the US, including nearly every one of the largest places. In the typical contest for city hall, the electorate polarized along racial lines, although skillful black politicians often managed to win just enough white votes to carry them into city hall (Sonenshein 1993, Kleppner 1985). In cities like Chicago and New York the politics of race sundered the traditional alliance of Jews and blacks, who had come together in the early civil rights movement, leaving a stark racial divide. In cities that became majority black, such as Atlanta, Cleveland, and Detroit, black challengers eventually emerged to run against black incumbents. These black-on-black elections have sometimes featured one candidate who is the clear choice of white interests, generating divisions in the electorate identical to the earlier white-on-black contests. However, with time, the prospect of a black mayor became less threatening to most whites, and many municipal elections with one or more black candidates have now lost their sharp racial edge. Blacks began to win the executive office in cities where black voters constituted less than a majority, such as Seattle, Minneapolis, and Denver.

Racial interests continue to define much of urban politics—police conduct and public school reform are examples—but new patterns of conflict have emerged around a broad set of development issues. In the old downtowns of major cities, the issues are how to use central space and how to apportion the costs of development between the public and private sectors. Developers of office towers compete with developers of loft housing for the attention of mayors and their economic development agencies, and both in turn compete with casino and hotel investors, professional sports teams, preservationists, and public parkland advocates. Another line of cleavage has opened between those who seek to invest capital in commercial and entertainment properties and those seeking to maintain neighborhood residential communities that occupy desirable development locales (Logan and Molotch 1987). Conflicts over development often dominate public discourse in major cities, transcending racial and ethnic cleavages or cutting across them in unexpected ways.

2. *Changing Preoccupations of Urban Politics*

In the heyday of the ethnic political machine, the object of politics was to win control of local government in order to get access to its spoils. Politics was a means of livelihood. Thus, the Irish, skillful practitioners of the politics of patronage, came to dominate the municipal workforce early in the twentieth century (Erie 1988). Eventually, the spread of civil service merit systems diminished the number of jobs that could be handed out by urban bosses.

The chief preoccupations of urban politics began to shift with the political emergence of African Americans. Certainly many of the political goals of black Americans recall those of the Irish and other white ethnic groups of the earlier period: blacks want a fair share of municipal employment and city contracts. But they brought to the streets and the ballot box, a political agenda whose instrumental ends were shaped by broader social justice concerns. Urban politics in the decades of black emergence revolved not simply around demands for jobs, but for an end to police bias, housing discrimination, and school segregation (Sugrue 1996).

By the 1990s black mayors were commonplace. Most urban police departments had been racially integrated, and many were administered by black police chiefs. School integration as an end in itself had receded in importance for many black parents, replaced by a determination to improve public education through vouchers or charter schools. As racial justice goals lost their urgency, a new generation of black mayors and their white colleagues as well, turned their energies to the development agenda.

Urban development takes a variety of forms, and choices are inevitably contested. Many cities have pursued a strategy designed to attract tourists and business visitors, investing in convention centers, stadiums, and riverside entertainment centers. Advocates for neighborhood housing, public schools, and social welfare programs tend to oppose such projects as frivolous. Other cities pin their development aspirations on technology parks; yet others on creating the infrastructure—world trade centers, port and airport facilities—to launch themselves into the global economy.

A central responsibility of the public sector in the development process is to create conditions conducive to profitable private investment. Such an undertaking

has typically inhered in crafting a favorable tax climate, adopting flexible land use regulations, and building good infrastructure. One means by which urban mayors integrated these tasks in the 1990s was to embrace a management reform agenda that proponents claimed would 'reinvent government' by introducing such initiatives as privatization and competition and by empowering public employees to act as problem-solvers rather than cogs in the bureaucratic wheel (Goldsmith 1999). Faithfully pursued, such a strategy was expected to impress and reassure investors by reducing the size and reach of local government, making it more efficient and responsive, and easing the tax burden. 'Government reinvention' became a preoccupation that transcended the lines of partisan and racial divisions, reducing some portions of urban politics to a technocratic debate over the nature of public management.

3. *Evolving Municipal Functions*

Through the first half of the twentieth century the singular function of city government was to offer a set of basic public services to promote public safety and health and to facilitate local commerce. These traditionally local responsibilities included public safety, streets, sanitation, libraries, parks, water systems, land use regulation, and occasionally, mass transit systems. City governments received little fiscal assistance and little guidance from either the state or federal governments. However, at mid-century the US Congress passed a series of housing laws that put an 'urban renewal' program into place, a combination of public housing subsidies and support for slum clearance and redevelopment. The result was to usher in a new functional role for city governments as partners with the federal government in administering a variety of national programs designed to address the cities' physical and social deterioration. Federal resources raised the stakes of urban politics.

This partnership lasted in full force until the election of XXX to the presidency in 1980. For three decades city governments planned the specific implementation of general federal programs and often provided matching funds in areas that ranged from housing and community development to policing, and from job training to the construction of sewage treatment plants (Gelfand 1975). In these years the city evolved from a self-financing and relatively autonomous level of local government to a major, though fiscally dependent, partner in a three-tiered (local, state, and national) federal arrangement. Urban politics in this age of federal partnership was often animated by disagreements not only over basic strategies of program implementation, but over where to locate certain federally funded facilities within the city (e.g., public housing projects) or who should control certain federal programs (the war on poverty programs in the 1960s and federal economic development empowerment zones in the 1990s are good examples). Some mayors eventually came to believe that as long as cities were held in the thrall of the federal government that their program priorities and spending decisions would always be distorted (Norquist 1998), but most relished the expansion of local capacity and responsibilities that federal programs underwrote.

With the substantial federal aid cuts that began in the Reagan presidency, cities entered a period of greater fiscal self-reliance. Although the primary function of city government remained the provision of basic local services, its role as a player in the federal system receded in favor of an emerging responsibility as steward of the local economy. This function called for the development of new public expertise in a range of financing, real estate, and entrepreneurial skills that were once the exclusive domain of business people. Cities established or greatly expanded their economic development departments, and city councils put into place an array of financing subsidies and business incentives to lure investors. Mayors became brokers of deals between developers and the financial community. Mayors and other local public officials led trade missions abroad to tout local industries and seek foreign investment, and cities established trade offices in other states as well as foreign capitals. It became common to speak of 'entrepreneurial cities' (Sbragia 1996).

4. *Conclusions*

The participants, preoccupations, and institutional setting of urban politics in the US give it a distinctive cast. Urban politics is not national politics written small. It is not party politics, nor is it shaped by regional conflicts. It is seldom animated by ideological disagreements, which may explain why Republican mayors have been easily elected in traditionally Democratic cities like New York and Los Angeles. Race and class divisions are common in the contests over development and the administration of public services that dominate public debate in big cities, although these issues are as likely to be fought out along other lines of cleavage such as newcomers versus old residents, downtown versus neighborhood actors, or corporate versus local business interests. Urban politics is an arena in which all sorts of crucial, if undramatic, decisions are made: the length and conditions of the daily commute to work, the level of security citizens feel on the streets, the quality and diversity of the venues that vie for people's leisure time and money, the availability of affordable housing, and the esthetic character of the built environment and urban open space. In all respects urban politics has become a major setting for collective debate over the quality of daily life for most people in America.

Urban Poverty in Neighborhoods

Opinions differ regarding what causes poverty in America and why it seems to be concentrated in certain areas. Regardless of these differences, there is a relatively new focus on urban poverty and an agreement that the number of persons in poverty is growing as is the concentration of poverty in urban neighborhoods.

1. *Poverty in America*

National interest in poverty was first triggered when John F. Kennedy, while running for president, was taken on a tour of poor areas in the rural south. What he and his entourage saw was staggering: children with bloated bellies, families living in tar paper shacks, high rates of unemployment, and illiteracy. In short, the other America—families living in a state of poverty, the likes of which most Americans had never seen. This experience so affected the young presidential aspirant that he vowed, if elected, his administration would do everything within its power to address issues of poverty in America.

During the 1960s, politics and the publication of Michael Harrington's *The Other America* (1963), helped to focus the nation's attention on the plight of the poor in urban areas. President Johnson, taking office after Kennedy's assassination, launched the 'War on Poverty' in an attempt to have the federal government significantly address problems of poverty. However, due to the Vietnam conflict this effort was short lived.

It wasn't until the publication of James Wilson's *The Truly Disadvantaged* (1987) nearly two decades later, that interest in poverty was rekindled. Wilson's book sparked a flurry of research projects seeking to provide answers to such questions as: how widespread is poverty in America, what causes poverty, where is poverty most severe, what types of individuals and/or households are likely to wind up in poverty, what does being raised in poverty do to people, can people escape poverty, and perhaps most important, what can be done to reduce the incidence of poverty, and who should be responsible for addressing poverty issues? The results of most of these studies have revealed that poverty in America is not limited to rural areas. Every major city in the USA contains poverty neighborhoods and, in spite of growing economic prosperity, more Americans find themselves increasingly concentrated in poverty neighborhoods.

A person in poverty is defined by the United States Bureau of the Census as one whose total family income falls below a federally defined level. This level varies according to family size and is adjusted annually for inflation. In 2000, for example, the poverty threshold for a family of four was $17,463. The poverty rate for a particular neighborhood is determined by dividing the number of poor persons who live there by the total number of poor and nonpoor persons. Census tracts are used as the geographic basis for identifying the location of poverty neighborhoods. Researchers differ on the cut-off level for defining poverty neighborhoods. The range is from 20 to 40 percent, with the higher level being used most commonly. While different names have often been ascribed to poverty neighborhoods, Jargowsky (1997) refers to African-American high-poverty areas as ghettos, while barrios describe Latino high-poverty neighborhoods, and slums are poverty neighborhoods comprised primarily of whites.

2. *What Causes Poverty and Why Does it Seem to be Concentrated in Certain Neighborhoods?*

A number of different explanations for what causes poverty and why poverty appears to be concentrated have been put forth. Some of these include: discrimination and segregation, immigration of rural farm workers from other countries to cities in America,

the poor quality of inner-city schools, crime and the prevalence of drugs, white flight, and the emergence of a global economy.

2.1 The Creation of Ghettos and Barrios: The Role of Segregation

During the 1940s and 1950s, the USA underwent a rapid expansion of its industrial and manufacturing sectors. African-Americans seeking to improve their quality of life migrated in large numbers from the south to major urban growth centers throughout the USA. Segregated housing, restrictive covenants, and zoning practices forced many of these African-American migrants to seek shelter in older sections of cities. Segregation and discrimination also limited employment and advancement opportunities, which in turn impacted earning power. As a consequence, African-Americans were disproportionately concentrated in low-income and often poverty neighborhoods called ghettos (Drake and Cayton 1945, Clark 1965, Dubois 1967). Even after the passage of Title VI of the Civil Rights Act of 1964 and Title VIII of the Civil Rights Act of 1968, real estate agents, mortgage brokers and lenders continued to make it difficult for African-Americans to acquire housing outside of inner city areas. As a consequence, African-Americans, unlike their white counterparts, have much lower home ownership rates, one of the key ways Americans accumulate wealth (Bullard et al. 1994, Oliver and Shapiro 1995). Massey and Denton are two scholars who maintain that racial segregation and not economic segregation have played a major role in the continued growth of ghetto poverty (Massey and Denton 1993).

During the 1970s, 1980s and 1990s, a large number of immigrants from Latin America, in particular from Mexico, have come to the USA. To a certain extent, these immigrants find themselves relegated to poverty areas or barrios, much like African-Americans did before them. More recently, immigrants from various Asian countries, particularly Vietnam, Cambodia, and Laos have been moving to American cities. In 1990, foreign-born residents constituted 10 percent of all those living in concentrated poverty areas, up from 3.5 percent two decades earlier (Mincy and Wiener 1993, Table 6). As of yet, no single term has emerged to describe Asian poverty neighborhoods. Although references to China Towns, Little Tokyos, and Little Vietnams often imply similar conditions to ghettos and barrios. Like African-Americans, the new immigrants also find that their poverty neighborhoods suffer from inferior schools, high crime rates, inadequate housing, and limited employment opportunities. Language barriers and low educational achievement seem to be key factors contributing to the concentration of these new immigrants in poverty neighborhoods.

While researchers have easily identified poverty neighborhoods with a predominance of racial minorities, that is ghettos and barrios, few predominately white poverty neighborhoods or slums are evident in metropolitan areas. This is not to say that there are no whites in poverty; quite the contrary, the largest number of individuals in poverty are whites. It is just that poor whites are distributed throughout cities and not particularly concentrated in certain neighborhoods.

2.2 Social Mobility

Social mobility, or as Wilson (1987) calls it, "neighborhood sorting," is another reason often put forward to help explain the growing concentration of urban poverty. There are two dimensions of this concept. The first focuses on white flight; that is, as more and more minorities move into urban areas, better educated and more affluent whites move to the suburbs. Reasons most often given for this out-migration of whites from central city areas include: a desire to provide better educational opportunities for their children, safer neighborhoods, better and cheaper services, more neighborhood amenities, and the ability to realize greater return on their investment in housing.

These same interests are propelling the move of middle-class African-Americans from inner city areas, leaving poor African-Americans behind. The consequence is, further concentration of poor people in central city poverty neighborhoods (Wilson 1987).

2.3 The Impact of the Global Economy

More recent literature has focused on what role deindustrialization, brought on by a growing global economy, has had on both increasing the number of persons in poverty and the growing spatial concentration of poverty (Bluestone and Harrison 1982). The growth of new jobs is occurring faster in suburban areas than in inner-city areas. This makes it increasingly difficult for residents of poverty neighborhoods to acquire employment. Kain (1968, 1992) calls this the spatial mismatch phenomena.

Rapid job growth in the service sector has reduced the impact of some losses of industrial employment. However, these jobs tend to pay relatively low wages with few, if any, benefits. This often means that, even though individuals residing in poverty neighborhoods can secure work, the jobs they obtain do not provide adequate income or sufficient benefits to lift them or their families out of poverty. Thus, there are a growing number of working poor residing in poverty neighborhoods (Pastor et al. 2000 and Berstein et al. 2000).

2.4 The Significance of Regional Economic Growth and Poverty Neighborhoods

Some of the more recent literature suggests that there is a link between the size and growth of poverty

neighborhoods and the robustness of a region's economy. Jargowsky, for example, shows that a rise in overall metropolitan mean income resulted in sharp declines in ghetto poverty concentration among African-Americans (Jargowsky 1997). Similarly, Pastor et al. found in 74 regions throughout the USA that regions which performed best economically were also ones that either reduced inner-city poverty or reduced the rate of growth of poverty neighborhoods (Pastor et al. 2000).

To date, the most comprehensive work examining the causes of poverty can be found in *Poverty and Place: Ghettos, Barrios, and the American City* by Paul Jargowsky. Unlike previous studies which are locale specific, this study examines national poverty data. Jargowsky finds that structural changes in the economy have in fact adversely affected those with lower educational levels and job skills by reducing their wages. He also finds that deconcentration of employment further reduces the possibility of these individuals finding work and that the flight of higher-income individuals from poverty neighborhoods is an important factor in increasing neighborhood poverty. However, he could not find any evidence that strongly supports the notion that segregation plays a direct role in the recent growth of poverty neighborhoods. Jargowsky concludes by suggesting that neighborhood poverty is the

> predictable result of the economic status of minority communities and the degree to which minorities are residentially segregated from whites and from each other by income (Jargowsky ,1997 p. 19).

3. *Why is it Important to be Concerned About Urban Poverty?*

One of the reasons for the concern with urban poverty is that place and neighborhoods matter. Therefore what happens to people living in these neighborhoods is of concern to policy-makers. Since the majority of residents of poverty neighborhoods are children often in female-headed households, they are of particular concern. What happens to children residing in poverty neighborhoods is the subject of considerable debate. There is ample evidence, for example, that many of these children are not adequately nourished, are in need of more regular medical care, are not properly supervised, and are constantly exposed to drugs and criminal acts. But there is no consensus on what should be done to improve the quality of life for these children, let alone who should do it, and how it should be financed. At the same time, most urban dwellers believe that something needs to be done. Passage of the 1996 Welfare Reform Act may have a significant impact on many of these households as mothers are required to transfer from public assistance to work.

To a lesser extent, some of these concerns apply to the elderly who are often trapped in poverty neighborhoods. Even though municipalities, for the most part, have been conscientious in providing some services to the elderly (most notably transit, housing, and nutrition), environments in which these elderly reside, by most accounts, can be hazardous.

A second reason for concern about poverty neighborhoods revolves around the question of equity, particularly in the provision of public services. Poverty neighborhoods contain the oldest housing stock most in need of repair, the most deteriorated infrastructure, have the highest levels of toxic waste concentrations, and the least amount of open space, particularly in comparison with more affluent neighborhoods. Given these conditions, how should public resources be allocated to address these problems?

A third reason for concern is that poverty neighborhoods are believed to be the cause of a number of undesirable social conditions, high crime rates, family disintegration, incidences of major health problems including high infant mortality, tuberculosis, HIV/AIDS, alcoholism, and other antisocial behavior. These conditions if left unchecked could spread to other neighborhoods.

Finally, the concern with poverty neighborhoods centers around the widely held belief that these neighborhoods adversely impact other neighborhoods. Here the concern is often with crime and violence, the impact on property values, and how much of a tax drain poverty neighborhoods cause for other areas of the city. There is also the concern, as was evidenced in Los Angeles in 1992, that intolerable conditions can lead to civil unrest which has proven to be extremely costly (Orfield 1997, Pastor 1993).

4. *Conclusion*

After nearly four decades of research and efforts at policy reform and program intervention, one thing is abundantly clear—the number of persons in poverty is increasing and persons in poverty are becoming more and more concentrated. Between 1970 and 1990, the number of poor people in high-poverty neighborhoods nearly doubled, from 1.9 million to 3.7 million. This rate of growth exceeded the overall rate of increase in the total population in poverty neighborhoods during this same time period, in spite of the fact that during the 1980s the nation experienced good economic times. Most perplexing is the growing poverty rate among households where one or both adults are working. A robust economy might have provided jobs but not at wage levels that moved people out of poverty.

What is wrong? One might conclude that problems of poverty cannot be solved. Or one might suggest that those who are responsible for providing policy leadership on this issue simply have not found the right solution yet. More disturbing, however, is the thought

that the vast number of Americans not in poverty simply do not care much about those who are.

Clearly, there is no simplistic solution to the question of poverty. Indeed this may be one of the problems. Politicians in their zeal to provide solutions respond to constituents or press accounts which usually focus on symptoms or sensational exposes. Researchers tend to focus on individual policy issues. What is needed, perhaps, is a more comprehensive policy approach which takes into account the structural sources of poverty, its multigenerational roots, and the link between individual neighborhoods and regions.

Urban Sociology

Urban sociology concerns itself with the social and cultural forms assumed by the urban phenomenon in the past and in the present. It endeavors to understand the worldviews of the various cultures that have produced cities, and the coherence or incoherence with which these worldviews have been given concrete form.

The city is the entity to which the Greek philosopher Aristotle attributed a capacity 'to suffice unto itself.' He argued in *Politics* that 'the perfection of existence' was possible in the city and he concluded that 'man is a political animal created to live in cities.' The history of cities displays wide typological differentiation: cities vary according to the manner in which they began and subsequently developed, and according to their geographical and cultural area. But there seems to be one feature shared by them all: a capacity to dominate and organize the space surrounding them by virtue of their concentration of power in its various forms—political and administrative, military, economic, cultural, scientific, and religious. There have indeed been societies and cultures without cities as their political, administrative, economic, and cultural points of reference, or which possessed them only to a limited extent—consider the Europe of the High Middle Ages—yet it is nevertheless true that the

organization and development of systematic control over a territory has always centred on a capital city, and therefore on a hierarchy of cities and settlements.

1. The City in History

Urban sociology seeks not only to describe and explain the rich variety of the phenomenon 'city,' but also to interpret the causal connections between the elements that constitute a city and the factors that first gave rise to them. This approach furnishes understanding of the complex as well as profound meaning of every urban reality. To study the history of cities is to study the history of civilizations, of societies, and of cultures: a far-reaching enterprise which involves numerous disciplines and is constantly enriched with the results of scientific research.

One might enquire whether urban sociology is able to identify a single interpretative theme linking what by now constitutes a vast complex of urban phenomena. A simple list of the best-known urban forms demonstrates the difficulty of the undertaking. The history of the city, in fact, displays a rich variety of forms, which may be summarily listed as follows: the Sumerian cities; those of the Mesopotamian kingdoms; the Greek *polis*; the Phoenician cities; Rome and the cities of the Eastern and Western Roman Empire; the cities of the Asiatic empires; the cities of the Central American cultures; the Muslim cities; the city communes of the Middle Ages; the cities of the seigniories; those of the European sovereigns; the cities of the industrial revolution; the cities of Africa, Latin America, and Asia that arose as a result of European colonization; the metropolises of the twentieth century, and those that have now become city region and global cities; as well as the metropolises of the Third World. Finding an interpretative theoretical paradigm that comprises this huge variety of urban forms is an arduous undertaking, unless one resorts to a set of generic statements which risk lapsing into triviality.

One approach might be to single out a set of shared features and then flank them with those specific to each individual form of urban society and culture. As will be shown, every urban form, in its birth and its development, is geared to the production and distribution of goods, and to the management of the surpluses that engender the city as the hub of functions, services, and political power, administrative and organizational. The city also develops and disseminates patterns of urban planning and organization, models for the construction of supply and service infrastructures. It is the engine of technological innovation and knowledge, the center of political, religious, and military activity. These features, however, vary considerably across the manifold historical forms of the city, and it would be a gross oversimplification to impose a single sociological framework on such diversity. The general considerations to be drawn from comparative sociological analysis take the form of a social-urban philosophy, albeit one grounded on analysis of specific sociological urban types. Examples are the (important) assertions that can be made concerning the relationship between the forms assumed by the city and freedom, democracy, and the reciprocal exchange of urban political power and other cultures.

2. The Territorial Stabilization of Social Life

The city was at first a permanent settlement of a population on a particular territory, a settlement which developed specific forms and functions. The advent of humankind began the process known as *civilization* (from the Latin noun for 'city,' *civitas*) with the birth of the first settlements devoted to farming and cattle-raising but also to a sacred element: cemeteries and shrines. 'The city of the dead antedates the city of the living. In one sense, indeed, the city of the dead is the forerunner, almost the core, of every living city' (Mumford 1961, p. 7). The villages of the Mesolithic age surrounded themselves with palisades, they 'specialized' space, and they organized themselves into a hierarchy, with a political, economic, and social system that the city would later develop and strengthen.

3. The Rise of a Space Symbol System and Culture

It was this revolution that gave origin to space as a symbolic system. By choosing to live in settlements, humankind opted for a form of social life that gave priority to social features expressed through increasingly rich forms of communication: language, tools, communal meeting-places, the recognition of a leader, obedience to the rules of the community, places and forms of worship. Language and the home were the distinctive features of the Palaeolithic village, while the inhabitants of the Neolithic village clung to their burial places and their vital significance for the social group, while continuing to develop agriculture and cattle raising.

The origin and evolution of human settlements produced the sociological meaning of the city through the stages outlined in the following sections.

4. Antiquity and Urban Revolution in the Near East

The origin and evolution of human settlements with their diverse geographical and temporal features were replicated in the birth and rise of the cities. At the end

of the last Ice Age, the alluvial plains of the Nile, Tigris, Euphrates, and Indus yielded abundant crops for the peoples who moved in from the South and organized themselves as farmers. Surplus produce was used to maintain a group of artisans, scribes, functionaries, priests, and soldiers who introduced the spatial distinction between city and countryside. The first known urban conglomeration arose five thousand years ago (Clark 1977).

Space organization was connected with structured social functions: the beginning of the ambivalent relation between the city and its surrounding territories and settlements. The city became the locus of power: the place where the allocation of surplus goods was established, where reliable communication over long distances was made possible by the written word, where construction techniques were developed, where stable patterns of behavior were formed, and where the law was formalized (the fundamental law and rules regulating everyday life which supplanted the family and kinship bonds). An entirely new social and spatial dimension arose, which opened the way for a more formal and objective legal order, one legitimated by the urban community and which, in some cases, acquired the form of a state. The production of material equipment was enormously increased by the advent of models fixed by writing and registration. Thus, culture as a set of symbols produced and reinforced technology, exerting a powerful influence over the material production of goods which, in the absence of that culture, would only have developed sparsely and slowly. City and civilization, therefore, were closely bound up with each other in their birth and development.

5. *The Development of a Governmental Hierarchy*

The city came to reproduce, in historically different ways, the structural elements of the first human settlements. Various factors induced settlements to grow into cities, but the most notable of them were the centralization of the population, the advent of market, the court and administration, the temple, science (writings), and the army.

The clay tablets unearthed during excavations of the Sumerian cities (Ur, Erech, Lagash) document the corporative government exercised by priests who considered themselves the stewards of land entrusted to them by God. This belief was reproduced in the physical form of the city dominated by the temple, with its dwellings, storehouses, and workshops, and around which the city articulated itself according to social and spatial differentiation. When the Sumerian cities came under the sway of a king with sacred status and power, they manifested a power and an administrative organization arranged in a hierarchy between the capital city and those of lesser status in authority and function. Regulating this hierarchy of cities and localities was a set of laws that ensured the consignment of surplus or appropriated goods to the more central cities, and then developed into a system of tax collection and military organization which produced a veritable state. The Egyptian city pivoted on the power of the god-like Pharaoh, who wielded absolute control over the economy, which he utilized to build temples, pyramids, and tombs that raised him above common mortals. In the second millennium BC, the cities of the Far East developed according to a similar hierarchical pattern whereby the provincial cities were dominated by the capital.

The Greek city was the template for Western urbanism. Born of an alliance among communities and their kings (synoecism), from the sixth to the fourth centuries BC the *polis* became a reality in which the Greeks developed a culture devoted to reproducing in the city a vision of the world whose central component was not absolute power and the conquest of neighboring territories, but rather human harmony, body and intellect expressed, both physically and spiritually, in literature and the figurative arts, and also in the social life reproduced concretely and organizationally in the *polis*. The term 'city' thus came to coincide with 'politics,' a city organized as a city-state, the place of orderly and individual freedom. The Greek *polis* of this period was a city whose walls protected the country people when attacked and which granted freedom to its citizens. The *polis* carefully regulated its size (surplus population moved away to found new colonies), the purpose being also to preserve harmony and to protect the system of self-government constituted by the *prytaneum*, the place where the community's divine protector was worshiped, the *agora* or citizens' assembly, and the *bulè*, the council of nobles and representatives of the assembly.

6. *Roman and Greek Urban Development*

The Greek city expressed in admirable harmony the relationship between the city and its rural surroundings, but it was a relationship that was always ambivalent. On the one hand, the city comprised a complex set of powers which subjugated the surrounding territory; on the other, it developed a political, legal, economic, and organizational order, and a network of services, which incorporated the smaller communities into a system of which the city was the center and the administrative seat. The Alexandrine city that arose from Alexander the Great's expansionary policies and conquests was symmetrical in form, ordered according to a Euclidean geometry which ensured control and the orderly deployment of troops; a cultivated, refined and monumental city. The concentration of powers in Alexandria gave it decisive dominance over nonurban territory (Mumford 1961).

Rome, the capital city that ruled the territories around the Mediterranean basin, invested its Senate,

consuls, praetors, aediles, tribunes, and quaestors with powers that produced one of the most stable empires of history. As *caput mundi*, the headquarters of the state, Rome undertook the division of urban and agricultural territory, the founding of new cities, the building of aqueducts, sewers, basilicas, baths, amphitheaters and circuses, and the construction of an immense network of roads and military outposts. Besides being the capital of the state and the empire, it was the locus in which political powers concentrated and evolved, and where the urban models of the empire's cities were developed (e.g., Th. Mommsen). Rome established an organic, almost biological, relationship with the world of the empire; but it was a relationship which, amid the city's estimable political, administrative, legal, organizational, and military system, permitted no form of political, and especially cultural, reciprocity. When Rome's powerful inner impetus subsided, its grand design imploded because it was unable to draw on resources arising from interaction with other cultures regarded as equals. One single legal order was admitted, and no other order was allowed that might introduce innovations.

7. *The Disappearance of the Ancient City*

The barbarian invasions destroyed the political and organizational structure of the Western Roman Empire, while the empire in the East fell to the advancing Muslim Turks. The urban structure of the Roman empire was replaced in the West by the Christian territorial organization based on large rural landholdings, while the cities and the road network lapsed into decay through disuse. In the East, the Muslim cities represented an extension of the power wielded by princes and merchant corporations: without specific autonomies, they served to protect citizens and to safeguard trade routes and the agricultural market, while for other commodities they added further urban components.

8. *European Cities in the Middle Ages*

The medieval city in Europe was the result of revival in the economic and commercial development of the coastal cities of the Mediterranean and northern Europe, and the resumption of agriculture and artisan industry. The cities were revivified and became the centers of corporations, guilds, and confraternities, while their citizens developed a legal order different and distinct from that of the medieval lordship. This was a 'nonlegitimate and revolutionary' legal order (Weber [1921] 1958) endowed with city walls, its own civil law (which regulated relations among citizens according to rules established independently), its own lawcourts, and an armed corps of citizens called upon to defend the new order; all of which were guaranteed by the oath-swearing (*conjuratio*) of those who perceived themselves as brothers in a common enterprise. The medieval city, with its public spaces for artisan, commercial, religious, and social activity, assumed a complex urban form: the social configuration of the new notion of an autonomous community, with a political and legal system that gave birth to the constitutional and civil law of the modern state. The medieval structure of many European cities resisted the assaults of the lords and princes of the Renaissance, and those of the seventeenth- and eighteenth-century kings. The latter decided to forgo their endeavor to change the city, and instead set about building royal palaces with parks and estates outside the cities (Versailles, Schönnbrunn, Aranjuez, Caserta). This separation between royal-noble power and the urban classes made up of shopkeepers and professionals was the prelude to, and ground for, the bourgeois revolution.

9. *The Modern City*

The bourgeois and industrial revolutions engendered the subsequent great urban revolution. Population growth, immigration from the countryside, the more articulated organization of the city, heightened demands for comfort: these factors upset the balance between traditional and new urban space. Flanking such ecological problems were the inequalities among the urban classes (bourgeoisie and proletariat) that socialist (e.g., F.-N. Babeuf, C. Fourier) and liberal theory analyzed, and which the urban policies of the constitutional states addressed, but only by creating public and social spaces and services, while giving free rein to speculation and the market under rules that applied to all the social groups admitted to the competition for social ascent.

Sociology arose in concomitance with the problems that attended the birth and growth of industrial society, and it analyzed the urban phenomena that embodied the urban revolution. Marx conducted his critique of capital by starting from the radical inequality between the owners of the means of production and an exploited proletariat forced to sell its labor in the city called Coketown. Max Weber sought to understand the birth and crisis of capitalism by studying the medieval European city as the origin of the free economic enterprise that gave rise to the new and free legal order; the city that gave liberty to all those who decided to join it, and whose motto was '*Die Stadtluft macht frei*' (The city air makes us free).

However, although this city produced a political and legal system by which citizens were free under the state and the modern legal order, it was not a city of equals: it may have been made up of formally equal citizens but it was marked by frequently profound social and spatial disparities.

The Chicago School analyzed the phenomena and problems of a modern industrial city under pressure from multiethnic immigration and with spatial and

social segregation according to income, ethnicity, and profession (Park et al. 1925), its conviction being that urban dynamics were similar to those of a biological organism. The modern city has developed this segregation into the new and dramatic form exemplified by the cities of the Third World. These urban conglomerations are unable to drive development because they consist of enormous concentrations of immigrants in search of sustenance and with little hope of finding stable and decent employment. They are cities, with their almost boundless demographic and spatial expansion, that lack ancient centers of historical importance with which their inhabitants can identify. The modern installations of the cities that have developed in the ex-colonial countries, their business districts and quarters restricted to the middle and upper classes, have forced their poor and marginalized inhabitants into the periphery.

The metropolises of the European and American West have become the world centers of political, economic, and financial power, of services and the organization of production. Extending as they do across the territory of several states, and incorporating the entirety of politics, science, technology, business, and leisure, for some time they have constituted the symbol, and become the Utopia, of the 'new order of ages' described by Jean Gottmann (1961) in *Megalopolis*, which suggests that the world is controlled and receives its meaning from an urban culture which acts as the engine of all development, material, social, and cultural.

10. The World as a City System

The contemporary city has burst through the boundaries that used to separate it from the countryside and surrounding space. It pervades them as does Gottmann's megalopolis, or it penetrates them and binds them with a network of communication and transport structures which do not stand in a reciprocal relation with the countryside and external space; on the contrary, it is thus that the city asserts its ramified supremacy. On this view, the city determines every type of production and the ways in which surpluses are utilized; it decides who should receive economic rewards and professional recognition; it establishes which spaces are to be allocated to services and which should be reserved for different social classes, according to a meritocratic hierarchy based on a scale of values determined by the elites of the city itself.

11. Urban and Regional Sociology

Cities do not change, even less do they dissolve in the regional dimension. On the contrary, the latter demonstrates that the urban dimension of power has not freed itself from the restrictions imposed by city walls, by administrative or jurisdictional boundaries, by the attraction of a market spatially identified with an area called 'city.' Finance and the organization of production and work do not rely solely on the automation and advanced technologies that require increasingly skilled workforces. One feature of the 'global city,' in fact, is its indifference to the spatial allocation of the production process. The increased production of nonmaterial goods and information technologies has led to the greater use of teleworking, which enables closer and more efficient monitoring of the quantity and quality of output.

The city continues to control the production of services and access to them, and has thus become dominated by tertiary activities. It ensures and refines its supremacy over increasingly broader territories, using instruments of ever greater sophistication but of decreasing visibility to public opinion. The city, in fact, has developed a new technological and professional perspective: that of communications, which is now one of the most highly developed and influential of production sectors, able to construct images which convey lifestyles, symbols of prestige and gratification, and, indeed, visions of the world. The global city displays the features of a market on the world scale which nation-states and international bodies are unable to regulate with effective policies. The city, precisely because it represents and coincides with the power centers of the global market, also produces the symbols and mechanisms that legitimate this planetary power; symbols and mechanisms of legitimation which the legal and political orders of states are unable to counteract or to replace.

Urban Sprawl

Urban sprawl is an imprecise but highly evocative, usually derogatory, term used primarily in the economically advanced countries of the English-speaking world to describe certain kinds of low-density urban landscapes with little comprehensive public planning. The chief arguments against this kind of settlement pattern are that it is inefficient, inequitable, environmentally damaging, socially irresponsible and aesthetically ugly. To halt sprawl, reformers have called for more highly planned, compact, transit-oriented cities. Among the remedies proposed to stop sprawl are political changes including the move of planning functions upward in the governmental hierarchy, the removal of subsidies supposedly supporting sprawl, the implementation of a system of incentives intended to create higher densities, growth restrictions, growth boundaries, greenbelts, open space conservation and historic preservation. Although the term was used by planners and other experts for at least a half century, it became a major public concern only in the economic boom period of the last years of the twentieth century. At the same time, however, it became clear that even the most basic assumptions about the definition of urban sprawl, its causes, and the effect of various proposed remedies were in dispute.

1. *History of the Term*

Described by various words over the years, the kinds of condition the term 'sprawl' would later refer to have almost certainly been matters of concern as long as towns have existed. By the nineteenth century, certainly, complaints about buildings straggling out from towns and villas marring picturesque landscapes were quite common in Britain. These complaints seem to have entered the political arena in a major way following the great prosperity of the 1920s. One of the most important critics was planner Thomas Sharp, who issued vitriolic attacks on the new 'semi-suburbia,' on 'ribbon developments' along roads leading out of town, and on suburban villas marring the countryside (Sharp 1932). His cause was taken up by groups such as the Council for the Preservation of Rural England with its heavy constituency of large landowners, and several bills passed in the 1930s aimed at restricting ribbon development and creating greenbelts around cities.

It appears to have been during the 1930s that the use of the word sprawl as a noun with something like its current sense came into general usage. One prominent use of the term occurred in the famous Greater London Plan of 1944 (Abercrombie 1945). It was also used on the other side of the Atlantic by Lewis Mumford in *The Culture of Cities* (1938). The original criticisms of sprawl were almost always based on aesthetic and symbolic considerations. It was ugly, and blurred the traditional distinctions between the city and the countryside (Bruegmann 2000).

Complaints about sprawl have continued to accompany every era of major prosperity since World War II, but they have changed considerably in content and have been modified depending on the time and place. Immediately after World War II, sprawl became less of an issue in Britain because it, like many continental European countries, had been exhausted economically by the war and at the same time had adapted the kinds of stringent controls on peripheral development around large cities that planners had advocated in wartime reconstruction plans. In the United States, on the other hand, the prosperity of the postwar years without any strong growth control planning led to a tremendous suburban boom. Consequently the most conspicuous negative reactions to sprawl came from the United States. At the same time, the focus started to expand to include objections based on notions of equity and quality of community. These paralleled closely the criticisms that were being made at that time by a number of prominent sociologists of suburbia in general. According to this analysis, the suburbs were conformist, alienating, homogenous, and boring (Riesman 1950, Whyte 1956).

The most conspicuous use of the term sprawl in the postwar decades came from William H. Whyte, who organized a conference for *Fortune Magazine* on the subject and then published a jeremiad against sprawl in *The Exploding Metropolis*, a book that he edited (Whyte 1958). For Whyte, as for the British, sprawl was primarily an aesthetic problem, but he made scattered comments that suggested that sprawl might also be inefficient economically and have negative social repercussions. These were arguments that would be expanded, starting in the 1960s, and combined with

new elements from the environmental movement. Whyte's essay also started what would become a common practice of using the Los Angeles metropolitan area as a prime example of low-density sprawl.

As the various strands of the sprawl argument were worked out and debated in the following decades, the term became more common but it never acquired a clear definition. By the late twentieth century, the term could mean many different things to different people using it. Almost everyone agreed that it referred to low-density development, but low density in a European city could still be denser than relatively high density in a city in the United States. Sprawl commonly referred to settlement that was scattered, discontinuous, leap-frog, or ribbon, but as many observers pointed out, with additional development the low-density discontinuous settlement of one era often becomes the highly admired, compact, and high-density settlement of the next (Lessinger 1962). Sprawl could also refer to automobile-dependent development or to development with poor access from home to work or to public open spaces, but many other observers have pointed out that, as cities have become wealthier, they have almost inevitably seen more automobile usage and, in many cases, commuting times have remained the same or fallen. The state of the term at the turn of the century can perhaps best be seen in a pair of articles published in the *Journal of the American Planning Association* in 1997, one by Harry Gordon and Peter Richardson, who challenged the idea that sprawl was a major problem; and the other by Reid Ewing who maintained, along with most mainstream planning thought, that it was indeed a problem. In some ways, the most remarkable part of the debate was not the conclusions about the problems and the proposed remedies but the lack of agreement about what sprawl was. The two essays, with the ensuing letters, made it clear, for example, that even as basic an issue as whether Los Angeles was a high-density, relatively compact city or a low-density sprawling city was in dispute (Ewing 1997, Gordon and Richardson 1997).

By the late 1990s, important coalitions to counter scattered, low-density, automobile-oriented growth at the periphery of urban areas were in evidence in virtually every affluent nation in the world, although the term sprawl was mostly used in the United States, Britain, Canada, and Australia. In the United States, the term 'smart growth' became important in the 1990s to designate efforts to combat sprawl. In England, Canada, and Australia, 'the compact city' tended to be the term used to refer to the opposite of sprawl. In all of these places, sprawl also tended to be contrasted with 'sustainable' development, another term with a large literature and extremely divergent definitions (Jenks et al. 1996). In continental Europe, in the face of a vast increase in automobile ownership, suburban development, and peripheral shopping centers, the European Economic Community declared itself in favor of compact, transit-friendly cities with single vibrant centers (Commission for the European Community [CEC] 1990, Nivola 1999). In Japan, the term *supurôru* was coined to designate what English commentators called sprawl, although the target was more haphazard growth and assurance of adequate infrastructure than any specific desire to make development more compact (Hebbert 1994). The concept of sprawl has also been used in Israel and elsewhere (Razin 1998).

2. *Objections to Sprawl*

Objections raised by reformers to sprawl have changed dramatically over the years and according to the viewpoint of the observer. They can, however, be classified under five major headings that range from the apparently quite objective to the obviously very subjective. These categories might be designated efficiency, equity, environmental sustainability, social responsibility, and aesthetic and symbolic suitability.

2.1 *Efficiency Concerns*

Although the earliest and most constant objections to sprawl have been aesthetic, the debate about public policy to curb sprawl has primarily been conducted in more objective terms. The earliest and most extensive segment of this literature has targeted the alleged inefficiencies of sprawl. The most important early summary of these issues in the United States in the postwar decades appeared in the costs of sprawl issued by the Real Estate Research Corporation (1974). Using hypothetical models of various kinds of development, this report concluded that master-planned communities at fairly high densities were much more efficient in terms of private development costs and public infrastructure costs than what they called 'unplanned' communities at low densities. This report was attacked immediately on several fronts. Before the report had appeared, several researchers had noted that what appeared to be scattered low-density development was often a high-density compact neighborhood in the making. In fact, scattered development often produced even higher densities in the end, than development built all at one time (Lessinger 1962). Another attack on the conclusions in the report came from reviewers who stated that the apparent savings actually were primarily due to the failure of the report to hold conditions constant in the various models (Altshuler 1977, Windsor 1979). Other researchers suggested that master-planning, as opposed to the hypothetical models used by the Real Estate Research Corporation, did not in practice yield the savings that should have been expected and was often more expensive (Peiser 1984). The supposed efficiencies of high density, likewise, were disputed (Ladd

1992). More recently, a new report on the costs of sprawl has tried to respond to these challenges (Burchell et al. 1998). According to this report, the dire predictions of previous researchers had not materialized but, it opined, the higher costs of low density settlement, particularly road and other infrastructure costs, would soon become intolerable.

2.2 Equity Concerns

The second charge against sprawl, that it is blamed by some for exacerbating economic and social inequities, was, until recently, much more common in the United States than elsewhere, because it was primarily in the United States that affluent individuals moved in great numbers from the central city to the far suburbs. Concerns about inequality became common in the wake of the civil unrest in American cities in the 1960s and concerns about the survival of the inner city. According to the view of many reformers, sprawl was not inevitable or even a freely made choice by most of the population.

Instead, it was a condition that was, at least in part, induced artificially by massive federal subsides in favor of homeownership, notably homeowner insurance guarantees, mortgage interest deductions that supposedly favored new suburban home building, and federal funding for the massive postwar highway building program. As affluent citizens moved out of the central city, this tended to maroon poor and minority families who were unable to move at the same pace. At the same time, it tended to deplete the tax base of the older municipalities as, according to this line of thought, they lost sales taxes and property taxes to outlying municipalities. Other observers have noted that none of these programs was designed to produce massive decentralization, and that any of them might have had quite different effects absent a high level of affluence and a strong underlying desire to decentralize.

2.3 Environmental Concerns

Environmental concerns started to play an increasing role in anti-sprawl polemics following the ecological activism of the late 1960s. According to this line of thought, low-density settlement led to excessive energy usage, particularly automobile usage (Newman and Kenworthy 1989). This in turn led to the depletion of resources and to increased pollution. Low-density settlement also led to the loss of farmland, most seriously prime farmland near urban areas, and to forests, wetlands, and other open lands. Attempts to stop sprawl for environmental reasons have often been grouped under the heading of sustainability (Jenks et al. 1996, Brotchie et al. 1995).

Clearly, energy usage has been shown to be much higher in the affluent countries of the world than in the developing world. Cities in the United States, moreover, use much more energy than their counterparts in Europe. For many environmentalists, this constitutes a fundamental human challenge that can only be solved by stringent conservation measures and replanning cities to be more energy-efficient. Other scholars have noted a history of decades of dire warnings about looming energy shortages and ecological disaster, none of which has come to pass, and have suggested that technology itself will be much more effective in finding answers to problems than efforts to turn the clock back.

Perhaps the most contentious area involving both energy consumption and environment remains the use of the private automobile. Sprawl reformers are almost all united in the belief that private automobile usage must be lessened and public transportation strengthened to reduce both congestion and pollution. On the other hand, other scholars have pointed out that both congestion and pollution levels are often higher in denser metropolitan areas than they are in areas of lower density. The idea that it will be possible to counter the rise in automobile ownership and per capita vehicle miles traveled (VMT), which is a feature of virtually every city in the world as it has become more affluent, or to counter the drop in the proportion of citizens riding public transportation, which has also been true in virtually all of these places, is, according to some observers, both unlikely and undesirable (Gordon and Richardson 1997).

One of the most emotional parts of the debate about sprawl has concerned the loss of farmland. According to many anti-sprawl reformers, cropland, particularly prime cropland, is an irreplaceable asset which is being fast eroded by urban expansion. Those who take an opposing view counter that very little of the farmland lost since World War II has been lost to development, at least in the United States, and that the pace of farmland loss is moderating in any case. The major reason for loss of farmland, according to this point of view, is that productivity has soared and there is less need for land planted in crops. The increase in land for urban uses, moreover, has been less than the amount of additional land added to the supply of permanently protected open spaces (Staley 1999).

2.4 Social Concerns

Another charge against sprawl coming out of the activism of the late 1960s, and most common in the United States, was a belief that sprawl leads to impoverished social relationships and communities. Antagonism to sprawl on social grounds has often been bound up with attacks on suburbs generally. These were seen as alienating, soulless places in the famous sociological studies of David Riesman and William H. Whyte. This literature reached a crescendo

in the postwar decades before it was rebutted by other sociologists, for example, Herbert Gans (Riesman 1950, Whyte 1958, Gans 1967). The equation of suburbia and sprawl with social alienation was revived in the 1990s. One of the most potent areas of concern has been the so-called privatization of public spaces, for example, the decline of Main Street shopping centers in the wake of suburban shopping malls (Sorkin 1992). Other observers have suggested that what is important in social relationships and community has not changed: they argue that only the outward forms of it have changed, and this should not be unduly troubling. A particularly thorny problem related to sprawl in the United States concerns the factor of race. Some writers have believed that sprawl has been caused in great part by racial tension, and that the low-density suburbs are an attempt by middle class citizens to distance themselves from social problems in the city. Other observers have noted that sprawl has occurred in much the same way in metropolitan areas with few minorities as it has in areas with large minority populations, suggesting that race, while important, may not be an underlying cause. They also note that suburban areas have always been and are increasingly diverse.

2.5 Aesthetic Concerns

The final complaint about sprawl, that it is ugly and symbolically inappropriate, has inspired the most constant and abundant literature throughout the years. The sprawling city has been said to be unplanned, chaotic, monotonous, neither urban nor rural but a combination of the worst aspects of each. One of the chief problems with this kind of judgment, however, has always been that various groups differ widely in their aesthetic sensibilities, and that, even within a single group, responses can change dramatically over the years. It has also been conspicuous, from the interwar complaints of British landowners down to the beginning of the twenty-first century, that there are class-bound aesthetic interests at work in this kind of critique.

3. Proposed Remedies for Sprawl

The most obvious and dramatic remedy to sprawl would be to stop new development outside existing urban areas altogether. This could be done by outright governmental prohibitions or by limiting the development of necessary infrastructure, notably roads, water delivery systems, and wastewater treatment facilities. By whichever means, stopping peripheral growth altogether has been tried but has rarely worked if population was growing. Immediately after World War II, zero growth appeared to be a possibility in European cities but it has since proved illusory. In the United States, on the other hand, growth was always considered a given. In the wake of the postwar boom period, the 'slow growth' and 'no growth' movements became prominent in a number of US cities. These were, in many ways, the precursors of turn-of-the-century anti-sprawl movements. In most cases, growth was stopped or slowed in a given municipality, but subsequent research has suggested that the growth merely migrated to adjacent communities (Porter 1997, Garvin 1996).

3.1 Channeling or Managing Growth

Attempting to manage or channel growth, rather than stop it altogether, on the other hand, has often been implemented over the years with at least limited success. One of the earliest and most important attempts to do this was the greenbelt system instituted around British cities, notably around London. In this system, a growth boundary was established marking the edge of a greenbelt in which development was forbidden. Any additional growth that could not be accommodated in the existing developed area was to be confined as much as possible to existing towns and villages beyond the greenbelt, and to newly established 'new towns.' This system, which borrowed many features from Ebenezer Howard and his garden city concepts, did in fact stop much, although not all, of the growth that otherwise might have invaded the greenbelt around London. It was not nearly as successful in containing growth beyond the belt. In fact, growth beyond the greenbelt eventually scattered across much of southeast England. Moreover, by restricting the land available for new development adjacent to the already built-up area, it very likely raised land prices considerably, making it more difficult for people of modest means to afford housing, and perhaps driving them further out than would have been the case without the restrictions (Hall et al. 1973). Still, the London model has been very influential. A similar kind of greenbelt, together with a set of policies encouraging compaction and public transportation, has been put in place by the regional government of Portland, Oregon. The experience of Portland, which has been America's most conspicuous exemplar of anti-sprawl planning, has been watched closely and debated hotly (Abbott et al. 1994, Mildner et al. 1996).

In other cities, other kinds of devices were used to channel growth. In Paris, for example, new development was to be channeled into specific growth corridors organized around transportation lines and large new towns. The same kind of system was proposed for the Washington DC metropolitan area. One virtue of these proposals was that they mirrored the way development had occurred historically along transportation routes. In practice, however, it proved difficult to enforce these corridors in the face of major

demand for new land to develop, and, because they tended to be based on rail transportation, they are thought by some to be inadequate for areas at the periphery where most people drive.

3.2 Open Space Conservation

Another measure sometimes counted as an anti-sprawl technique involves the creation of permanent open space. This can be done by legislative fiat, by the purchase of land or of development rights by private or public bodies, or some combination of these mechanisms. Although these measures are often counted as anti-sprawl measures, they do not, in themselves, stop sprawl but merely channel whatever growth would otherwise occur in specific directions. They also tend to reduce gross densities, arguably fostering sprawl.

3.3 Governmental Structures and Incentives

Other techniques for curbing low-density settlement and promoting high-density growth involve governmental policies and structure. In the United States many sprawl reformers blame competition rather than cooperation among units of local government. The American tradition of deciding land use policies at the local level, combined, in many cities, with a very fragmented system of municipal government, has been seen by reformers as a major reason for lack of coherence in planning, and as a major incentive for development to sprawl (Gottdiener 1977). The remedy, for reformers, is to form metropolitan-wide governments with strong planning responsibilities, or to push responsibility for planning up to the state or federal level, so that local competition for tax dollars will be less an influence in planning decisions. Moreover, tax revenues would be shared more evenly, making it difficult to move to avoid taxes, and allowing the possibility of a more equitable distribution of income for schools and other public services (Orfield 1997). Among the most important metropolitan governments in North America are those of Portland, Minneapolis-St. Paul, and Toronto. States that have initiated strong growth management laws include Oregon, Florida, and New Jersey. Whether or not these policies will have any substantial effect in stopping the outward decentralization of people and jobs in the long run is still unknown.

Another area targeted by reformers involves tax policies and other governmental fiscal policies. Sprawl was subsidized by federal mortgage insurance policies and by the mortgage interest deduction on the federal income tax, according to reformers. Low-density settlement was also subsidized by heavy federal subsidies provided for roads, and the lack of subsidies at the same scale for public transportation. Many reformers would like to see the end of the federal mortgage interest deductions, heavy taxes on gasoline and vehicles, and much greater funding for transit. One influential group has justified these moves as correctives to make the market reflect more adequately the externalities caused by things like automobile use (Downs 1994). Other observers suggest that any major program to introduce sharp increases in fees on private transportation would be highly regressive; and they question whether, given the apparently inexorable trend toward low density, the higher fees on private transportation and more funding for projects such as rail transit would actually lead to a corresponding rise in transit use, or just to yet higher levels of highway congestion, pollution, and economic hardship (Gordon and Richardson 1997).

3.4 Design Solutions

A final set of recommendations to deal with sprawl has been made at the level of urban design. Proposals for transit-oriented design (TOD), in which high density uses are planned near transit stations, or 'New Urbanist' designs, which attempt to create a mix of uses to promote community and transit use, have all been advocated, and some building has actually occurred (Katz 1994). It is again too early to judge the success of these efforts, which to date have been very modest, but, in the last years of the twentieth century, there was little evidence that these developments, mostly suburban and at quite low densities, had had any effect on overall urban patterns.

3.5 The Sprawl Debate

Beyond the question of problems supposedly created by sprawl, or the efficacy of any particular remedy, is a larger set of questions about whether sprawl is recent, whether it is accelerating or is actually declining, and whether it is peculiarly American or whether American cities merely represent an advanced stage in a process that is visible everywhere in the world. There has actually been very little research on many of these questions but there does seem to be some evidence that in the United States, where the debate at the end of the twentieth century was hottest, decentralization and sprawl might have had their greatest per capita development in the period between the 1920s and the end of the postwar decades, and might actually be declining. There is also a fundamental question about whether the denser cities of Europe and elsewhere are actually different from American cities, or exhibiting all of the same characteristics but merely evolving at a slower rate and less obviously because of the large mass of existing urban fabric (Bruegmann 1996).

In the United States and Britain, the chief opposition to sprawl since World War II has come from the left side of the political spectrum and tends to unite academic planners, land conservationists, and historic preservationists. The anti-sprawl efforts have been opposed primarily by individuals from the right side of

the political spectrum, particularly land economists and those who favor an increased role for the private market. Elsewhere in the English-speaking world, particularly in Australia, the situation appears to be somewhat different, with reformers to the left of center objecting that efforts to enforce more compact development for efficiency reasons will inevitably have a negative impact on the less affluent part of the population, and exacerbate existing inequalities in levels of service and amenity (Troy 1996).

R. Bruegmann

Urban Studies: Overview

Urban studies is the interdisciplinary academic field concerned with understanding cities. Scholars from the social and behavioral science disciplines of history, sociology, geography, economics, political science,

and anthropology and the professional field of urban planning have produced most substantive urban studies knowledge. Urban studies scholars primarily use social science research methodologies. They have developed a body of theory about cities. The field of urban studies has its own academic courses and degree programs, professional associations, and scholarly journals.

While cities have attracted scholarly attention for more than two millennia, rapid urbanization during the industrial revolution stimulated the first systematic urban studies research and writing in the nineteenth century. In the early twentieth century urban studies entered academic curricula through programs in urban planning, sociology, and then other social science disciplines. The field grew slowly through the end of the 1950s. The 1960s saw a huge increase in urban studies research, courses, and academic degree programs.

Today urban studies is sometimes pursued in interdisciplinary urban studies programs; sometimes as part of curricula in geography, sociology or other academic disciplines. Urban studies material is taught as part of professional urban planning curricula. There are many niche subfields within urban studies where two or more disciplines or fields intersect. Urban political economy, urban planning history, urban economic geography, and urban political sociology are examples.

1. The Field of Urban Studies

1.1 Urban Studies, Academic Disciplines, and Professional Fields

The categories into which universities divide human knowledge are ever changing and their boundaries are not clear. Universities usually organize academic disciplines such as sociology and economics separately from professional fields such as urban planning and architecture. Most urban studies material comes from social and behavioral science disciplinary perspectives; some from other humanities, natural sciences, creative arts and elsewhere.

Scholars in the social science disciplines of geography, sociology, economics, anthropology, political science, and history (which is sometimes classified as one of the humanities) have generated most of the urban studies literature. Urban planners, architects, urban designers, and landscape architects have contributed to the field. Journalists like Robert Caro, Neil Peirce, and Joel Garreau have written important urban studies books, as have self-taught polymaths like Jane Jacobs and Lewis Mumford. Key writings by scholars for different disciplines have been collected in an anthology edited by Richard LeGates and Frederic Stout (LeGates and Stout 1999).

Since the object of study is so large and the perspectives that can and have been brought to bear on it so diverse, the boundaries of the field of urban studies are harder to define than disciplines such as paleontology and botany. The field is partly descriptive—seeking to describe the physical form and social characteristics of cities. It is partly explanatory—concerned with explaining physical and social attributes of cities. Description and explanation lead urban studies scholars into prediction and prescription.

1.2 How Urban Studies is Organized Within Universities

Sometimes departments or programs in urban studies hire faculty trained in sociology, political science, economics, history, anthropology, urban planning and other disciplines and professional fields to teach urban studies courses. Often they have relationships with faculty-based disciplinary departments. For example, an urban studies program which does not have an urban economist on its faculty may have an urban economist teach a course for their students.

Urban studies material is part of the curricula of geography, sociology, and other social science disciplines. It is taught in professional urban planning, architecture, landscape architecture, and urban design programs. Faculty based within disciplines emphasize scholarship from their respective disciplines, but almost all disciplinary-based courses incorporate writings by scholars from other disciplines.

1.3 Urban Studies and Related Degree Programs

Many universities offer BA degrees in urban studies. Brown, Cleveland State, Cornell, Columbia, Hunter, Minnesota, MIT, Pennsylvania, Pittsburg, Rutgers, San Francisco State, Stanford University, and Vassar are examples (Urban Affairs Association 1995). Michigan State, New Orleans, Ohio, Ohio Wesleyan, Portland State, and Temple offer masters degrees in urban studies. Portland State, Michigan State, and the University of New Orleans offer Ph.D. degrees in urban studies.

Many universities offer degrees with names like urban studies and planning, urban affairs, and metropolitan affairs. Graduate urban planning programs at MIT, Portland State, Virginia Commonwealth University, the University of Maryland and elsewhere offer masters degrees through departments of urban studies and planning (ACSP 1998).

Two academic associations organize conferences, set standards, publish academic journals, and work to advance scholarship in urban studies. In North America the Urban Affairs Association (UAA) has an annual meeting, publishes the *Journal of Urban Affairs* and a newsletter, and has published a *Guide To Programs in Urban Studies and Affairs* (UAA 1995). A European counterpart organization, the European

Urban Research Association (EURA), was created in 1998.

The *American Planning Association Journal* in North America, the *Town Planning Review* in the UK, *The International Journal of Urban and Regional Research*, the journal *Urban Studies*, and many more specialized journals publish scholarly urban studies material.

1.4 Urban Studies Research Methodology

Urban studies scholars employ both quantitative and qualitative research methods, primarily from the social sciences. Scholarly writing about how to do urban studies research is sometimes explicit; often implicit in the methodologies urban studies scholars have actually employed in their research.

Training in applied statistics is a regular part of most urban studies curricula. Urban studies students are trained to use computerized statistical packages to do quantitative analysis. Because many urban phenomena have a spatial dimension geographical information systems (GIS) software is increasingly important in urban studies education and practice.

Urban studies scholars also employ qualitative methods. William Whyte's study of how people use urban parks and plazas is a notable example of observation. Urban anthropologist Oscar Lewis conducted exhaustive field research. Sam Bass Warner did archival research on the records of ordinary developers of ordinary Boston streetcar suburbs. Planner John Forester conducted interviews of dozens of urban planners to understand planning in the face of conflict. Urban studies research often employs both quantitative and qualitative research methods to triangulate on the object of study.

2. The Evolution of Urban Studies

While scholars have studied, thought, and written about cities for more than two millennia, systematic studies of cities did not begin until the nineteenth century. Academic recognition of the field occurred only in the twentieth century, and most urban studies scholarship has taken place since 1960.

2.1 Early Urban Studies

Cities have excited the interest of scholars since the earliest times. In *The Republic*, the Greek philosopher Plato envisioned the ideal polis in the fourth century BCE. The Roman architect Vitruvius formulated principles for planning cities. Monks worked out a detailed plan for the physical and social organization of the monastery of St. Gall, Switzerland, and by extension other mediaeval communities, in the eighth century AD. Florentine architect Leon Battista Alberti reminded his peers of what cities could contribute to the rebirth of humanism during the renaissance.

2.2 The Industrial Revolution, Nineteenth Century Industrial Cities, and Urban Studies

Prior to the industrial revolution there were few cities and—with the exception of imperial Rome—cities were very small. As water- and then steam-driven machinery fueled the industrial revolution, urbanization proceeded with unprecedented speed and on a scale never before seen in human history. Industrial cities arose in textile towns of the English midlands, then through much of Europe and North America. By the middle of the nineteenth century unplanned, congested, polluted slums jammed with a new impoverished urban proletariat dominated nineteenth century industrial cities. Friederich Engels, Edwin Booth, and Asa Briggs conducted empirical investigations of nineteenth century cities. Robert Owen, Charles Fourier, and Henry de Rouvreoy, Saint-Simon and their followers planned, and sometimes built, utopian communities. Anarchist Petr Kropotkin agitated for cities built around factories in fields to replace the nation state. Karl Marx and Friedrich Engels called for the liberation of the urban proletariat and the elimination of distinctions between city and countryside. Landscape architects Andrew Jackson Downey and Frederick Law Olmsted led an urban parks movement. German land economists Johann Heinrich von Thünen and August Lösch developed models that blossomed into twentieth century location theory. German sociologists Ferdinand Tönnies and Max Weber and French sociologist Emile Durkheim developed theories of societal organization that prefigured urban sociology. Civil engineers like Baron Haussman in Paris and Alberto Soria y Mata in Madrid, public health officials like Benjamin Ward Richardson in London, and settlement house workers like Jane Adams in Chicago studied, theorized about, and agitated for the improvement of nineteenth century industrial cities. But it was not until the twentieth century that academic courses and degree programs in urban studies were created.

2.3 Academic Urban Studies in the Twentieth Century

The University of Liverpool in England and the Massachusetts Institute of Technology in the United States began the first formal courses devoted to cities (Hall 1996). Liverpool established a degree program in town and country planning in 1909 and MIT instituted a course taught by urban planner Thomas Adams the same year. These courses emphasized physical planning and design, but, fortunately, both Thomas

Adams at MIT, and Stanley Adshead and Patrick Abercrombie at Liverpool were well-read interdisciplinary academics who incorporated historical, economic, social, and political material into their urban planning courses, textbooks, and academic writings.

Systematic research and urban studies teaching took a giant leap forward beginning a decade later when the University of Chicago created the world's leading center of urban sociology starting in the 1920s. The Chicago school of sociology attracted creative and talented scholars who used neighborhoods surrounding the campus to study urban society. They developed the field of urban sociology and inspired development of the urban studies content of other disciplines.

Coursework with cities as the unit of analysis slowly penetrated other social science disciplines and the number of urban planning programs grew during the 1930s, 1940s and 1950s. Still, by the end of 1950s, there were only a handful of courses in urban politics, urban history, and urban anthropology, not one text in urban economics, and just a few dozen small design-oriented urban planning programs in the entire world.

Ghetto riots, and a massive increase in federal aid to cities in the United States in the 1960s greatly expanded urban studies. The 1960s saw works by Lewis Mumford in urban history (Mumford 1961), Oscar Lewis in urban anthropology, Edward Banfield in urban politics, Herbert Gans (Gans 1962) in urban sociology, and Wilbur Thomson in urban economics. Jane Jacobs' *The Death and Life of Great American Cities* was a best seller. Discipline-based and interdisciplinary urban studies courses proliferated during the 1960s and early 1970s and many of today's academic urban studies programs were created at that time.

3. Core Urban Studies Concerns

Following is a list of 12 core concerns in the field of urban studies. Notable scholars and key scholarship in each area are discussed.

3.1 The Evolution of Cities

Historians have made the greatest contribution to understanding the evolution of cities. They have been joined by archeologists, geographers, political scientists, economists, architects, and other scholars.

Archaeologist V. Gordon Childe in Mesopotamia, Mortimer Wheeler in the Indus River Valley, James Mellaart in Antolia, and Dame Kathleen Kenyon in Israel excavated Ur in present day Iraq, Mohenjo-Daro and Harrapa in Pakistan and India, Catal Hüyük in Turkey, and Jericho in Israel. These scholars developed descriptions of what the earliest cities were like and conflicting theories of why they arose.

Historians have approached the study of cities from many different perspectives. Raymond Mohl (Mohl 1997) has proposed an 11-category typology of American urban history which provides a useful introduction to all historical urban studies. Mohl's categories are: urban political history, suburbanization, city and region, sunbelt cities, technology and the city, planning and housing, the urban working class, immigration and ethnicity, African-American urban history, urban policy history, and urban culture.

Urban planners such as John Reps (Reps 1965), Eugenie Birch, Christine Boyer, and Mellior Scott in the United States and Sir Peter Hall and Steven Ward in England have developed the subfield of urban planning history. They have been joined by historians Carl Abbot, Mary Corbin, Christopher Silver, William H. Wilson, David Schuyler, and Stanley Buder, geographer Jay Vance, architectural historian Spiro Kostof (Kostof 1991) and many others studying topics as varied as the building of Athens, Michaelangelo's work in renaissance Rome, Baron Hausmann's rebuild of Paris in the mid-nineteenth century, city beautiful planning for early twentieth century Chicago, and the vision and reality of planned garden cities.

3.2 Urban Culture

Cities have always been centers of both high and low culture. Historian Arnold Toynbee, geographer/planner Peter Hall (Hall 1998), polymath Lewis Mumford and many others have studied urban culture.

Greek drama, poetry, art, and sculpture flourished in Athens in the fifth century BCE. Imperial Rome produced both culture for elites and gladiatorial spectacles for the masses. Florence was an incubator of renaissance art, architecture, sculpture, poetry, and literature. Elizabethan London generated the theaters and dramatic troops that made Shakespeare's plays possible.

Lewis Mumford pioneered the study of urban culture in the late 1930s in *The Culture of Cities* (Mumford 1938). Historians Warren I. Susman, Gunther Barth, Neil Harris, and others have studied the history of urban culture. Richard Sennett has collected studies of urban culture by sociologists, geographers, and others (Sennett 1969).

The dominant strand in current culture studies of cities is postmodernism. Geographers David Harvey and Edward Soja, sociologist Sharon Zukin, social critic Mike Davis and many other scholars are fascinated and often horrified by the clash of cultures and values most manifest in contemporary cities.

3.3 Urban Society

The Chicago school of sociology encouraged faculty and students to study Blacks in Bronzeville, prostitutes in the Gold Coast, hobos, polish peasants, gangs, and many other Chicago groups. Urban ethnographies—detailed field research on urban subcultures continue this tradition. Anthropologist Elliot Liebow's poig-

nant descriptions of poor, black streetcorner men and homeless women are exemplary of this tradition.

Another urban studies concern is with how rural migrants adapt to city settings. There are many studies of urban immigration, acculturation, and assimilation such as Oscar Handlin's studies of the Boston Irish and Ron Takaki's studies of Asian immigrants to the West coast of the United States. Chicago school sociologists pioneered urban ecology to describe the structure and processes of urban ethnic neighborhood change, and the study of urban ecology continues (Berry and Kasarda 1977).

Problems of poverty are central to urban studies. Anthropologist Oscar Lewis' controversial theory that a distinct culture of poverty exists stimulated scholarly debate in the 1960s and 1970s. Harvard sociologist William Julius Wilson's studies of the urban underclass continue the debate.

Yale Professor Dolores Hayen and sociologists Lynn Lofland and Janet AbuLughod study the way in which humans use public space. Anthropologists and sociologists have studied the way in which human beings use the space around them. Edward T. Hall studied how people respond to intrusions into their space. Robert Sommers has observed behavioral aspects of how people use the space in such diverse settings as prisons, airports, and jury rooms. These behavioral and social science studies provide guidance to planners and designers.

Another enduring concern in urban studies is the nature of community. Emile Durkheim and Fernand Tönnies regretted a loss of community in large, impersonal nineteenth century cities. Louis Wirth concluded that big-city life created a distinct—and not very attractive—human personality type (Wirth 1938). Other social scientists have identified positive networks and supportive communities within cities. For example, sociologists Herbert Gans (Gans 1962) characterized Boston's West End as an urban village where migrants from southern Italy retained many of the relationships and folkways of their villages of origin. Michael Young and Peter Willmott's classic study of family and kinship in East London found positive networks in a London slum and far less community in new housing estates built for the relocated slum dwellers. The nature of community is one strand in the large and growing urban studies literature on suburbia by scholars such as historian Kenneth Jackson, political scientist Robert Wood, and sociologist Mark Baldassare.

3.4 Urban Politics and Governance

The study of how cities are governed is a central concern for political scientists. A recent review of the literature on how to study urban politics by New York University political scientist John Mollenkopf summarizes the evolution and current status of the subfield of urban politics (Mollenkopf 1992).

Historians like Amy Bridges, Leo Hershkowitz, and Martin Schefter have provided historical studies of urban political bosses and political machines. Samuel Hayes and Roy Lubove, have studied urban progressives and reformers. Economist James O'Connor, geographer David Gordon, social work professor Francis Fox Piven and other urban political economists have brought Marxist and related critical theory to bear on understanding urban politics. Public choice theorists—mainly based on economics—have developed theories about how local governments do (and should) make the economic decisions that constitute the core of urban governance. Scholars like David Osborne and Ted Gaebler from public administration study how cities are (and should be) managed. Journalist Robert Caro won a Pulitzer prize for his monumental study of Robert Moses and the politics of planning the twentieth century New York region.

Sociologist Floyd Hunter and political scientist Robert Dahl in classic studies of governance in Atlanta, Georgia and New Haven, Connecticut developed elitist and pluralist models of urban community power respectively. Other pluralists like Edward Banfield, Herbert Kaufman, Martin Meyersen, Wallace Sayre, and Douglas Yates conflict with Peter Bachrach, Morton Baratz, John Manley, William G. Domhoff and other theorists who continue to advance elitist explanations of community power.

Marxist political theorists like political scientists Ira Katznelsen, William Tabb, and David Gordon, economist James O'Connor, and French geographer Henri Lefebre posit structuralist theories of urban political power. Structuralist interpretations argue that underlying economic and class relationships pre-determine most of what is important to decide at the city level. Structuralists see city governments as unable to control national and international capitalist forces. For them, urban politics is largely irrelevant.

Regime theory is an approach to studying community power, developed by Political Scientist Clarence Stone. Stone, Frank R. Baumgartner, Richard DeLeon, Steven Elkin, Brian D. Jones, Gerry Stoker, and other regime theorists conclude that complex, public/private regimes involve not only local elected officials, but also people involved in business, church leaders, unions, the media, and other interest groups. Regime theorists do not deny the structural constraints local governments face, but they argue that complex, shifting public/private regimes are important to local political outcomes.

3.5 Urban Economics, Urban Public Finance, and Regional Science

The economics of cities is primarily the province of economists. Since Wilbur Thomson's *Preface to Urban Economics* urban economics has been recognized as a subfield of economics. Economic base theory, input–output analysis, location theory and other constructs

as well as numerous studies of specific city economies enrich scholarly understanding of cities.

Economic geographers have studied the production and exchange of goods within and between cities. Historians interested in both economics and cities—like Belgian historian Henri Pierenne and French historian Fernand Braudel—have developed the subfield of urban economic history and have illuminated the relationship of capitalist institutions and trade to the rise of cities.

Two other interdisciplinary subfields closely related to economics help inform urban studies. Urban public finance is sometimes taught in economics departments; sometimes is business schools. It contributes to an understanding of how local governments raise revenue and the nature of their expenditures. The subfield of regional science includes economists, geographers, and others who study regions rather than cities. Regional scientists generally employ quantitative methodologies. They have their own professional associations and scholarly journal.

3.6 Urban and Metropolitan Space and City Systems

Another core area of concern in urban studies is the physical organization of cities and regions and relationship among cities. This work is often classified into studies of the internal structure of cities and studies of systems of cities. Geographers are particularly interested in these issues, but sociologist Ernest W. Burgess and economist Homer Hoyt originally did pioneering work on the internal structure of cities. Writings about the internal structure of cities have been collected in an anthology edited by University of Toronto geographer Larry Bourne (Bourne 1982).

German geographer Walter Christaller's careful studies of the size and function of settlements in southern Germany during the 1930s caused him to formulate central place theory—a unified explanation of the way in which cities of different sizes are related to each other in a distinct hierarchy or system (Christaller 1993). Christaller's work led to many empirical studies of systems of cities. University of Toronto geographers Larry S. Bourne and J. W. Simmons have collected systems of cities studies (Bourne and Simmons 1978).

3.7 Mega Cities and Global City Systems

The rise of enormous cities with populations of 10 million or more people has captured the attention of urban studies scholars. So have the increasingly integrated world economic system and the close connections between cities and regions around the globe.

One strand of research and writing concerns the rise of mega cities by Janet AbuLughod, Manual Castells, Susan Fainstein, Peter Hall, Alan Gilbert, John Kasarda, Fuchen Lo, Janice Perlman, Saskia Sassen (Sassen 1994), Yue-man Yeung and authors of UN-commissioned city-specific mega city studies. The nature, causes, and appropriate policy response to mega cities is particularly important in Asia and South America, where most of the mega cities are emerging.

A related area concerns development of huge urbanized regions—what Scottish biologist Patrick Geddes in the early twentieth century termed conurbations and French geographer Jean Gottman in a study of the eastern seaboard of the United States named megalopolis.

A third area of inquiry involves the increasingly close relationship among cities caused by economic and political integration and by information technology. Spanish sociologist Manuel Castells uses the term informational city to describe advanced cities today and the term network society to describe the current global system in which information-rich multinational corporations are increasingly beyond the control of city government, citizens, and even nation states. University of Chicago and London School of Economics, urban planning professor Saskia Sassen (Sassen 1994) has documented the current global system of cities.

3.8 Technology and Cities

A number of urban studies scholars are interested in aspects of technology in cities. Transportation has received the most attention, but public infrastructure has also been of interest. The impact of the Internet and other information technologies on cities is attracting increasing attention and promises to be even more important in the twenty-first century.

There is a large literature on the impact of transportation technology on cities. Historians like Sam Bass Warner, Charles W. Cheape, and Clifton Hood have documented the way in which the electric streetcar directly affected first the spatial structure of cities and metropolitan regions and, as a consequence, their social and economic structure. Mark S. Foster, William Issel, Kenneth Jackson, Clay McShane, Mark H. Rose, and others have studied the impact of automobiles on the rise of suburbia. They are interested in public policy regarding freeways and automobiles and its impact on urban and regional physical form, social structure, and culture. Policy analysts and planners like Anthony Downs and Robert Cervero write about transportation policy and planning issues.

3.9 Urban Planning, Urban Design, Landscape Architecture, and Architecture

Urban studies overlaps the professional fields of urban planning, urban design, architecture, and landscape architecture. Writings about cities and urban planning have been collected by Jay Stein (Stein 1995).

Professors of urban planning in departments that belong to the Association of Collegiate Schools of Planning (ACSP) in North America, the Association of European Schools of Planning (AESOP), and the Asian Planning Schools Association (APSA) study cities in order to help plan them. Twentieth century land use planning books by Patrick Abercrombie, Thomas Adams, Alan Altschuler, Edward Bassett, F. Stuart Chapin, Anthony Catanese, Barry Cullingworth, Alexander Garvin, Peter Hall, Jack Kent, John M. Levy, Edward J. Kaiser, David Gotschalk, and James C. Snyder combine material related to geography, economics, politics, sociology, and the design professions with applied material on plan preparation.

Ever since nineteenth century Austrian architect Camillo Sitte derived urban design principles from his careful observation of public spaces in European cities and how people use them, urban designers have been close observers of city space and contributors to urban studies. Kevin Lynch blended history, sociology, psychology, and humanistic material in *The Image of the City* (Lynch 1961). Sociologist William Whyte's studies of urban park and plaza design, planner Allan Jacobs' studies of great streets, Spiro Kostoff's studies of urban form (Kostoff 1991) and works by urban designers Edmund Bacon, Gary Hack, Clare Cooper Marcus, Wendy Sarkissian and other design scholar/practitioners have made major contributions to the field of urban studies.

Ever since the pioneering work of Frederick Law Olmsted in the nineteenth century, landscape architects have contributed to understanding the relationship between the natural and built environments. Systematic study of how to plan human settlements in harmony with the natural environment were pioneered by Scottish biologist Patrick Geddes before World War I and revitalized by Scottish landscape architect Ian McHarg's approach to design with nature in the 1960s. This approach resonates with advocates of ecological design, sustainable urban development, and the new urbanism today.

Architects like Frank Lloyd Wright in the USA, Raymond Unwin in England, and LeCorbusier in France moved far beyond design of individual structures to think and write about the design of entire communities and of society itself. Peter Calthorpe, Andres Duany, Peter Katz, Elizabeth Plater-Zyberk, Daniel Solomon, Sim Van der Ryn, and other new urbanists have made notable contributions to the field of urban studies. Key new urbanist writings have been collected in a recent anthology (Katz 1994).

3.10 Race, Ethnic, and Gender Relations in Cities

William Edward Burghardt Du Bois' 1899 study of the Philadelphia Negro began a tradition of studies by African-American scholars about urban black society. Horace R Cayton, Kenneth Clark, St Clair Drake, E. Franklin Frazier, and William Julius Wilson have continued that tradition.

Historian Oscar Handlin, political scientist Daniel Patrick Moynihan, and sociologist Nathan Glazer's early studies of the urban experience of Irish and Jewish immigrants to cities on the East Coast of America have been followed by many studies of Irish, Jewish, central European, southern European and other ethnic groups in cities. Studies of the urban immigrant experience of Asians and Hispanics are now appearing. Ron Takaki's study of Asian immigrants and writings by and about Latino barrios edited by Joan Moore and Raquel Pinderhughes (Moore and Pinderhughes 1993) are important contributions to urban studies.

Sociologists, anthropologists, historians, planners, and women's studies scholars are generating an interdisciplinary literature about women in cities. Yale professor Dolores Hayden pioneered this subfield with studies on the relationship between gender, work roles and the built environment highly critical of the male-built environment. Eugenie Birch, Ann Forsyth, Jacqueline Leavitt, Lynn Lofland, Claire Cooper Markus, Ann Markusen, Risa Palm, Marsha Ritzdorf, Leonie Sandercock, Wendy Sarkissian, Catherine Simpson, Daphne Spain, and others have helped inject feminist concerns into urban studies and planning. Writings about women in cities have been collected into an anthology (Stimpson et al. 1980).

3.11 Urban Issues and Policy

Urban studies is also concerned with urban issues and policy. It was poverty, overcrowding, congestion, disease, crime, vice, and other urban problems that inspired many nineteenth century studies. Urban pathology was a concern of the Chicago school of sociology. The focus on urban problems dominated urban studies after the ghetto riots of the 1960s.

Current urban studies curricula have broadened the urban problems orientation to also consider community assets and strengths. Today applied coursework in urban studies programs balances studies of positive neighboring contributions, and potential of urban community development with the study of racism, poverty, crime, and other enduring urban problems.

Most urban studies programs include applied coursework in policy areas such as land use, housing, community development, environment, transportation, and economic development. Some have coursework on crime, health, homelessness, education, welfare and other policy areas. A tiny sampling of urban studies scholars with applied interests include John DeGrove (land use), Anthony Downs (housing),

Sim Van der Ryn (the environment), Robert Cervero (transportation), Michael Porter (economic development), James Q. Wilson (crime), Leonard Duhl (health), Talmadge Wright (homelessness), James Coleman (education), and Francis Piven (welfare).

3.12 Urban Futurism

A final strand in urban studies is reflection on probable, possible, and desirable urban futures. Virtually all demographers anticipate massive population growth and continuing urbanization—particularly in the third world. There will be more congestion, sprawl, pollution, exhaustion of natural resources, and proliferation of megacities and vast urban conurbations unless governments intervene to plan and regulate city development far more strictly than they have ever done in the past.

Studies of sprawl and ex-urban development raise the possibility that the rate of growth in cities may slow or even that counter urbanization may occur in the future—at least in the developed world. Some writers believe information technologies will make cities unnecessary and a few even predict a withering away of cities, though there is no evidence that this is occurring.

In addition to prediction, urban futurists have formulated different normative visions for alternative urban futures. Ebenezer Howard (Howard 1898), Patrick Geddes, Lewis Mumford, and Raymond Unwin opposed further growth of large cities and proposed systems of human-scale garden cities. Frank Lloyd Wright went further and advocated Broadacre city—a neo-Jeffersonian future in which each family would live on an acre. Soviet-era anti-urbanists took Marx's ideas of eliminating distinctions between the city and the countryside as a call for de-urbanization. Megastructuralists like Le Corbusier and Paolo Soleri took the opposite view. They proposed—and in Soleri's case are actually building—huge, self-contained structures that would house the human population on a small portion of the Earth's surface.

Urban System in Geography

In geography the term 'urban system' has a rather precise meaning: it refers to attempts to order and classify cities according to some underlying criterion or criteria. Thus, most simply, cities within any given geographical area—ranging from the local to the global—may be arrayed in terms of population size. More commonly, cities are classified in terms of the

economic functions they perform; in particular, the services they provide for themselves and their surrounding areas or spheres of influence. From this comes the concept of a 'central place system': a system in which cities are arrayed in terms of the range of services they provide and the areas over which they provide these services. In turn this has been extended into a general urban system that forms an important part of general location theory (q.v.).

1. Two Central Concepts: Rank-size and Central Place

1.1 The Rank-size 'Rule'

It has long been noticed that in many parts of the world, cities and towns are quite regularly spaced. In fact, for any two adjacent towns of similar size, the distance between them is given quite well by the formula $(P1/P2)/D = A$, in which $P1$ and $P2$ stand for the populations of the two towns, D is the distance between them, and A is a constant for any given region reflecting general population density; thus, it is greater in Iowa than in the United Kingdom, and greater in Iowa than in Indiana (Lösch 1954), but the distance between the smallest towns nevertheless seems constant for a wide range of densities. From this, it has also been shown that the distribution of towns by size follows a so-called rank-size rule: if cities are arrayed by population in descending order, then the size of the nth town is $1/n$ the size of the largest city, following a series: 1, 1/2, 1/3, 1/4 … $1/n$ (Stewart 1958).

Zipf, who first demonstrated this rule, produced a great deal of empirical justification for it, but also showed that there were many divergences from it (Zipf 1949): it works robustly for highly self-contained regions, but less so in regions where there is a great deal of interaction with other regions. This means not only that in many highly-developed parts of the world it works less well, but also that it may tend to break down over time as international trade increases. Many major cities, like London, Paris, and Tokyo, appear larger than they should do according to the 'rule' because they provide services for very large areas of the world, even the whole world; such cities are said to be 'primate' and the resulting population distribution is said to show 'primacy.' In other countries primate functions may be shared among two or more cities (for instance, New York and Washington within the United States, or Amsterdam, The Hague, and Rotterdam in the Netherlands, or Rome and Milan in Italy); such countries often exhibit a flattening of the top of the curve of city size distribution. Stewart's empirical examination (Stewart 1958) showed that the five largest cities in every country showed considerable divergence from the 'rule,' and that even in countries which fitted better (such as the United States and Brazil), smaller subdivisions (such as states) showed major deviations from it. Other work showed that France and Mexico showed considerable divergences from the rank-size distribution, while Canada and Italy were much closer to it (Browning and Gibbs 1961).

1.2 The Central Place Hierarchy

The idea of a size–class hierarchy is related to the rank-size concept, but in a very indirect way. First, it tends to have been derived theoretically, and to have been tested empirically only later. Second, by definition 'There is no coincidence, even theoretically, between the rank-size rule for cities and a functional size–class hierarchy of the type postulated by Christaller and Lösch. The former yields a smooth descending curve of town sizes; the latter a ladder of successively lower size classes of towns, grouped around a limited number of discrete normal values corresponding to discrete functional constellations' (Stewart 1958). Third, since the hierarchy is derived from the performance of functions, there is no necessary relationship between this measure and population size; the rather casual assumption seems to be that so many employees will be needed to provide the services, and that this total will relate generally to population numbers.

The real key to a possible relationship lies in the work of Christaller, the German geographer who first developed central place theory (Christaller 1966/1933). His basic assumption was that there was a constant relationship between the numbers of cities found at each level of the hierarchy. He suggested that the commonest relationship was one derived from service (market) areas around cities, which yielded the constant $k = 3$; thus, there would be one city at the topmost level, three at the next, nine at the next, and so on. But the theory also suggests a similar relationship in the sizes of cities: thus, second-level cities are one-third the size of the first-order city, and so on. Further, the market areas of all levels of city, which were hexagonal in shape because a hexagon is the figure derived from 'packing' circles to eliminate overlap or blank space, nested precisely within the larger hexagonal market areas of higher-order cities; the theory simultaneously established the sizes of cities, their relationships, and the sizes and shapes of their market areas.

Therefore, at $k = 3$, there is exact accordance with the rank-size rule. Berry and Garrison (1958a) comment that 'The Christaller scheme is consistent with Zipf's empirical observations, but consistency requires a rigorous choice of relationships.' In fact, Christaller also suggested that in some cases a different value for k might apply: thus along strong transport corridors, where the key was to maximize the number of settlements along transport lines, he suggested that a ratio of $k = 4$ might be more appropriate, while

Table 1
The Christaller central place system (1933)

Type	Market area Radius, km	Population of town	Population of market area	Centrality (Telephones/popn)
M (Marktort)	4.0	1,000	3,500	0.5–2.0
A (Amtsort)	6.9	2,000	11,000	2.0–4.0
K (Kreisstadt)	12.0	4,000	35,000	4.0–12.0
B (Bezirkstadt)	20.7	10,000	100,000	12.0–30.0
G (Gaustadt)	36.0	30,000	350,000	30.0–150.0
P (Provinzstadt)	62.1	100,000	1,000,000	150.0–1200.0
L (Landstadt)	108.0	500,000	3,500,000	150.0–1200.0

Source: Christaller (1966), 67; Dickinson (1967), 51.

political–social (administrative) centers were governed by the principle of separating regions administratively, suggesting a ratio of $k = 7$. So the correspondence with the rank-size rule applies only in the one special case, albeit the one that appears to be the most common one.

Christaller derived the theory from pure principles, but then sought to confirm it empirically. Curiously, he based this work largely on the number of telephone connections in each city, particularly their ratio to the city's population. He developed a sevenfold hierarchy (Table 1). His map shows that over wide areas the marketing principle appears to work satisfactorily, but it is modified in practice by transport lines and by basic variations in natural resources which affect population density. Further, especially at higher levels, political history may be significant: thus, Munich, which is set at the highest theoretical level (Landstadt), is in fact intermediate between this level and an even higher one, not represented in this region, Reichstadt or national capital, because Munich was for centuries the capital of the independent state of Bavaria before being embodied in a unified Germany in 1871.

Subsequent to Christaller, but before translation of his work into English, British and North American geographers made a number of studies of national urban hierarchies. In Great Britain the most notable are by Smailes (1944, 1946, 1947), Carruthers (1967) and Smith (1968, 1970, 1978). Below London, regarded as a unique case, Smailes distinguished only five hierarchical levels (major cities, cities, minor cities, towns, and subtowns; Carruthers distinguished eight, and Smith (who used a similar scheme to Carruthers') 10). All these studies were strictly empirical, and interestingly made no reference to Christaller. The North American studies tended to concentrate on low-density agrarian regions such as Iowa, South Dakota, Washington State, and Saskatchewan, and therefore did not distinguish a complete range of upper-order settlements; comparing Southwestern Wisconsin and Southern England, Brush and Bracey were able to distinguish only two levels of service center (Berry and Garrison 1958a, Berry and Parr 1988, Brush and Bracey 1955, Hodge 1965). However, Berry extended the principle to Chicago and its suburbs, where he found a systematic hierarchy of centers and subcenters, albeit strongly arrayed along major radial transportation lines (Berry 1963, Berry and Parr 1988).

1.3 Towards a General Urban-location Theory: The Work of August Lösch

Six years after Christaller, a German economist sought to extend his work (and that of others, such as Alfred Weber on industrial location and Johann Heinrich von Thünen on agricultural location) into a general theory of economic location. Specifically, he secured an ingenious combination of Christaller's market and transport principles: starting with a distribution of hexagonal market areas around a single (first-order) metropolitan center, he rotated them so as to obtain six sectors with many production sites, and six with only a few, their boundaries established by six through transport lines that radiated through the central metropolitan city. He could, thus, argue that city distributions and sizes are different in transport-rich and transport-poor sectors. (He argued that Christaller had been mistaken in distinguishing the market and transport principles; this was due to an accident, that when $k = 3$ all places lie symmetrically with respect to the six through transport lines, so that no thickly or thickly settled areas appear.) Depending on the basic assumptions made, the middle or two outer segments in transport-poor sectors would have few towns. But in addition, the immediate environs of the metropolis would be city-poor, because only a few local goods could be profitably produced there (Lösch 1954).

Lösch described the resulting arrangement as an economic landscape. He gave only two sketchy empirical illustrations, based on two midwestern American cities (Indianapolis and Toledo), and nowhere attempted a rigorous proof. And, because his system is much more complex than Christaller's (though superficially similar; Lösch does not accept Christaller's basic principle that lower-order areas nest within larger ones, but derives them all independently), it is inherently more difficult to demonstrate empirically.

However, subsequent work, notably that of Berry on Iowa and by Hodge on the northern Great Plains of Canada, suggests that in these quintessential agricultural areas, the central place system essentially developed along rail lines as they were built (Berry and Parr 1988, Hodge 1965).

2. *The Dynamics of Urban Systems*

Christaller himself recognized that central place patterns would change over time, for instance, because of new transport connections, especially in the modern era (Christaller 1966); the pattern of cities would be set by the original transport mode, but their relative significance might change as new modes emerged, and also as wider ranges of goods came to be traded. He wrote: 'We observe a very great frequency of places called towns and market spots; and we may consider the central places of ancient times, of the Middle Ages, and of modern times, the results of the economic conditions, values, and production of each period' (Christaller 1966). However, he did not try to demonstrate this rigorously. Subsequent work has suggested that urban hierarchies can change in three possible ways: in their initial establishment (top-down or bottom-up); later, through changes in the level at which an individual function is supplied; and through changes in the basic structure of the hierarchy, either in terms of the numbers of levels or the numbers of centers belonging to a given level (Berry and Parr 1988). Empirical work has shown, for instance, that in North America, improved transportation—especially the spread of automobile use—caused small trade centers to decline faster than large ones, though the decline did not increase regularly down the scale (Hodge 1965). Some work has been done to incorporate observations of this kind into formal models (Parr and Denike 1970, Mulligan 1980).

3. *From Central Place Systems to General Systems Theory*

The final question has to be whether central place systems can be generalized into General Systems Theory. A system can be regarded as containing: a set of objects (central places), their attributes (e.g., population); inter-relations among objects (e.g., locations); inter-relations among attributes (e.g., logarithmic relationships); and interdependencies between objects and attributes (e.g., a hierarchy). Systems can be closed and open. In a closed system, available energy is dissipated gradually until it becomes random through the system; it will have reached a state of maximum entropy, in which all trace of hierarchy had disappeared. Several attempts have been made to analyze central place systems in this way. An open system in contrast will settle into an equilibrium between the tendency to maximize entropy and the need for organization; this is known as a 'steady state.' Most central place systems correspond to this model, and it is expressed by rank-size regularity, which will tend to persist over time (Berry and Parr 1988).

However, the central place system is only a part of the wider urban system; 'there are many aspects of the economic and social organization of urban systems that are wholly beyond the scope of central-place theory' (Berry and Parr 1988). In 1977 Pred argued that 'In conventional geographic and planning literature on systems of cities excessive emphasis is placed on the hierarchical structure of interdependencies', which'is highly unrealistic as a description of the *total* structural composition of city-system interdependencies in advanced economies' (Pred 1977). This, Pred argued, was because in the Christaller system the largest urban unit was required to be completely self-reliant, because there could be no interdependence between large cities in the form of lateral exchanges of goods and services between second- or third-order cities, and because finally each 'nesting' arrangement below a single first-order places is effectively a closed system. The Lösch system performed rather better because it did allow lateral exchanges, but it too required the top-order city to be totally self-supporting. In the real world, 'the most critical growth-generating city-system interdependencies in economically advanced countries are largely the product of input-output relationships, or of job-control and decision-making relationships within multilocational business and government organizations' (Pred 1977).

Pred sought to demonstrate in detail how such interdependencies had developed historically in the American urban system between 1790 and 1910. In his account, access to specialized information plays a crucial and increasingly important role. Because the largest cities early acquire privileged access, even in the era before the telegraph or railroads, they tend to maintain it with each successive technological advance. This sets up a system of positive multipliers and positive feedback loops which tend to consolidate and enhance their position. Pred shows that to a remarkable degree, in advanced industrial countries the rank ordering of cities has remained stable over a long period; in the United States, where new cities arose during the western expansion, the rule is nevertheless true for each major regional division (Pred 1977). He concludes that there is a 'tendency of early established major channels of interdependence, or interurban growth transmission, to be self-reinforcing, thereby becoming increasingly entrenched and influencing subsequent channels of interurban growth transmission' (Pred 1977). However, city-systems in different countries do demonstrate very different patterns and trajectories, depending on different histories; there is an instructive contrast here between France, with

Table 2

Cities are ordered in terms of world city-ness values ranging from 1 to 12.

its highly centralized history, and Australia, whose city system essentially derives from its colonial past.

A key question concerns change at the top of the hierarchy. Most studies within the central place paradigm, including Christaller's, do not even provide specifically for a national metropolitan centre. But globalization appears to result in centers with a global range (Castells 1989, Sassen 1991). It would appear that centers are in effect dropping out at the bottom of the hierarchy and are being added at the top. Hall (1999) has suggested that the two bottom levels of the Christaller hierarchy have in effect disappeared from the hierarchy, becoming mere villages, while a global and a subglobal level have been added at the top. Research by Beaverstock and Taylor suggests that global-level cities can be distinguished both by key attributes (such as concentrations of specialized services) and by relationships (such as exchanges of personnel). The latter are more significant but are more difficult to measure, since data are often not available. But they use data on branch offices of specialized financial and business services to establish a new hierarchy based on an index of 'globality' (Table 2) (Beaverstock et al. 1999). The significance is that this research rather precisely illustrates the Pred hypothesis: that, in a world increasingly based on the exchange of specialized information, the relationships are increasingly horizontal in terms of the hierarchy of cities, and global in scale. Without doubt, central place systems have been a useful conceptual device, and they still illustrate important features of the modern world (for instance local trading and commuting systems). But, for a fuller understanding, the need for the future is to integrate them into a wider systems framework.

User Interface Design

This article discusses those design principles that enable the interface between a user and a device to form a synergistic partnership that is user centered and task oriented. The original term for this work was 'man–machine interface design.' However, the term 'man–machine' has been replaced by the more inclusive 'human–machine.' In turn, this term has given way to 'user interface design.' 'User' emphasizes the role the human plays in the system and also highlights the dominant framework for developing and applying interface design, namely user-centered design. 'User interface design' is concise and has currency in recent books by Barfield (1993), Cooper (1995), and Shneiderman (1998). The article is organized around four key concepts: affordances, user models, feedback, and error handling.

1. *Affordances*

When an animal perceives an object it will perceive fundamental properties that signal possible interactions. The size, shape, and solidity of a chair affords sitting for a person, but not for an elephant. A vine affords swinging for a monkey or Tarzan, but not for me. The concept of affordances originates with Gibson (1979), who was interested primarily in actions that take place in natural environments. The term affordance was extended to users interacting with artifacts by Norman in his influential books on user-centered design (1988, 1993, 1998). For Norman, affordances are the set of action–outcome pairings perceived by a user. Affordances derive from a user's past experience and provide obvious clues for how things operate. If the designer and user share the same knowledge, then actions can be signaled naturally, not arbitrarily: switches are for flipping and knobs are for turning.

Affordances are very important in the design of artifacts that users will walk up and use, or are manipulated directly. Users must resolve quickly the issues of what actions are possible, and where and how the selected action is performed. The closed door of an emergency exit affords opening, but the hardware should tell you to push, not to pull or slide. A broad, flat plate that affords little to grasp on the right side broadcasts where to push. In contrast, imagine a sliding door with the type of handle that usually affords grasping, twisting, and pulling. Harry Potter or Harry Houdini would have difficulty escaping such a malevolent design.

Constraints reduce the number of possible actions. Affordances and constraints, working in tandem, allow the user to discover the correct sequence of actions, even in a novel situation. Constraints can be physical, semantic, cultural, or logical (Norman 1988). If you want to leave our courtyard via the gate, the vertical handle affords gripping and the thumb lever just above it affords pressing. However, the crossbar rests and catches on the indented bracket and it is clear that the crossbar must be raised, by pressing on the thumb level, before pulling will do any good. This simple, two-step process is much harder for guests to get right when they first arrive because the physical constraint, the crossbar, is not visible from the opposite side of the opaque door.

Affordances offer a range of possible actions and should be made visible, not hidden. An actual affordance that is not also a perceived affordance contributes nothing to usability. The design of the human–computer interface often relies on conventions to convey affordances. The scrollbar on the side of a computer window affords vertical movement, but a novice may fail to perceive this affordance. These conventions enable experienced users to transfer their user models positively from one application to the next, but one must stretch to think of these conventions as visible and natural affordances to the novice user.

2. *User Models*

User models refer to the user's understanding of how the device can be used in order to perform tasks and accomplish goals. Good user models enable the user to determine the optimal procedures for accomplishing routine tasks, and to infer the solution to somewhat different or even novel tasks. Designers of user

interfaces rely on different techniques for revealing good models to users. A user model may emphasize the underlying technology, a metaphor, or the user's task (Cooper 1995).

2.1 Implementation Models from the Technology Paradigm

The technology paradigm is based on an understanding of how things work. If the mechanism is simple and visible this is an obvious choice. If the affordances lead a person to the right place, suggest the right action, and it is easy to see the consequences of that action, then the user has a very handy mental model. An implementation model even enables the user to repair the device, as I recently had to do with our courtyard gate. Unfortunately, the human–computer interface is often expressed through the technology paradigm in terms of how the software works. Thus, the user must learn how the program works in order to use it effectively. Once acquired, this is also a very handy mental model. The user could even modify the program to suit new needs or preferences. However, for most of us, the cost of gaining an implementation model will be horrendous. It is better to emphasize a functional model of how to use the tool to accomplish specific tasks.

2.2 Borrowed Models from the Metaphor Paradigm

A quick way to provide a user with a model of how a tool works is to draw an analogy to a tool the user already knows how to use. The similarities between the known and unknown allow the user to intuit use without understanding the mechanics of the hardware or software. The most famous metaphor of them all is the desktop metaphor invented by Xerox PARC and successfully implemented by Apple Macintosh. By definition a metaphor involves an implicit comparison, in which the tenor of comparison (e.g., computer screen) resembles the vehicle (e.g., desktop). The set of attributes shared between the tenor and the vehicle form the basis for the metaphor.

The metaphor paradigm for conveying a user model initially received reviews as stellar as the pig who built a brick house, but interface design pundits have huffed and puffed to flatten the metaphor paradigm (Cooper 1995, Norman 1998). Metaphors have several weaknesses. The set of features that are shared between tenor and vehicle may include irrelevant similarities that just clutter the user model. The useful ones are not necessarily the salient ones. There may also be dissimilarities that encourage inappropriate actions. There may be novel features of the tenor (computer interface) that are outside the scope of the vehicle that actually impede the user's discovery of these new features. Finally, metaphors may not scale as size and complexity increases. For example, keeping track of three or four documents on a messy desktop or computer screen is not too difficult, but when I'm working with dozens of articles, books, tables, figures, and printouts my desktop resembles a pigsty and there may be a better way to organize and use a similar electronic collection.

2.3 Task-oriented Models from the User Centered Paradigm

The important idea behind task-oriented models is that if there is a good tool with a good interface one can quickly, easily, and naturally learn how to use it. Interface objects and actions focus on the user's task regardless of how the device actually works.

Cooper's chapter 'Lord of the Files' provides one of the very best detailed examples of the tension between designing an interface based on the underlying technology vs. designing the interface from the viewpoint of the user's task. Consider the 'file' menu from any standard graphical-user interface. The menu options displayed for the user are focused on managing files, particularly the managment of the copy stored on the disk and the copy active in RAM. Many users of application programs have never developed a mental model that correctly reflects the relationship between the yin and yang of these two 'copies.' Nor should they, because the user's task is to generate a usable document. These users would benefit from a revised interface that hides the file management task (a computer implementation problem) and presents a single document that the user 'appears' to control from initiation, through revision, to completion. From a task oriented perspective, the 'file' menu should be replaced by a 'document' menu, where users can find options that correspond to current goals that are a frequent and integral part of document construction (e.g., options to rename a document, make a snapshot copy, move the document to a new location, or make a milestone copy).

3. Feedback

A basic principle of good design is that every user action should be followed by a visible reaction. When you push on the hand plate of an emergency door you hear it click, feel the bar move, and see the door open. Several feedback distinctions are useful: (a) real vs. abstract (Barfield 1993), (b) articulatory vs. semantic (Hix and Hartson 2000), (c) delayed vs. immediate (Shneiderman 1998), and (d) positive vs. negative (Cooper 1995).

When I rotate the switch that turns my car lights on at night I get real feedback when the lights come on. I receive concurrent, but abstract feedback, when the indicator light on the dash shows that the headlights

are on. Redundancy of real and abstract feedback can be good, because abstract feedback can exaggerate real changes that are subtle such as the differences between high- and low-beams, particularly at dusk. Abstract feedback is, of course, necessary when the real effect is remote or, by necessity, hidden from the user.

Articulatory feedback tells users their hands worked correctly, while semantic feedback tells them their heads worked correctly. For example, when the user selects 'open' from a pull-down menu, the choice may blink briefly just before the menu disappears and the dialogue box appears. Paap and Cooke (1997) recommend that menu panels should provide feedback indicating: (a) which options are selectable, (b) when an option is under the pointer and, therefore, can be selected, (c) which options have been selected so far, and (d) the end of the selection process. The latter three provide articulatory feedback that helps the users select the intended options. The first is more semantic: if the desired option is not available for selection then the user has probably made a navigation or mode error.

In an ideal world our interfaces would guide us with continuous and immediate feedback. In the real world some delays are inevitable. Whenever the system is performing a lengthy process the user should be given feedback, a status indicator, that processing is ongoing and not suspended. It is most useful to display an indicator showing what portion of the task has been completed.

Both Cooper (1995) and Norman (1988, 1993) are strong advocates of using more positive feedback and less negative feedback. They argue that designers should try to see users as making imperfect progress toward their goals, and that error messages should be friendly, make clear the scope of the problem, and provide alternative solutions (not just OK buttons). Don't think of the user as making errors; think of their actions as approximations to what is desired. Even the quintessential error recovery mechanism, the undo command, can be reconceptualized as a method of exploration.

4. Error Handling

The distinction between positive and negative feedback brings us to the special topic of errors. An interface with a good design will help users to detect errors, diagnose the cause of errors, assist error recovery, and prevent errors in the first place. In a dynamic system, many dangerous states can be avoided by forcing the operations to take place in proper sequence. Opening the door of a microwave oven switches the oven off automatically. Norman (1988) and Barfield (1993) have useful discussions of different types of forcing functions that prevent dangerous errors from occurring.

4.1 Slips: Errors of Action

A slip occurs when the user has formed the correct intention, but the appropriate action is waylaid on the way to execution. Slips often occur in the context of actions that are highly automatic and under unconscious control (Norman 1988). As such, slips are more likely to emanate from highly skilled users. Slips should be easy to detect because there will be an obvious discrepancy between the goal and result. However, detection is likely only if there is effective and immediate feedback.

Slips include the infamous mode error. Mode errors occur when devices have different modes of operation and the same action produces different results depending on the mode. Mode errors can be benign in digital watches or catastrophic in automatic pilots. They are more likely to occur when tasks are interrupted and time elapses between mode setting and action selection. Mode errors can be prevented either by eliminating modes or by making the mode visible and attention catching. Cooper (1995) offers a cogent defense of well-designed modes.

Description errors are slips caused by performing the right action on the wrong object. When driving in Australia, I usually signal my intention to turn by flipping the left-hand lever, thereby turning on the windshield wipers. Consistency may be the hobgoblin of little minds, but violations of consistency will constantly frustrate the ingrained habit of skilled users. Relative frequency also matters. A high-frequency object may surreptitiously replace the intended target, particularly if they are similar. For example, the frequently summoned file 'mybook' accidently replaces the newer file 'mydoodle', resulting in the unintentioned request to 'delete mybook.' Potentially critical errors like this usually are 'prevented' by confirmation boxes. However, when confirmations are issued routinely, users get used to approving them routinely, even when the confirmation warns of an impending disaster. When experts are working on automatic pilot, it is sometimes better to make sure they can recover from slips easily. The Macintosh trash basket and the Windows recycle bin serve such a purpose.

4.2 Mistakes: Errors of Intention

Mistakes, unlike slips, are errors of intention and are often caused by an incorrect user model. Affordances and feedback should help form correct user models, but even error detection is difficult for general purpose technology that is powerful and flexible. When there are a large number of ways of accomplishing a large array of goals, there will be countless numbers of action sequences that are perfectly legal, but most of them will not move the user closer to task completion. If I turn right on Triviz, it is an error because I will eventually run into a construction detour, but nothing

on my car's dash flags that error, because it has no knowledge of where I want to go and no knowledge of current route conditions. Specialized technologies, such as GPS navigation systems, can have user-centered, task-oriented designs. The user and the interface share goal information and, consequently, errors can be detected and solutions prompted.

The general-purpose PC and its powerful applications programs are plagued with the same problem in error detection. Having evolved within the technology paradigm, the interface detects when user actions violate the program, but the interface offers little or no help as users perform a complicated series of legal actions that the program slavishly follows. The user must detect errors by inspecting the document to see if the intended changes have been made. A specialized program for preparing psychology research articles in the format prescribed by the American Psychological Association, could detect and prevent far more errors and offer more useful guidance because it would have far more knowledge of the task at hand. These considerations play a large role in recent calls to shift from general-purpose devices to information appliances (Norman 1998, Mohageg and Wagner 2000).

5. *Evaluating Usability*

Usability engineers and designers should get involved early and often. Landauer (1995) makes an impressive case for the economic benefits of usability in product development. Guidelines such as those discussed in this article need to be augmented by expert reviews and usability testing. There are a variety of expert-review methods (Shneiderman 1998), of which, Nielson's (1994) heuristic evaluation method may be the most popular. Heuristic evaluation involves having three to five usability experts examine an interface with respect to ten usability heuristics or guidelines. Heuristic evaluation is vastly superior to no review, but not as effective as user testing (Desurvire 1994). User-centered design should include tests with real users doing real work. The benefit of such activities is simply enormous, almost always over 20 to 1, and often in the 200 to 1 range (Landauer 1995).

Utilitarian Social Thought, History of

Standard utilitarian theory encompasses two essential elements: (a) the rightness/wrongness of an action is determined by the goodness/badness of its consequences, and (b) the only thing that is good in itself is pleasure and the only thing bad in itself is pain, and happiness is taken to be the sum of particular pleasures (Quinton 1988, p. 1). Implicit in this ethical hedonism is the premise that the motives to action are rooted in self-interest. Based on these elements, the doctrine is then expressed in the form of the greatest happiness principle or the principle of utility. In *A Fragment on Government* (1776) the legal philosopher Jeremy Bentham (1748–1832) declared it 'a fundamental axiom' that 'it is the greatest happiness of the greatest number that is the measure of right and wrong,' and that 'the obligation to minister to general happiness, was an obligation paramount to and inclusive of every other' (Bentham 1977, pp. 393, 440–1). In 1781 Bentham coined the name utilitarian for this theory.

1. *Origins of the Theory*

Although Bentham is usually cited as the founder of utilitarianism, the antecedents of utilitarian principles have a far older vintage in the philosophy of Plato, Aristotle, and Epicurus, and in early Christian thought

(Scarre 1996, Chap. 2). Other significant dimensions of the theory can be traced to the seventeenth century writings of Thomas Hobbes, John Locke, and Richard Cumberland. It was the 'moral sense' philosopher Francis Hutcheson who first spoke of 'the greatest Happiness of the greatest Numbers' as a principle of moral conduct in *An Inquiry Concerning the Original of Our Ideas of Virtue or Moral Good* in 1725 (Shackleton 1972).

1.1 Religious Utilitarianism

In the eighteenth century, utilitarian social thought began to assume its classic form in the moral philosophy of the religious advocates of the utility principle. Advocates of religious utilitarianism included John Gay (1699–1745), John Brown (1715–66), Edmund Law (1703–87), Abraham Tucker (1705–74), and William Paley (1743–1805). The ethical hedonism developed by these moralists was premised on the existence of a God who would punish and reward in the afterlife according to the degree to which individuals acted to enhance general happiness in the present life (Albee 1902, Crimmins 1998). Among the religious exponents of the theory, only Paley offered a comprehensive and systematic social philosophy founded upon the utility principle, encompassing morals, government, law, and political economy, in his popular *Principles of Morals and Political Philosophy* (1785).

1.2 Secular Utilitarianism

Bentham's secular version of the theory was derived from a more progressive strain of enlightenment thought: empirical, analytical, and antagonistic towards organized religion. Unaware of Hutcheson's formulation of the utility principle, Bentham attributed it to the Italian law reformer Cesare Beccaria (1738–94) and sometimes to the dissenter and natural philosopher Joseph Priestley (1733–1804). Other progenitors to whom he traced his intellectual inheritance included David Hume (1711–76) and Claude Helvétius (1715–71). In Hume's secular moral philosophy the source of the rules of justice were located in general utility, but he explained the psychology of moral conduct in terms of a theory of 'moral sentiments' rather than motives supplied by pleasures and pains. Helvétius provided a systematic if rudimentary explanation of human motivation in terms of utility perceptions and expectations and some useful suggestions for the application of this knowledge to law and other social questions.

2. Bentham's Science of Morals and Legislation

In *An Introduction to the Principles of Morals and Legislation* (1789), Bentham delineated the component parts of his 'science' of morals and legislation founded upon the utility principle. The general purpose of the science was 'to rear the fabric of felicity by the hands of reason and of law.' (Bentham 1970, p. 11) The *Introduction* was then considered by Bentham to be the foundational text of his philosophy and his plans for future works were intended to elucidate the practical application of the utility principle in the areas of civil and penal law, judicial procedure, legislative reward, constitutional law, legislative procedure, international law, finance, political economy, and 'universal jurisprudence' (Bentham 1970, pp. 5–6).

2.1 The Principle of Utility

At the base of Bentham's theory was the assumption of 'the governance of two sovereign masters, *pain* and *pleasure*. It is for them alone to point out what we ought to do, as well as to determine what we shall do' (Bentham 1970, p. 11). As a first principle used to establish everything else, the utility principle was not itself subject to proof, but Bentham claimed there was sufficient testimony to the fact that it had always been generally accepted as the standard of right and wrong (Bentham 1970, p. 13). This foundational principle referred to a feeling or sentiment which served to approve the utility of an action. As Bentham explained, 'The principle here in question may be taken from an act of the mind; a sentiment; a sentiment of approbation; a sentiment which, when applied to an action, approves of its utility, as that quality of it by which the measure of approbation or disapprobation bestowed upon it ought to be governed' (Bentham 1970, p. 12). Utility also meant public utility, and the utility of the individual was a part of the public utility in which the individual shared. Thus a person approved of an act or law to the degree to which the happiness of all the individuals affected by it was advanced. For Bentham, the relationship between happiness and pleasure and pain was straightforward and did not require elaboration: pleasure contributes to happiness, while pain detracts from it. In these terms the public interest is constituted of the aggregate of individual interests, construed in terms of the balance of pleasures and pains experienced by each person.

2.2 Motives and Consequences

All motives have their source in the anticipation of pleasure or pain. Bentham delineated four *sanctions* or sources of pain and pleasure, which he may have learnt from John Gay: physical, political, moral, and religious. These sanctions are available to the moralist and to the legislator in guiding and determining an individual's moral conduct, and explain how an essentially self-interested individual can be directed to perform actions which enhance general happiness. In Bentham's theory of motives the dictates of utility were neither more nor less than the dictates of the most

extensive and enlightened benevolence. Other motives were categorized either as 'semisocial' motives (such as love of reputation, desire of amity, and religion), which may or may not coincide with the principle of utility, and purely 'self-regarding' motives (such as physical desire, pecuniary interest, love of power, and self-preservation), which were the least likely to coincide with utility. All motives, including the most extensive benevolence, are rooted in self-interest in one form or another; in these terms, the notion of a *dis*interested motive is implausible.

While the consequences of an act are partly dependent on the motives which give birth to the act (and partly on the empirical circumstances in which the act is performed), in Bentham's theory the utility of an act is not dependent on its originating motive(s). The relative utility of an act is determined solely by its consequences: the advantages and/or disadvantages that result. When deciding whether to act or which act to perform the individual must calculate as best as he or she can the pleasures and pains which may reasonably be expected to accrue to the persons (including him- or herself) affected by the acts under consideration. Bentham's *hedonistic* or *felicific calculus*, by which the value of pleasure and pain may be measured was constituted of the following elements: intensity, duration, certainty or uncertainty, propinquity or remoteness, fecundity, purity, and extent. A similar calculation should guide the legislator in formulating laws. However, Bentham recognized that it was not normally feasible for an individual to engage in such a calculation prior to acting, hence he spoke of the general tendencies of actions to enhance happiness as a sufficient guide. The consequences of acts were central to Bentham's theory of punishment, in which the utilitarian objective was to ensure that the punishment was in proportion to the mischief produced by a crime and sufficient to deter others from committing the same offence. To this end Bentham developed a series of rules to guide the lawmaker in the construction of a utilitarian penal code, including the elements involved in the calculation of the mischief caused by an offence and the appropriate punishment.

3. *John Austin*

Although sometimes described as an act utilitarian, it is generally acknowledged that for Bentham properly constituted *rules*, based on calculations of general utility, ought to be the guides for human action (Baumgardt 1966). John Austin (1790–1859), a disciple of Bentham's jurisprudence, is usually cited as the first explicit rule utilitarian. However, in *The Province of Jurisprudence Determined* (1832), he made it clear that he learnt the significance of rules from Paley, from whom he also borrowed the theological elements of his theory.

4. *James Mill*

James Mill (1773–1836) has often been credited with influencing Bentham's conversion to democratic principles in 1808–9; however, Bentham had already developed utilitarian arguments for democratic reform in manuscripts written around the time of the French Revolution. What Mill certainly brought to the political cause of utilitarianism was clarity of thought and expression, which he demonstrated to telling effect in his *Essay on Government* (1819). Based on the premise that government has the purpose of producing the greatest happiness of the greatest number, in this essay Mill made a succinct case for the radical reform of British political institutions (universal manhood suffrage, secret ballot, and annual parliaments). The essay was roundly criticized by T. B. Macaulay in the *Edinburgh Review* in 1829, largely for its narrow view of human nature and the *a priori* science of politics that it contained.

5. *John Stuart Mill*

It was largely through the sympathetic criticism of John Stuart Mill (1806–73) that Victorian moralists became acquainted with Bentham's utilitarian theory, though Mill's own moral philosophy was also influenced by Austin. Partly in response to the challenge of Macaulay's criticism of his father and partly the result of his own reflections on his intellectual inheritance, Mill developed a revised version of utilitarian theory. This revisionism took concrete form in his essay 'Bentham' (1838) and received definitive expression in *Utilitarianism* (1861). In the latter, Mill sought to defend the basic hedonism of utilitarian theory while offering refinements designed as responses to critics of the doctrine. The most problematic of these is the distinction between the *qualitative* differences of types of pleasures. While adhering to the basic Benthamic analysis of motives, Mill introduced the concept of higher pleasures, by which he meant the pleasures of the intellect, which he claimed were intrinsically more desirable than other pleasures. However, this qualitative distinction undermined the aggregative dimension of the theory and introduced questions concerning the appropriate judge of which pleasures were preferable. Mill only raised further questions about the integrity of the theory by arguing that the constituent elements of an individual's happiness might encompass objectives such as the pursuit of truth, beauty, and virtue, without consideration for the utility they may bring. This was a view later adopted by G. E. Moore (1873–1958) in the *Principia Ethica* (1903). Rejecting the hedonism of Bentham and Mill, Moore set forth a 'consequentialist' theory now known as *ideal* utilitarianism, in which the 'good' to be attained is more expansive than the summation of pleasures, and contains within itself

certain objective features of the universe, pre-eminently the beauty of its constituent parts (Scarre 1996, p. 114).

To the criticism that utilitarianism sacrificed principles for expediency, Mill replied that it was expedient to observe the *rules* associated with general utility and implied that only saints could be utilitarians, able to calculate continually the consequences of their actions. Finally, the supposed conflict between utilitarianism and Mill's commitment to individualism and individual liberty in the essay *On Liberty* (1859) is resolved when liberty is defended, not for its own sake but on the utilitarian grounds of the benefits which accrue to the individual and to the society of which the individual is a member.

6. *Liberal Utilitarianism*

Utilitarianism has enjoyed a sustained if ambiguous presence within the liberal tradition. Bentham's 'liberalism' is largely based on his writings on civil law and political economy, where he introduced subordinate principles to guide the legislator in giving effect to the utility principle: security, subsistence, abundance, and equality, in this order of priority. The stress on the *security* of the individual and *security of expectations* gave a priority to individual liberty when crafting law and tended to introduce a conservative element into the legislator's reform agenda, while the egalitarian principle held out the prospect of redistributive policies. Which of the subordinate principles was most in accord with the dictates of utility at any one point, and therefore should be acted upon by the legislator, depended on the particular context and particular issue. To the 'security-providing' principle Bentham later added the 'disappointment-preventing' principle, based on which disappointed expectations (loss of public office, for example) were to be compensated in the reform process.

Commentators who emphasize the importance of these subordinate principles tend to view Bentham as a *liberal* utilitarian, who intended that laws should be modeled to facilitate individuals in the pursuit of happiness in ways they, rather than the legislator, thought appropriate (Kelly 1990). This interpretation contrasts with the traditional view of Bentham as an aggregative legislative utilitarian (Crimmins 1996). Mill is also interpreted as a *liberal* utilitarian, whose theory of justice stressed the utility value of *security* (Riley 1998). This placed definable limits on the functions of law and implied a gradualist approach to achieving optimal utilitarian outcomes through social and political reform. Nevertheless, in a society of literate people neither Bentham nor Mill saw any barriers to the introduction of democratic institutions, including the extension of the suffrage to women on equal terms with men. Moreover, in later life Mill inclined toward collectivist solutions to social problems (Riley 1996).

In *Man versus the State* (1884) and other writings Herbert Spencer (1820–1903) employed the utility principle to enhance the liberty of the individual, defend the existing social order, and attack the drift towards socialism and 'slavery.' James Fitzjames Stephen (1829–94), Henry Sidgwick (1838–1900), and A. V. Dicey (1835–1922) all advocated versions of utilitarian individualism, although Sidgwick occasionally gave voice to 'socialist' sentiments in developing his *intuitional* utilitarian theory in *The Methods of Ethics* (1874). Reform-minded liberals such as J. A. Hobson (1859–1940) and L. T. Hobhouse (1864–1929) found in the protean nature of utilitarianism a justification for distinctly nonindividualist policies. Thus Hobhouse in *Liberalism* (1911) incorporated utilitarianism into a new liberal discourse that, in addition to laissez-faire economics (and notwithstanding Herbert Samuel's quasi-Benthamic motto 'the greatest liberty of the greatest number') also bridged elements of socialism, social Darwinianism, and the idealism of T. H. Green, and out of which emerged the beginnings of Britain's welfare state.

7. *The Modern Debate*

One of the most effective critiques of utilitarianism was mounted by John Rawls in *A Theory of Justice* (1971). Rawls argued that in counting *only* interests and aggregating *across* persons to arrive at the appropriate action or policy the utilitarian fails to 'take seriously' the distinction between persons. In reply it could be argued that at the level of private ethics utilitarian calculations implicitly acknowledge that different and distinct persons are involved in most situations about which individuals have to make moral judgements. This means that a consistent utilitarian will treat the interests of different people affected by his or her actions as of equal importance. However, the problem with this reasoning is that it risks making utilitarianism primarily a theory of equal consideration and effectively relegates the aim of maximizing utility to the status of a byproduct, not the ultimate ground of the theory.

The implications of an aggregate-utilitarian calculation for societies in which unpalatable sacrifices appear to be determined by simple calculations of optimal utility are frequently noted by critics of the theory. In an indiscriminate calculation where only total quantity of pleasures count, minorities are especially vulnerable to risk. Although Bentham was aware of the problems associated with the potential exclusion of minority interests under the phrase 'the greatest happiness of the greatest number,' the literature on utilitarianism abounds with discussions of the

potentially negative consequences of employing a rigid act utilitarian calculation to determine the individual's appropriate course of action or the legislator's policy choice. This debate is represented in the exchange between the modern act utilitarian J. J. C. Smart and his critic Bernard Williams in *Utilitarianism: For and Against* (1973). Other modern utilitarians who defend the theory as a practical guide to moral conduct and to public action include Robin Barrow in *Utilitarianism: a Contemporary Statement* (1991) and Richard B. Brandt in *Morality, Utilitarianism, and Rights* (1992).

Utilitarianism: Contemporary Applications

Utilitarianism is a moral and political theory that can be characterized as a combination of a theory of welfare and a concern with welfare as the good. Although there are many forerunners, utilitarianism arose in the Scottish Enlightenment. Thereafter, it was forcefully articulated by Jeremy Bentham (1970), who applied it to the design of legislatures and other institutions and to legislation and law; it was applied to law by John Austin (1954); and it flourished in the writings of John Stuart Mill (1969), Henry Sidgwick (1907), and many nineteenth- and twentieth-century economists. The focus on welfare as the good has been virtually constant from the beginning, although the scope of that concern sometimes expands to cover animals other than humans. The theory of welfare, however, has undergone frequent, substantial changes, largely because it is central to the discipline of economics.

Surprisingly often, sophisticated academics suppose that utilitarianism is solely about self-interest, that it is the moral theory of egoism. Among anti-utilitarian moral theorists, it has been characterized as virtually the opposite of egoism: as beneficence run wild. Sidgwick (1907) supposed that egoism and utilitarianism were two great, contrary divisions of moral theory.

Utilitarianism had been the chief moral theory in law for more than a century until recent decades, which have seen the rise of competing rights talk (Hart 1983). The movement of law and economics, which arose at about the same time as the move toward rights talk and which has come to dominate many areas of the civil law, has continued the utilitarian tradition and has even displaced rights talk in many contexts.

Utilitarianism is the principal moral stance of contemporary economists, although the more common term may now be welfarism. The focus of much economic thought since before the time of Adam Smith has been on what the economy does for the welfare of people in a market society. From the time of the Scottish Enlightenment through the nineteenth century, economics and utilitarianism developed together in Anglo–Saxon thought, with many authors contributing to both. During the twentieth century, philosophical utilitarianism became disconnected

from economic reasoning, and it therefore lost contact with further developments of value theory in economics as—some would say—it also lost contact with morality in the real world.

1. Value Theory

The split from economics was a misfortune for utilitarian thought in philosophy. The sometime theory of welfare of Bentham and many utilitarians, including such economists as F. Y. Edgeworth (1881), tended to conceive welfare or utility as cardinal and additive across individuals. From Vilfredo Pareto through the 1930s, there was a revolution in value theory in economics that jettisoned the interpersonal comparisons required for summing across individuals and then jettisoned cardinal-value theory altogether. Contemporary economics is largely grounded in an ordinal-value theory that merely ranks states of affairs and does not allow interpersonal comparisons.

If we cannot aggregate across individuals, then we are limited to making ordinal Pareto comparisons in which we can say that one state of affairs, X, is better than another, Y, only if at least one person is better off in X than in Y and no one is worse off in X than in Y. The beauty of a Benthamite additive utility is that, in principle, it would allow us to give complete rankings of all states of affairs. In Pareto's world of no interpersonal comparisons or aggregations, we cannot rank two states of affairs if some people are better off in one of them and others are better off in the other. Since it is relatively implausible that any significant social or economic policy could fail to make some worse off than in the status quo, we seem to be restricted to living with the status quo.

Contemporary policy analysts solve this restriction to the status quo by using cost–benefit analysis to commend many policies, such as public expenditures on highway programs. In such analyses, the costs and benefits to all are added, and a policy is adopted only if it has a positive sum—especially if that sum is relatively large. On the surface, this sounds like a cheat, as though a century of value theory were being ignored. Even those who accept only the more refined ordinal-value theory without interpersonal comparison, however, might agree *ex ante* that the status quo is worse for us individually than the *expected value* of an alternative. It would therefore be mutually advantageous for us to create institutions to make policy choices that would allow us to reach a new state, the expected value of which is greater. From an ordinal stance, we can choose *ex ante* to have an institution that makes some decisions on the basis of some kind of cardinal assessment, even though we could virtually always be sure of any project that it would cause harm to some.

Often we could recognize directly that a policy would serve mutual advantage *ex ante*. For example, vaccination against a grim disease might be expected to cause harm to a few but to protect virtually everyone else from the disease. *Ex ante*, I do not know whether my child will be one of those harmed or one of those benefited, but I might have a good sense of the probable advantages to my child, and those advantages might weigh heavily in favor of adopting the vaccination policy. If the economic cost of vaccination is negligible, as it generally has been, this approximates a simple cost–benefit analysis in which both the costs and benefits are measured in lives. In the case of a disease that has only human carriers, as is true of smallpox, it is even possible to eradicate the disease altogether. This has been done with smallpox and may soon be done with polio.

2. Institutions

More generally, we create mutual-advantage institutions, which are utilitarian in an ordinal welfarist sense (Hardin 1988). The policy-making institutions we create could adopt a policy of using cost–benefit analysis for many classes of policy problems. In this two-stage account, the use of cost–benefit analysis serves mutual advantage *ex ante* and is therefore ordinally welfarist, despite being based on cardinal, interpersonally comparable values. Any application of the method will lead to policies that harm some while benefiting others, but the adoption of cost–benefit analysis by the institution will be a mutual advantage move *ex ante*. We can make similar arguments for the creation of constitutional arrangements, a criminal justice system, and civil law. *Ex ante*, they can all serve mutual advantage and can therefore be ordinally utilitarian.

Even economists have difficulty with ordinal thinking in many contexts, despite the facts that they think ordinally regularly in their microeconomic theorizing and that they sometimes insist that cardinally additive reasoning is philosophically incoherent. Yet they commonly fall back on cardinal thinking when they do policy analysis. Since much of their policy analysis addresses questions of how to allocate money to various programs, they have devices that make their problems approximate merely the addition and comparison of numbers of dollars. Despite massive criticism of these devices by many non-economists and some economists, it is hard to imagine doing policy analysis or justifying policies at all in some realms without such additions. It is typical to criticize standard cost–benefit analysis for disregarding non-monetary values but to give no alternative scheme for handling the pressing issues such analysis is used to address (Gutmann and Thompson 1996). It is a great advantage of a theory that has real content that it can be criticized in such specific ways. One wishes the alternative theories were sufficiently articulate to be susceptible to criticism.

An inherent implication of an ordinal, as opposed to a Benthamite cardinal, utilitarianism is that we must be more modest in our claims about the good we might do in the world, because our theory often yields ambiguous implications—or, essentially, no implications at all—for what policy we should adopt. This is a conclusion that all moral theorists might well take to heart. If moral debate allowed greater play for ambiguity and indeterminacy, it would have a less assertive and dismissive quality. It would then seem more moral. It would also be more relevant. In any case, on our present understanding of personal welfare, there is little prospect of doing cardinal comparisons and aggregations of welfare over populations in many important policy contexts. It is therefore unfortunate that, although we regularly do it in daily life at the personal and small-number level, thinking ordinally is especially difficult when we think of broad social policy. There are easy cases, such as vaccination, but when the values at stake are not so simply uniform across an entire population, we have much greater difficulty making the comparisons.

For some policies, we can identify the losers *ex ante* and therefore cannot say that these policies are ordinally utilitarian. We can meet this objection by compensating anyone who evidently is made worse off by a policy. There are two substantial problems with such compensation. First, the promise of compensation is likely to provoke exaggerated claims that one is made very much worse off. Compensations, therefore, tend to be standardized as though all have similar values. *Ex ante*, this might be acceptable, and we can therefore make serious policy choices. *Ex post*, such standardization may seem unfair for anyone with unusual preferences or beliefs (Calabresi 1985).

Second, compensation to anyone who is made worse off by any change at all cannot be a plausible program, because it would entail compensating people for the economic failures that are a natural implication of technological and other economic changes. If the state must compensate every bankrupt, the economy will stagnate. One might suppose that the economy is more nearly a force of nature than a matter of public choice and that therefore we need not be concerned with compensation for the harsh results of the market. If, however, we could compensate for market harms and yet do not, we implicitly permit trade-offs across individuals for the sake of greater market productivity overall. Anyone who thinks that economic progress is good in at least some states of development must countenance losses to some for the perhaps greater gains of others.

The chief contemporary use of utilitarian reasoning is in *ex ante* specification of institutional structures and devices, not in direct application to immediate policy choices. Even cost–benefit analysis, which might seem to be the preeminent use of utilitarian reasoning is, in fact, justified not directly as though it were directly a utilitarian calculation. Rather, it is justified only *ex ante*. For a very simple case such as vaccination, direct calculation works because we can make ordinal judgments. For more complex problems, it does not work, because we cannot make such judgments.

Utility and Subjective Probability: Contemporary Theories

Contemporary theories of utility and subjective probability are motivated by decision under uncertainty where a person must choose a course of action from a set of possibilities whose outcomes or consequences depend on which state of an uncertain world actually occurs. Utilities assess the person's preferences for outcomes; subjective probabilities measure the person's beliefs about the states' relative likelihoods. A theory of utility and subjective probability makes assumptions about preferences that lead to measures

of utility and subjective probability that combine to evaluate courses of action. The rule of combination is usually a form of mathematical expectation.

1. Decision Under Uncertainty

The standard formulation of decision under uncertainty (Savage 1954) evolved from a theory of expected utility for decision under risk (von Neumann and Morgenstern 1944), where outcome probabilities are assumed to be known, and a theory of subjective probability (de Finetti 1937). This section outlines Savage's formulation. The next provides background on utility theory, with and without explicit mention of probabilities, and the third section discusses quantification of uncertainty by subjective probability. Utility and subjective probability are then combined in Savage's theory of subjective expected utility, followed by alternative theories motivated by perceived shortcomings of his theory.

Savage's formulation envisions an individual faced with choosing one course of action from a set of courses of action. The chosen action will result in exactly one outcome from a set X of outcomes. It is presumed that outcomes are the primary sources of value for the individual.

The chosen action's outcome depends on which state of an uncertain world is the true state, or 'obtains.' The individual knows the set S of states and the outcome that will occur for every action–state pair, but is uncertain about the state that obtains. It is presumed that all relevant uncertainty resides in S and that the chosen action does not influence the true state.

Given S and X, a course of action, or *act* for short, is a map f from S into X. If f is chosen and state s obtains, the outcome is $f(s) \in X$. The set F of acts is a subset of the set X^S of all maps from S into X. Savage's axioms impose conditions on the individual's preference relation $\succsim$ on F, where $f \succsim g$ signifies the act f is preferred or indifferent to act g. Relations of strict preference $\succ$ and indifference $\sim$ are defined from $\succsim$ by $f \succ g$ if $f \succsim g$ and not $(g \succsim f)$, $f \sim g$ if $f \succsim g$ and $g \succsim f$. A constant act assigns the same outcome to every state. When F includes all constant acts, $\succsim$ extends to outcomes by $x \succsim y$ if $f \succsim g$ when $f(s) = x$ and $g(s) = y$ for all $s \in S$. Ordering and dominance axioms illustrate conditions for $\succsim$. The primary ordering condition, transitivity, says that if $f \succsim g$ and $g \succsim h$ then $f \succsim h$. One dominance axiom asserts that if $f(s) \succ g(s)$ for every s, then $f \succ g$.

The family S of subsets $A, B, \ldots$ of S over which subjective probabilities are defined is assumed to be a Boolean algebra, that is,

(a) $S \in S$
(b) $A, B \in S \Rightarrow A \cup B \in S$
(c) $A \in S \Rightarrow S \setminus A \in S$

Members of S are events; event A obtains if some $s \in A$ obtains. When A is an event and $x, y \in X$, let xAy be the act with outcome x if A obtains, and y if $S \setminus A$ obtains. If $x \succ y$ and $xAy \succ xBy$, the individual prefers to take his or her chances on A rather than B for the preferred outcome. According to de Finetti (1937) and Savage (1954), this means that the individual regards A as more probable than B. It is then natural to assume that, for all $x \succ y$ and $x' \succ y'$, $xAy \succ xBy \Rightarrow x'Ay' \succ x'By'$, so that the underlying comparison between events depends only on the direction and not the degree of preference.

2. Utility

Utility theory, broadly construed, concerns quantitative representations of qualitative preference relations. The set on which preferences are defined might be finite or infinite, it may or may not involve probabilities or outcomes with multiple attributes, and so forth. A few basic definitions follow. Let $\succsim$ be a binary preference relation on an arbitrary nonempty set X. Usually it is assumed that $\succsim$ is an ordering relation. The most common assumption is that $\succsim$ is a weak order, which means that it is transitive and complete (for all $x, y \in X$: $x \succsim y$ or $y \succsim x$). When $\succsim$ is a weak order, the indifference relation $\sim$ is an equivalence relation (reflexive: $x \sim x$; symmetric: $x \sim y \Rightarrow y \sim x$; transitive) that partitions X into equivalence classes, with x and y in the same equivalence class if and only if $x \sim y$. A more empirically realistic assumption is that $\succ$ is asymmetric ($x \succ y \Rightarrow$ not $(y \succ x)$) and transitive. This admits nontransitive indifference, as when $x \sim y$, $y \sim z$, and $x \succ z$. Another assumption, which allows preference cycles such as $x \succ y$, $y \succ z$, and $z \succ x$, presumes only that $\succsim$ is complete.

2.1 Ordinal Utility

When X is finite, there is a real-valued function u on X that preserves $\succsim$ in the sense that, for all $x, y \in X$,

$$x \succsim y - u(x) \geqslant u(y) \tag{1}$$

if and only if $\succsim$ is a weak order. In this case, u is an ordinal utility function. An ordinal utility function also exists when $\succsim$ is a weak order and X is countably infinite, but not necessarily when X is uncountable. The lexicographic order $\succ_L$ on $[0, 1] \times [0, 1]$ defined by $(x_1, x_2) \succ_L (y_1, y_2)$ if $x_1 > y_1$ or $(x_1 = y_1, x_2 > y_2)$ illustrates the problem. If u were an order-preserving utility function for $\succ_L$, there would be uncountably many nondegenerate and mutually disjoint real intervals, which is impossible.

An additional condition is needed for Eq. (1) when the set $X/\sim$ of equivalence classes in X is uncountable.

Given a weak order $\succsim$ on X, define $>$ on the equivalence classes $a, b, \ldots$ in $X/\sim$ by $a > b$ if $x \succ y$ whenever $x \in a$ and $y \in b$. A subset T of $X/\sim$ is $>$-order dense in $X/\sim$ if, whenever $a, b \in (X/\sim)\backslash T$ and $a > b$, there is a $t \in T$ such that $a > t > b$.

Theorem 1. *Suppose $\succsim$ is a weak order on X. Then there is an ordinal utility function for $\succsim$ if and only if some countable subset of $X/\sim$ is $>$-order dense in $X/\sim$.*

Proofs are included in Fishburn (1970) and Krantz et al. (1971). Although countable order denseness is not intuitively appealing, other conditions that ensure real-valued utilities are more intuitive. They are referred to as *Archimedean axioms*.

Other utility theorems for partially ordered preferences, comparable preference differences, multiattribute outcomes, and so forth, are included in the preceding references (see also *Measurement, Representational Theory of*; *Measurement Theory: Conjoint*).

2.2 Expected Utility

The preceding subsection applies to preferences in any situation. The present one considers the special case of decision under risk, where preferences apply to decisions with known outcome probabilities. Expected utility (von Neumann and Morgenstern 1944) applies $\succsim$ to a convex set P of probability distributions $p, q, \ldots$ on a set X of outcomes. Convexity means that $\lambda p + (1-\lambda)q \in P$ whenever $p, q \in P$ and $0 \leqslant \lambda \leqslant 1$. With $p(x)$ the probability that p yields outcome x, the probability that $\lambda p + (1-\lambda)q$ yields x is $\lambda p(x) + (1-\lambda)q(x)$.

The axioms of expected utility are: for all $p, q, r \in P$ and all $0 < \lambda < 1$,

A1. $\succsim$ on P is a weak order;

A2. $p \succ q \Rightarrow \lambda p + (1-\lambda)r \succ \lambda q + (1-\lambda)r$; and

A3. $(p \succ q, q \succ r) \Rightarrow \alpha p + (1-\alpha)r \succ q \succ \beta p + (1-\beta)r$ for some $\alpha, \beta \in (0, 1)$.

A2 is an independence axiom that preserves $\succ$ under similar convex combinations. A3 is an Archimedean axiom.

A utility function u on P is linear if, for all $p, q \in P$ and all $0 \leqslant \lambda \leqslant 1$

$$u(\lambda p + (1-\lambda)q) = \lambda u(p) + (1-\lambda)u(q) \tag{2}$$

When u satisfies certain conditions, it is unique up to a positive affine transformation if another function v on P satisfies the same conditions if and only if there are constants $a > 0$ and b such that $v(p) = au(p) + b$ for all $p \in P$.

Theorem 2. *There is a linear, order-preserving real-valued function u on P if and only if* A1, A2, *and* A3 *hold, and such a u is unique up to a positive affine transformation.*

Proofs appear in Fishburn (1970, 1988). When every degenerate probability distribution on X is in P and u on P is extended to X by $u(x) = u(p)$ when $p(x) = 1$, linearity implies $u(p) = \Sigma p(x)\, u(x)$ to give the expected-utility form

$$p \succ q - \sum_X p(x)\, u(x) > \sum_X q(x)\, u(x)$$

for probability distributions with finite supports in X. Its extension to general probability measures is discussed in Fishburn (1970, 1982) along with other topics for expected utility.

One of these (Hausner 1954) generalizes Theorem 2 by dropping the Archimedean axiom A3 and adding the indifference comparison of A2 ($p \sim q \Rightarrow \lambda p + (1-\lambda)r \sim \lambda q + (1-\lambda)r$). These changes lead to a notion of linear utility vectors ordered lexicographically as follows. Let $(T, <_o)$ be a linearly ordered set ($<_o$ is transitive and $t \neq t' \Rightarrow t <_o t'$ or $t' <_o t$) and let K be the set of all real-valued functions on T that are nonzero on at most a well-ordered subset of $(T, <_o)$, with addition and scalar multiplication defined pointwise. Define the lexicographic order $>_L$ on K by $k >_L k'$ if $k \neq k'$ and $k(t) > k'(t)$ for the first t in $(T, <_o)$ at which $k(t) \neq k'(t)$.

Hausner proves that A1, A2, and its $\sim$ companion hold if and only if there is such a $(K, >_L)$ and a map U from P into K such that, for all $p, q \in P$, and all $0 \leqslant \lambda \leqslant 1$, $p \succ q - U(p) >_L U(q)$, $U(\lambda p + (1-\lambda)q) = \lambda U(p) + (1-\lambda)U(q)$. The latter expression is the linearity property for multidimensional utilities.

2.3 Nonlinear Utility

Many studies, including Allais (1953), MacCrimmon and Larsson (1979), and Kahneman and Tversky (1979) demonstrate systematic violations of A2. In one monetary case from Kahneman and Tversky (1979) with $r(\$0) = 1$ and

p: \$3,000 with probability 1;

q: \$4,000 with probability 0.8, nothing otherwise;

$p' = \frac{1}{4}p + \frac{3}{4}r$: \$3,000 with probability 0.25, \$0 otherwise;

$q' = \frac{1}{4}q + \frac{3}{4}r$: \$4,000 with probability 0.20, \$0 otherwise;

a majority of 94 respondents violated A2 with $p \succ q$ and $q' \succ p'$. Consequently, alternatives to expected utility theory that weaken A2 have been proposed.

An early alternative (Allais 1953) assesses u on X by preference–difference comparisons that do not involve probabilities and defines u on P by

$$u(p) = \sum_X p(x)\, u(x) + \theta(p^*) \tag{3}$$

where p^* is the probability distribution induced by p on the differences of outcome utilities from their mean and θ is a real-valued function. A later alternative by

Machina (1982) for the same context returns to the von Neumann–Morgenstern paradigm and assumes in place of A2 that u on P is smooth and linear locally. Machina's generalization has economically interesting implications that generalize those of expected utility.

Kahneman and Tversky (1979) outline a theory, called prospect theory, that modifies expected utility by transforming P's probabilities by an increasing function τ from [0, 1] on to [0, 1]. This responds to the observation that people often overvalue small probabilities and undervalue large probabilities. The number $\tau(\lambda)$ is a subjective equivalent for the objective probability λ, and τ is referred to as a probability weighting function (Wu and Gonzalez 1996, Prelec 1998). Other behavioral findings have been integrated into prospect theory.

Quiggin (1993) also uses an objective-to-subjective probability transformation τ but applies it to cumulative probabilities in a theory of rank-dependent expected utility. Quiggin assumes weak order with $p \succsim q - u(p) \geqslant u(q)$. When the possible outcomes of p are linearly ordered from worst to best as $x_1 \prec x_2 \prec \ldots \prec x_n$

$$u(p) = \sum_{k=1}^{n} u(x_k) \left\{ \tau \left[\sum_{j=1}^{k} p(x_j) \right] - \tau \left[\sum_{j=1}^{k-1} p(x_j) \right] \right\} \quad (4)$$

This reduces to ordinary expected utility when $\tau(\lambda) = \lambda$ for all λ.

Another weak-order theory, weighted utility theory (Chew 1983, Fishburn 1988), retains A1 and A3 and replaces A2 by a convexity axiom and a weak independence axiom: for $p,q,r \in P$ and $0 < \lambda < 1$

convexity: $(p \succ q, p \succsim r) \Rightarrow p \succ \lambda q + (1-\lambda) r$
$(q \succ p, r \succsim p) \Rightarrow \lambda q + (1-\lambda) r \succ p$;

weak independence: $p \sim q \Rightarrow$ for every $0 < \alpha < 1$ there is a $0 < \beta < 1$ such that, for every $r \in P$, $\alpha p + (1-\alpha) r \sim \beta q + (1-\beta) r$

These axioms imply the existence of real-valued linear functions u and w on P with $w \geqslant 0$ such that, for all $p,q \in P$

$$p \succsim q - u(p)\, w(q) \geqslant u(q)\, w(p) \quad (5)$$

When $w > 0$, this gives $p \succsim q - u(p)/w(p) \geqslant u(q)/w(q)$. Fishburn (1988) axiomatizes generalizations of weighted utility, including a theory that accommodates strict preference cycles in P. It uses a skew-symmetric bilinear real-valued function ϕ on $P \times P$ in the representation

$$p \succsim q - \phi(p,q) \geqslant 0 \quad (6)$$

where skew symmetry means that $\phi(p,q) + \phi(q,p) = 0$ and bilinearity means that ϕ is linear separately in each argument. The function ϕ is unique up to multiplication by a positive constant. Fishburn (1988, chap. 6) describes implications of the theory, including the fact that the convex hull of every finite subset of P contains a distribution that has $\succsim$ to all others.

3. Subjective Probability

Let $\succsim$ be a comparative probability relation on a Boolean algebra $\mathscr{S}$ of subsets of a set S of states of the world. A finitely additive probability measure π on $\mathscr{S}$ agrees with $\succsim$ if, for all $A,B \in \mathscr{S}$, $A \succsim B - \pi(A) \geqslant \pi(B)$. The relation $\succsim$ is a qualitative probability if it satisfies the following for all $A,B,C \in \mathscr{S}$:

S1. $\succsim$ on $\mathscr{S}$ is a weak order;
S2. $S \succ \emptyset$, where $\emptyset$ is the empty set;
S3. not $(\emptyset \succ A)$;
S4. $(A \cup B) \cap C = \emptyset \Rightarrow (A \succ B - A \cup C \succ B \cup C)$

These conditions are necessary for agreement.

3.1 Agreeing Measures

De Finetti asked whether every qualitative probability on a finite $\mathscr{S}$ has an agreeing measure. This was resolved negatively by Kraft et al. (1959), who proved that agreement is possible for a qualitative probability if and only if it satisfies an extension of S4. When $\mathscr{S} = 2^S$, the algebra of all subsets of S, their new axiom says that if $m \geqslant 4$, if $A_1, \ldots, A_m, B_1, \ldots, B_m \subseteq S$, and if $|\{j: s \in A_j\}| = |\{j: s \in B_j\}|$ for every s, then it cannot be true that $A_j \succsim B_j$ for all j with $\succ$ for some j. If this fails and an agreeing π is presumed, addition over j and cancellation over S give $0 > 0$.

Savage (1954) considers infinite S and shows that the following Archimedean axiom (S5) obviates the need for the extension of S4.

Theorem 3. *Suppose $\mathscr{S} = 2^S$ and $\succsim$ on $\mathscr{S}$ is a qualitative probability that satisfies the following for all $A,B \in \mathscr{S}$:*

S5. *$A \succ B \Rightarrow$ there is a finite partition $\{C_1, \ldots, C_m\}$ of S such that $A \succ (B \cup C_j)$ for $j = 1, \ldots, m$.*

Then there is a unique probability measure π that agrees with $\succsim$, and for every $A \in \mathscr{S}$ with $\pi(A) > 0$ and every $0 < \lambda < 1$, there is a $B \subset A$ for which $\pi(B) = \lambda \pi(A)$.

Proofs also appear in Fishburn (1970, 1988). Given S1–S4, S5 is equivalent to the assumption that, for every m, S can be partitioned into m equally likely events. Necessary and sufficient conditions for agreement are given in Chateauneuf (1985).

3.2 Nonadditive Subjective Probability

Many other contributions to the theory of subjective probability are discussed in Savage (1954), Fishburn (1988, 1994), and Machina and Schmeidler (1992) (see also *Subjective Probability Judgments*). Of special interest here are approaches in which subjective probabilities are not additive. This was previously considered for decision under risk through the probability weighting function τ. In decision under uncertainty,

failures of additivity were highlighted by examples in Ellsberg (1961) critique of the approach advocated by de Finetti (1937) and Savage (1954).

Consider an urn filled with 90 balls, 30 of which are red (R). The others are black (B) and yellow (Y) in an unknown proportion. One ball is to be drawn at random with a payoff of \$0 or \$2,000 depending on the act chosen and the color of the drawn ball. Four potential acts, shown according to their payoffs for R, B, and Y, respectively, are

f: \$2,000, \$0, \$0
g: \$0, \$2,000, \$0

and

f': \$2,000, \$0, \$2,000
g': \$0, \$2,000, \$2,000

Many people prefer f to g because of R's specificity (30 balls) relative to B's (an unknown number of balls between 0 and 60). By Savage's definition, $f \succ g$ implies $\pi(R) > \pi(B)$. Many people prefer g' to f' for a similar reason. Then $g' \succ f'$ gives $\pi(B \cup Y) > \pi(R \cup Y)$. Under additivity, $\pi(B \cup Y) > \pi(R \cup Y) \Rightarrow \pi(B) > \pi(R)$, which contradicts $\pi(R) > \pi(B)$ via $f \succ g$. The preceding judgments violate S4 when $\succ$ in S4 is interpreted through preference. The theories of subjective expected utility described in the next two sections forbid such violations, but they are allowed by some theories in the final section.

4. Savage's Theory of Subjective Expected Utility

Savage's theory applies $\succsim$ to the act set $F = X^S$ with event set $\mathscr{S} = 2^S$. For any event $A \in S$, write

$f = {}_A x$ if $f(s) = x$ for all $s \in A$,
$f = {}_A g$ if $f(s) = g(s)$ for all $s \in A$, and
$f = xAy$ when $f = {}_A x$ and $f = {}_{A^c} y$,

where $A^c = X \backslash A$. Event A is null if $f \sim g$ whenever $f = {}_{A^c} g$; $\mathscr{N}$ denotes the set of null events. For each $A \in \mathscr{S}$, define a conditional preference relation $\succsim_A$ on F by

$f \succsim {}_A g$ if, for all $f', g' \in F$,

$$(f' = {}_A f, g' = {}_A g, f' = {}_{A^c} g') \Rightarrow f' \succsim g'.$$

This reflects the notion that preference between f and g should depend only on states where their outcomes differ. Similar definitions pertain $\succ_A$ and $\succ_A$.

Savage (1954) uses seven axioms. They apply to all $f, g, f', g' \in F$, all $x, y, x', y' \in X$ and all $A, B \subseteq S$:

P1. $\succsim$ on F is a weak order,
P2. $(f = {}_A f', g = {}_A g', f = {}_{A^c} g, f' = {}_{A^c} g') \Rightarrow (f \succsim g - f' \succsim g')$,
P3. $(A \notin \mathscr{N}, f = {}_A x, g = {}_A y) \Rightarrow (f \succ {}_A g - x \succ y)$,
P4. $(x \succ y, x' \succ y') \Rightarrow (xAy \succ xBy - x'Ay' \succ x'By')$,
P5. $z \succ w$ for some $z, w \in X$,
P6. $f \succ g \Rightarrow$ [given x, there is a finite partition of S such that, for every event E of the partition, $(f' = {}_E x, f' = {}_{E^c} f) \Rightarrow f' \succ g$, and $(g' = {}_E x, g' = {}_{E^c} g) \Rightarrow f \succ g'$],
P7. $(f \succ {}_A g(s)$ for every $s \in A) \Rightarrow f \succsim {}_A g$; $(f(s) \succ {}_A g$ for every $s \in A) \Rightarrow f \succsim {}_A g$

Axioms P2 and P3 are Savage's sure-thing principle. P2 says that preference should not depend on s for which $f(s) = g(s)$, and P3 ties conditional preferences to outcome preferences. P4 is a consistency postulate for subjective probability because $\pi(A) > \pi(B)$ corresponds to $(x \succ y, xAy \succ xBy)$. P6 (cf. S5) is Savage's Archimedean axiom. P7 is a dominance axiom used to extend expected utility for finite-image acts to arbitrary acts.

Theorem 4. *Suppose* P1 *through* P7 *hold for* $\succsim$ *on* F. *Then there is a probability measure* π *on* 2^S *that satisfies the conclusions of Theorem 3 when* $A \succ B$ *corresponds to* $\{xAy \succ xBy$ *for all* x *and* y *with* $x \succ y\}$, *and for which* $\pi(A) = 0 - A \in \mathscr{N}$, *and there is a bounded real-valued function* u *on* X *such that, for all* $f, g \in F$

$$f \succ g - \int_S u(f(s))d\pi(s) > \int_S u(g(s))d\pi(s),$$

with u *unique up to a positive affine transformation.*

A complete proof is included in Fishburn (1970).

Ellsberg's (1961) criticism is directed at P2. Other dissatisfactions include the implication that $\mathscr{S}$ is infinite (Anscombe and Aumann 1963, Pratt et al. 1964) and the assumption that F contains all constant acts (Karni 1985). Related axiomatizations are noted in Fishburn (1982, 1988, 1994).

5. Lottery Theories of Subjective Expected Utility

This section describes two alternatives to Savage's theory for finite S that use extraneous scaling probabilities to provide the scaling power inherent in P6.

5.1 Lotteries and Real-valued Utilities

Let P_X denote the set of all lotteries or finite-support probability distributions on X, and let $\boldsymbol{F} = P_X^S$, the set of lottery acts, so each $\boldsymbol{f} \in \boldsymbol{F}$ assigns a lottery in P_X to every stage. The convex combination $\lambda \boldsymbol{f} + (1-\lambda)\boldsymbol{g}$ is defined by $(\lambda \boldsymbol{f} + (1-\lambda)\boldsymbol{g})(s) = \lambda \boldsymbol{f}(s) + (1-\lambda)\boldsymbol{g}(s)$, so $\boldsymbol{F}$ is convex and A1–A3 of Theorem 2 can be used for $\succsim$ on $\boldsymbol{F}$. Also take $\boldsymbol{f} = {}_A P$ if $\boldsymbol{f}(s) = p$ for all $s \in A$, define $\succsim$ on P_X by $p \succsim q$ if $\boldsymbol{f} \succsim g$ when $\boldsymbol{f} = {}_s p$ and $\boldsymbol{g} = {}_s q$, and define the set $\mathscr{N}$ of null events in 2^S by $A \in \mathscr{N}$ if $\boldsymbol{f} \succ \boldsymbol{g}$ whenever $\boldsymbol{f} = {}_{A^c} \boldsymbol{g}$.

Theorem 5. *With* $S = 2^S$ *and* $F = P_X^S$, *suppose* $\succsim$ *on* $\boldsymbol{F}$ *satisfies* A1–A3 *along with the following for all* $A \subseteq S$, *all* $\boldsymbol{f}, \boldsymbol{g} \in \boldsymbol{F}$, *and all* $p, q \in P_X$

A4. $p' \succ q'$ *for some* $p', q' \in P_X$ *and*
A5. $(A \notin \mathscr{N}, \boldsymbol{f} = {}_A p, \boldsymbol{g} = {}_A q, \boldsymbol{f} = {}_{A^c} g) \Rightarrow (\boldsymbol{f} \succ \boldsymbol{g} - p \succ q)$

Then there is a unique probability measure π on $\mathscr{S}$ with $A \in \mathscr{N} - \pi(A) = 0$, and a real-valued linear function u on P_X, unique up to a positive affine transformation, such that, for all $\boldsymbol{f}, \boldsymbol{g} \in \boldsymbol{F}$

$$f \succsim \boldsymbol{g} - \sum_S \pi(s)\, u(\boldsymbol{f}(s)) \geqslant \sum_S \pi(s)\, u(\boldsymbol{g}(s)).$$

Axioms A4 and A5 correspond respectively to Savage's P5 and his sure-thing principle. Proofs of the theorem appear in Fishburn (1970, 1982) where it is noted that the representation extends to infinite S under addition of a dominance axiom (cf. P7) which says that $(\boldsymbol{f}(s) \succ \boldsymbol{g})$ for all $s) \Rightarrow \boldsymbol{f} \succsim \boldsymbol{g}$ and $(\boldsymbol{f} \succ \boldsymbol{g}(s)$ for all $s) \Rightarrow \boldsymbol{f} \succsim \boldsymbol{g}$.

5.2 *Subjective Expected Lexicographic Utility*

The theory of subjective expected lexicographic utility described in LaValle and Fishburn (1996) applies $\succsim$ to the set P_F of all lotteries on $F = X^S$. Lotteries in P_F are act lotteries. They are denoted as $\boldsymbol{p}, \boldsymbol{q}, \ldots$. With $(\lambda \boldsymbol{p} + (1-\lambda)\boldsymbol{q})(f) = \lambda \boldsymbol{p}(f) + (1-\lambda)\boldsymbol{q}(f)$, P_F is a convex set, so A1–A3 and similar conditions can be used for $\succsim$ on P_F.

The marginal probability distribution induced by $\boldsymbol{p}$ on X for state s is denoted by $\boldsymbol{p}_s : \boldsymbol{p}_s(x) = \Sigma_F\{\boldsymbol{p}(f) : f(s) = x\}$. For $\boldsymbol{p}, \boldsymbol{q} \in P_F$, $p \in P_X$, and $A \in 2^S$

$\boldsymbol{p} =_A p$ means that $\boldsymbol{p}_s = p$ for all $s \in A$ and

$\boldsymbol{p} =_A \boldsymbol{q}$ means that $\boldsymbol{p}_s = \boldsymbol{q}_s$ for all $s \in A$.

When $\boldsymbol{p} =_s \boldsymbol{q}$, $\boldsymbol{p}$ and $\boldsymbol{q}$ can assign different probabilities to acts so long as they have identical marginals for every state. Event A is null if $\boldsymbol{p} \sim \boldsymbol{q}$ whenever $\boldsymbol{p} =_{A^c} \boldsymbol{q}$.

For outcome x, $\bar{x}$ denotes the constant act in P_F with $\bar{x} =_s x$. The relation $\succsim$ on P_F is extended to the set P_X of lotteries on X by the definition

$$p \succsim q \text{ if } \boldsymbol{p} \succsim \boldsymbol{q} \text{ whenever } \boldsymbol{p}(\bar{x}) = p(x) \text{ and } \boldsymbol{q}(\bar{x}) = q(x) \text{ for } \textit{all } x \in X.$$

The ensuing axioms imply that $p \succsim q$ if $\boldsymbol{p} \succsim \boldsymbol{q}$ whenever $\boldsymbol{p} =_S p$ and $\boldsymbol{q} =_S q$. The axioms of the present theory are: for all $\boldsymbol{p}, \boldsymbol{q}, \boldsymbol{r} \in P_F$, all $p, q \in P_X$, all $A \in 2^S$, and all $0 < \lambda < 1$,

L1. $\succsim$ on P_F is a weak order; $\bar{x} \succ \bar{y}$ for some $x, y \in X$,

L2. $\boldsymbol{p} \succ \boldsymbol{q} \Rightarrow \lambda \boldsymbol{p} + (1-\lambda)\boldsymbol{r} \succ \lambda \boldsymbol{q} + (1-\lambda)\boldsymbol{r}$; $\boldsymbol{p} \sim \boldsymbol{q} \Rightarrow \lambda \boldsymbol{p} + (1-\lambda)\boldsymbol{r} \sim \lambda \boldsymbol{q} + (1-\lambda)\boldsymbol{r}$,

L3. $\boldsymbol{p} =_S \boldsymbol{q} \Rightarrow \boldsymbol{p} \sim \boldsymbol{q}$,

L4. $(\boldsymbol{p} =_A p,\ \boldsymbol{q} =_A q,\ \boldsymbol{p} =_{A^c} \boldsymbol{q},\ \boldsymbol{p} \succ \boldsymbol{q}) \Rightarrow p \succ q$, and

L5. $(P_F, \succsim)$ is finite-dimensional.

L1 combines weak order with nontriviality, L2 corresponds to A2 and its indifference companion, L3 is a state independence condition, and L4 relates $p \succ q$ to $\boldsymbol{p} \succ \boldsymbol{q}$. L5 replaces the Archimedean axiom A3 for P_F by a much weaker condition which says that a multidimensional linear utility function U on P_F of the type described for Hausner's (1954) theory need have only a finite number of dimensions in its lexicographic structure.

Let J denote the minimum lexicographic dimension of $(P_F, \succsim)$ under L5, and let U be a J-dimensional linear lexicographically order-preserving function on P_F. Hausner's theory applies also to $(P_X, \succsim)$ to yield a linear lexicographically order-preserving u on P_X of dimension $K \leqslant J$. Under admissible transformations, U on P_F and u on P_X can be related as

$$U(p) = \sum_S \Pi(s)\, u(\boldsymbol{p}_S) \tag{7}$$

where $\Pi(s)$ is a $J \times K$ real matrix that premultiplies the column vector $u(\boldsymbol{p}_s)$. The $\Pi(s)$ are state matrix probabilities which can be constructed so that $\Pi(s)$ begins with c_s nonzero columns whose leading nonzero entries are positive and in successively lower rows, followed by $K - c_s$ columns of zeros. In addition, state s is null if and only if $\Pi(s)$ is the zero matrix, and $\Sigma\Pi(s)$ is a 0–1 matrix with exactly one 1 in each column. When the 1's of $\Pi(S)$ are in cells $(j_1, 1)$, $(j_2, 2)$, …, and (j_K, K), we have $1 = j_1 < j_2 < \ldots < j_K \leqslant J$.

6. *Other Theories for Decision under Uncertainty*

Excepting Allais (1953), this section discusses theories motivated by Ellsberg (1961) and subsequent behavioral research. Allais's approach uses a preference-free view of subjective probability. He maintains that a person's probability for event A ought to be assessed by having the person identify a chance event A^* of a well-calibrated random device whose occurrence is judged to be equally likely to the occurrence of A. Then $\pi(A)$ equals the objective probability of A^*. An act's utility is then given by Allais's form for the utility of a risky prospect with probabilities given by π.

6.1 Choquet *Expected Utility*

Choquet expected utility offers a generalization of Savage's theory which replaces π by a monotonic set function σ, called a capacity, and computes the utility of an act by Choquet integration rather than ordinary integration. Choquet summation for finite S is similar to the summation of rank-dependent utility (Quiggin 1993) for the monotonic probability weighting function τ.

The initial axiomatization of Choquet expected utility (Schmeidler 1989) uses Theorem 5's lottery approach. Subsequent developments, including modifications of Savage's axioms, are described in Sarin and Wakker (1992). An outline of Schmeidler's theory follows.

A capacity σ on $\mathscr{S}$ is a monotonic $(A \subseteq B \Rightarrow \sigma(A) \leqslant \sigma(B))$ real-valued function with $\sigma(\emptyset)$

$= 0$ and $\sigma(S) = 1$. The Choquet integral $\int_S w(s)d\sigma(s)$ of a real-valued function w on S with respect to the capacity σ is defined by

$$\int_S w(s)\, d\sigma(s) = \int_{t=0}^{\infty} \sigma(\{s: w(s) \geqslant t\})\mathrm{d}t - \int_{t=-\infty}^{0} [1-\sigma(\{s: w(s) \geqslant t\})]\mathrm{d}t \quad (8)$$

If $S = \{s_1, s_2, \ldots, s_n\}$ and $w(s_1) \leqslant w(s_2) \leqslant \ldots \leqslant w(s_n)$, then evaluation of the integrals at the change points gives

$$\begin{aligned}\int_S w(s)\, d\sigma(s) &= w(s_1) + \sum_{i=1}^{n-1} [w(s_{i+1}) - w(s_i)]\sigma(\{s_{i+1}, \ldots, s_n\}) \\ &= \sum_{i=1}^{n} w(s_i)[\sigma(\{s_i, \ldots, s_n\}) - \sigma(\{s_{i+1}, \ldots, s_n\})] \quad (9)\end{aligned}$$

This is analogous to Quiggin's rank-dependent form (Sect. 2.3). Schmeidler (1989) applies $\succsim$ to $\boldsymbol{F}$. Lottery acts $\boldsymbol{f}, \boldsymbol{g} \in \boldsymbol{F}$ are comonotonic if no $s, s' \in S$ have $\boldsymbol{f}(s) \succ \boldsymbol{f}(s')$ and $\boldsymbol{g}(s') \succ g(s)$. His axioms retain A1 and A3, weaken A2 to a comonotonic independence axiom A2*, and assume nontriviality and a dominance condition: for all $\boldsymbol{f}, \boldsymbol{g}, \boldsymbol{h} \in \boldsymbol{F}$, and all $0 < \lambda < 1$

A2*. ($\boldsymbol{f}, \boldsymbol{g}$, and $\boldsymbol{h}$ are mutually comonotonic, $\boldsymbol{f} \succ \boldsymbol{g}) \Rightarrow \lambda \boldsymbol{f} + (1-\lambda)\boldsymbol{h} \succ \lambda \boldsymbol{g} + (1-\lambda)\boldsymbol{h}$,

A4*. $\boldsymbol{f}' \succ g'$ for some $\boldsymbol{f}', g' \in \boldsymbol{F}$, and

A5*. ($f(s) \succsim g(s)$ for all $s \in S) \Rightarrow f \succsim \boldsymbol{g}$.

Theorem 6. *Suppose A1, A2*, A3, A4*, and A5* hold on the subset of finite-image lottery acts in* $\boldsymbol{F}$. *Then there is a unique capacity* σ *on* $\mathscr{S}$ *and a real-valued linear function* u *on* P_X, *unique up to a positive affine transformation, such that, for all finite-image* $\boldsymbol{f}$ *and* $\boldsymbol{g}$

$$\boldsymbol{f} \succsim \boldsymbol{g} - \int_S u(\boldsymbol{f}(s))\, d\sigma(s) \geqslant \int_S u(\boldsymbol{g}(s))\, d\sigma(s) \quad (10)$$

A similar result holds for all bounded lottery acts (Schmeidler 1989).

6.2 A Nontransitive Representation

Another generalization of Savage's theory (Fishburn 1988, pp. 208–17) retains his structure and additivity but weakens transitivity and replaces u by a skew-symmetric function ϕ on $X \times X$. The representation is

$$f \succsim g - \int_S \phi(f(s), g(s))d\pi(s) \geqslant 0 \quad (11)$$

The main axiom change weakens P1 to: on $\succsim$ F is complete, and $\succsim$ on $\{f \in F: f(s) \in \{x, y\}$ for all $s \in S\}$ is a weak order for every pair $\{x, y\} \subseteq X$. The representation holds for all finite-image acts with π unique and ϕ unique up to multiplication by a positive constant.

6.3 Rank- and Sign-dependent Utility

Many people have different attitudes toward outcomes perceived as favorable or positive, and those perceived as unfavorable or negative. Utility theories designed to account for this are referred to as sign-dependent theories. Two recent examples are a theory based on a notion of joint receipt (Luce and Fishburn 1991) and a revision of prospect theory called cumulative prospect theory (Wakker and Tversky 1993). Both also have a rank-dependent aspect.

The joint-receipt theory and cumulative prospect theory assume that $\succsim$ is a weak order and that there is a neutral reference outcome x_0 that divides positive from negative outcomes and creates a three-part partition of X with parts

$X^+ = \{x \in X: x \succ x_0\}$
$X^0 = \{x \in X: x \sim x_0\}$
$X^- = \{x \in X: x_0 \succ x\}$

The reference outcome is assigned utility 0, so members of X^+ have positive utilities and members of X^- have negative utilities. In the theories' representations, outcome utilities are unique up to multiplication by a positive constant. The representations treat X^+ and X^- differently and have ways of decomposing an act into positive and negative parts. Each part has its own subjective probability or capacity weighting procedure, and an act's utility is the sum of a positive-part utility and a negative-part utility. In addition, each theory makes assumptions about the relationship between the positive and negative domains for overall scaling consistency.

The cumulative prospect theory axioms in Wakker and Tversky (1993) take $F = X^S$ with S finite and X a connected topological space. For each $f \in F$, $f^+(s) = f(s)$ if $f(s) \succsim x_0$ with $f^+(s) = x_0$ otherwise, and $f^-(s) = f(s)$ if $x_0 \succsim f(s)$ with $f^-(s) = x_0$ otherwise. It is assumed that $\succsim$ on F is a continuous weak order and that some f has both $f^+ \succ x_0$ and $x_0 \succ f^-$. In addition, there is an axiom for gain–loss consistency (if $f^+ \sim g^+, f^- \sim g^-$ and $f \sim x_0$ then $g \sim x_0$) and a more complex condition referred to as sign-comonotonic tradeoff consistency. The representation uses capacities σ^+ and σ^- associated with positive and negative outcomes respectively and takes

$$u(f) = \int_{t \geqslant 0} \sigma^+(\{s: u(f(s)) \geqslant t\})\mathrm{d}t - \int_{t \leqslant 0} \sigma^-(\{s: u(f(s)) \leqslant t\})\mathrm{d}t \quad (12)$$

with u continuous on X, $u(x_0) = 0$, $f \succ g - u(f) \geqslant u(g)$. The capacities are determined uniquely.

The theory in Luce and Fishburn (1991) takes $\mathscr{S}$ as an algebra of events in S and applies $\succsim$ to a set G that

contains g and h with $g \succ x_0 \succ h$. G is endowed with a binary operation $\oplus$ of joint receipt such that $x_0 \oplus x_0 \sim x_0$, $g,h \in G \Rightarrow g \oplus h \in G$ and, for all $g,h,k \in G$, $g \sim h \Rightarrow g \oplus k \sim h \oplus k$ and $k \oplus g \sim k \oplus h$, $g \succ h \Rightarrow g \oplus k \succ h \oplus k$ and $k \oplus g \succ k \oplus h$. The interpretation of $g \oplus h$ are received.

For any $A \in \mathscr{S}$, a map from a finite event-partition of A into X is a first-order gamble, and a map from the same partition into the union of X and the set of first-order gambles that uses at least one of the latter is a second-order gamble. G equals X in union with all first-order gambles and some second-order gambles.

The axiomtization has two phases. The first proposes axioms for $(G, \succsim, \oplus)$ which imply the existence of a real-valued u on G and scaling parameter such that $u(x_0) = 0$ and, for all $g, h \in G$, $g \succsim h - u(g) \geqslant u(h)$ with

$$u(g \oplus h) = \begin{cases} a^+u(g) + b^+u(h) + c^+u(g)u(h) & \text{if } g,h \succsim x_0 \\ a^+u(g) + b^-u(h) & \text{if } g \succsim x_0 \succsim h \\ a^-u(g) + b^+u(h) & \text{if } h \succsim x_0 \succsim g \\ a^-u(g) + b^-u(h) + c^-u(g)u(h) & \text{if } x_0 \succsim g,h \end{cases}$$

where a^+, b^+, a^- and b^- are positive, $c^+ \geqslant 0$ and $c^- \leqslant 0$.

The second phase considers gambles' internal structures in more detail. For any event-partition $\{A_1, \ldots, A_m\}$ of $A \in \mathscr{S}$ and first-order gamble g: $\{A_1, \ldots, A_m\} \to X$, let A^+ be the union of the A_j for which $g(A_j) \succ x_0$; define A^0 and A^- similarly. Also define first-order gambles g^+ on A^+, g^0 on A^0, and g^- on A^- by $g^i(A_j) = g(A_j)$ if $A_j \subseteq A^i$, for $i \in \{+,0,-\}$. These define the sign-partitioned second-order gamble g_2 on partition $\{A^+, A^0, A^-\}$ of A by $g_2(A^i) = g^i$ for $i \in \{+,0,-\}$. The g_2 thus defined are the second-order gambles in G.

A key second-phase axiom says that, under independent realizations for A^+ and A^-, $g_2 \sim [(g^+ \text{ if } A^+, x_0 \text{ if } A \setminus A^+) \oplus (g^- \text{ if } A^-, x_0 \text{ if } A \setminus A^-)]$. Given u from phase one, the axioms imply that for every nonnull $A \in \mathscr{S}$ there are unique real-valued functions $\sigma^+(\cdot|A)$ and $\sigma^-(\cdot|A)$ from $\mathscr{S}$'s subalgebra on A into [0, 1] such that, for g from the partition $\{A_1, \ldots, A_m\}$of A into X

$$u(g) = a^+u(g^+)\sigma^+(A^+|A) + b^-u(g^-)\sigma^-(A^-|A) \quad (13)$$

A second formula for constant-sign gambles allows $u(g^+)$ and $u(g^-)$ to be reduced to rank-dependent expressions in outcome utilities. In each iteration of the reduction procedure, the remaining outcome nearest to x_0 is separated out and 'subtracted' from other outcomes. The weights that multiply the outcome utilities in the rank-dependent expression depend on the order of reduction in a manner related to Choquet summations for σ^+ and σ^- in cumulative prospect theory. Further contributions along the lines of the preceding developments as well as other important areas of utility theory are presented in Luce (1999).

P. Fishburn

Utility and Subjective Probability: Empirical Studies

In the last few decades, empirical studies of choice, probability assessment, and certainty equivalents have demonstrated that utilities are *not* independent of subjective probabilities. People are often pessimistic about the odds of a possible outcome if the outcome is bad. Rank-dependent theories and configural-weight theories can describe these interactions by allowing decision weights to vary with the rank orders of outcomes. Holding objective probability constant, lower-ranked outcomes typically receive greater weight than higher-ranked outcomes. (See also *Utility and Subjective Probability: Contemporary Theories*.)

Despite the enthusiasm with rank-dependent theories, recent studies have shown that these theories have difficulties describing choices when options have more than two outcomes. Choices are consistent with configural-weight theories. However, configural-weight theories can not account for interactions across options. Regret theories describe these interactions in emotional terms, but there are probably many reasons for the interactions. An important challenge for future theorists is to describe both types of interactions within a single theoretical framework. For further reading on utility theories and empirical tests, see Edwards (1992) and Luce (2000).

1. Prospect Theory

In a now classic paper on risky choice, Kahneman and Tversky (1979) proposed an alternative to expected utility theory called prospect theory. Rational rules were replaced with psychological principles. The value function in prospect theory applied to changes in wealth, not total wealth. Furthermore, changes had diminishing marginal value, such that a change from \$0 to \$10 had greater impact than an identical change from \$1000 to \$1010. Finally, negative changes had greater impact than positive changes of equal magnitude, an asymmetry known as loss aversion.

Prospect theory also made psychological assumptions about decision weights. Decision weights were nonlinearly related to objective probabilities; weights for small probabilities were larger than objective probabilities, and weights for large probabilities were smaller. In addition, weights at the endpoints were discontinuous. An event with *no* chance of occurring was psychologically different from an event with a one percent chance of occurrence (e.g., contracting a horrible disease), and a sure thing was psychologically different from an event with a 99 percent chance of occurring (e.g., winning a million dollars in the lottery).

Prospect theory accounted for a variety of empirical phenomena. One example was the reflection effect, which suggested that risk attitudes varied around the status quo. Consider a choice between a gamble with an 80 percent chance to win \$4,000 and a sure win of \$3,000. Most people prefer the sure thing. Now consider a choice between a gamble with an 80 percent chance to lose \$4,000 and a sure loss of \$3,000. Most people prefer the gamble. Although expected utility theory assumed that risk attitudes were constant across all levels of wealth, prospect theory asserted that the shape of the value function differed in the gain and loss domains. Preferences were risk averse in the gain domain and risk seeking in the loss domain. Despite its success, prospect theory had a major drawback. It predicted that people would violate stochastic dominance. Stochastic dominance implies that a decision maker will select the alternative that is as good or better in all respects than other alternatives. Prospect theory predicted that, in some cases, people would choose the inferior option. Despite evidence that people violate stochastic dominance, there was a strong desire to find a general representation that served both normative and descriptive needs. Interest turned to cumulative rank-dependent theories.

2. Cumulative Rank-dependent Theories

In cumulative rank-dependent theories, the decision weights associated with outcomes can vary with the rank orders of outcomes. Furthermore, weights are cumulative or decumulative probabilities, an assump-

tion that makes violations of stochastic dominance impossible. Several versions of cumulative rank-dependent theories were proposed, three of which are presented in more detail.

2.1 Rank- and Sign-dependent Utility Theory

Luce (1991) and Luce and Fishburn (1995) proposed an account called rank- and sign-dependent utility theory. This version was built on the assumption of joint receipt (the simultaneous receipt of two or more objects, such as gambles). Luce and his colleagues tested several of the axioms, including segregation, duplex decomposition, and the additivity of certainty equivalents over joint receipt. Segregation implied that the value of a gamble with positive outcomes was equal to the value of the joint receipt of the gamble with the lowest outcome subtracted from all outcomes and the value of the lowest outcome. Duplex decomposition asserted that the value of a gamble with mixed outcomes was equivalent to the joint receipt of a subset of the gamble with all positive outcomes and a subset of the gamble with all negative outcomes. Finally, additivity of certainty equivalents over joint receipt implied that the certainty equivalent for positive outcomes was combined additively with that of negative outcomes.

Tests were conducted with judged certainty equivalents and choice certainty equivalents. Judged certainty equivalents are indifference prices between a sure thing and a gamble, and choice certainty equivalents are indifference points that are inferred from choices between sure things and gambles. Segregation was supported by one measure, duplex decomposition was supported by both measures, and additivity of certainty equivalents was supported by neither measure. In sum, the tests yielded mixed results.

But not all of the evidence was mixed. Tests of an axiom called event commutativity were supportive. Event commutativity implies that the order of events should not matter as long as the outcomes arise under the same conditions. Results were consistent with rank- and sign-dependent utility theory. Camerer and Ho (1994) found more supporting evidence with an axiom called betweeness. Betweeness is a weakened form of the independence axiom and states that a preference for a probability mixture of two gambles should fall between the preferences for the two separate gambles. Violations of the axiom were robust and consistent with cumulative rank-dependent theories.

2.2 Cumulative Prospect Theory

Tversky and Kahneman (1992) developed a theory called cumulative prospect theory. It was axiomatized differently from rank- and sign-dependent utility theory, and it also made different assumptions about values and decision weights. Decision weights had an inverse S-shape form. The value function was a concave power function for gains and a convex power function for losses with a steeper slope for losses than gains.

Empirical tests of cumulative prospect theory were done with global fits to data, and results were generally supportive. One-parameter versions of the S-shaped weighting function provided good fits to median data (Camerer and Ho 1994, Wu and Gonzalez 1998, Prelec 1998). More recently, two-parameter weighting functions that describe individual differences in discriminability and gambling preference were proposed.

2.3 Security Potential/Aspiration Theory

Lopes (1990) developed a cumulative rank-dependent theory called security potential/aspiration theory. She argued that participants making risky choices were both security minded (i.e., they wanted to avoid the worst outcomes) and potential minded (i.e., they wanted to achieve the best outcomes). An S-shaped weighting function reflected the 'optimism' that people feel with smaller probability outcomes and the 'pessimism' they feel with larger probability outcomes. Security potential/aspiration theory described choice as a combination of rank-dependent utilities and consideration of an aspiration level. Results were generally supportive.

3. Configural-weight Theories

Birnbaum and his colleagues turned to another class of theories called configural-weight theories. In these accounts, decision weights were noncumulative and permitted violations of stochastic dominance. Birnbaum and McIntosh (1996) and Birnbaum and Navarrete (1998) provided additional evidence of such violations by showing that people select the dominated option when making choices with certain three-outcome gambles. Configural-weight theories predicted the results.

Birnbaum (1999) also demonstrated that choice behavior violated a property called coalescing. Coalescing, also called event splitting, applies to probability-outcome combinations with identical outcomes. Cumulative rank-dependent theories predict that probability-outcome combinations with identical outcomes should be equivalent regardless of whether they are presented separately or as a sum. For example, a 20 percent chance of \$10 and a 15 percent chance of \$10 should be equivalent to a 35 percent chance of \$10. Birnbaum showed that choices differed with the two modes of presentation. Identical outcomes presented separately had greater impact than identical outcomes presented together. Again, configural-weight theories predicted the results.

Cumulative rank-dependent theories and configural-weight theories differ in several respects. Configural-weight theories allow decision weights to vary

with additional factors, including the value of an outcome, the number of outcomes, the spacing of outcomes, and the decision maker's point of view. The flexibility of the decision weights implies that these theories can describe violations of independence, including branch independence, cumulative independence, and interval independence. However, this flexibility has a downside; it is not easy to reject configural-weight theories. The key assumption of these theories is that utilities are invariant across all factors that influence weights. Birnbaum and his colleagues argue that tests of this assumption have generally supported the theories.

4. *Interactions across Options*

Not only do utilities and subjective probabilities interact within an option, but several studies show that utilities and subjective probabilities interact across options. Chechile and Cooke (1997) and Chechile and Luce (1999) presented participants with a reference gamble and two outcomes of a comparison gamble. Participants adjusted the probability of the better outcome until the comparison gamble and the reference gamble seemed equivalent. Chechile and his colleagues showed that rank-dependent theories could be represented as linear functions with invariant slopes across reference gambles. Results showed that the slopes systematically varied; the utilities of reference gambles depended on the comparison gambles with which they were paired. Mellers and Biagini (1994) also demonstrated interactions across options in the form of strong stochastic transitivity violations and similarity effects. They represented the interactions in terms of attribute weights and argued that people shifted their attention from attributes with similar levels to those different levels to best discriminate among options.

Regret theories also describe interactions across options. People often anticipate the regret they will feel if their outcome turned out to be worse than the outcome of another choice. Theories of regret assume that people avoid such feelings when making choices (Loomes and Sugden 1982, Bell 1982). Numerous developments have occurred along these lines (Mellers 2000), and results are promising. Although no single unifying theory has been suggested yet, future theorists will undoubtedly provide a general representation of the interactions both within and across options.

Utopias: Social

'Utopia' refers to fictions or essays which purport to describe an ideal and feasible community at some, generally undefined, future date. 'Utopia' is a doubly

ambiguous word coined by Sir (and Saint) Thomas More as the title of a book he published in 1516. First of all, the neologism itself has a Greek etymology which can be read as either 'no place' (*U-topia*) or 'good place' (*Eu-topia*). Second, the label 'utopian' can be restricted to utopias as pictures, namely the detailed narrative portrayals of ideal communities, or it can be stretched to include also blueprints which reflect utopian tendencies, namely any systematic exposition of the underlying principles of such communities.

The position taken hereafter will be both comprehensive and restrictive. Comprehensive, as it includes both interpretations under the general heading of utopian impulse—the conviction that 'a definitive and insurpassable condition is attainable' (Kolakowski 1990, p. 132). From Plato on, the attainment of the perfect society has been a constant preoccupation in the West, and it would be unduly restrictive to rule out nonfictional utopian writings. However, some limitation seems suitable in order to retain only those visions of the ideal society which are meant to be implemented by human agency. In other words, the necessary and sufficient condition to be let into the Utopian club is to have been dreaming or speculating about a more perfect social order (or, more often than not, doing a bit of both), starting from the presupposition that human life takes place within a societal framework which is plagued by countless evils, but the cure, a radical one, is at hand, to be followed by indefinite perfection on this earth.

1. *Visiting Utopias*

The utopian quest for a definitive answer to the hypothesized human predicament looks very much like an extended multiple-choice questionnaire with items such as where is this place of bliss located, who are its residents, and what rules do they follow?
