undertakes to capture the full social complexity of epidemics as they emerge. Dealing with both causes, and effects of emerging infections requires both an historical and an ethnographic approach. Engagement with emerging infectious diseases, which highlight the unexpected consequences of social inequality, the plight of the world's poor, and the shortcomings of global public health in today's globalizing world, has made medical anthropology an increasingly politicized discipline (Farmer, 1999; Whitman, 2000).

THEORETICAL HERITAGE

Anthropological engagements with non-Western and Western medical systems has left a rich theoretical heritage that is drawn on studies of emerging epidemics. Three theoretical frameworks for analyzing health and illness phenomena in a cross-cultural perspective have emerged from these engagements. A *realist* framework explains local variations in disease phenomena as culturally driven deviations from a biological universal; this use of biology as the ontological ground of disease phenomena is a resolutely *modernist* position. In contrast, a *relativist* framework examines how scientific discourses, practices, and institutions “construct” the biological world as objective and manipulable phenomena; the use of such *social constructivist* explanations for local variations has a *postmodernist* sensibility. Finally, a *radical constructivist* framework focuses on how biological and social processes are historically and geographically contingent and intertwined; these processes are understood to co-produce disease phenomena in variable ways. This is an *a-modernist* position that grants ontological privilege neither to the biological nor the social world. The significance of these three frameworks for consideration of emerging infectious diseases will now be explored in order.

Although anthropology was not overtly concerned with health issues in the tropical climates where it cut its ethnographic teeth, the engagement with “primitive culture” left a theoretical legacy that shapes anthropological approaches to emerging infections to this day. Anthropologists examining indigenous medical systems sought to understand how these achieved healing outside of a Western, biomedical framework. To do this, two options were available to anthropologists. The first was to assume that non-Western medical traditions had biological

efficacy because of their ability to manipulate physiological states through the use of biologically active substances or the psychological manipulation of body states; in short, herbs and trances. This modernist approach was also *realist*, in that it was committed to a universal biology as the yardstick for measuring therapeutic outcome. It remains germane to contemporary attempts to reinforce the role of traditional medical practitioners in the response to infectious diseases such as AIDS and sexually transmitted infections, as well as with medical anthropologists sympathetic to a biomedical basis for understanding, and responding to, epidemics.

As historians have pointed out, epidemics are social events that require understanding not only how disease is produced in bodies, but also how it is reproduced in social relations (Ranger & Slack, 1992). Similarly, anthropological examinations of emerging infections seek to extend our understanding of them beyond the biology and epidemiology of these diseases in order to demonstrate how epidemics are embedded in economic relations and anchored by social systems of meaning. This social dimension furnishes the conditions of emergence of epidemics in space and time. Social relations configure exposure to risk, transmission, and susceptibility, as the 19th-century pathologist and father of social medicine, Rudolph Virchow, first taught us. Epidemics are caused by pathogenic social relations, whether in the case of tuberculosis amongst South African mineworkers, cholera outbreaks in refugee camps, or epidemics due to hamburger meat or water being contaminated by *Escherichia coli* O:157.

Within this realist framework, several approaches to elucidate the social pathways of disease causation have been drawn by anthropologists, archeologists, medical geographers, and epidemiologists. Political-economic approaches have stressed how economic structures perpetuate social inequalities that increase the risk of disease amongst the disadvantaged, while culturalist approaches have emphasized the role of local beliefs and practices in modifying risk of exposure, impacting transmission, and shaping susceptibility to pathogens. Both draw attention to the nature of power and how it is exercised in society, leading anthropologists to focus on how individuals are enacted through, negotiate, and resist power relations to modify their own health.

The second explanatory framework, which can be glossed as relativist, sought to situate the therapeutic effect of non-Western medicine in operations that constructed

medical objects and therapeutic effects within a self-vindicating, cultural system. Sociologists of science applied the skeptical stance of anthropological approaches to non-Western medical systems to biomedicine. Not to do so, they argued, was to succumb to an a-symmetrical and a-sociological program. Biological claims of efficacy could no longer be privileged over social explanations in a symmetrical program of investigation. These critical scholars of science, often referred to as “social constructivists,” inspired anthropologists’ attempts to examine biomedicine—and the question of therapeutic efficacy—in social and cultural terms. If biomedicine works, then, a broad corpus of anthropological studies of biomedicine argue, it is because biomedicine is able to harness the symbolic and material means necessary to achieve healing. Therapeutic efficacy is neither a matter of just herbs and trances, nor drugs and surgeries, but requires power, access to economic resources, and the ability to fashion meaning.

Drawing on this framework, these studies emphasize that pathogens themselves are socially constructed. Sociologists of science have argued convincingly that pathogens are invisible outside of the plethora of laboratory techniques that visualize and represent them in scientific documents, making them into social actors that “act” through social practices and “speak” through scientific discourses. In addition, scientific knowledge is driven by political, economic, and institutional concerns that frame the questions that get asked, researched, and published. This is not to say that pathogens are to be dismissed as figments of a fertile social imagination. Pathogens are real *precisely because* the effects they engender in bodies and societies are mediated through scientific practices. Without epidemiology and molecular virology, for example, the HIV epidemic would be less “real” precisely because we would not have the scientific instruments that allow us to see it and to understand it as the common denominator across multiple registers, whether embodied or social.

More recently, a third theoretical framework has emerged from critical consideration of the knowledge garnered from advances in biotechnology, namely the increasingly detailed epidemiological maps afforded by global surveillance programs, and cross-cultural research on disease entities (Diamond, 1997; Ruffié & Sournia, 1984). This view, which I call the radical constructivist view, argues that *social relations can change pathogens themselves*, as well as the representations we have of

them. In short, biology is *local* rather than *universal* (Lock, 1993). The notion of genetically engineered pathogens so feared by bioterrorism experts is a dramatic example; a far more mundane one is the creation of drug-resistant organisms through irrational prescribing practices. Drug-resistant bacteria and viruses such as HIV are different organisms from their drug-sensitive ancestors, not only in genetic make-up but also, in some cases, in terms of their biological behavior. Social relations can change pathogens by impacting the environments within which these evolve—the “fitness” landscapes that drive evolution one way or another.

The radical constructivist view is most strongly supported by molecular biological studies of emerging epidemics. Many emerging infections are caused by pathogens derived from a-virulent organisms that did not cause epidemics previously. Biologists concerned with the conditions of emergence focus on how such organisms become pathogenic. The organisms most likely to trigger epidemics are those with the most plastic—changeable—genomes. The simplest, and most mutable, pathogens are RNA viruses;—indeed, almost all new epidemics have been caused by RNA viruses, from AIDS to West Nile Virus (Burke, 1998). The biggest reservoir of potential new pathogens is not humans, but animals. Almost all the major infectious diseases of humans came from zoonotic, or animal, reservoirs (with the notable exceptions of polio and smallpox). Culture and social relations are powerful determinants of the relationship between humans and domesticated animals. Trypanosomiasis—African sleeping sickness—emerged as a major public health problem in colonial Africa largely because the colonial economy disrupted existing agricultural and animal husbandry practices. Cultural beliefs acted as a public health system by dictating the separation of herds from human settlements, which prevented transmission of the parasite from the tsetse fly to human populations (Ford, 1971). The zoonotic origins of emerging epidemics identifies a constellation of human practices that have the potential to condition exposure to new pathogens. These may impact exposure directly, as in the case of animal husbandry, hunting, or pet-keeping, or indirectly, as in the case of shifting agricultural and economic practices that transform the habitats of these zoonotic reservoirs (Hardin, 2001).

All three frameworks agree that the material effects of epidemics far surpass our ability to grasp them through epidemiological surveys and laboratory investigations. These material effects include the production of disease

in bodies, certainly, but also a diverse range of representations, practices, and technologies deployed to understand, prevent, and treat disease. Mass vaccinations, public health campaigns, media stories, rumours, and gossip are powerful social mechanisms through which pathogens act on society. The rubric of culture allows these phenomena to be grouped together as an object of anthropological analysis. In this view, pathogens are like onions, and anthropologists have sought to peel back the cultural skins that envelop the biological pathogen and charge it with its social valence.

In summary, anthropological approaches allow a broader consideration of how epidemics, and pathogens themselves, are deeply socialized. This tells us that emerging infectious diseases cannot be taken for granted as “natural” phenomena—they are part of larger biosocial processes that play out both at the “micro” and “macro” levels. The potential of these theoretical approaches to deepen our insight into the emergence of infectious diseases has been underutilized, as anthropologists have largely served as “cultural interpreters and ‘troubleshooters’ ... brought into projects to anticipate, or to provide post-hoc explanations of, negative community responses” (Inhorn & Brown, 1997, p. 12).

CLASSICAL METHODS: FROM EPIDEMIOLOGY TO CULTURE

Ethnography is the close study of everyday life, the representations that are drawn upon in the conduct of social relations, and the practices through which these are reproduced. These qualitative insights can prove crucial to understanding how epidemics emerge. Ethnography and epidemiology have been most closely linked in forensic investigations, familiar to us from numerous accounts depicting public health sleuths hot on the trails of a new outbreak (see, e.g., McCormick & Fischer-Hoch, 1996). In approaching emerging infectious diseases, these methods have been widely used by clinicians, biologists, and astute public health practitioners, as well as by anthropologists. After all, ethnography is much like private detective work. Both require a keen sense of observation, familiarity with social worlds different from one’s own, a certain street-wise character, and an intuition for both the mundane and the exceptional.

What is often regarded as medical anthropology’s greatest triumph, the discovery of the cause of the slow

degenerative disease called *kuru* among the Fore people of Highland New Guinea, was accomplished by biologist Carleton Gajdusek’s painstaking marriage of biological and ethnographic research. Gajdusek was faced with a perplexing situation: the terrible disease followed a peculiar epidemiological pattern, affecting only young children and older women—a pattern that could not be explained if the disease was genetic or transmitted like known infectious agents. However, pathological evidence of similar brain lesions and cultural evidence concerning funereal practices involving endocannibalism led to the hypothesis that an infectious agent was being transmitted from the brains of deceased victims to the living through the preparation of bodies for funeral rites. Gajdusek’s work ultimately demonstrated that *kuru* is caused by infectious protein particles called prions. Such funereal practices were not always practiced among the Fore, but were borrowed from neighboring tribes (Lindenbaum, 1979, p. 22), an example of how even in apparently isolated societies, diffusion of cultural practices can play a role in social change.

The case of *kuru* illustrates how an emergent epidemic can result from the juxtaposition of a random event (in this case, a genetic mutation generating a pathogenic, infectious protein) and a particular social practice. Cultural practices accounted for the epidemiology of the disease, explaining why certain individuals were affected while others were spared, and why the disease was confined to a specific cultural group.

Kuru in the New Guinea Highlands and sleeping sickness in colonial Africa highlight the biosocial nature of emerging epidemics. On one side, evolutionary mechanisms produce biological variation and, occasionally, a newly virulent pathogen. On the other, a key, culturally driven practice provides the crucial link between, or separation of, pathogen and host. However, in considering how these two processes come together, it is difficult to separate the biological from the social. Biological variation can be driven by social changes that shift local disease ecologies and the “fitness landscapes” within which evolution occurs. Novel biological phenomena can themselves drive social change, as countless historical examples of the reaction to epidemics can attest.

The critical potential of anthropology became most visible with the HIV epidemic, where a new, lethal pathogen has emerged over the last three decades to claim over 15 million lives, and infect upwards of 40 million more. The epidemic has resuscitated anthropological

concern with biosocial processes. Biological and medical anthropologists had long been interested in processes of bio-cultural adaptation; the AIDS epidemic demonstrated that such processes could have acute relevance. Initially, however, anthropologists were slow to take up the biological dimension of this biosocial event, as it involved consideration of the epidemic's origins and, in the early years of the epidemic, the question of "causes" and "origins" was heavily freighted with blaming and victimization. At the time, critical anthropologists denounced lurid theories advanced by other anthropologists, journalists, and scientists alike as more indicative of a propensity to accuse the victims than as a constructive engagement with a serious public health issue (Farmer, 1992). In the response to the epidemic, realist positions have prevailed, largely because of the overwhelming toll of the epidemic. Social constructivist positions have been acknowledged in attempts to overcome stigma and in the activist goal to achieve empowerment through knowledge, with those that doubt that HIV causes AIDS relegated to a marginal fringe.

Thus, initial anthropological work on AIDS concentrated on representations of the disease and pitted culturalist accounts of disease spread against more political analyses. For the former, the spread of HIV was best understood in terms of specific cultural practices, ranging from sanguinary religious rites to sexual behaviors. A more political-economic view has argued that AIDS spreads along the "fault-lines" of society, striking the poor and socially excluded whose vulnerability makes them most likely to be afflicted. Epidemiological research has largely supported the latter view, while pointing to the need for an ethnographic thick description—and the engagement with diverse communities this requires—to give a more finely grained picture of an increasingly heterogeneous epidemic.

Significantly, this debate has revealed weaknesses in epidemiology as an analytic science of epidemics. Its power in detecting associations and temporal patterns makes it a clumsy tool for explaining the rare events that trigger epidemics. Epidemiology is not a predictive science of epidemics. This is not surprising, given that epidemiology is a quantitative, descriptive science that is able to generate hypotheses but is weak at validating or invalidating them outside the social laboratory of the clinical trial or the case-control study. In the "real world" outside of the laboratory, epidemiological methods are unable to manage the presence of myriad known—or

unknown—confounding factors that can account for an epidemic having emerged in one place but not another.

The landmark case of *kuru* demonstrated the importance of cultural beliefs in accounting for the contingency of biological phenomena such as epidemics. A growing body of evidence on HIV/AIDS has reinforced this view, showing that epidemics are constrained by social forces and local configurations of culture, political economy, and power. In this sense, it can be advanced that the science of emerging epidemics will be a medical anthropology that includes a dialogue across biological and social disciplines, and is reflexive; that is, takes account of the politics inherent in the production of knowledge.

NEW METHODS: FROM MOLECULAR BIOLOGY TO SOCIAL CHANGE

The cause of multi-drug-resistant tuberculosis (MDRTB) has always been assumed to be a social one: that is, patients not taking their medications properly. Unfortunately, rarely were the causes of that "non-compliance" investigated; blaming patients remained the most comfortable option. Farmer and his group marshalled the diagnostic power of Harvard University hospitals to investigate an outbreak of MDRTB in the shantytowns of Lima, Peru. This research demonstrated the importance of new biotechnologies to understanding emerging biosocial phenomena, and of establishing a dialogue across the biological and social disciplines. Interestingly enough, as this case illustrates, biological knowledge demonstrates the role of large-scale social forces in producing epidemics.

The investigation used molecular epidemiological techniques to identify the distribution and evolution of drug-resistant TB strains over time in the Peruvian community where they were working. They were able to disprove the prevailing view that this epidemic was due to poor adherence to treatment. Farmer and colleagues, ethnographically attuned to local realities, were skeptical of this claim, as it did not reflect their experience with the community. Aware that the inaccessibility of health care was leading to careless antibiotic usage, they suspected that patients were being infected by TB strains that were already resistant to one or two drugs. This meant that subsequent treatment with the standard three-drug regimen in public TB control clinics would be inadequate, as only one or two of the drugs would be active against the bacteria. These investigators hypothesized that TB control

programs were generating a multi-drug-resistant epidemic by treating individuals with already partially resistant TB.

This hypothesis was borne out by molecular resistance testing of bacteria isolated from patients. Development of drug resistance was attributed to the breakdown in curative public health services and the partial availability of antibiotics in the private sector. This is a product of social inequalities increasingly visible throughout the developing world, where a lucky few turn to private health care, creating a market for biomedicines. As a result, the poor are able to gain access to antibiotics through the informal economy; however, that access is partial and fragmented and leads to improper use and, consequently, the risk of drug resistance. The evolution of MDRTB is tied to growing social inequalities and the “privatization” of global health care through policies elaborated far from the communities where they have their impact. Privatization was due to economic structural adjustment programs mandated by Washington-based Bretton Woods institutions. These required that cash-strapped Third World governments slash social spending—and public health programs—in order to meet the conditions for further loans. However, in a world where knowledge of the efficacy of biomedicines is truly globalized, it is difficult to scale back the expectations of the sick, even when they are poor (Kim, Irwen, Millen, & Young et al., 2000).

The pathogenic potential of the conjugation of pathogenic socio-economic shifts with biomedical globalization is visible in the outbreak of MDRTB in the former Soviet Union. There, in the aftermath of communism, social insecurity, coupled with growing social inequality, has been blamed for skyrocketing crime. Increased crime has led to increased incarceration rates; the inability of the criminal justice system to hear the cases means that thousands are incarcerated while awaiting trial. Simultaneously, breakdown of the public health system has been implicated—through drug shortages—in the emergence of MDRTB epidemics. The Russian prison system plays an important role in amplifying the epidemic, as the cramped and overcrowded conditions favor the spread of already-resistant TB from ill inmates. The pathogen is then spread back into the community as prisoners are released (Farmer, 1999; Hous, 1999; Kimmerling, 2000; Shilova & Dye, 2001). The Peruvian experience has been used as a model to develop an ambitious control program for Russia that has garnered impressive international support, demonstrating the potential for medical anthropology to lead the

way in the development of programs to control emerging infections.

Farmer’s Peruvian research was innovative because it used molecular biological evidence in dialogue with ethnographic data. It also broke new ground by emphasizing social *change*—rather than immobile cultural practices, such as funereal rituals—as the key process on the cultural side of the bio-social equation. Consonant with the anthropological understanding of culture prior to the 1980s, studies of *kuru* and other earlier epidemics often assumed a timeless, unchanging quality to culture and, as a result, social practices. What social change was observed was assumed to result in adaptation and acculturation.

The case of MDRTB indicates that anthropologists could no longer be content to attribute the phenomena at hand to timeless cultural structures, nor to assume that the sphere of analysis did not extend beyond the local. The dramatic scope of the MDRTB epidemic in the former Soviet Union only too clearly illustrates how “macro” transformations in political economy—and the large-scale social forces that drive them—register at the “micro” level of everyday practice and patterns of resort. Increasingly, the “culture” that explains pathogen emergence and transmission is not the “traditional” culture so prized by classical anthropologists, but the “culture” of international institutions that enact and regulate global economic policy and public health implementation.

CULTURES OF BIOMEDICINE

Biomedicine plays an important role in mediating the emergence of new infectious diseases for four, linked reasons. Hospitals and clinics are places where the sick congregate in search of treatment, and as a result they concentrate pathogens and multiply the chances of cross-contamination. Secondly, the biomedical repertoire includes practices that represent exceptional powerful interventions into the biological realm, and thus have unprecedented power to change organisms and modify disease ecologies. Thirdly, biomedical efficacy requires extensive infrastructure—working hospitals, laboratories, and public health bureaucracies—in order to ensure the effectiveness of its biological interventions. This infrastructure is extraordinarily resource-hungry—a fact that motivated the move to less expensive and, it was hoped, more sustainable primary health care in developing countries in the 1970s. In an era of decreased expenditure on

health care, the “downsizing” of public health has made under-funded hospitals dangerous places. Finally, confronted by the global public’s desire and need for curative biomedical services, a vast private—and largely unregulated—private market for biomedical services and bio-commodities (from pharmaceuticals to organs) has proliferated around the world. This private market has led to increasingly irrational use of biologically active substances, further increasing the risk of emerging epidemics.

The iatrogenic potential of biomedicine can be seen both in settings of poverty and wealth. In Africa, lack of sterilizing equipment has most dramatically been implicated in outbreaks of Ebola; however, anecdotes of improper sterilization practices and re-use of injection equipment are legion and are widely believed to have played a role in spreading blood-borne pathogens such as HIV and Hepatitis C. In wealthy countries, increasingly invasive procedures on sicker patients has led to greater instrumentation of patients whose immune systems are less robust. As a result, intensive care units have become breeding grounds for drug-resistant “super-bugs” such as MRSA and VRE. Spread to other patients is enhanced when overworked staff do not have the time to ensure proper hygiene. Both in wealthy and poor countries, the iatrogenic potential of biomedicine is evident although, in conditions of poverty, the consequences are far more devastating.

Perhaps more worrisome has been the unwitting implication of earlier public health campaigns in the propagation of unrecognized pathogens. It has been hypothesized that the HIV epidemic was triggered by the administration to over a million Africans in the 1960s of batches of an experimental oral polio vaccine that was inadvertently contaminated with HIV’s simian ancestor, SIVcpz (Hooper, 1999). While this is unlikely, it does point to the potential for large-scale use of biologicals to unwittingly transmit pathogens, a potential that has been acknowledged in other hypotheses about the epidemic’s origins (see Weiss & Wain-Hobson, 2001). In Egypt, it appears that 15% of the population has been contaminated with Hepatitis C as the result, it is believed, of earlier campaigns to eradicate schistosomiasis using parenteral treatments with inadequately sterilized injection equipment (Frank et al., 2000). Data on Hepatitis C from developing countries is still sparse, but it is not unreasonable to expect that re-use of injecting equipment in the past has spawned a major epidemic across

the world that may, in time, come to dwarf the HIV epidemic.

Ethnographic studies of the therapeutic itineraries resorted to by the ill, as well as examinations of the everyday life of the clinical encounter, illuminate how the individual experience of illness is negotiated through cultural frames, enacted in social relations, and constrained by political and economic conditions. As a result, they describe how biomedicine is deployed according to local circumstances and offer crucial insights into how biomedical practices may inadvertently contribute to the emergence of epidemics, as in the case of the Peruvian and Russian MDRTB epidemics. Ethnographies of public health in developing countries have painted a devastating picture of breakdown in public health and the consequences of power struggles over increasingly meagre resources (Hours, 1985). From the point of view of preventing drug-resistant epidemics, too little biomedicine is worse than none at all. However, with the globalization of biomedical commodities and desires, the “nothing” option does not exist. *Too much* biomedicine can also lead to difficulties, as in the case of drug-resistant epidemics fanning out from intensive care units demonstrates.

Because biomedicine has become an increasingly important mediator of the global disease ecology, the conditions that compromise or distort its impact (such as partial antibiotic use) may set the stage for emerging epidemics. Close attention to biomedical practices—or those that are inspired by biomedicine’s modernist promise of healthy living—in different geographical and social contexts provides important evidence for understanding how patchiness in the implementation of biomedicine textures the disease landscape. In an era of intensified and accelerated global exchanges of peoples and goods, both organic and inorganic, this patchwork biosocial landscape offers new opportunities for new pathogens to spread, as well as new breeding grounds for existing pathogens such as tuberculosis. New infections such as HIV, Hepatitis C, or West Nile virus are known examples; however, increases in genetic manipulation and in the circulation of biologicals—already cited in evaluations of the threat of bioterrorism—raise concern for the future. As we have seen in the case of MDRTB, medical anthropology has an important role to play, as a critical examination of the conditions under which biomedicine is both globalized and localized, and as a critique of the institutional practices and representations that inform global health policy.

FUTURE DIRECTIONS

Growing interest in the link between globalization and health has stimulated anthropological research on how large-scale social forces and transnational movements produce local cultural forms. Local inadequacies in public health infrastructure, local disease ecologies that explain differences in exposure to pathogens, and local variations in biology have all been identified by medical anthropologists, and other researchers, as factors influencing the emergence of epidemics. Given the disproportionate impact of biomedical practices in influencing the disease ecology, this has been a good place to start.

However, anthropological attention must be paid to the impact on infectious diseases of global processes, whether they be ecological (as in the case of global warming) or socioeconomic (as in changes in agricultural production or forms of social inequality). For instance, deadly outbreaks of *E. Coli* O:157 epidemics have occurred, and have been linked to inadequate treatment of water and food. This underlines the potential of transformations in the industrial production of food to play a role in generating and/or spreading epidemics. The most dramatic example is the epidemic of new variant Creutzfeld–Jacob disease (vCJD), the modern form of *kuru*. “Mad cow disease” (Bovine Spongiform Encephalopathy, or BSE) led to an epidemic of vCJD in humans, because sporadic genetic events that produced disease-producing prions were amplified through industrial food production processes. Afflicted animals were “recycled,” their carcasses used in the production of feed for other cows, in effect cannibalizing them. This introduced the pathogen into the bovine food chain as animal flour, spreading the disease to other cows and, eventually, to the humans that ate them. Debate over genetically modified foods (GM foods) has cited the BSE epidemic as a warning.

In the past, medical anthropologists have worked alongside public health practitioners to promote healthy dietary habits and encourage the adoption of hygienic measures to reduce the risk of water-borne infectious diseases (Nichter, 1989). As cultural diagnosticians, anthropologists adapted public health interventions to be congruent to local beliefs, and worked to ensure that public health interventions could be adopted to maximum effect—for example, by designing interventions to “sell” ORS as a treatment for childhood diarrhea. Morbidity and mortality from such water-borne infections remains a major health challenge, increasingly because clean water

is no longer affordable for the poor, who must purchase it from privatized urban water systems. However, the increasing burden of morbidity and mortality due to TB, HIV, and respiratory diseases (as smoking increases and air quality decreases in the sprawling cities of the Third World where more and more of the world’s population is concentrated) indicates that anthropologists cannot be content to intervene post facto, but have a role to play in addressing these social ills upstream, before they crystallize as epidemics.

The lessons are clear. While understanding of micro-social processes, such as the beliefs and practices that inform everyday behavior, offers important insight, these must be complemented by social analysis that understands how local and micro-social processes are constrained by, or proliferate from, large-scale social forces. Medical anthropologists increasingly will be called upon as partners in public health and biomedical interventions targeting the “modern plagues” of HIV, MDRTB, and Hepatitis C. Ensuring the success of vaccine trials and anti-microbial treatment programs should not detract from the critical dimension of understanding inequities in access to these interventions, and understanding the processes that contribute to these inequities, as they furnish important insights into the biosocial processes that can crystallize as epidemics.

With the phenomenal advances in biotechnologies that allow us to track the molecular origins of epidemics with increasing accuracy, medical anthropologists have been furnished with powerful new tools for tracking the inscription of the social in the natural realm. Molecular epidemiology furnishes a biological archive that can be brought into dialogue with the historical record to answer important questions about the emergence of epidemics, as has been done with MDRTB and could be done with HIV and other emerging infections. This dialogue will be an important step to developing a global science of emerging epidemics.

Genetic Disease I: History and Mechanisms

Larry Leon Mai

A genetic disease may be defined as any condition caused or influenced by a malfunctioning gene or cytogenetic (chromosome) error that affects an organism's capacity for adaptation. Excepting lethal defects and sterility, genetic diseases display certain familial modes of inheritance and exhibit morbidity and mortality patterns that may compromise direct fitness. Genetic diseases have been called “inborn errors of metabolism,” molecular defects, hereditary diseases, and familial diseases (Mai, Young Owl, & Kersting, 2004). Synonyms for

“disease” in this context include anomaly, condition, morbid effect or defect, deficiency, disorder, and syndrome.

Some sources restrict discussions of genetic disease to defects of single genes; others include polygenic disorders and the cytogenetic defects as well (Habener & Williams, 2001; King, Rotter, & Morulsky, 1992).¹ This entry touches on all three manifestations of mutation.

Worldwide, more than half of all conceptions, and about 7% of all live-born children, are affected by some form of genetic disease.

Many folk taxonomies of “disease” classify affected individuals with due consideration to exceptional phenotypic signs (including non-visual signals), whether self-reported or externally diagnosed (Atran, 1998). Western nosology² also considers phenotypic signs and manifestations, but differs significantly from folk medical systems in the ascription of meanings to those signs—to the etiologies, or causes of phenotypic morbidity (Marks, 2001, pp. 62–64; McKee, 1987). As Western medicine diverged in recent centuries from its folk-based roots, its etiologies incorporated at first histological, then cellular, and finally, sub-cellular and molecular aspects. Each of these diagnostic levels has been progressively dependent upon an evolving and sometimes invasive technology. Consequently, the Western process of clinical diagnosis has become, in large part, a taxonomy of inferred mechanisms and nanomechanisms appended to classic phenotypic descriptions.

Among the most esoteric and counter-intuitive aspects of Western medical subsystems is the ascription of “genetic” causes to phenotypic morbidity. A genetic etiology has three facets: the exceptional phenotype, a familial mode of transmission (when reproduction is possible), and a cryptic mode of defect (mutation). Historically, the realization of these facets proceeded in that order, as well. Although most traditional medical systems acknowledge abnormal phenotypes, exact knowledge of transmission modes is sometimes problematic, and full knowledge of the mechanisms of mutation is for the most part recent and specifically Western.

A BRIEF HISTORY OF GENETIC DISEASE

Antiquity

Herodotus to Maupertuis. The Greek historian and geographer Herodotus in the 4th century BCE became the first scholar to produce an attributable description of a genetic condition in humans: “The goddess [Aphrodite] afflicted the Scythians ... and all their descendants forever with *hermaphroditism*³ ...” (*Historiae*, book I: 105). According to myth, the original Hermaphroditus was first a son of the Greek god Hermes and goddess Aphrodite; Hermaphroditus later fused with the nymph Salamacis to produce a single individual with both female and male characters. Conversely, Mittwoch has interpreted the Hebraic version of Eve’s creation to mean that Adam was first a hermaphrodite who was then

bisected into a male and a female. Other hermaphroditic gods, such as Ardhanarisvara (the fusion of Siva and Sakti), can be found the literatures of India and Persia (Mittwoch, 1986).

In the *Corpus Hippocraticum* of the Greek physician Hippocrates of Cos (460–377 BCE) are found anecdotal comments on familial *epilepsy*, and also descriptions of people from the Caucasus who possessed congenital skull deformations that he termed macrocephalia (probably *Proteus syndrome*). Aristotle of Stagira (384–322 BCE) described several familial conditions that “skipped generations.” *Dwarfism*, *albinism*, and *hemophilia* were all described as far back as the 1st century of the Christian Era. Speculations abound that Old Testament writings imply that Noah himself may have been affected with albinism. The biblical giant Goliath may have been afflicted with *acromegaly*.

As these early examples show, stories exist in many cultures to explain the existence of exceptional humans. In order to explain their presence, their etiologies (at least in the Western view) have been confounded within a fabric of mythology and evolving local medical knowledge. *Sickle cell disease (SCD)*, for example, is a classic genetic disease (see Table 2) that for centuries prior to Western knowledge of its existence had been known to run in Nigerian families in either a “not-so-severe” or a “severe” form (Konotey-Ahulu, 1991). Until recently, this clinical entity was also caught up in an indigenous belief that a second child born with SCD to a family was almost certainly a reincarnation of the previous sibling who had already died of the disease (Nzewi, 2001; Onwubalili, 1983).

It was, however, the French naturalist Pierre Louis Moreau de Maupertuis (1698–1759), who, in *Venus Physique* (1746), provided a dissertation on the origin of skin color which contained statements that were antecedents to the modern genetic concepts of epigenesis, mutation, and particulate inheritance. Maupertuis also analyzed pedigrees of families with *polydactyly*, and although his work was non-experimental, he provided the first truly modern understanding of the heritable nature of certain diseases, antedating Mendel by over a century (Glass, 1968).

X-linked inheritance, because of its peculiar pattern, was reported early, by M. Lort in 1779, when he described *color blindness* in humans. Forty years later, in 1820, C. F. Nasse proposed that *hemophilia* occurred only in males, and could be transmitted by unaffected females. In 1761, Joseph Kölreuter observed segregation of autosomal

recessive traits in the pea plant, as did John Goss in 1822, and Thomas Knight in 1823. Other familial diseases in humans—such as *Leber's hereditary optic neuropathy*, described in 1871—were documented in the 19th century, but the nature of the familial patterns was not then generally understood.

The Recent Historical Period

Mendel, Darwin, Weismann. In 1865 Gregor Mendel (1822–1884), conducted now classic experiments with the common garden pea *Pisum sativum*, and defined several basic genetic principles, such as trait segregation and the notion of recessive inheritance, in his explanation of discontinuous variation. Mendel demonstrated that what he called “factors” (*elementen*, today’s genes) are discrete, particulate units that segregate in predictable patterns, even though they may skip generations. Two papers (1866, 1870) and a few letters are all that remain of his scientific experiments, a body of work that was misunderstood and thus infrequently cited during his lifetime. When Mendel’s work on discrete variation was rediscovered in 1900, it became the foundation of modern genetics (Dunn, 1991).

The biological explanation of discontinuous variation was, along with transmutation (evolution), one of the intractable biological problems of its day: neither Herbert Spencer’s “living units” (1864) nor the hydraulic “gemules” in Charles Darwin’s pangenesis (1868) contained adequate explanations of inheritance. Indeed, Mendel’s formulation of particulate “factors” and recessive inheritance is such a profoundly non-intuitive insight that even today’s genetic counselors have difficulty explaining these concepts to patients. Embedded within the metaphor of sanguine transmission is an inherent perception that traits that “run in the family” (in the blood) cannot skip generations. Genetic transmission is especially difficult to understand when conditions such as *breast cancer* can be passed down through unaffected males, or when the kinship system of the family in question conflicts with the pattern of genetic transmission offered by the counselor (Richards, 1997).

It was in *The Germ-Plasm: A Theory of Heredity* (1893) by the German cytologist and physician August Weismann (1834–1914), that the first accurate (i.e., non-Lamarckian) description of the separation of germ cells from body cells was achieved. Weismann proposed that the germ-plasm is continuous from one generation to the next and is isolated from the soma (“Weismann’s

barrier”). Weismann’s barrier between the germ-plasm and the soma was one of a set of three great eponymous ideas that coalesced at the beginning of the 20th century: the others were Mendelism (segregation and recessive inheritance) and Darwinism (natural selection). This triad of fundamental concepts is prerequisite to any accurate formulation that a disease could be “genetic.”

The Modern Era

The Foundation of Genetics. The traditional foundation of genetics, and therefore of medical genetics, dates from the 1900 “rediscovery” of Mendel’s papers (Dunn, 1965). Between the years 1902 and 1909, several additional, clarifying terms were defined by the “founder of genetics” William Bateson (1861–1926) and his colleagues; these included cornerstone concepts such as genetics, segregation, P1, F1 and F2, allelomorph (allele), homozygosity and heterozygosity, epistasis, and indeed Mendelism itself.

Working with R. C. Punnett in 1906, Bateson reported the first exceptions to Mendel’s second principle (independent assortment), and thus demonstrated the first case of trait linkage (in the sweet pea).

American geneticist Thomas Hunt Morgan (1866–1945) and his students discovered chromosomal rearrangements such as inversions and translocations, mapped the first genes to chromosomes, and deduced the earliest linkage groups. Members of this research group both discovered and caused new (*de novo*) morbid mutations in the *Drosophila* genome.

“Inborn Errors of Metabolism.” The English physician Archibald Edward Garrod (1857–1935), in collaboration with Bateson, first applied Mendel’s principles to a human condition, *alkaptonuria* (see Table 1 of the entry Genetic Disease II). They concluded that alkaptonuria was a monogenic heritable genetic disease, and that it was a classic example of Mendel’s autosomal recessive mode of inheritance. Garrod was later to show that *albinism* and other genetic conditions behaved in a similarly predictable manner. Garrod’s famous phrase, “inborn errors of metabolism” was the title of both a 1902 paper in the *Lancet*, and of a landmark 1909 book.

The Rise and Fall of Eugenics. British statistician (and cousin of Charles Darwin) Francis Galton (1822–1911) believed that complex or “continuous” physical traits (in contrast to Mendel’s discrete,

discontinuous traits) were also heritable and could be quantified. Stature and total fingerprint ridge count are well-documented examples of such traits. Galton was one of the inventors of the “twin method” of heritability estimation (see *multiple births* in Table 1 of the entry Genetic Disease II). Galton was the first, in 1889, to describe degrees of genetic similarity, then known as Galton’s law, which states that in bisexual lineages (such as in humans) each individual receives, on average, one half of his or her inherited characteristics from each parent, one quarter from each grandparent, one eighth from each great grandparent, and so on.

In addition to these productive discoveries, Galton was also an outspoken advocate of the application of useful scientific information to human affairs, and to this end he coined the term *eugenics*. Eugenics is the controversial study of cultural mechanisms that may improve (or impair) the hereditary physical or mental qualities of future generations of human populations. One of its earliest advocates was geneticist Charles Benedict Davenport (1866–1944), an outspoken leader of the American eugenics movement. Although well intended—it sought to remove all forms of genetic disease from society—this international movement suffered from a choice of traits with complex inheritance, including some with large environmental factors (e.g., “feeble-mindedness”), and from controversial legal and political applications (compulsory sterilization, genocide). Thus its influence in America was fleeting, and much of its conceptual vocabulary and rationale has been ignored.

Molecular Genetics. Molecular geneticists study heritable systems at the chemical level, and attempt to understand the control of metabolic processes, including regulatory processes, by genes and gene products (Collins & Gelehrter, 1992). One of the first major steps in this endeavor occurred in 1949 when Linus Pauling and colleagues showed that structural changes (“sickling”) occurred to the red blood cells of individuals with *SCD*. Subsequent to the crucial work of Rosalind Franklin, and of the follow-on description of the structure of DNA by James Watson and Francis Crick in 1953, Pauling was able to describe the first substitutional mutation in humans. In 1964 Pauling reported the displacement of one amino acid (glutamic acid) by another (valine) at sequential position six in the beta chain of adult hemoglobin—the exact substitutional mutation responsible for the sickle cell allele. Pauling coined the

term “molecular disease” to stand for this new level of etiological description.

MECHANISMS OF GENETIC DISEASE

There are two major classes of genetic disease: cytogenetic conditions (caused by chromosomal mutations), and molecular genetic conditions (caused by mutations to DNA).

Cytogenetic Conditions

During the 20th century it became apparent to geneticists that chromosomes (the structures that package the genes) could be mutated independently of the genes themselves. Any cytogenetic condition, that is, a genetic disease caused solely by the rearrangement of whole or parts of chromosomes, came to be called a *major chromosome anomaly* (MCA). Among the better-known examples of MCAs are *Down syndrome (trisomy 21)*, *Turner syndrome (monosomy X)*, *Klinefelter syndrome (XXY aneuploidy)*, and *Cri-du-chat syndrome (5del)* (see Table 1 of the entry Genetic Disease II).

Chromosomal Mutations. These include changes in chromosomes that are either numerical (too many or too few chromosomes, causing aneuploidy) or structural (the translocation or repatterning of portions of chromosomes). A standard karyotype for each species, including humans, is used for comparison. Among the more common modes of chromosome mutations are deletions, fusions, dissociations (fissions), inversions, and translocations. Many MCAs can profoundly influence phenotypic features. In the 1860s, Dr. John Langdon Haydon Down identified a striking phenotype that he called Mongolism, later renamed *Down syndrome*.⁴

The causal mechanism of Down syndrome was characterized in 1959 as a failure of homologous chromatids to separate normally during meiosis (non-disjunction), resulting in a fetus with three copies of a chromosome, now termed trisomy (in this case, trisomy-21).

The probability of experiencing certain chromosome mutations such as Down syndrome can be a function of maternal age. This change in probability is known in general as an advanced parental age effect, and is significant for some chromosome mutations that cause congenital genetic diseases after the mother reaches

about age 35. The probability of having *dizygotic twins* also increases in frequency with advancing maternal age.

Researchers soon described other MCAs that involve whole or large portions of chromosomes: the *Philadelphia chromosome* (a balanced translocation), *Edward syndrome* (trisomy 18), *Patau syndrome* (trisomy 13), *triplo-X syndrome* (XXX aneuploidy), and *double-Y syndrome* (XYY aneuploidy). As cytogenetic techniques improved, many additional MCAs were identified in humans, involving mechanisms such as Robertsonian translocations, inversions, duplications, and deletions.

Cytogenetic irregularities are responsible for roughly one half of all naturally terminated pregnancies.⁵ Nature thus seems to eliminate most cytogenetic mutations; still, 1% of all live-born children possess a congenital cytogenetic disease.

Molecular Genetic Conditions

In contrast to cytogenetic conditions, which involve large packages of genes, molecular diseases are usually monogenic (involve only one gene) and are often due to a single point mutation in DNA, such as that in hemoglobin described by Pauling. Among some better known examples of genetic disease due to molecular changes in DNA are *sickle cell disease*, *Tay-Sachs disease*, and *achondroplasia* (see Table 1 of the entry Genetic Disease II).

Subsequent to the discovery of vitamins by Funk in 1911—as the result of dietary deficiencies described in animal models—the etiology of several human “nutritional diseases,” such as scurvy, was better understood. Some humans, however, fail to respond to vitamin therapy, and have been found to possess errors in the biochemical pathways that involve vitamin metabolism. These deficiencies tend to be rare, and are due usually to a point mutation in the DNA that codes for the proteins in the pathways involved. Examples of such molecular genetic diseases include *maple syrup urine disease* and *familial hypophosphatemia* (see Table 1 of the entry Genetic Disease II).

Mutations to DNA: “Point” Mutations. These are changes in single base pairs within a linear DNA sequence. Point mutations are rare, unpredictable, and permanent changes that result in a small, localized alteration to the chemical structure of DNA. Mutation is one of the mechanisms or forces of evolution, and

the ultimate source of all new genetic variation in populations. When a point mutation occurs in a coding portion of DNA (as in a gene) it sometimes, but not always, results in a change in a protein with deleterious effects to the phenotype, and the event may affect the fitness of the individual who possesses it.

Not all mutations to DNA are point mutations, however. Many recently described mechanisms, such as those that are the cause of the nucleotide triplet repeat expansion disorders, involve more than single base pairs (see the discussion of *anticipation* below).

Although unpredictable, mutations to DNA exhibit spatial clustering near causal agencies such as, for example, regional sources of radiation. Interestingly, the probability of experiencing certain mutations is also a function of advancing parental age, usually after about age 50. The incidence of *achondroplastic dwarfism*, for example, increases with advancing paternal age. Paternal age effects have also been confirmed for *Marfan syndrome* and for the *progerias* (see table 1 of the entry Genetic Disease II).

About 6% of all live-born children possess a molecular genetic defect,⁶ although not all such defects manifest at birth.

Some molecular genetic defects manifest during later stages of life. Examples of late-onset molecular conditions include *Marfan syndrome* (in the second decade), *hereditary hemochromatosis* (third decade), *Huntington disease* (fourth decade), *amyotrophic lateral sclerosis* (fifth decade), and many forms of *cancer* (variable onset, e.g., *breast cancer*, *familial adenomatous polyposis*, and *malignant melanoma*).

MENDELIAN MODES OF INHERITANCE OR TRANSMISSION

Mendel described only one pattern of inheritance, namely the monogenic recessive mode of inheritance. Five additional monogenic modes of inheritance unknown to Mendel have since come to be known by convention as Mendelian. These modes are summarized in Table 1.

Autosomal Inheritance

Autosomal Recessive Inheritance. The key feature of the recessive mode is that a new mutation does not result in a new phenotype, so that only two

Table 1. Mendelian Modes of Inheritance^a

	AR	AC/I	AD	XR	XD	YL
Chromosomes	Pairs 1–22	Pairs 1–22	Pairs 1–22	X only	X only	Y only
Attribute(s)	Two phenotypes, new mutation is hidden in the heterozygote Aa, aa often has lowered fitness	Three phenotypes, new mutation is exposed in AB, heterozygote phenotype is intermediate	Two phenotypes, new mutation is exposed in aa, AA often inviable	Two phenotypes (AA + Aa, AY) and (aa, aY), the latter pair often have lowered fitness, new mutation hidden in female Aa but exposed in male aY	Two phenotypes (aa, aY) and (aa + AA, AY), the latter pair often have lowered fitness (or AA, AY are inviable if A is lethal), new mutation exposed in female aA and male AY	Because males are hemizygous, SNPs on the Y chromosome cannot be evaluated for dominance or recessivity
Genotypes	AA, Aa, aa	AA, AB, BB	aa, aA, AA	♀ : X ^{AA} , X ^{Aa} , X ^{aa} ♂ : X ^A Y, X ^a Y	♀ : X ^{aa} , X ^{aA} , X ^{AA} ♂ : X ^a Y, X ^A Y	XY ^a
Direction	A → a	A → B	a → A	A → a	a → A	N/A
Sex affected	Both, equally	Both, equally	Both, equally	Primarily males	Both; 2 ♀ : 1 ♂	Males only
Pedigree features	Matings between carriers (Aa × Aa) produce 25% affected offspring; mating between an affected person (AA × aa) produce unaffected heterozygotes; all children of two affected people will be affected; trait can skip generations	Both alleles are expressed in phenotypes of heterozygotes; mating between heterozygotes produce all three phenotypes, 25% AA, 50% AB, and 15% BB	Affected person has an affected parent; aa × aA mating has 50% affected offspring; unaffected children have unaffected children and grandchildren	Female carriers are usually normal and 50% of her sons are affected; affected males never have affected sons, but all daughters are carriers (or affected); can skip generations	Affected males transmit the trait to all daughters; female carriers transmit the trait to half of their children, both males and females; affected females transmit the trait to all children	Father transmits trait to all sons, but not to daughters
Example(s)	Oculocutaneous albinism, cystic fibrosis, hyperlipoproteinemia, neurosensory deafness, pseudohemaphroditism, situs inversus	Familial hypercholesterolemia, alpha thalassemia	Achondroplasia, amyotrophic lateral sclerosis, lactose intolerance, long-QT syndrome, neurofibromatosis, porphyrias	Androgen insensitivity syndrome, colorblindness, G6PD deficiency, hemophilia, muscular dystrophy, X-linked mental retardation	Congenital generalized hypertrichosis, Rett syndrome	Sex-determining region of the Y, zinc finger protein

^aThe major modes of monogenic inheritance in humans, also known as the Mendelian modes. Abbreviations used include AD for autosomal dominant, AR for autosomal recessive, AC/I for autosomal codominant (or incomplete dominance), XR for X-linked dominant, XD for X-linked recessive, YL for Y-linked. The direction of mutation is shown in the row labeled “Direction”, with the normal or “wild-type” allele shown on the left, and the new mutant allele to the right.

phenotypes exist, one containing at least one dominant allele, and the other containing two copies of the recessive allele. An original example of the autosomal recessive mode is pea shape in Mendel's common garden peas.

Incomplete Dominance (“Co-dominance”). The key features of the dominant mode are that a new mutation results in a new phenotype in the heterozygote, and its phenotype is intermediate between the two homozygotes. A familiar human example is the wavy-haired heterozygous offspring of straight- and curly-haired homozygous parents. The A and B alleles in the ABO blood groups interact in a co-dominant fashion.

Complete Dominance. The key feature of the dominant mode is that a new mutation results immediately in a new phenotype in the heterozygote. In many cases the subsequent homozygote (AA) is inviable.

Sex-linked Inheritance

X-linked Inheritance. The key feature of the X-linked mode is that males and females are affected disproportionately. X-linked genes are transmitted in either a monogenic dominant or recessive mode of inheritance. Females can be either homozygous or heterozygous for X-linked traits, whereas normal males are always hemizygous for loci located on the X chromosome.

Y-linked Inheritance. The key feature of the Y-linked mode is that only males carry the gene. Y-linked inheritance is displayed by genes located on the non-recombinant region of the Y chromosome. Normal females never possess a Y chromosome, and normal males are always hemizygous for the Y chromosome. Absence of the *SRY* gene on a Y chromosome, through either mutation or crossing-over (to an X chromosome), results in a condition known as the *XY female syndrome*.

NON-MENDELIAN MODES OF INHERITANCE

Non-Mendelian modes of inheritance have received increased attention during the past few decades. Several lines of evidence, such as twin studies and animal models, had long suggested that certain human conditions were likely inherited; however, classic Mendelian models failed

to explain their observed patterns of inheritance. While yet controversial, some of these modes—especially certain epigenetic⁷ modes such as *genomic imprinting* and *anticipation*—are promising.

Monogenic Factors

Mitochondrial Inheritance. Mitochondria are cytoplasmic organelles that contain extranuclear DNA (mtDNA). Mitochondria are responsible for certain oxidative metabolic functions that store and release energy. Children (both males and females) inherit mtDNA from their mothers only. Since the father's mtDNA is located in the sperm midpiece (the mitochondrial sheath), which is lost at fertilization, all children of the same mother are hemizygous for maternal mtDNA and are thus identical to each other and to their mother. Because of its cytoplasmic location in eukaryotes, mtDNA does not undergo meiosis and there is normally no crossing-over, hence there is no opportunity for introgression of the father's mtDNA. All mtDNA is thus inherited maternally; mtDNA has been used to infer the pedigree of the well-known “mitochondrial Eve.” In mammals, the mtDNA ring contains some 16,000 base pairs and codes for 13 proteins, 22 tRNAs, and two rRNAs. Mutations in mtDNA can result in maternally-transmitted conditions that compromise cell respiration, such as *mitochondrial encephalopathy lactic acidosis syndrome (MELAS)* and other *mitochondrial myopathies*.

Penetrance and Expressivity. Penetrance is the frequency of expression of a certain phenotype; some alleles, even when present, are expressed less than 100% of the time, and thus are said to have a lowered penetrance. Examples of variable penetrance conditions include *asthma*, *diabetes*, *dyslexia*, and *PTC tasting*. Expressivity is the range of phenotypes exhibited by a certain specific genotype as a variant from the normal. Examples of variable expression include *familial adenomatous polyposis* and *long-QT syndrome*.

These ambiguous and perhaps outdated concepts may soon be supplanted by other terminology as newer epigenetic factors, such as genomic imprinting and anticipation, are discovered and described.

Epigenetic Factors

Genomic Imprinting, Uniparental Disomy, and Anticipation. *Genomic imprinting*, also known as parental imprinting, is an epigenetic, non-Mendelian

phenomenon that occurs during gametogenesis in which the expression of a gene or chromosome region depends on whether it is inherited from the mother or the father, who is then called the parent-of-origin. Two modes have been proposed to explain the phenomenon: (1) inheritance of two copies of a gene from one parent as in cases of uniparental disomy (see below); and (2) methylation of the allele contributed by one parent, making an offspring effectively hemizygous for the other parent's allele. Four confirmed examples of genomic imprinting in humans include: (1) *myotonic dystrophy*, (2) *retinoblastoma*; (3) *Huntington disease*, where affected individuals have more severe clinical signs if the trait is inherited from the father; and (4) the *Prader–Willi/Angelman syndromes*, where a single genetic cause (a small deletion) if inherited from the father results in one syndrome (Prader–Willi), while if inherited from the mother results in another, completely different phenotypic syndrome (Angelman).

Double copies of certain alleles inherited from a male seem to control normal placental development. Double copies of certain alleles inherited from a female seem to control normal embryogenesis. Imprinting has been suggested as a mechanism that may be partly involved in the evolution of conflicting reproductive strategies between males and females (Haig, 2000; Terleph, 2000).

Genomic imprinting caused by *uniparental disomy* (as in mode (1), above) may be accompanied by *loss of heterozygosity* (LOH) of all loci along an entire chromatid. In other words, several loci on a chromatid seem to convert spontaneously from heterozygosity (Rr) to homozygosity (rr). LOH is a feature of many malignant cell lines in genetic disease, and is an important non-Mendelian epigenetic phenomenon. LOH may be achieved by several modes, but it is suspected that non-disjunction is the most common modality. In this case, an individual who is heterozygous (Rr) in germline DNA for a cancer gene such as *retinoblastoma* could later acquire the cancer “spontaneously” during a cell division event and become an rr homozygote. During cell division the individual would be temporarily hemizygous at the RB locus due to isochromy in one cell line (R), and polyzygous (Rrr) due to trisomy in a second. The isochromic cell line containing the single R allele would most likely be inviable and resorb. In the remaining cell line, however, if the third trisomic chromosome is then lost such that the temporarily polysomic (Rrr) cell line reverts to a disomic (rr) cell line, this second mutation could give

rise to a converted cell line in which the subsequent clone would be homozygous (rr) for all the loci on the affected chromatid pair. This altered cell line would be malignant.

Uniparental disomy, as this mechanism is termed, is one of several important new epigenetic non-Mendelian mechanisms that can now explain many formerly elusive developmental phenomena at the cellular level. One of the other important new epigenetic mechanisms is anticipation.

Anticipation is a phenomenon whereby a genetic disorder becomes increasingly severe from one generation to the next (the age of onset usually gets lower, as well), and is a feature of about 40 nucleotide triplet repeat expansion disorders in humans. In anticipation, a gene gets progressively longer, as generations pass, usually due to unequal crossing-over. This succession of lengthening events usually makes the gene progressively more dysfunctional with time, and apparently explains many cases where symptoms are similar, yet differ by degrees. Examples of genetic diseases characterized by anticipation are *androgen insensitivity syndrome*, *fragile X syndrome*, *Huntington disease*, and *myotonic dystrophy* (see Table 1 of the entry Genetic Disease II).

Genomic imprinting and anticipation have been recently implicated in the etiology of certain conditions long suspected to have a genetic component but that did not yield to simple Mendelian models of disease. Among the multifactorial, high heritability conditions that are being re-evaluated in the light of these new mechanisms are the *major affective disorders* (both bipolar and manic-depressive phases), *Tourette syndrome*, and *schizophrenia* (Anonymous, 1997a, 1997b).

Polygenic Factors

Heritability and Risk of Inheritance in Multifactorial Disorders. Heritability may be defined as the additive proportion of total phenotypic variance in a polygenic trait attributable to genetic variation in a population. The values of heritability estimates can range from 0% to 100%. Heritability is a function of genetic factors, environmental factors, and the interaction of genetic and environmental factors. Simple Mendelian traits have a heritability of 100%. Diseases with a heritability of less than 100% are inevitably controversial, such as those listed in the previous paragraph.

Other non-Mendelian mechanisms of clinical significance have been recently re-evaluated in terms of new

molecular knowledge (the “new genetics”), but are not considered in this review (Anonymous, 1997a, 1997b). These mechanisms include: X inactivation, dosage compensation, epistasis, ectopic recombination, meiotic drive, position effects, microdeletions, other contiguous gene syndromes, chimerism, pleiotrophic homeotic mutations, slippage, and germline mosaicism.

Phenocopies

Kuru, New Variant CJD, and the Other Prion Diseases. Phenocopies appear initially to be inherited conditions, but upon closer inspection turn out to be, either wholly or in part, due to an environmental agency. The thalidomide babies of the 1960s, for example, were teratogen-induced phenocopies of *phocomelia*.

Kuru is a chronic, progressive, uniformly fatal transmissible neurodegenerative disease now suspected to be a phenocopy, and is caused by a prion. Several other *prion diseases* also exist, such as new variant *Creutzfeldt–Jakob disease (vCJD)*; because the prion diseases may *not* be wholly environmental, however, these will be discussed in more detail below.

DISTRIBUTIONS OF GENETIC DISEASES

The genetic epidemiology and distributions of genetic disease is the subject of the companion entry, Genetic Disease II.

ONLINE SOURCES OF CURRENT INFORMATION ABOUT SPECIFIC GENETIC DISEASES

Online Mendelian Inheritance in Man (OMIM) is a Federally-funded, searchable database of virtually all 6,000 known or suspected heritable conditions or traits. Each trait is assigned an OMIM identification number referred to as “McKusick’s ID,” after the founder of the database, Dr. Victor McKusick. The URL of OMIM is: <http://www.ncbi.nlm.nih.gov/Omim/>

Merck Manual Online is a searchable database containing most morbid conditions, including many with a genetic component. The URL is: <http://www.merck.com/pubs/mmanual/sections.htm>

The Human Genome Project (HGP) has an excellent subsection on genetic diseases. In the Table of Contents at the HGP site, find the Frame/Section titled “Medicine and the New Genetics,” and click on “Genetic Disease Information-pronto!” The base URL is: <http://www.ornl.gov/hgmis/>

BIOTECHNOLOGY AND “DARWINIAN MEDICINE”

Demographic Transition(s) and Genetic Disease

Demographic theory suggests that as human populations become economically developed, there will be a reduction in mortality that leads to population growth, sometimes (but not always) followed by a reduction in fertility that leads to growth equilibrium. There are three or sometimes four stages to this process; the fourth stage invokes the reduction of morbidity, as well. In the early stages of a demographic transition, life spans are short, and morbidity and mortality are related to trauma and infectious disease. In the latter stages, average life spans are much longer, and morbidity and mortality are more due to degenerative processes and age-dependent genetic diseases. Most diseases (such as cancer) and degenerative processes (such as arthritis), even though not classified as “genetic,” impact human metabolic and physiological processes that are themselves the result of gene-mediated processes, and will come in time to have a larger molecular aspect to their etiology. Thus, many developmental, congenital, metabolic, infectious, allergic, neoplastic, thrombotic, and some psychiatric conditions will likely come to be understood, in some sense, as increasingly genetic (Childs, Moxon, & Winkelstein, 1992). Only trauma, certain functional/ psychosomatic defects, and some psychiatric conditions seem to be destined to escape this fate. Many of the emerging diseases appear to have a genetic or molecular component: several cancers, degenerative diseases, and many infant diarrheas are now understood by Western researchers to have at least a partially molecular etiology.

Examples of cancers or cancer-related agents with a genetic component include: some *breast cancers*, *Burkitt lymphoma*, chronic myeloid leukemia (see the *Philadelphia chromosome*), *colon cancer* and *familial adenomatous polyposis*, *malignant melanoma*, those

conditions affected by mutations to the *p16* and *p53 tumor suppressor(s)*, the *Ras oncogene*, and *retinoblastoma*.

Degenerative genetic diseases with a late onset are well known: in addition to those already mentioned are *essential tremor* and *Parkinson disease*. Among examples of late-onset, “normative” degenerative diseases of aging that have an acknowledged genetic component are: rheumatoid arthritis, osteoarthritis, osteoporosis, and systemic lupus erythematosus, although each has a significant environmental components as well.

Similarly, among the many examples of malabsorption diseases with a genetic component, and that are significant contributors to the prevalence of diarrhea, worldwide, are: *disaccharide intolerance* (including *lactose intolerance*), *familial Mediterranean fever*, *fructose intolerance*, *galactosemia*, *glucose–galactose malabsorption*, *glycogen storage disease*, and *inflammatory bowel disease*.

The Human Genome Project

The Human Genome Project (HGP) project was initiated in 1989 and funded by the U.S. government, with one of its explicit goals set as the understanding and cure of genetic disease. The HGP’s initial task was to locate and identify all the coding genes in the human genome by the year 2005. A secondary goal, to sequence the DNA in the entire human genome, was expected to take somewhat longer. The American HGP was eventually combined with the international Human Genome Organization (HUGO) to make the project global in scope. Currently, the worldwide HGP is substantially ahead of schedule. One of the major findings of the rough draft of the human genome, completed early in 2001, was that the number of human genes may be closer to 30,000 than to the previously higher estimate of 70,000, and that the enormous library of human proteins is produced by fewer complete cistrons (coding sequences) than initially estimated. The human genome thus has an apparent protein: gene ratio higher than 3:1, yet some other species maintain a ratio that is closer to 1:1. This seems to be due in humans (and some other organisms) to differential splicing of segments of genes called exons (“exon shuffling”). The human genome appears to be composed of thousands, perhaps even hundreds of thousands, of these smaller functional segments, rather than complete and contiguous larger genes. Through differential splicing of these exons, many large and complex genes can apparently be

constructed. This organization of the human genome has dramatically affected how research in genetic disease is being approached.

Many of these smaller segments are almost identical in their DNA sequences to segments found in “lower” species such as mice, fruit flies, and even yeast. One can use the analogy of an arm to understand that it might be constructed of functional exons that separately code for elbows, long bones, carpals, and metacarpals, rather than from one large gene called “human arm.” The elegance of this strategy is that each of the many smaller segments, such as a molecular “elbow,” had to evolve only once, and that through “exon shuffling” they can be used in many different ways in many different organisms. The function of such genes within other organisms can be studied, and the results extrapolated to humans. This study of the differential use of linear DNA and the assembly of nearly identical segments of DNA across species is known as *genomics*. Processes that occur within the organism after the genes are transcribed are called *epigenetic* processes.

Interest in epigenetic processes is increasing dramatically, and the prion diseases provide an illustration. “True” genetic diseases are transmitted vertically; that is, from one generation to the next. The discovery in 1957 that certain genetic conditions also have *phenocopies*—conditions that mimic a known genetic disease or a genetic mode of transmission, but that can also be transmitted horizontally, by infection—was startling. Even more surprising was a suggestion made in the 1980s by Stanley Prusiner, known as the “protein only hypothesis,” that the agent of these phenocopy infections lacked DNA, unlike any then-known infectious agent. Prusiner’s “proteinaceous infectious particles,” or *prions*, were soon validated (Prusiner & Scott, 1997), and they quickly blurred the distinction between vertical (genetic) and horizontal (infectious) transmission.

Although scrapie was known to cause neurodegeneration in sheep, the first of these prion-transmitted conditions to be described in humans was *Kuru*, a neurodegenerative disease found in the Highlands of New Guinea, and now well known to medical anthropologists (Gajdusek & Zigas, 1957; Matthews et al., 1968; Rhodes, 1997). *Kuru* was at first thought to be a genetic disease, as family members of those afflicted with *Kuru*, primarily females and children, were eventually also affected. *Kuru* was next thought to be the action of a “slow virus,” when infected human tissue caused the onset of similar symptoms in a chimpanzee infected experimentally. Only

much later was the infectious agent shown to be a prion, passed to women and children who customarily ate the brains and other parts of cadavers, which men almost never did. Today, *Kuru* is thought of as an infectious disease. Whether or not this perception is valid will depend upon future research on the prion diseases (see below).

Creutzfeldt–Jakob Disease (CJD)

CJD is a rare, partly inherited disease (about 15% of cases are classically inherited; other cases are either infectious or sporadic). Shortly after the outbreak of “mad cow disease” in Great Britain, the incidence of CJD also increased dramatically. CJD, which had been thought of until that time as a purely genetic condition, was being precipitated in humans after ingestion of contaminated beef. The infection pathway was circuitous: the cattle had been fed supplemental bone meal from dead sheep previously infected with scrapie, a disease also effected by a change in the *prion protein (PrPc)*. The prion that caused scrapie in the infected sheep had transformed normal bovine PrPc to cause bovine spongiform encephalitis (BSE), and the infectious form of the BSE prion (PrPSc) when ingested by humans caused some of them to contract an analog, a new variant of CJD.

Researchers soon asked: Is CJD, like *Kuru*, an infectious disease, rather than a genetic condition? The answer turned out to be both yes and no. The gene for PrPc (PRNP) was mapped to the long arm of human chromosome 20, and it was soon cloned and sequenced. This sequencing revealed that humans are polymorphic for several single nucleotide polymorphisms (SNPs) found in native PrPc. Of the 253 amino acids in PrPc, humans can have any of several amino acids at certain locations—especially at codon 129. People can have either valine (V) or methionine (M) at this position, so the possible PrPc genotypes at position 129 are VV, VM, and MM. People with the MM genotype (“methionine homozygotes”) overwhelmingly manifested the new transmissible variant form of CJD (called *vCJD*, formerly *nvCJD*, for new variant). In other words, methionine homozygotes (MM) have the *vCJD*-susceptible genotype. VM heterozygotes and VV homozygotes sometimes acquired the infectious form of CJD, but their incubation times were significantly longer than people with the homozygous MM genotype. How the infectious prion interacts with native prion (PrPc) to form transformed prion (PrPSc) is

currently unclear. It is understood, however, that a second mutation at position 178 (aspartic acid to asparagine) is also required before native PrPc can be changed into the infectious form, PrPSc. Position 178 is located next to one of several bridging sites where a strong hydrogen bond holds the molecule in its proper 3D conformation; the normal topology is somehow disturbed by this second mutation, causing a process known as templated refolding, and results in PrPSc, a mutant conformational isoform of native PrPc.⁸ Furthermore, a new, even smaller (176 base-pair) prion-like particle called Doppie (Dpl, “double,” PRND) has also been discovered on chromosome 20p, just downstream from native PrPc. Dpl shares significant biochemical and structural homology with PrPc. Dpl also seems to interact *in vivo* with PrPc during this process of transformation to PrPSc (see Table 2).

More clarity was achieved when it was found that a related neurogenetic disease, familial fatal insomnia (FFI), was manifested predominately in VV genotype individuals who also had the mutation at position 178. Likewise, *Kuru* patients were almost all found to possess the MM genotype.

Both *Kuru* and new variant *Creutzfeldt–Jakob disease (vCJD)* have begun to look suspiciously like classic cases of a *balanced genetic polymorphism* in which VM heterozygotes have a higher fitness than either genotypic class of homozygotes (MM or VV), both of which seem to have a higher susceptibility to prion-like diseases.

Like humans, sheep have specific PrPc genotypes that predispose susceptibility to transmissible scrapie (the “S” in PrPSc indicates that the original agent is scrapie).

Because PrPc is conserved in mammalian species, refolded PrPSc can apparently be shuttled between several species, causing similar but species-specific conditions called the transmissible neurodegenerative diseases (TNDs, or the *prion diseases*; for an excellent popular account of these events, see Rhodes’ 1997 book, *Deadly Feasts*). Homologous Dpl has also been found in several mammals.

The search for similar epigenetic processes such as those observed in the prion diseases—processes that occur after linear DNA has been transcribed into spliceable fragments within a species, called the *transcriptome*—has begun to take precedence over the sequencing effort for researchers in both the government-funded and private sectors. This effort, involving both DNA and several RNAs, is called *functional genomics*. The accumulation of

Table 2. Summary of Genotypic Data for New Variant Creutzfeldt–Jakob Disease^a

Population	Sample size	MM	MV	VV	<i>p, q</i>	Ref. ^b
Control	109	0.45	0.39	0.16		1
Control	300	0.43	0.49	0.08		2
Total Control	409	0.44	0.46	0.10		
H-W equilibrium		(0.43)	(0.45)	(0.12)	0.67, 0.33	
nvCJD	15	0.73	0.14	0.13		1
nvCJD	67	0.69	0.06	0.25		3
nvCJD	35	1.00	0.00	0.00		4
Total nvCJD	117	0.79	0.05	0.16		

^aFour studies have provided genotypic data on two control and three affected populations. The two control populations (top) total 409 individuals; allele frequencies for the pooled groups are methionine (M) = 0.67, and valine (V) = 0.33. The population appears to be in Hardy–Weinberg equilibrium.

Pooled data for the three nvCJD study groups ($N = 117$) indicates that a significant number of affected nvCJD individuals have prion genotype MM (79% observed vs. 44% expected) or VV (16% observed vs. 10% expected); although 46% of MV heterozygotes were expected to acquire nvCJD, only 5% of this group actually acquired the disease. These differences are highly significant ($p < 0.0001$), and strongly suggest that MV heterozygotes are at a selective advantage relative to either of the homozygote classes.

massive amounts of sequence and gene interaction relationship data is the work of those who practice *bioinformatics*. The old dogma of “one gene, one enzyme” has given way to a vision that a “gene” is an amalgam of fragments that can be used in several ways in many different organisms, and the path from raw gene sequence to final gene product may not be linear, or even determinate. The study of gene expression and how proteins are assembled and modified by both RNAs and other proteins (including prions) is called *proteomics*. Many agencies have already transferred resources from the HGP to this new effort; with less fanfare than the HGP launch in 1989, the Human Proteome Project (HPP) was funded by Congress in 2001. Because many of these epigenetic processes are so similar in both higher and lower species, proteomics seeks to understand both individual cases of dissimilarity and the cause of massive similarity in these processes across so many species, including the recently recognized domain of the *Archaea*. This research has given rise to an entirely new field of endeavor, *Darwinian Medicine*, the search for evolutionary explanations of vulnerabilities to disease (Nesse & Williams, 1996; Stearns, 1999; Trevathan, McKenna, & Smith, 1999).

Biotechnology

Biotechnology is the industrial development of commercial products through the modification and extension of

biological processes, and their commercial production through bulk processes such as fermentation. The development process may utilize intact organisms (e.g., bacteria or yeast) or natural substances (e.g., enzymes) extracted from such organisms. Biotechnology, as a modern human endeavor, dates to 1972 when scientists at Stanford University recombined fragments of DNA from different organisms, and the era of “genetic engineering” was born.

Recent events in biotechnology, including the HGP’s draft of the human genome, have proven dramatic, and the evolution of this technology has occurred rapidly. Some critics hold that changes have come too fast for reflective human assimilation. Proponents counter that biotechnology is not new, that humans have been manipulating genotypes and phenotypes for some 10,000 years, since the time of early plant and animal husbandry, and that only the degree of technical sophistication has changed in recent decades.

Most of these events in the recent history of biotechnology directly impact the treatment and cure of genetic disease; those that do not, such as agricultural biotechnology, utilize methodology that has spun off from the primary medical endeavors. Among the banner events with both short-term (or proximate) and potentially long-term (ultimate) consequences for humanity are stem cell research, whole organism cloning, and human gene therapy.

Stem Cell Research and Cloning

Stem Cell Research. An embryonic stem (ES) cell is any cell taken from a pre-implantation embryo. ES cells are totipotent, that is, they retain the potential to form any specialized cell type in the body. Totipotency is a characteristic of cells in the inner cell mass of a pre-implantation blastocyst. A non-embryonic stem cell, on the other hand, is a cell from a slightly later stage of fetal development that can proliferate in an undifferentiated state, as well as give rise to differentiated cell lines. These latter stem cells are merely pluripotent, that is, relatively unspecialized stem cells not yet committed to becoming specific types of derived cells; for example, a dermal stem cell that can give rise to the several types of dermal tissues, but cannot give rise to brain tissue. Both types of stem cells can be manipulated in gene targeting and whole organism cloning.

Cloning. Whole organism cloning depends upon the manipulation of totipotent embryonic stem cells, or—as in the well-known case of Dolly the sheep—the technical reversion of a pluripotent stem cell into one that is thought to be totipotent. Advocates of cloning argue that unrestricted stem cell research is a critical prerequisite to realize any of the potential benefits of whole organism cloning.

Whole organism cloning is the creation of a collection of genetically identical individuals that have been derived from a single parent cell; that is, the clone has been reproduced asexually. In biotechnology, cloning usually involves growing genetically identical vectors or host cells—usually bacteria, yeast, or non-human mammalian cells grown in culture—which all contain the same piece of inserted recombinant DNA, including the target gene.⁹

One of the aims of stem cell research and whole organism cloning is the husbandry of pharmaceutically valued DNA fragments that have been successfully recombined into a larger organism. These fragments can then be harvested at will from that organism or from other clones of that organism. Recombinant human insulin, for example, is currently harvested from clones of bacteria that multiply rapidly in industrial-sized fermenting vats. The clones yield pounds of less toxic and less expensive product. Biotechnologists argue that the insertion of the same human insulin gene into a mammal instead of a bacterium so that product can be harvested daily from normal transgenic mammalian milk, is a logical quantitative

but not qualitative next step in this process. The proximate benefit of this process, it is argued, is a safer medical product (insulin, in this case) that can be substituted by injection for a patient’s defective gene product, and that humanely saves the lives of juveniles afflicted with *insulin-dependent diabetes mellitus (IdDM)*.

Knowledge of these processes is not yet widespread, and one of the medical specialties that seeks to inform the public about these issues is genetic counseling.

Genetic Counseling and Gene Therapy

Genetic Counseling. This is an allied medical specialty that provides an understanding of medical genetics, including the estimation of the empirical risk of recurrent inherited disorders that may be inherent in prospective families. Such counseling may include details of the laws of inheritance and pedigrees, a complete natural history of a genetic disorder, along with empirical risk estimates and the currently available options for testing and treatment. One of the options that may be available is gene therapy.

Gene Therapy. This is the treatment of a genetic disease by substitution of a working copy of a gene for a defective copy. This can be done by repeated injection, which is transient, or by the permanent insertion into cells of a normal gene or DNA segment that can correct an abnormal cellular function or disease. Three potential levels of gene therapy can be applied to genetic diseases.

Potential Levels of Gene Therapy. *Level 1: Substitutional gene therapy* is a transient, non-heritable replacement or augmentation of a working product for a null gene product, one typically knocked out by a mutation. The repeated use of recombinant human insulin by *insulin-dependent diabetics* as a replacement for genetically defective insulin, and glucocerebrosidase in the case of *Gaucher disease*, are examples of successful substitutional gene therapy.

Level 2: Somatic cell gene therapy is a longer-term, non-heritable modification of somatic cell genomes to cure or prevent deleterious conditions, without modification of gametes or the germ-line. Typically, body cells are removed from an individual, genetically modified or engineered, and placed back into the same individual.

The first successful application of somatic gene therapy in humans occurred in the well-known case of Ashanti DaSilva, a four-year-old girl affected with a genetic form of SCID called *adenosine deaminase deficiency*, who, on September 14, 1990, at 12:52 pm,¹⁰ successfully received a transfusion of her own cells in which her defective ADA gene had been genetically modified. An aerosol system that delivers a genetically engineered CFTR product to *cystic fibrosis* patients has also been developed.

These first two levels of gene therapy substitute or repair genes in a patient's body cells only and, very importantly, the sex cells remain unaffected. If the patient then chooses to reproduce, children may be affected with the same condition as the parent.

Level 3: Gametic gene therapy is the proposal of the permanent genetic engineering of either a patient's gametes or a fertilized pre-morula zygote, after which certain alterations are perpetuated in all the cell lines of a resulting embryo and the normal gene may be transmitted to future generations if the patient later chooses to reproduce. To date, gametic gene therapy has never been attempted in humans. Gametic gene therapy is also called germ-line or germ-cell gene therapy.

Gametic gene therapy is the only form of gene therapy that can potentially eliminate a genetic disease from an individual family line—by engineering *both* body and sex cells—so that subsequent reproduction results in unaffected offspring.¹¹

Bioethical Concerns

Proximate versus Ultimate Effects of Intervention. Anthropologists often point out that in the PTC taste blindness polymorphism there are nil frequencies of non-tasters among many recent hunting peoples, but high non-taster frequencies in cosmopolitan areas, where humans have been longer removed from a foraging subsistence (Boyce et al., 1976; Pool, 1992) (see *PTC tasting* in Table 1 of the entry Genetic Disease II).¹²

The classic explanation for this observation is that modernization provides both enhanced tools and special environments in which such a gene-based condition can survive and perhaps thrive—that culture in some respects buffers the harsh effects of natural selection, and that the former tension due to natural selection has been “relaxed.” As populations modernize, the argument goes, the need to personally detect goitrogens and other toxic alkaloids becomes less and less necessary, and—like an

unused organ that has atrophied through disuse—the result is a vestige of a former adaptation.

On the other hand, it has been argued that such cultural interventions into “natural” processes, while offering attractive short-term solutions, can ultimately result in a burden. Such ameliorative processes may ultimately only increase the genetic load of populations that exploit strategies that are only beneficial in the short term.

New forms of disease can be inadvertently introduced by iatrogenic measures.¹³ In some cases, new forms of disease are produced as a direct result of proximate intervention. In the well-known case of *phenylketonuria*, the humane intervention by dietary management has the proximal effect of buffering the naturally debilitating course of this condition during the critical period of post-natal development, but can result in an entirely new form of the disease in subsequent generations, known as *maternal phenylketonuria* (see Table 1 of the entry Genetic Disease II).

In a more modern—and ethically more complex—case, the cultural response to the genetic disease *IDDM* was, in the 1920s, due directly to the development of a molecular etiologic model of this mostly genetic disease. This led immediately to substitutional therapy: to the prophylactic substitution of defective human insulin molecules with working analogs of insulin extracted from pigs and cows. These porcine and bovine molecules were used until the 1980s, when less expensive recombinant human insulin produced in transgenic bacteria became available. The proximate, humane result of this medical intervention was that lives were saved, suffering was relieved, and the quality of life for those affected was vastly improved. Furthermore, *IDDM* individuals who prior to this prophylactic technology would probably have died before reproducing, now survived to procreate, and to achieve fitness parity with the unaffected population. Ironically, to the extent that *IDDM* (or any disease) is genetic, this meant that affected individuals survived to place new copies of their defective *IDDM* genes into the next generation, thus potentially increasing the incidence of the disease. Increases in *IDDM* incidence have been reported in Michigan (1949–1972), France (1988–1995), and in all the Nordic countries, where a secular increase in *IDDM* incidence has been noted for the past 70 years (Joner & Sovik, 1989; Levy-Marchal, 1998; North et al., 1977).

Under the laws of natural selection, nature is the primary arbiter of life and death. In the case of “relaxed” selection—or what has most recently been called *directed*

evolution—humans have co-opted this role. With our cultural solutions, humans have sometimes become the alternative arbiters of life and death. Formally, directed evolution is a mode of biological selection in which the agent of differential reproduction or differential mortality is a human, or a human-based medical system. The concept is not new. During Darwin's time this process, when applied to plants and animals, was called domestic selection (Darwin, 1868) and was well known to husbandrymen (Russell, 1986).

As a neologism, directed evolution was coined as a supplement to the older term "relaxed selection." Relaxed selection had originally been applied to the cultural buffering of natural selection, but was also a core concept employed by (and therefore negatively associated with) the eugenics movement in pre-World War II America. Today, the term directed evolution has been suggested specifically for cases in which domesticated DNA has been manipulated to serve human ends.¹⁴

The "unnatural" cultural modification of a "natural" process may result ultimately in new generations of children born with the gene for IDDM, and such cultural interventions—regardless of the humane motivation for the proximate medical treatment—may increase the incidence of genetic diseases. Proponents of gene therapy hold that humans are now in the early stages of such genetic manipulation, and that the anthropogenic (human-caused) manipulation of genetic diseases can succeed only if followed through to a third logical level of manipulation: gametic gene therapy. But because this third level of gene therapy involves techniques such as embryonic stem cell manipulation and *in vitro* fertilization, human gametic gene therapy is unlikely to be realized in the current political climate without the advocacy of political lobbyists, genetic counselors, and bioethicists.

Bioethicists are concerned with behaviors and policies concerning biological materials. Issues pertinent to bioethics include organ transplantation, induced abortion and life termination, artificial insemination and sex selection, the use of embryonic tissue in research, and the engineering of genomes. Some of the current bioethical issues are these apparent disparities between the short- and long-term outcomes of medical intervention policies, and costs versus benefits of genetically engineered plants, animals, and humans.

These are complex issues, not only technically, but ethically and morally, as well (see, e.g., Zilinskas & Balint, 2001). In the coming decades, it should be of

immense interest to medical anthropologists to follow not only the directed cultural evolution of the new biotechnologies, but also to observe the dynamic of the associated bioethical concerns.

NOTES

1. Unless a specific work is cited, material contained in this work is common knowledge to human geneticists, and may be found in introductory genetics texts such as Mange and Mange (1999), Vogel and Motulsky (1999), or Lewis (2001).
2. Nosology: knowledge of, and the systematic classification of diseases.
3. Genetic conditions italicized in the text are summarized in Table 1 of the companion entry Genetic Disease II.
4. There has been a trend in recent years to omit the possessive case when an eponym is associated with a syndrome; Down's has become Down syndrome. This convention is followed here. Names for certain diseases, for example Alzheimer's disease, still feature the possessive case.
5. Leridon (1977, table 4.20, and pp. 76–81), and Carr and Gedeon (1977).
6. While some defects are life threatening, others, such as male pattern baldness or colorblindness, are more benign.
7. Epigenetics: study of the causes and course of development, especially those mechanisms that affect the timing and interaction of gene expression and tissue induction (Mai et al., in press).
8. Several other, less frequent mutations, including deletions and insertions, also cause transformational folding of the prion protein, and result in clinically similar—but not identical—phenotypes.
9. Whole organism cloning should not be confused with DNA cloning, which is the amplification of a segment of DNA (the clone) after *in vitro* insertion of the clone into a suitable DNA vector, such as a modified virus.
10. This date and time has become an understandably famous landmark among medical geneticists, because of the historical importance of the treatment.
11. Other *in vitro* techniques, such as fetal cell sorting, offer this same promise.
12. Similarly, the incidences of congenital hearing loss, congenital blindness, and juvenile-onset myopia have markedly increased in urban populations for presumed similar reasons (although myopia has both a genetic and a large environmental component).
13. Iatrogenic: an effect, usually negative and unintended, introduced directly through the treatment of a healer.
14. Directed evolution is also known by the labels anthropogenic selection, directed selection and directed molecular evolution.

Genetic Disease II

Genetic Epidemiology of 150 Common or Informative Diseases¹

Larry Leon Mai

GENETIC EPIDEMIOLOGY²

In 1874, when Charles Darwin's younger cousin Francis Galton published *English Men of Science: Their Nature and Nurture*, Galton was no doubt aware of Shakespeare's priority, for when Prospero spoke of Caliban in 1611, calling him "A devil, a born devil, on whose nature nurture can never stick; ...,"³ one of the most entrenched dialectics in all of biology was born.

The impasse, widened in 1690 by John Locke's now well-worn metaphor of the newborn mind as a *tabula rasa*,⁴ a blank slate on which nature had scribbled nothing, became contentious when Galton insisted, to the contrary, that nature had ordained not language itself, but differential capacities for language; not genius, but differential predispositions for the realization of genius. It was as if Galton had supposed that nature had indeed written on Locke's clean slate, but that she had written her messages in invisible ink, and that the slate had to be held over a flame before the messages could be read.

Somewhere between these polarized philosophical views, between the *nature uber alles* of Galton and the environmental determinism of Locke, an empirical middle ground is currently being excavated, a middle ground that rejects neither view and that successfully incorporates components from each. Nowhere has this become clearer than in the complex interactions of disease agents, disease vectors, and the gene-based responses of their human hosts.

Genetic epidemiology is the study of genetic elements of disease, and is a growing methodology for understanding how those elements function in complex biological systems. Genetic epidemiologists seek to discover and understand the genetic basis of diseases, traits with complex inheritance patterns, and risk factors associated with gene-based diseases within specific environmental contexts (Mai, Young Owl, & Kersting, 2004; Motulsky, 1984).

The conjunction of the terms "genetic" and "epidemiology" at first may seem a forced blend; an attempt to meld two separate approaches that is doomed to chronic marbling rather than complete synthesis. However, some of the recent work of geneticists, epidemiologists, and, indeed, genetic epidemiologists, has blurred the once distinct barrier between these approaches. Classical Mendelian genetics has an increasingly limited utility in terms of understanding the complexity of many diseases and genetic predispositions to cytotoxic agents. The new mechanisms that have only recently become understood are for the most part *epigenetic* rather than genetic.

This review will address the possibility of an epidemiological transition, and end with a discussion and illustration of "transmissible" (in the epidemiological sense) genetic disease.

The concept of an epidemiological transition as a continuum that can be organized into stages similar to the well-known demographic transition has existed for some

time (Corruccini & Kaul, 1983; Lappe, 1994). Such a continuum might extend well back into Miocene primate ecology, and from there forward into the Plio-Pleistocene foraging, scavenging, and hunting behaviors of early hominids. During these millennia, hominids continued to adapt genetically. They brought forward with them not only the genetic markers of prior adaptations, but also a host of commensal and parasitic “heirloom species” (Barnes, Armelagos, & Morreale, 1999). Humans cohabit a parallel evolutionary universe with body lice and enterobacteria that evolve and speciate in synchrony with us (Hafner & Nadler, 1988; Klassen, 1992). We possess anticarcinogens against most plant-related agents (Ames, 1983; Steinkellner et al., 2001) but fewer against meat-related agents, especially heterocyclic amines (HCAs) in cooked meat (Adamson et al., 1996; Sugimura, 2000). These observations reflect the long, slow process of this epidemiological transition.

The roots of the anatomically modern human epidemiological transition extend back at least 10 millennia, to a time when humans began to exploit marine environments extensively, and adapted both immunologically and digestively to the consumption of shellfish and other marine organisms (Walter et al., 2000).

The beginning of the human epidemiological transition proper, however, occurred when some human groups shifted from gathering and hunting to primary food production and the domestication of animals (Corruccini & Kaul, 1983; Diamond, 1997, p. 207). A second transition occurred when acute infectious diseases were controlled and the prevalence of chronic, noninfectious, and degenerative diseases increased; a third transition, according to some researchers, is defined by the “re-emergence and emergence of antibiotic-resistant diseases on a global scale” (Barnes et al., 1999; note 1, pp. 229–230).

Genetic diseases such as *sickle cell disease (SCD)*⁵ could be considered classic stage one/two “noninfectious” adaptations. “Genetic epidemiology” describes the distribution of gene-based adaptations when driven by an environmental agent, in this case the distribution of the infectious agents of malaria, various species of *Plasmodium*.

Genetic diseases are increasing in prevalence, and perhaps in incidence as well. Some of this change may be an artifact of expertise, as higher resolution diagnostic tools are invented, and as diagnostic skills improve. A substantial proportion, however, is a sequela of improved

treatment, and is the consequence of relaxed selection (see the entry Genetic Disease I).

Genetic diseases exhibit focal patterns. Some are as well known as *SCD*, others are less well understood. Some residual genotypic spatial distributions are thought to reflect past episodes of infection, such as cline of the I^B allele in Europe that may be due to selection against the I^A allele during a smallpox epidemic (Bodmer & Cavalli-Sforza, 1976, p. 404). Other conditions with genetic manifestations will eventually be shown to be congruent with the distributions of nonorganic agents, such as foci of chemical mutagens, regions of high radioactivity, or pools of environmental carcinogens. Age-dependent genetic diseases will be found to cluster where demographically aged populations reside.

Classically, the distribution of some genetic diseases can be attributed a few already well-understood factors. Foremost among these are consanguinity (inbreeding), and the founder effect (drift).

Every genetic entity with significant present-day prevalence can be traced, at least theoretically, back to an ultimate mutation, the single source that was the founder of the modern distributions. Nowhere has this been more obvious than among the closed demes, where many genetic conditions—including *breast cancer* and *Tay-Sachs disease* (among the Ashkenazim); *autism*, *lactose persistence*, and the $\Delta 32$ mutation in the *CCR5 gene* (among Icelanders); *polydactyly*, *dwarfism*, and *maple syrup urine disease* (among the Old Order Amish of Lancaster County, PA); *congenital adrenal hyperplasia* (among the Yu’pik Eskimos); and *achromatopsia* (among the Pingelapese people in Micronesia)—have been accounted for by these mechanisms (Lewis, 2001, p. 246).

The geographic removal of closed demes from one region to another is at times the sole mechanism invoked to explain the spatial variation of a genetic disease, known as a founder effect. For example, 30,000 living Afrikaaners (out of 2.5 million) have *porphyria variegata*. These affected individuals are all descended from a single pair of peripatetic colonizers who emigrated from Holland to South Africa in 1688.

In other cases, the slower dispersion of expanding populations into hominid-empty ecological niches appears to be the simplest explanation. Native Americans, for example, seem by some accounts to have entered

North America from Siberia in three major waves between 33,000 and 5,000 years ago; by other accounts, there was only one continuous dispersion event (Dillehay, 2000, p. 241). The second of these alleged waves, between 15,000 and 12,000 years ago, consisted of founders whose descendants today have high incidences of *albinism* and the *New World syndrome*. Any of the well-documented diasporas has left a similar genetic trail (Brown, 1990; Owens & King, 1999).

In any case, most simple monogenic conditions, if they are compatible with life, and if reproduction is possible (or permitted), and if sustained in a population for many generations, can potentially be reconstructed. Most of these reconstructions will resemble a dendritic funnel, with many branches at the open mouth ending in clusters of demes composed of living individuals that carry the inherited alleles. These extend back in time, downward into the throat of the funnel, twigs joined together into branches, branches into limbs, and limbs into a single ancestral trunk representing the family of the individual with the original mutation.

In the absence of other forces, a unique founder will have offspring who will live and die more or less in situ, as will grandchildren and all future heirs of the mutant allele. In this most simple—and most unlikely—of all cases, an undisturbed distribution would, at least in theory, appear as a perfect circle with the greatest density (highest allele frequencies) near the center. Humans are not bacteria, however, and while it may be possible to find such a neat distribution in a Petri dish, most human distributions have been affected dramatically by the contingencies of history: by wars and local catastrophes, by colonization, by economics, by the depletion of regional resources that necessitated out-migrations, by cycles of prey movement, by the ebb and flow of weather patterns. Entire branches of the human tree have been broken off and flung to the winds, some being crushed in the process. Others have withered, while yet others have flourished and increased, pushing smaller demes toward lands with marginal resources.

The reconstruction of the human tree has already commenced. A body of journal articles, books, and computer programs under the general rubric of “genes, people and languages,” provides an entrée to the literature that documents this ongoing task (Cavalli-Sforza & Cavalli-Sforza, 1995; Layrissé & Wilbert, 1999).

DISTRIBUTIONS OF GENETIC DISEASES

Genetic diseases currently fall into three epidemiological groups: (1) familial, (2) transmissible, and (3) sporadic.

Simple cases of familial genetic disease exhibit classic Mendelian patterns of disease with uniform, unambiguous phenotypic presentations. These are cases with a “family history,” even if generations are skipped, or even if affected persons receive the condition through progenitors of the opposite sex. *Tay–Sachs disease* and familial *Down syndrome* are examples of familial conditions. More complex genetic diseases are now known to exist, as well. These are cases where “non-Mendelian” mechanisms such as *anticipation*, *genomic imprinting*, or *mitochondrial inheritance*, are a major factor (see Genetic Disease I). In either case, familial genetic diseases exhibit genealogical clustering: there is often a clinical propositus or proposita, and other family members with the condition are thereby discovered.

Transmissible cases of genetic disease are more ambiguous but usually manifest as a well-defined clinical entity, such as in the *prion diseases*. In some cases there may be no known family history. The criterion that distinguishes this group from the others is that those affected have a clear gene-based potential for disease acquisition, but an environmental co-factor is required to precipitate the condition. One of the difficulties of diagnosis inherent in these conditions is that, because both a common predisposing genotype and an environmental co-factor are involved, some diagnosticians will be disposed to emphasize either one or the other—the condition will be perceived arbitrarily as either genetic (nature) or environmental (nurture)—rather than as co-factorial. Both *Kuru* and *new variant Creutzfeldt–Jakob disease* can now be viewed as clear members of this category (see Genetic Disease I). Transmissible genetic diseases exhibit spatial clustering. Because the environmental agent will appear to have a point of origin, and will appear to have spread outward from that point, such cases usually will appear at first glance to be epidemiological in nature. Affected individuals may be the first in their family, in recent memory, to acquire the condition. Only upon close examination of DNA will it become clear that affected individuals also have in common a predisposing genotype, and without that genotype others are—even upon exposure or

infection—"immune" to the condition, or experience a milder form, or display a delayed onset, etc.

Sporadic cases of genetic disease exhibit neither familial nor spatial clustering. These cases are neither widely diffused nor epidemic, occur only occasionally, and appear not to be directly inherited. *Sporadic Creutzfeldt–Jakob disease* will serve as an example. These sporadic cases are entertained as "genetic" only because of a consistent clinical presentation that cannot be excluded from other such cases with a known pattern of inheritance. Some of these may be true phenocopies. This is a difficult but intriguing group, and may have in common some of the same non-Mendelian mechanisms such as *anticipation* discussed under the familial category, above.

Eventually, worldwide distributions of genetic diseases will be described in terms of regional geography in much the same way that the classic non-morbid gene systems (*ABO*, *PTC*, etc.) and certain portions of DNA have already been analyzed (Cann, 2001; Cavalli-Sforza, Menozzi, & Piazza, 1994). However, genetic epidemiology is yet in its infancy, and comprehensive tables of morbid distributions have yet to be developed beyond those for blood groups where maternal–fetal incompatibility is an issue (e.g., *Rhesus isoimmunization*, the *Diego antigen*), and for the hemoglobinopathies (*SCD* and the *thalassemias*).

This survey is necessarily limited in scope; selections were made after consideration of historical significance, prevalence,⁶ and representation of etiologies. Many of the more common conditions that are known to have a genetic component are not included.⁷ In consideration of the interests of medical anthropologists, certain conditions relating to malabsorption and diarrhea have been over-represented; causes of cancer and degenerative conditions are under-represented.

Existing prevalence or incidence information for populations is sketchy; a portion of the extant data is summarized in Table 1, which consists of four columns.

Column one contains the name of the trait and its acronym (e.g., Achondroplasia, ACH), its assigned McKusick *OMIM* number(s) (e.g., 100800), mode of inheritance (e.g., AD), and mapped chromosomal location of the implicated gene or region (e.g., 4p16.3). A hyphen (-) in column one indicates that a datum is missing or unknown. Abbreviations used include AD for autosomal dominant, AR for autosomal recessive, AC for autosomal codominant (or incomplete dominance), XR

for X-linked recessive, XD for X-linked dominant, YL for Y-linked, MF for multifactorial, MCA for major chromosomal anomaly, and Unk for mode of inheritance unknown. A chromosomal location, such as 4p16.3, indicates that the trait has been mapped to the shorter p arm (the longer arm is the q arm) of chromosome pair 4, to or including Q-band 16.3. Sometimes a mapped range is given, such as q16.3–q16.6. See the reference list on page 453 for the URL of *OMIM*, where further details concerning standard nomenclature can be located.

Column two contains a brief list of presenting symptoms, onset and course of the disease, and prognosis, as well as facts about the cause of the condition, its known or suspected molecular etiology, mutation rate, and relationship, if any, to similar conditions.

Column three contains, where known, incidence, prevalence, and/or allele frequency data, and geographic regions or populations characteristically affected by the condition. Incidence refers to the frequency of new cases of a genetic condition in a specific population per unit of time. Prevalence refers to the frequency of a genetic condition at a particular time in the general population.

Column four provides an entrée to the current literature for each condition, usually selected either as a recent journal article(s) not posted in *OMIM*, or as a book or monograph that, as a rule, would not be posted in *OMIM*.

Table entries are excerpted from the forthcoming *Dictionary of Human Biology and Evolution* (Mai et al., 2004), and are published here with the permission of Cambridge University Press.

Table 1. Human Genetic Disease Synopsis A—A Selection of 150 Syndromes or Disease-Related Entities with a Known or Highly Probable Genetic Etiology

Trait	Description	Regional variation	Ref.
45,X0 syndrome	See Turner syndrome .		
45,Y0	Aneuploidy that is incompatible with full term development.		
46,XX male syndrome	See XX male syndrome .		
46,XY female syndrome	See XY female syndrome .		
47,X ₁ ,13+ syndrome	See Patau syndrome .		
47,X ₁ ,18+ syndrome	See Edward syndrome .		
47,X ₁ ,21+ syndrome	See Down syndrome .		
47,XXX syndrome	See Triplo-X syndrome .		
47,XXY syndrome	See Klinefelter syndrome .		
47,XXY syndrome	See Double-Y syndrome .		
Achondroplasia (ACH; 100800, AD, 4p16.3)	Dwarfism is one of the oldest known familial conditions, although an exact understanding of its etiology is recent. There are several types of dwarfism. ACH is a congenital, hereditary form of dwarfism that results from a failure of cartilage to be converted into bone in the epiphyseal disks. ACH affects mainly the long bones by causing rhizomelic shortening, but may also cause trident hand, frontal bossing, and mid-face hypoplasia; the cranial base may distend, causing the cranium to become enlarged (megalencephaly). The defective gene is fibroblast growth factor receptor-3 (FGFR3), normally expressed in the chondrocytes of developing bones. Mating between affected individuals who are heterozygotes (aa × aa) produce 25% homozygous normal children (aa). The homozygous AA genotype is usually lethal; (AKA short-limbed dwarfism, nanism). A slightly rarer form, thanatophoric dwarfism, causes neonatal death. Pygmies have another condition known as human growth hormone resistance. See HGH-resistant dwarfism and pituitary dwarfism .	ACH usually is sporadic with a directly measured mutation rate of 50–60 × 10 ⁻⁶ , incidence is estimated at 1:4,000 (Lebanon) to 1:10,000 births (Australia). Almost 90% of cases are due to de novo mutations; affected individuals have lowered fitness. Because ACH shows clear indications of a paternal age effect after age 35, the condition tends to cluster demographically in populations with greater life expectancies.	001
Achromatopsia Acromegaly (10220, AD,-)	See Color blindness . A form of gigantism often confused with several similar disorders of which acromegaly is a feature; it is genetically heterogeneous. Familial acromegaly is characterized by continued growth after a normal adolescent growth spurt resulting in coarseness of features, and is due to overproduction of human growth hormone (hGH) secondary in the majority of cases to an hGH-secreting pituitary adenoma. Onset is in the third or fourth decade (mean age of presentation is 44), and sexes are affected equally (AKA familial somatotrophinoma). In gigantism proper, proportional overgrowth of all body tissues	Rare but informative: population prevalence of 0.6:10,000 and an annual incidence of 0.03:10,000.	002

Table 1. (Contd.)

Trait	Description	Regional variation	Ref.
<p>Adenomatous polyposis of the colon, familial (FAP); 175100,AD, 5q21–q22)</p>	<p>commences at or even before the adolescent growth spurt, and annual growth can be as much as 6 in. per year. Gigantism is sporadic, and often due to a pituitary tumor that not only increases the volume of hormones, but compresses the optic nerve and other adjacent tissues.</p> <p>One of the two most common forms of hereditary colorectal cancer. FAP is found in adolescents who present with abdominal pain, diarrhea, and rectal bleeding. An extensive carpet of precancerous growths (desmoid tumors) in the lining of the large intestine, usually the colon, progresses to colorectal cancer (CRC, 114500). Penetrance is complete, but expression is variable. The mutant gene is adenomatous polyposis coli (APC); about 740 different mutations in this gene have been identified, split evenly among germline and somatic mutations. Simultaneous loss of heterozygosity (1/3) or mutation (1/3) to the p53 tumor suppressor gene occurs in about 2/3 of cases. Treatment with cyclooxigenase-2 inhibitors has been successful.</p> <p>There is some evidence for a paternal age effect. AKA familial polyposis of the colon (FPC). Polyps can also develop in other tissues. Radiopaque osteomata occur in 95% of cases; multiple impacted teeth and external polyps sometimes present as Gardner's syndrome. Juvenile polyposis syndrome (JPS; 174900, AD, 18q, 10q) is a different condition, involving the SMAD4/DPC4 and PTEN genes. Cf., colon cancer, hereditary nonpolyposis.</p>	<p>Prevalence is 0.2:10,000 in northern England; incidence worldwide is 1:13,500 births. Among Ashkenazim, 1:17 are carriers of some common alleles. The mutation rate in somatic cells is $2-3 \times 10^{-6}$.</p>	003
<p>Adenosine deaminase deficiency (ADA; 102700, AD, 20q13.11)</p>	<p>One of the primary immunodeficiency diseases (PIDs) characterized by skeletal and neurological abnormalities; frequent infections, fatal if untreated. Death usually occurs by the age of 7 months due to infection. Toxicity to lymphocytes results in severely impaired immunity; accounts for about 15% of all severe combined immune deficiency (SCID) cases. Mutations in the ADA gene result in a dysfunctional ADA enzyme that impairs purine processing and results in a deficient immune system: there are no T-cells, and B-cells do not produce antibodies. Cf., agammaglobulinemia. An ADA-deficient-SCID girl was selected as the first person with a genetic disorder to be treated by somatic gene therapy, using a viral vector, in September 1990.</p>	<p>Rare; informative, historically significant; between 100 and 700 PID cases per country in Europe and the United States.</p>	004
<p>Adrenoleukodystrophy, X-linked (ALD, 300100, XR, Xq28)</p>	<p>ALD is characterized by dementia, seizures, paralysis, loss of speech, deafness, blindness; neonatal death is usual, and inevitable by age 3. Variable symptoms: the X-linked</p>	<p>Rare, 1:100,000.</p>	005

form is less severe than the AR form (neonatal, 202370). Defect is in the ALD membrane transport protein, a peroxisomal enzyme; adrenal insufficiency causes an excess of long-chain fatty acids. The condition is associated with HLA DR3, relative risk 6.3× (AKA Addison disease). Featured (although incorrectly) in the popular film *Lorenzo's Oil* (1992).

See **Polycystic kidney disease, adult**.

Adult polycystic kidney disease

Agammaglobulinemia, Bruton type (300300, XR, Xq21.3–q22)

One of the heritable primary immunodeficiency diseases (PIDs) characterized by lack of mature B-cells associated with immunoglobulin (Ig) heavy chain rearrangements. Affected individuals cannot synthesize certain antibodies. Defect is caused by mutations in the Bruton-type tyrosine kinase gene (BTK), an essential regulator in B-cell development (AKA agammaglobulinemia, X-linked, XLA). An AD form also exists (186973, AD, 5q32). Cf., **ADA deficiency** and **severe combined immunodeficiency disease**.

Rare; between 100 and 700 PID cases per country in Europe and the United States. 006

Albinism, ocular, type I, X-linked (OA1; 300500, XR, Xp22.2)

The term albinism refers to any one of several inherited conditions in animals and plants. In humans, albinism is usually caused by an autosomal recessive allele that blocks a step in the production of the pigment melanin by failure to produce an enzyme essential to the process; associated with a lack of pigment in the skin, hair, eyes and/or other tissues (amelanic melanocytes). In X-linked OA1, only the eyes lack pigmentation; females more severely affected than males. A second form of X-linked OA also exists (OA2, 300600, XR, Xp11.4–p11.23). See **OCA**, below, and **Hermansky–Pudlak syndrome**.

Rare; incidence is about 1:60,000. 007

Albinism, type I, oculocutaneous, tyrosinase negative (OCA1; 203100, AR, 11q14–q21)

Absence of the pigment, melanin. In OCA1 (complete or “classic albinism”) absence of melanin affects the eyes, hair, skin, and hearing. Affected individuals also lack stereoscopic vision as a result of misrouting of optic nerve fibers in the brain; they are often also cross-eyed and blind. OCA1 is a condition that affects melanin synthesis. The impaired protein in OCA1 is tyrosinase, an enzyme that normally reduces the amino acid tyrosine into DOPA or DOPA into dopaquinone; melanocytes thus lack melanin pigments. More than 60 causal mutations in tyrosinase have been identified; it is therefore a heterogeneous condition. Most OCA1 individuals are compound heterozygotes; AKA tyrosinase-negative albinism. There are about a dozen other forms of albinism.

Affects at least 1:20,000 children worldwide (regardless of parental “skin color”), but OCA1 is about four times more common among the Irish than among Canadians. 008

Table 1. (Contd.)

Trait	Description	Regional variation	Ref.
<p>Albinism, type II, oculocutaneous, tyrosinase positive (OCA2; 203200, AR, 15q11.2-q12)</p>	<p>Absence of the pigment, melanin. In OCA2, functional tyrosinase is present; two phenotypes occur, those with and those without freckles. Sequelae include skin cancer and gross visual impairment. Some pigment is present at birth but lost during childhood. Cause is a deletion in the P protein, which encodes a melanosomal membrane protein. Matings between OCA1 and OCA2 individuals produce double heterozygotes that are unaffected (AKA P-gene related OCA2, tyrosinase-positive albinism).</p>	<p>OCA2 is the most common form of albinism. In Nigerian Ibos, the frequency of OCA2 is about 1:1,100; half of all Ibos with OCA2 develop skin cancer by the age of 26 and die by age 40. The frequency of OCA2 among the Bantu in South Africa is about 1:4,000. Worldwide the frequency is 1:36,000. The deletion in the P protein apparently rose only once about 2–3 millennia ago, before these groups diverged. A variant of OCA2 is also prevalent among Native American tribes in the southwest: about 1:200 for the Zuni, Hopi, Tele Cuna, and Jemez. OCA2 is also the form also found in the Brandywine "triracial" isolate. Prevalence of OCA2 in the United States as a whole is about 1:36,000, but is the most common form of albinism among African Americans (1:10,000).</p>	009
<p>Albinism, type III, oculocutaneous, tyrosinase positive (OCA3; 203290, AR, 9p23)</p>	<p>Absence of the pigment, melanin. In OCA3, functional tyrosinase is present; affected individuals are less sensitive to sunlight than OCA1 or OCA2. Freckled skin and reddish hair may be present. Defect seems to be a nonsense mutation in tyrosine hydroxylase that reduces but does not entirely eliminate enzyme activity.</p>	<p>Rare; found in low frequencies in Nigeria and Puerto Rico.</p>	010
<p>Alkaptonuria (203500, AR, 3q21-q23)</p>	<p>Defects in the enzyme (homogentisic acid oxidase, HGO) that normally breaks down homogentisic acid (alkapton) results in the relatively benign excretion of high levels of that acid, which causes urine to turn black upon exposure to air, especially when allowed to stand; black pigmentation of cartilage and collagenous tissues is also a feature. Most people with alkaptonuria also develop arthritis. This trait was the first trait ever discovered to be the result of a <i>metabolic block</i> (among others, such as albinism).</p>	<p>Unusually frequent in the Czech Republic, the Dominican Republic, and Germany, very rare elsewhere.</p>	011
<p>Alzheimer's disease, early onset, familial (AD; 104300, 104311, 600759, 605055; AD, 14q24.3, 1q, 3, 19, 21)</p>	<p>"Presenile Dementia," so-called by Alois Alzheimer in 1907 when he described a disability characterized by memory loss that affected the middle-aged and elderly. Manifests in the fifth or later decades of life. Only 5–10% of Alzheimer's</p>	<p>AD is twice as common in women than in men, and is the fourth leading cause of death in American adults.</p>	012

cases are inherited. Brain tissue contains unusual amounts of two gummy proteins, the beta- and tau-amyloids. Intraneuronal tangles of neurofibrils are also a feature. One early-onset variant in the PSI (= AD3) gene has been mapped to chromosome 14, and is responsible for about 80% of all familial, early-onset cases. Other variants associated with the disease (AD1, AD2, ..., etc.) have been mapped to HSA 1, 3, 19, and 21. There seem to be several modalities by which converging symptoms can be precipitated. Cf., **Parkinson disease**.

Compromised sexual development due to a variety of causes both environmental and genetic. AKA syndromes of abnormal sex differentiation. Among the approximately 40 genetic conditions that have ambiguous genitalia as a major feature are partial and/or complete **androgen insensitivity syndrome**, **adrenal hyperplasia** (several varieties), **male and/or female pseudohermaphroditism**, and **true hermaphroditism**.

013

Conservative estimates (e.g., Johns Hopkins) place the incidence of ambiguous genitalia in live-born children at 1:2,000; other estimates due to all causes approach 1:100 worldwide (UCLA), higher than Down syndrome and cystic fibrosis combined. Fausto-Sterling (2000) estimates the frequency (with disclaimers) at between 1% and 2% of all live births.

Amyotrophic lateral sclerosis, familial (FALS or ALS; 105400, AD, 21q12.2-q22.1)

Neurological condition characterized by an asymmetrical, progressive deterioration of cells in the brain stem and spinal cord; paralysis and death are inevitable. Manifests in the fifth decade of life. The defective gene is SOD1, which codes for superoxide dismutase, an antioxidant enzyme that converts cellular superoxide "free radicals" to nontoxic chemicals (AKA Lou Gehrig's disease).

014

Rare, reported incidence averages 2:100,000.

Androgen insensitivity syndrome (AIS; 300068, XR, Xq11-q12)

A developmental anomaly in which a chromosomal XY male embryo with testicular tissue does not respond to male hormones (both testosterone and DHT are present) and the individual thus appears phenotypically female. Testes are undescended, and spermatogenesis is absent. AIS is caused by mutations (microdeletions; CAG and CG repeats) in the X-linked gene for the androgen receptor (AR, 313700). There are two clinical classes: complete (CAIS) and partial (PAIS). CAIS individuals possess what some have described since 1958 as the "supermodel" phenotype: affected individuals are tall, highly symmetrical, and phenotypically "attractive" females with well-developed breasts, little pubic hair ("hairless pseudofemale"), and lack menstruation (due to a blind vagina). AKA testicular feminization (TF), androgen resistance syndrome, Lutbs syndrome.

015

The most common form of **male pseudohermaphroditism**.

Incidence estimates range from 1:10,000 to 1:12,500 XY births. The frequency of the CAG repeat mode of mutation is lowest in African Americans, intermediate in non-Hispanic whites, and highest in Asians. AIS is about 1.5 times more common than **male pseudohermaphroditism with syncromastia**.

Table 1. (Contd.)

Trait	Description	Regional variation	Ref.
Angelman syndrome (AS); 105830, AD, 15q11-q13)	Uncommon heterogeneous condition characterized by seizures, mental impairment and growth retardation, protruding tongue, floppy muscle tone, large jaw, an inability to talk, and excessive and inappropriate laughter. Exhibits evidence for genomic imprinting; AS is caused by a small deletion in chromosome 15, inherited maternally. The ubiquitin ligase gene (UBE3A) has been implicated. AKA "happy puppet" syndrome, Prader-Willi/Angelman syndrome .	Rare (< 1:100,000); highly informative.	016
Anosmia (254150, AR, -)	The inability to detect by smell certain musk-like sexual odors; a polymorphism which may be caused by deletions due to unequal crossing-over; There are several modes of anosmia; AKA smell blindness.	Affects 7% of individuals of European ancestry, 0% of African ancestry.	017
Asthma (600807, AD, - 5q31 q33)	Disorder of airways and lungs characterized by reversible inflammatory obstruction, breathing difficulties, wheezing, and hypersensitivity. A potential susceptibility region has been identified: cytokine genes on HSA 5 are known to regulate IgE production resulting in various severities of allergic diseases. An interaction between another one of many candidate genes, CD14, and an environmental agent, endotoxin, is also suspected. Yet another candidate gene on HSA 11q13, the high affinity IgE beta (2)-adrenergic receptor (beta(2)AR) gene, is strongly linked to maternal smoking during pregnancy. The interleukin-4 gene has also been studied. The CCRS locus also apparently attenuates the severity of asthma. The trait also exhibits evidence for genomic imprinting. Asthma is an atopic condition, possibly with incomplete penetrance, and is clearly a multifactorial disorder.	Asthma affects 5–15% of children: African and Asian countries have a low prevalence of about 5–10%; Australia, New Zealand and Urban Venezuelans have the highest prevalences in the world (15–25%). Males are affected more often than females in many studies. The incidence of asthma has reportedly increased steadily since the 1980s. It has been suggested that asthma is found most frequently in individuals with hyper-responsive IgE due to an indigenous parasite load, and who then remove to regions where parasite load is low.	018
Ataxia telangiectasia (A-T1); 208900, AR, 11q22.3)	Condition characterized by poor muscle coordination, involuntary eye movements, capillary dilation in eyes and skin; sensitivity to light (radiosensitivity), immune defects, and susceptibility to infections and cancer (9× normal controls); chromosome breakage is a feature. Onset in the first decade of life. AT is a heterogeneous condition with at least 2 distinct subtypes. The causal agent is believed to be a gene (ATM) involved with DNA processing and repair; ATM functions normally to signal several cellular responses to DNA damage. Several hundred SNP mutants have been reported. AKA Louis-Barr syndrome.	Rare: 1:100,000 births, but important because of the molecular mechanisms it reveals. Carrier frequency about 2.8:100.	019

Autistic disorder (209850, AR, 7q)

A pervasive developmental disorder (PDD) features impairment of reciprocal social interaction and communication, ritualized patterns of behaviors and interests; onset from infancy to age 3. Risk in an affected sibship is 75× that of normal controls. AKA Autism spectral disorder.

Population prevalence is 4:10,000, slightly higher in Iceland (4–9:10,000). 020

Bipolar affective disorder

See **Major affective disorder**.

Bloom syndrome (BLM); 210900, AR, 15q26.1)

Pre- and post-natal growth deficiency results in dwarfism, sun sensitivity results in skin rashes, dilated capillaries, impaired immunity, increased risk for cancer; chromosomal instability. Death before age 50; usually much sooner. A DNA excision–repair disorder in which a DNA ligase gene is defective and slows DNA replication. Exhibits evidence for somatic recombination.

Found in high frequency among Ashkenazi Jews. Rare elsewhere, but informative regarding DNA repair mechanisms. 021

Bombay phenotype (211100, AR, 19q13.3)

Normal individuals have certain combinations of antibodies complementary to their ABO blood group phenotype; rarely, some also have the anti-A + anti-B + anti-H constellation. The latter is an antibody to the H antigen, a short precursor carbohydrate chain that is characteristic of blood type O individuals, and to which is appended an additional sugar (different for each blood type) in types A and B. This short chain of sugars is synthesized by enzymes (FUT1 and FUT2); mutations to the first of these, alpha-L-fucosyltransferase (FUT1, H transferase) aborts the sugar-appending process and results in an individual that is neither type A nor B nor O, and who then synthesizes anti-H since they lack the H antigen. The “downstream” Lewis antigen and secretor (FUT2, Se locus) phenotypes are also affected.

Exceedingly rare, but highly informative; fewer than 50 known pedigrees worldwide, many on Reunion Island off India, from which emigrants had been found in Bombay in 1952. Europeans with the phenotype have a different mutation in the FUT1 enzyme. 022

Breast cancer, familial, type I (BRCA1); 113705, AD, 17q21.2)

Tumors in female breast tissue; rare but known in males. Onset usually in the fourth decade. The most common form of cancer among American women, with about 44,000 female (vs. 300 male) deaths annually. The chance of contracting BC are about 13% overall; only about 5–10% of all breast cancer cases are familial, but the penetrance is high—between 80% and 90% with the gene are at high risk. It took the principal researcher (Mary Claire King) and her team 183 tries to locate the chromosomal region containing the gene; the BRCA1 gene (113705) has been mapped to chromosome 17q21.2, and is suspected to be a transcription factor gene. In the subsequent 5 years, at least three more related genes have also been mapped. Breast cancer gene 2 (BRCA2; 600185, -, 13q12) was mapped in 1994. BRCA3 (600048, -, 11q) and BRCA4 (605365, -, 13q21) soon followed. One of the features of

Specific mutations in the BRCA1 gene are about 10 times more frequent in the Ashkenazim (1:50) than in other human populations (1:800). Another mutation in the BRCA2 gene is specific to Iceland. Although males account for only about 1 of every 150 cases of breast cancer, they can pass on susceptibility mutations to their daughters. 023

Table 1. (Contd.)

Trait	Description	Regional variation	Ref.
<p>Burkitt lymphoma (BL); 113970, 151410; AD, 8q24.2–q24.13)</p>	<p>these cancers is a characteristic loss of heterozygosity (LOH) in chromosomal regions contiguous with the affected gene. The possession of a BRCA1 gene (but not BRCA2) also increases the probability that a female will develop ovarian/cervical cancer during her lifetime. These BRCA genes normally function to repair radiation-induced breaks in double-stranded DNA. In some breast sarcomas, tumor-generated MDM-2 proteins inhibit the effects of the p53 gene, permitting additional tumor growth.</p> <p>Endemic BL is a malignant form of lymphatic cancer that develops in the jaws and face bones of children, found predominantly in central and subequatorial Africa in the same regions as endemic malaria. In Africa, the tumors are associated with infection by the mosquito-borne Epstein–Barr virus (EBV, a form of herpes virus), which causes chromosome translocations that involve the c-myc proto-oncogene normally located on chromosome 8. No EBV has been detected in European or American BL patients. The most common translocation is t(8;14). The Myc gene normally functions to control cell growth and proliferation, but at its new position next to a highly expressed antibody gene on chromosome 14, this function of Myc is altered and it is over-expressed, becoming an oncogene. Other EBV-precipitated cancers include nasopharyngeal carcinoma and Hodgkin’s disease. Cf., the Philadelphia chromosome.</p>	<p>Predominately affects children in Central Africa.</p>	<p>024</p>
<p>CFTR protein</p>	<p>See Cystic fibrosis.</p>	<p>CMT is the most common inherited peripheral neuropathy, and found worldwide. Incidence has been estimated at 1; 2,500; 20% of all cases are due to new mutations.</p>	<p>025</p>
<p>Charcot–Marie–Tooth disease 1A (CMT1; 118200, 118220; AD, 17p11.2)</p>	<p>Set of related conditions characterized by progressive loss of feeling in arms and legs, progressive limb atrophy; CMT is caused by mutations in the peripheral myelin protein 22 (PMP22). CMT is heterogeneous; there is also an AR and an X-linked form (CMTD2), each of which has several types and subtypes. CMT is associated with a similar condition, Dejerine Sottas syndrome (DSS).</p>	<p>Δ32 heterozygosity has been estimated at 20%, and homozygosity at 1% in Europeans, yielding an estimated allele frequency of 11%. A N–S European cline has been suggested, with frequencies as high as 16% in Finland and 4% in Sardinia. The Δ32</p>	<p>026</p>
<p>Chemokine (C-C) receptor 5 (CCR5; 601373, -, 3p21)</p>	<p>The CCR5 receptor has been identified as a coreceptor for the human immunodeficiency virus-1 (HIV-1). The other major coreceptor is CD4. The coreceptors are found on the plasma membrane of CD4+ T cells. The gene that codes for the CCR5 protein is CMKBR5. A 32-base pair deletion (designated Δ32) in the CMKBR5 gene results in a frameshift and premature termination of mRNA translation. The resulting product cannot be utilized by the HIV-1, and</p>		

is at least partly responsible for certain long-term survivorship in HIV-1-exposed individuals. Almost 20 mutations in the CCR5 receptor, including $\Delta 32$, confer immunity or variable resistance to HIV-1 penetration of CD4+ T cells, with homozygotes being at an advantage relative to heterozygotes. Although the $\Delta 32$ polymorphism is the best characterized, multiple non-functional CCR5 alleles exist in various human populations. The CCR5 locus also attenuates the severity of rheumatoid arthritis infection.

See individual anomalies: 22q11 deletion syndrome, **Cri-du-chat syndrome**, Deletion, Dicentric Y syndrome, **Down syndrome**, Duplication, **Double Y syndrome**, **Edward syndrome**, Isochromosome, **Klinefelter syndrome**, Monosomy 21, **Mosaicism**, Paracentric inversion, **Patau syndrome**, Pericentric inversion, **Philadelphia chromosome**, Polyploidy, Translocation (reciprocal), Translocation (Robertsonian), Triploidy, **Triplo-X syndrome**, Trisomy 22.

Inherited disorder characterized by short stature, sensitivity to light, and the appearance of premature aging in type I, onset is after one year, progressive; type II is congenital. Either of two genes are mutated, CSA or CSB; also involves excision-repair cross-complementation group 8 (ERCC8). Mutations compromise normal transcription-coupled repair during DNA replication.

Hereditary colon cancer is caused by mutations that occur in DNA repair genes. There are two major varieties, type I and type II. In type I colorectal cancer, the affected gene is *MLN1* (AKA familial colon cancer, type I, FCC1). Type II (HNPCC2; 114500, AD, 2p, 3p21.3; 7, 8, 10, 14, 15, 17) is caused by multiple mutations in genes such as MSH2, MSH6, and MLH1; but defects at up to 13 loci have been documented. Loss of heterozygosity is a feature at these loci. AKA colorectal cancer (CRC); familial colon cancer type 2 (FCC2).

In humans, trichromatic color vision is the normal state in about 90% of all people. Partial color blindness is the hereditary inability to distinguish one or more colors in one's environment, independent of the ability to distinguish light, shape, and form. Either red or green color blindness is the most common form of partial color blindness; both are rare, and due to an interaction of recessive allele(s) at two loci (deutan, 303800; and protan, 303900), both loci are on the X(q28) chromosome, mutations produce quantitatively-defective opsins in the retina of the eye. A red-blind

mutation has frequencies of 1–5% in the Middle East and India; it appears to be absent in Africans, Native Americans, East Asians, and Tamil Indians. This distribution has led to speculation that it was founded in Scandinavia and was spread southward by Vikings in the 8th–10th centuries.

See individual listings.

Rare, but informative regarding DNA repair mechanisms.

Almost 100,000 cases of colon cancer are diagnosed annually in the United States; of these, almost half cause death.

About 8% of the male and 0.4% of the female U.S. population is affected. Roughly 75% of color blind males have a defect in green opsin, while 25% have a defect in red opsin. Achromatopsia is rare worldwide (0.5:10,000), but common among some Polynesian people, such as the Pingelapese (4–10%).

Chromosomal anomalies, major (MCA)

Cockayne syndrome type I (CKNI; 216400, AR, 5)

Colon cancer, hereditary nonpolyposis type I (HNPCC1, 120435, AD, 22p22–p21)

Color blindness (several types)

Table 1. (Contd.)

Trait	Description	Regional variation	Ref.
<p>Congenital adrenal hyperplasia (CAH, 201750, AR, 6p21.3)</p>	<p>individual has protanopia and cannot produce the pigment erythrolabe. A green-blind individual has deuteranopia and cannot produce the pigment chlorolabe. A blue-blind individual has tritanopia and cannot produce the pigment cyanolabe, and is a much more rare form, AKA blue opsin defect (tritan, 190900, AD, 7q). Achromatopsia, the inability to discriminate among all colors of the rainbow (complete color blindness) is sometimes found combined with other conditions such as myopia and cataracts.</p> <p>Any one of half a dozen enzyme deficiencies that causes male sex hormones to accumulate abnormally in tissues. In 90% of cases, the deficient enzyme is 21-hydroxylase; the result is a highly polymorphic system with multiple alleles and four genotypic combinations. (1) In the salt-wasting form, shock/death occurs within a few weeks of birth. (2) Early onset 46,XX congenital virilizing adrenal hyperplasia (CVAH) is a simple masculinizing form in which females have normal internal reproductive organs but enlarged clitorises, and males have enlarged penises and experience precocious puberty. (3) In the more common late-onset form, profound masculinization of females occurs at puberty. (4) In the cryptic form, there are no phenotypic symptoms but enzyme and hormone levels are elevated. Enlarged adrenal glands is a feature in all cases. Certain HLA haplotypes predispose individuals to this condition: that is, B47, increases the relative risk by 15×.</p>	<p>Frequency estimates range from 1:5,000 to 1:12,500 worldwide. Fausto-Sterling (2000) gives the frequency of late-onset CAH as 1:67. Highest frequencies are among Ashkenazi populations (1:30). Frequent in Yupik Eskimos (1:282) and Italian populations (1:300), very rare in New Zealand (1:200,000).</p>	031
<p>Creutzfeldt–Jakob syndrome (CJD; 123400, AD, 20pter-p12)</p>	<p>In humans, a slow but fatal heritable degenerative disease of brain tissue caused by two simultaneous conditions: a mutation from aspartic acid to asparagine at position 178 in the prion protein, and homozygosity at position 129. A related heritable condition, familial fatal insomnia (FFI), like CJD, is caused by valine homozygosity at position 129. The transmissible form is new variant, nvCJD.</p>	<p>Worldwide frequency of CJD is low (1:1,000,000), but highest in Jewish populations expelled from Spain in 1492 and found today in Spain, Italy, Libya, Tunisia, and Chile. It is estimated that 1:10,000 is infected with nvCJD at the time of death.</p>	032
<p>Cri-du-chat syndrome (123450, MCA, 5del)</p>	<p>Congenital syndrome marked by profound physical deformity (low set ears, facial disproportion, microcephaly, wide-set eyes), profound mental retardation, and a shrill vocalization in infancy that sounds like a cat's cry. Cause is a deletion in HSA chromosome 5. Most affected individuals are aborted spontaneously or die in the first year of life, but some live into adulthood (AKA cat's cry syndrome, 5p-syndrome).</p>	<p>Rare: < 1:20,000 live births; 15% are familial cases.</p>	033

Crohn disease

Cystic fibrosis (CF; 219700, AR, 7q31.2)

See **Inflammatory bowel disease**.

Heritable exocrine disease caused by an autosomal recessive allele, one of the ion channel diseases. Clinical indications include a chronic buildup of mucus in the respiratory tract, a mucus-clogged pancreas, lung infections, very salty sweat, slow growth, and "failure to thrive."⁷ CF is characterized by malfunction of the pancreas and other glands, and the production of abnormal secretions of glycoprotein, a sticky mucus, particularly in the respiratory tract (provides a medium in which infections can occur that overwhelm the immune system), and results in misshapen secretory channels in selected alveolar cells that trap chloride salts inside the cells and thicken secretions outside. The ultimate effect is a decreased life expectancy. Any of tens of known mutations (the most common is a 3-bp deletion, ΔF-508) which result in an abnormal protein called the cystic fibrosis transmembrane-conductance regulator (CFTR). Affected individuals are homozygous (ff); males are sterile. The genotype of carriers is Ff. Heterozygote advantage has been proposed in the presence of cholera typhoid fever, and/or infant diarrhea. Because of its high prevalence in North America, biotechnology companies have targeted the gene as a likely candidate for profitable gene therapy. There are CF homologues in other species. AKA mucoviscidosis, cystic fibrosis transport regulator.

Deafness, neurosensory 1
(nonsyndromic, 220290, AR, 13q11-q12)

Deafness is impairment of the sense of hearing, either congenitally or through post-natal loss; the term can refer to either partial or complete deafness. Although over 70 genes are known to cause congenital hearing loss, in the most common mode, hearing loss is due to mutations in the gap junction protein connexin 26 (C × 26). Inherited deafness is hearing loss that is genetic in origin, which is about half of all cases; two major forms of inherited deafness are recognized: syndromic deafness and non-syndromic deafness. Non-syndromic deafness is a genetic defect in a single gene that causes multiple medical problems, only one of which is deafness; for example, **Waardenburg syndrome**; 70% of cases of inherited deafness are non-syndromic (i.e., 35% of all cases). Syndromic deafness is a genetic defect in a single gene that causes a single medical problem, deafness; for example, **Pendred syndrome**; 30% of cases of inherited deafness are non-syndromic (i.e., 15% of all cases). AKA hereditary hearing loss.

034

The estimated frequency of this recessive allele (f) in several studies ranges from 0.016 to 0.042. CF affects somewhere between 1:500 and 1:3,500 live births to American parents of European ancestry, and is the most common fatal genetic disease in those populations; as many as 1:25 may be carriers of an impaired CF allele. CF is rare among Hispanics (1:8,500), Asian Americans (1:31,000), and African Americans (1:15,000); similar low prevalence figures are found in continental Africa (1:17,000) and it is even rarer in Polynesia (1:90,000).

035

Common: 1:2-2.3:1,000 children have congenital hearing impairment; about half are genetic in origin, that is, about 12 million people worldwide have genetic-based hearing loss.

Table 1. (Contd.)

Trait	Description	Regional variation	Ref.
<p>Depression, unipolar</p> <p>Diabetes insipidus, nephrogenic, type 1 (NDI1, 304800, XR, Xq28)</p>	<p>See Major affective disorder.</p> <p>Genetic disease of the kidneys marked by great thirst and dehydration and that causes copious urination and defective urine concentration by alcohol dehydrogenase. Four known causes, all elements involving the vasopressin-regulated water transport pathway in the kidneys: the AD forms are due to mutations in the vasopressin precursor protein gene (AQP2, 12q13) or the vasopressin gene itself (AVP 20p13), while the more common XR (NDI1) form is due to mutations in the vasopressin receptor gene (AVPR2) (AKA non-saccharine diabetes, polydipsia).</p>	<p>Moderate frequencies found in diverse regional populations worldwide. Males are affected most often in the XR form.</p>	036
<p>Diabetes mellitus, type I (IDDM1; 222100, AD, AR, 6p21.3 (IDDM1), 7p15.3-p15.1 (GCK), 11p15.5 (IDDM2), 19)</p>	<p>Juvenile onset, insulin-dependent diabetes mellitus (IDDM) is an inherited condition characterized by abnormal sugar metabolism; a lack of the pancreatic hormone insulin results in chronic hyperglycemia and other metabolic anomalies and susceptibility to infections, and which often leads to a coma. In IDDM, the immune system attacks and kills beta cells in the pancreas that produce insulin; one of the autoimmune disorders. IDDM is treatable by substitution of functional insulin through recurrent injection (substitutional therapy); homologous porcine or bovine insulin was first prescribed in 1922, recombinant human insulin became available in the 1980s. IDDM accounts for 10–15% of all cases of DM. Affected individuals also tend to have specific HLA haplotypes: DR-3, DR-4, and DQ (15× risk for either, 30× if two or more are present). IDDM is a multifactorial disorder in which several genes are involved (as many as 11–16), including IDDM1 and IDDM2. Glucokinase (GCK) is involved in some variants. Also exhibits evidence for genomic imprinting and incomplete penetrance. AKA type I insulin dependent diabetes mellitus, insulin-dependent diabetes, childhood onset diabetes, juvenile onset diabetes (JOD), ketosis prone diabetes, brittle diabetes.</p>	<p>About 2 million people are currently affected in the United States (incidence about 2:10,000). The highest known incidence of IDDM occurs in the Scandinavian countries; incidence in Finland is almost 2.9:10,000. Other countries: Puerto Rico (1.2:10,000), France (0.93:10,000).</p>	037
<p>Diabetes mellitus, type II (NIIDM; 125853, MF, 20q12-q13.1, 17q25, 13q34, 11p12-p11.2, 2q32, 2q24.1)</p>	<p>Non-insulin dependent diabetes mellitus is an abnormal, partially acquired condition characterized by the lack of an ability to utilize sugar, and by an excess secretion of sugar in the urine. Adult onset, 2nd–6th decades; penetrance is variable; polygenic, and at least three genes have been strongly implicated. Affected individuals usually are noticeably overweight and have the so-called metabolic syndrome: diabetes, insulin resistance, hypertension, and</p>	<p>About 16 million people are affected in the United States, about 5% of the population worldwide. Latin Americans and Navajo Native Americans have very high frequencies (12%), especially the Pima (50%). MODY is found in high frequency in the Oji-Cree</p>	038

<p>hypertriglyceridemia. In type II diabetes, insulin is present at near normal or even above normal levels, but the tissues do not respond optimally to it (insulin resistance). Less frequently, non-obese adolescents acquire type II DM in the form of maturity-onset diabetes of the young (MODY). “Generic” non-insulin dependent diabetes was first described about 100 CE; the aspect of a dysfunctional pancreas was identified in 1889. AKA insulin-independent diabetes, adult onset diabetes, non-insulin-dependent diabetes, maturity-onset diabetes (MOD), ketosis-resistant diabetes, stable diabetes.</p>	
<p>The Diego blood group antibodies, anti-Di(a) and anti-Di(b), are “familial” or “low incidence” antigens that can result in hemolytic disease of the newborn. The antigens were discovered in a South American family in 1953, and are mutational variants of the SLC4A1 gene (solute carrier family 4, anion exchange member 1).</p>	<p>populations of Canada. Neel’s original “thrifty genotype” hypothesis has recently been challenged by a “thrifty phenotype” hypothesis that invokes poor fetal and neonatal nutritional factors.</p>
<p>DiGeorge syndrome (DGS); 188400, AD, 22q11del</p>	<p>One of the useful so-called “Mongoloid” markers that track the emigration of peoples from the Mammoth Steppe between the Tibetan Plateau and Mongolia to modern destinations in India, New Guinea, Kamchatka, and the Americas as far south as Chile.</p>
<p>DiGeorge syndrome (DGS); 188400, AD, 22q11del</p>	<p>Type I DGS has a reported incidence of 1:4,000; type II is very rare, 1:200,000.</p>
<p>Disaccharide intolerance type I (222900, AR, 3q25–q26)</p>	<p>Sucrose intolerance exists in high frequency (10%) in Eskimos; about 0.2% worldwide.</p>
<p>Disaccharide intolerance type III (223100, AR, 2q21.3)</p>	<p>Because adult animals also lose the ability to digest lactose, and because of the worldwide prevalence in humans, lactose malabsorption and intolerance is considered the normal state for human adults. Lactase persistence,</p>

Table 1. (Contd.)

Trait	Description	Regional variation	Ref.
<p>Double-Y syndrome (-, MCA, XYY)</p>	<p>ingestion of milk products. Type III is the adult form, in which the enzyme functions only in youth, but is then lost in some populations, producing the persistence/nonpersistence polymorphism. Lactose is a disaccharide consisting of glucose and galactose. Human milk contains 7% lactose; other mammalian milks contain about 4%. Adult heterozygotes usually experience gas pain after consuming dairy products. This nonpersistence condition is polymorphic and found in high frequency among many human populations that did not domesticate cows or other domesticated mammals, and that have not maintained through natural selection a functional allele of the enzyme. Sometimes called adult lactase deficiency, when described in terms of the enzyme itself. Lactase deficiency may also be environmental, commonly induced by heavy parasitic infections (e.g., the protozoan <i>Giardia lamblia</i>) that cause damage to the small intestine. Other related conditions include disaccharide intolerance II AKA congenital lactase deficiency (223000, AR, 2q21), common in Finland.</p>	<p>found in few populations, is the rarer, derived form of the polymorphism, and generally characterizes pastoral populations in northern Europe, Arabia, and East Africa. Globally, there are four common haplotypes that account for most lactase persistence/nonpersistence polymorphisms: A (found in Europe and India), B (found in Europe), C (found in Europe and India), and U (found in Africa and absent in Indo-European populations). Diversity in African U-type haplotypes is consistent with the "Out of Africa" model of recent human dispersion.</p>	043
<p>Down syndrome (sporadic, trisomy 21 +; 109685; or familial (translocation type, t21;14)</p>	<p>Chromosome aneuploidy (2N = 47, XYY) in which the extra Y chromosome produces phenotypically tall males prone to acne, and that are alleged to possess extra copies of genes (a dosage effect) that putatively increase aggressive and criminal behavior; this hypothesis is incorrect. The controversial initial studies concerning behavior have never been satisfactorily replicated (AKA Jacob syndrome). Profound phenotype caused by three copies of all the genes on chromosome 21, a true dosage effect. Clinical features include short stature, a characteristically "pleasant" face caused by oblique eyelid openings and a pseudoepicanthic fold, palm creases, a wide and flat skull, Brushfield spots on the iris, a furrowed tongue, and neck and finger webbing. Down syndrome individuals are at an increased risk for Alzheimer's syndrome, respiratory infections, deafness, and leukemia. Few reach the age of 50 years of age. A major chromosome anomaly, an example of aneuploidy due in the majority of cases to nondisjunction of the maternal 21st chromatids during meiosis I, resulting in an ovum (gamete) with 24 rather than the normal 23 chromatids. When fused with the gamete from the opposite parent (usually a sperm with 23 chromatids), the zygote begins development with</p>	<p>Affects 1:1,000 males.</p> <p>In populations where amniocentesis is not routinely available, Down syndrome affects 1:650 live births. Where genetic counseling is available, incidence is about 1:1,000. Incidence increases dramatically as a function of maternal age such that 1:16 children born to mothers aged 49 and older have trisomy-21.</p>	044

47 chromatids rather than the normal 46. Both males and females may be affected. An analog of Down syndrome has been observed in higher primates, where the cause is usually trisomy 22. Formerly called mongolism, but this term is now discouraged. Maternal nondisjunction is responsible for 90% of all cases, with the probability of de novo nondisjunction increasing dramatically after maternal age 35. Paternal origin is implicated in 5%. The translocation form is familial, and causes the other 5%, in which there is no parental age effect, and usually involves chromosomes 14 and 21; (t14;21 AKA familial Down syndrome); the balanced translocation can be hidden in a carrier and passed from generation to generation.

Duffy blood group (FY),
119799,AD, 1q21-q22)

FYO(a-b-) occurs with relatively high frequencies in Africa, in Yemenite Jews, in some Roma (gypsy) populations in the Czech Republic, in Caribs and African Americans, and in New Guinea where malaria is endemic.

045

The Duffy antigen is an erythrocyte membrane-bound glycoprotein (GPD) that has two major antigenic determinants defined by their anti-Fy(a) and anti-Fy(b) antibodies. A rare third phenotype defined by the anti-Fy6 antibody is also known. Duffy negativity, Fy(a-b-), seems to confer resistance to malarial infection. Both Fy(a+) and Fy(b+) are apparently an integral part of the *Plasmodium* receptor on RBCs. When certain chemokines (IL-8 and MGSA) are bound to the Duffy antigen site, the malarial agent fails to bind to and enter RBCs. Three major alleles have been identified: FYB (a-b+), FYA (a+b-), and FYO (a-b-); FYB is the suggested ancestral (chimpanzee-like) allele. The polymorphism also gives rise to the possibility of **hemolytic disease of the newborn**.

Dwarfism, pituitary, type I
(262400,AR, 17q22-q24)

One of four types of hypopituitary dwarfism, all AR, in which hypotrophy begins prenatally. Type I is AKA primordial dwarfism, in which only growth hormone (GHI) is deficient, and results in a "midget" of normal proportions. Type II (262500) is ateliosis, AKA Laron type dwarfism due to HGH-receptor deficiency. Type III (262600) is AKA the panhypopituitarism type of dwarfism, in which all hormones of the anterior pituitary are deficient. Type IV (262650) is AKA Kowasaki syndrome dwarfism. The genetic forms are as a group less common than hypopituitarism caused by a tumor or secondary to an infection. Cf., **achondroplasia**.

The mutation rate for the recessive allele has been estimated at 3.2×10^{-6} . While there are familial and populations clusters with higher frequencies, in most populations the prevalence seems to be about 20:10,000.

046

Dwarfism, pygmy

Dyslexia (DYX1; 127700,AD, 15q21)

See **HGH-resistant dwarfism**.
Reading disability, specific (DYX1 is one of 9 types with a genetic basis). Thought to be caused by chemical disruption during the third trimester (7th month) of gestation. The condition exhibits incomplete penetrance, ambiguity, or characteristics of a multifactorial disorder; heritability is about 60%. Other loci have been implicated on chromosomes 6 and 18.

Dyslexia has a prevalence of about 5-6% in American school-age children, comparable with that of both dyscalculia and attention-deficit-hyperactivity disorder.

047

Table 1. (Contd.)

Trait	Description	Regional variation	Ref.
Ectodermal dysplasia, anhidrotic type (EDA); 305100, [22:4900, 129490], XR, Xp12-q13.1)	Affected males have hypertrichosis, abnormal or missing teeth, and absence of sweat glands (with hypohidrosis). Heterozygous female carriers show milder symptoms. Affects thermoregulation (AKA hypohidrotic type ED).	Estimates of female carriers in various populations range from 1:50 to 1:500, but the condition tends to cluster, for example the “Whitaker negroes of Mississippi” or the “toothless men of Sind” (Hyderabad, India) mentioned by Darwin in 1875.	048
Edward syndrome (-, MCA, 18+)	Three copies of all the genes on chromosome 18 cause, due to a dosage effect, mental impairment, extreme abnormalities in all organ systems, and muscle tonus that twists the head oddly (AKA Trisomy 18).	1:6,000 live births.	049
Emphysema, congenital (130710, AD, 14q)	Defective alpha-1 antitrypsin (AAT) causes inflation and degeneration of lung tissue due to loss of elasticity. The defective gene is a protease inhibitor, Pi.	Three clinically significant alleles (of over 70 known) are common in Spain, Portugal, and Scandinavia; nearly absent in black African and Asian populations.	050
Epilepsy, progressive myoclonic 2 (EPM2A); 254780, AR, 6q24)	Involuntary tremor is a feature of more than 100 syndromes. EPM2A is a neurological condition characterized by seizures (e.g., grand mal) caused by electrochemical discharges in the brain. One of about 12 recognized gene-based forms. This form is AKA LaFora disease, caused by mutations in the EPM2A gene that coded for Laforin, a protein phosphatase that balances blood sugars in the brain. Highly variable age of onset. There is also a mitochondrial form (“red ragged fibers”). Cf., essential tremor and Parkinson disease .	Prevalence of all forms of epilepsy is about 1.0% worldwide. Individual gene-based forms have reported frequencies of 1:2,000–1:6,000.	051
Erythroblastosis fetalis	See Rhesus isoimmunization .		
Essential tremor (ETM1, 190300, AD, 3q13)	ETM may be the most common hereditary movement disorder; a late onset (4th–6th decades) characterized by uncontrollable tremors of the arms, but other muscles may be involved. Affected individuals are reported to live significantly longer than unaffected family members. A heterogeneous degenerative condition, similar symptoms are caused by another gene (ETM2) that maps to 2p25–p22. ETM is more common and less acute than epilepsy and less debilitating than familial Parkinson disease .	Common in northern European populations, where the prevalence in one Finnish deme exceeds 50%.	052
Factor V Leiden thrombophilia (227400, AR, 1q23)	The factor V Leiden mutation predisposes individuals to venous thrombosis (blood clots in the limbs). Heterozygotes have lowered levels of Factor V but never exhibit abnormal hemorrhaging.	Found in almost 1:10 individuals of European origin.	053
Familial fatal insomnia (FFI, 600072, -, 20pter-p12)	Hereditary autosomal dominant disorder characterized by tremors, progressive insomnia and a dream-like status,	Very rare; highly informative.	054

progresses to coma and death; duration averages 13 months. Like **Creutzfeldt–Jakob disease**, FFI is associated with homozygosity at position 129 (for valine, in this case) and the “folding” mutation at 178 in native **prion protein** (PrPc). It is likely that yet another mutation specific to FFI is responsible for its activity, as the FFI form of prion affects a different area of the brain, a specific region of the thalamus. AKA fatal familial insomnia.

See **Mediterranean fever, familial**.

Although all normal adults possess a small proportion of fetal hemoglobin, some individuals of African ancestry have higher levels of fetal Hb. The condition has been found in Africans and Greeks carrying either the beta-thalassemia or sickle cell genes, and is probably an additional mode of adaptation to malaria, since individuals with adult Hb^s would be at less risk for a sickling crisis in the presence of fetal Hb. There is a second form: **Fetal hemoglobin, hereditary persistence, pancellular (HFPFH; 141749, AD, 11p15?)**, in which at least 7 different mutations in either the HBG1 or HBG1 genes results in hereditary persistence of fetal hemoglobin, resulting in F cells constituting about half of RBCs in adults.

FRAX is a pervasive developmental disorder that results in profound mental retardation, a consistent facies, and large testicles in males. FRAX is the most common heritable syndrome with symptoms of mental impairment and behavioral change. Transmitted as an X-linked recessive, it affects hemizygous males far more frequently than females; females are usually heterozygous and exhibit milder symptoms, as they possess one working copy of the gene. The syndrome is caused by a mutation in the fragile X mental retardation protein (FMR1 gene), which amplifies a three nucleotide repeat up to 200 times, so that the FMR1 protein is not produced. Normally, the FMR1 protein functions to bind RNA. Female carriers of the disorder have permutations that can be identified at the molecular level. The fragile X gene (FMR1) is responsible for the characteristic non-staining gap or break in an affected X chromosome at band q27.

Inability to metabolize fructose. Symptoms include hypoglycemia, sweating, nausea, tremors after ingesting fruit sugar; liver and kidney damage; failure to thrive; fatal if untreated. Defective enzyme is fructose-1-phosphate aldolase (aldolase B, ALDOB). About a dozen allelic mutations are known. AKA ALDOB deficiency. One of two types of fructose intolerance with a genetic basis.

055

Highest frequencies (up to 7%) found in West Africa, Ethiopia, Southern Europe, and Southeast Asia. Frequency of 0.35% of the heterocellular form in Americans of African ancestry.

056

Rare; highly informative. Prevalence is low in the United States (about 0.15:10,000), higher in Western Europe (1.6:10,000).

057

More than 10 alleles are known; in Great Britain, 1.3% of the general population is heterozygotes.

Familial Mediterranean fever

Fetal hemoglobin, hereditary persistence, heterocellular (HFPFH; 142470, AD, 6q22.3–q23.1)

Fragile X syndrome (FRAX; 309550, XR, Xq27.3)

Fructose intolerance, hereditary, type I (229600, AR, 9q22.3)

Table 1. (Contd.)

Trait	Description	Regional variation	Ref.
Galactosemia, type I (230400, AR, 9p13)	Inability to digest milk sugar; symptoms in "classic" galactosemia (type I) include muscle weakness, enlargement of liver; cataracts, palsy, seizures and mental impairment; death if untreated. The defective enzyme is galactose-1-phosphate uridylyl transferase (GALT). GALT catalyzes step 2 of galactose to glucose reduction. About 150 different mutations to the GALT enzyme have been identified worldwide. AKA GALT deficiency. Cf., disaccharide intolerance type III.	Six common variants account for most cases of galactosemia; cumulative allele frequencies amount to up to 9% in some regions.	058
Galactosemia, type II (230200, AR, 17q24)	Inability to digest milk sugar; symptoms in type II galactosemia are similar to type I. The defective enzyme is galactokinase (GALK1). GALK1 catalyzes step 1 of galactose to glucose reduction. AKA GALK deficiency, galactokinase deficiency.	Rare worldwide; but found in high frequencies among Italian and Romani (gypsy) populations, where carrier frequency is as high as 1:300.	059
Galactosemia, type III (230350, AR, 1p36-p35)	The defective enzyme is UDP-galactose-4-epimerase (GALE). AKA GALE deficiency.	Incidence is about 1:23,000.	060
Gaucher disease, type I (GDI; 230800, AR, 1q21)	Heritable lysosomal storage disease with variable symptoms: pain, fatigue, enlarged liver and spleen, nervous system impairment, bone degeneration with fractures, arthritis, skin pigmentation defects; fatal if untreated. Of several modes, type I is caused by defective glucocerebrosidase. Substitutional gene therapy has been available since 1991; the working enzyme is injected intravenously every two weeks, similar to insulin therapy in diabetes.	Found in high frequency among Ashkenazi Jews (1:400). The incidence in the general population is 1:100,000.	061
Gerstmann–Straussler–Scheinker disease (GSSD) 137440, AD, 20pter-p12)	GSSD is a rare "familial" disease thought in the 1980s to exhibit an autosomal dominant mode of inheritance. Onset is typically in the 4th–5th decades. It was noted in cases such as a "family of shepherders" who exhibited ataxia, progressive dementia, and absence of lower limb reflexes. Course of the disease is 2–10 years; amyloid plaques are found on autopsy and GSSD was later reclassified as one of the human transmissible spongiform encephalopathies (TSEs) similar to kuru and new variant CJD . Like these other diseases associated with the prion protein , GSSD is characterized by certain predisposing genotypes, in this case a proline to leucine substitutional mutation at position 101, as well as valine at positions 117 and 129. AKA Gerstmann–Straussler syndrome (GSS), subacute spongiform encephalopathy, prion dementia.	Rare; clinically informative cases appear to be restricted to Europe.	062

<p>Gilles de la Tourette syndrome (GTS, 137580, MF; 2p11.8q22, 11q23)</p>	<p>Multifactorial neurological condition characterized by motor and vocal tics; behavioral anomalies common. Onset in youth, usually in the 2nd decade. Diagnosed individuals often share co-morbidity with autism, obsessive-compulsive disorder, and/or attention deficit disorder. About 10% of probands have a family history of the condition. AKA Tourette syndrome (TS).</p>	<p>Rare, but incidence is dependent upon diagnosis, which is influenced by cultural perception. Has been described globally, with a notably high prevalence in Afrikaansers of European descent.</p>	<p>063</p>
<p>Glaucoma, open-angle type 1 (137750, AD, 1q25 and 9q24)</p>	<p>High hereditability condition (98% in MZ twins) caused by progressive damage to the eye and optic nerve; blindness if untreated. The damage is due to obstruction of fluid outflow at the angle of the anterior chamber of the eye. The defective gene is GLC1A.</p>	<p>About 3 million Americans have open-angle glaucoma. Significant prevalence in Iceland.</p>	<p>064</p>
<p>Glucose-6-phosphate dehydrogenase (G6PD) deficiency (305900, XR, Xq28)</p>	<p>Acute hemolytic anemia precipitated by certain substances such as fava beans, primaquine, aspirin, sulfas, and some 340 other drugs. Defect is any one of 325 known allelic mutations in DNA specifying a low-activity variant of the red blood enzyme (RBC) glucose-6-phosphate dehydrogenase. The precipitating substances deplete reduced glutathione (GSH, a component of RBC membranes), and the low-activity G6PD variants cannot restore GSH, resulting in a rapid loss of RBCs. G6PD deficiency may confer resistance to malaria (AKA favism, a defect in the B allele; and primaquine sensitivity, a defect in the A allele).</p>	<p>G6PD deficiency is the most common human enzyme deficiency, and affects an estimated 400 million people (mostly males) worldwide. The defective B (or Mediterranean) allele is found in high frequency in northern Italy, Greece, Sardinia, northwest India, and among Sephardic Jews. The defective A allele is found at a frequency of 0.20 in many black African populations. Two other common allelic variants are the Canton variant, found in southern China, and the Constantine variant, found among Arabs.</p>	<p>065</p>
<p>Glucose-galactose malabsorption (GGM; 182380, AD, 22q13.1)</p>	<p>GGM is a cell membrane transport defect characterized by severe diarrhea and dehydration in early infancy; death if lactose and sucrose sugars are not removed from the diet and replaced by a fructose-based formula. The defective gene is solute carrier family 5, member 1 (SCC5A1, AKA SGLT1), that normally transports glucose and galactose from the lumen of the small intestine into the intestinal cells. Mutations in SGLT1 interrupt this process, and the unabsorbed sugars draw water from the intestinal cells instead, causing diarrhea.</p>	<p>The double G-G form is rare, only 200 cases diagnosed annually worldwide, but less severe forms (glucose intolerance) affect 10% of the world's population.</p>	<p>066</p>
<p>Glycogen storage disease, type 1 (232000, AR, 17q21)</p>	<p>Accumulation of cellular glycogen due to metabolic errors; the major sign is hepatomegaly. The deficient enzyme is glucose-6-phosphatase (AKA Von Gierke's disease). Nine forms (0–VIII) of glycogen storage disease with a genetic basis are known.</p>	<p>Incidence varies from extremely rare (type IV) to common in some populations (e.g., type II in Israel).</p>	<p>067</p>

Table 1. (Contd.)

Trait	Description	Regional variation	Ref.
<p>Guevedoces</p>	<p>See Pseudohermaphroditism, male.</p>		
<p>Hemochromatosis, hereditary (HH or HFE1; 235200, AR, 6p21.3)</p>	<p>An autosomal recessive condition characterized by defective iron metabolism that overloads iron storage sites such as the liver, and that can progress to liver cancer. Symptoms include chronic fatigue, infections, hair loss, skin pigmentation, infertility, muscle pain, liver damage, diabetes, and the perception of feeling cold. Fatal if left untreated. Current treatment includes therapeutic phlebotomy and ferritin monitoring. Type 1 affects predominantly males; more homozygous men than women of reproductive age display symptoms because women lose iron every month during menstruation. Of four common forms, the classic (type I) and juvenile onset (type II) forms are the most prevalent; each form may correspond to a different allele. Paternally transmitted mutations result in symptoms that are more marked, that is, there is a parent-of-origin effect. The affected locus (mutation C282Y in the HFE gene) can be detected by a simple clinical test, and is associated with or linked to the class I HLA proteins (HLA A3, B14). A more severe form (Hemochromatosis, juvenile, type 2 (JH, HFE2; 602390, -1q)) with onset before age 30 affects both sexes.</p>	<p>According to the CDC, hemochromatosis is the most common serious genetic disorder in humans. About 1:8 Americans is a carrier of a defective HFE gene, and about 1.5 million homozygous people have the disease. The condition is found in high frequencies in persons of Irish, Scottish, and British descent, in which the gene frequency is higher than 10%, resulting in about 1:200 affected persons in western, northern, and eastern Europe. The frequency is low (1:6,000) in Ashkenazim.</p>	068
<p>Hemoglobin (Hb) alleles</p>	<p>There are three major ontogenetic forms of hemoglobin (Hb): embryonic, fetal, and adult. Although hereditary persistence of fetal hemoglobin is an important but less well known and secondary adaptation to falciparum malaria, the primary population adaptations to malaria seem to be allelic variants of adult hemoglobin. Hb^S, the most common and well-known variant, is responsible for sickle cell disease. Other significant Hb variants are known. Hb^C is caused by a lysine for glutamic acid substitution at position 6 in the beta chain. Hb^D is an electrophoretic variant later found to consist of three common mutations: Hb^D Punjab, glutamic acid to glutamine at beta 121; Hb^D Ibadan, threonine to lysine at beta 87; and Hb^D Bushman, glycine to arginine at beta 16. Hb^F is caused by a glutamic acid to lysine substitution at beta 26. All of these polymorphisms are found originally in regions where malaria is endemic, and are expected to confer some fitness advantage to the heterozygotes in the presence of malaria. Mutations and deletions of Hb chains are also responsible for other hemoglobinopathies, cf., thalassemia.</p>	<p>Hb^C is found in highest frequencies in West Africa and, due to migration, in lower frequencies American populations. Hb^D is found in highest frequencies in India and West Africa and, due to migration, in lower frequencies throughout the world. Hb^F is found in highest frequencies in Southeast Asia where its frequency approaches 50% in some populations and, due to recent migration, in lower frequencies in North American populations.</p>	069

Hemolytic disease of the newborn (HDN, erythroblastosis fetalis)	Any condition resulting in the abnormal destruction of blood products, but usually refers to Rh incompatibility between a mother and fetus (see Rhesus Isoimmunization ; AKA erythroblastosis fetalis). The ABO form of HDN results in destruction of the erythrocytes of a fetus, a maladaptive condition roughly twice as common as the Rh-incompatibility form of HDN, but almost always clinically milder in its manifestation. Caused by some of the smaller anti-A or anti-B antibodies in a mother's immune system that can permeate the placental membranes. HDN can also be a clinical feature of the Diego, Duffy, Kell-Cellano, and Gerbich blood groups.	See individual listings.	070
Hemophilia A (HEMA; 306700, XR, Xq28)	One of several inherited blood disorders caused by failure of one component of the normal blood-clotting system (factor VIII). HEMA is characterized by spontaneous, unchecked bleeding into large joints and muscles, easy bruising, poor blood clotting, hematomas, and chronic arthritis; fatal if untreated. HEMA is the best known form (the "royal hemophilia"), accounting for 80% of all coagulation disorders, and is due to a mutant gene on the X chromosome. An even rarer condition, Factor XI deficiency, has a frequency of 5–9% in European Jews.	The de novo mutation rate is $30\text{--}60 \times 10^{-6}$. Found 1.25:10,000 births; HEMA is 5× more frequent than HEMB. HEMA had a high prevalence among the interrelated royal families of 19th-century Europe.	071
Hemophilia B (HEMB; 306900, XR, X)	HEMB is a rare, abnormal X-linked recessive condition in which clotting factor IX is deficient and that allows poor blood clotting (AKA Christmas disease, after a patient with the surname "Christmas").	The de novo mutation rate is $0.5\text{--}10 \times 10^{-6}$. Found in high frequency among Ashkenazi Jews.	072
Hereditary fructose intolerance, type I	See Fructose intolerance, hereditary .		
Hereditary nonpolyposis colon cancer, familial (HNPCC)	See Colon cancer .		
Hermansky-Pudlak syndrome (HPS; 203300, AR, 10q24-q25)	A form of albinism similar to OCA1 and OCA2 with the additional complications of fibrosis and colitis; these can be severe and lead to death.	A mode of albinism that is common in Puerto Rico.	073
Hermaphroditism, true (235600, AD, -)	The presence in the same individual of both ovarian and testicular tissues. In humans, true hermaphroditism are mosaic for the sex chromosomes, that is, some cells in the body are XX, others XY, or XXY. Such individuals possess both ovarian and testicular tissue, present either in separate gonads or together in a single gonad (AKA ambiguous genitalia , intersexuality).	True hermaphroditism are very rare, about 1:100,000, worldwide, but see pseudohermaphroditism .	074
HGH-resistant dwarfism (Pygmy; 265850, AR, [12q])	Pygmies are dwarfs constituting entire breeding populations characterized by universally short stature. Many of these populations consist entirely of individuals that are homozygous recessives for a hepatic growth	Entire populations may be deficient in adolescence for the causal factor; such populations are found in Africa, Australasia, Ecuador, and on the	075

Table 1. (Contd.)

Trait	Description	Regional variation	Ref.
<p>Hunter syndrome</p> <p>Huntington disease (HD); 143100, AD, 4p16.3)</p>	<p>hormone (or hormone receptor) normally stimulated by HGH, such as insulin-like growth factor 1 (AKA somatomedin C deficiency; insulin-like growth factor 1 deficiency, IGF1).</p> <p>See Mucopolysaccharidosis, type II.</p> <p>Inherited condition characterized by progressive degeneration of the nervous system and premature death; onset generally occurs at middle age, but onset decreases with each generation due to anticipation (see below). Caused by a dominant mutation in an autosomal gene (HD, which codes for the huntingtin protein) located on HSA 4p. The defect consists of up to 85 expansion repeats or “stutters” of the nucleotide sequence CAG. First described by Lund in 1860 as “chorea St. Vitus,” again in 1872 by George Huntington as “hereditary chorea.” Exhibits evidence for both anticipation of a trinucleotide repeat and for genomic imprinting; the symptoms appear in adolescence and are more severe if inherited from the father, less severe and occur in middle age if inherited from the mother. AKA Huntington’s chorea, Woody Guthrie disease.</p>	<p>Andaman Islands in the Indian Ocean.</p>	076
<p>Hurler syndrome</p> <p>Hydrops fetalis</p> <p>Hypercholesterolemia, familial (FH or FHC; 143890, IAD, 19p13.2-p13.3)</p>	<p>See Mucopolysaccharidosis, type I.</p> <p>See thalassemia.</p> <p>One of the genetic forms of coronary heart disease that manifests in the 4th or 5th decade of life. Genetically deficient low-density lipoprotein (LDL) protein receptors (LDLRs) in the liver cause LDL cholesterol to accumulate in the blood, resulting in high blood cholesterol, atherosclerosis, and heart disease. Most mutations prevent the synthesis of LDLR; others prevent its removal from the endoplasmic reticulum; still other mutations interfere with LDL binding. Homozygous individuals are often compound homozygotes; individuals with two affected alleles, but in which each allele is a different mutation. The condition is a rare example of incomplete dominance in humans.</p>	<p>Worldwide, the incidence of FH heterozygotes is 20:10,000, but homozygotes are rare (0.01:10,000). Among Afrikaaners of Dutch origin, incidence is 100:10,000; South African Jews of Lithuanian origin have a frequency of 150:10,000, all due to one mutation. Incidence is also high among Lebanese Christians and French Canadians (5 variants).</p>	077
<p>Hyperlipoproteinemia, type I[a] (238600, AR, 8p22)</p>	<p>Heritable condition with symptoms that include abdominal pain, xanthomas (in some types), elevated LDL, and plasma triglycerides; additional symptoms are secondary to obesity and/or cardiovascular disease. Type I is one of five major types and subtypes, all inherited. The defective enzyme is lipoprotein lipase (PLP), but lipoprotein receptor-related protein 5 (LRP5) variants have also been implicated. PLP</p>	<p>Very common; up to 2% of the general population.</p>	078

lines the walls of capillaries, and it is activated by HDLs (high-density lipoproteins) such that it metabolizes LDLs (low-density lipoproteins, the “bad” cholesterol). The enzyme also regulates cell size; certain PLP alleles are expected to contribute to high levels of triglycerides and/or increased cell size (hypertrophy). Simple clinical tests are available to detect elevated HDL, LDL, and triglycerides. Clinical severity is associated with apolipoprotein genotype. AKA Frederickson’s hyperlipoproteinemia, lipase D deficiency, leptin deficiency. Another variant (Hyperlipoproteinemia, Type I[b] (207750, AR, 19q13.2)) causes hypoproteinemia due to Apolipoprotein C-II deficiency. Type I, PLP, LRP5, and apoE variants are also implicated in **type II diabetes**.

A rare X-linked dominant congenital condition characterized by an increase in the number of hair follicles in locations such as the face and upper body, resulting in hirsutism; has been called an atavistic gene (a “reactivated” ancestral DNA sequence). AKA the “wolf man” syndrome. Related conditions include hypertrichosis universalis (145700), and congenital generalized hypertrichosis with gingival hyperplasia (135400). The term hypertrichosis can also refer to the growth of hair along the rim and on the auricle of the ear, or on the elbows. Hypertrichosis is a feature of many other syndromes, including Ambras syndrome, Brachmann–Cornelia–de Lange syndrome, and 14q32.3 deletion syndrome.

Vitamin D resistant rickets; causes a type of bow-leggedness that cannot be cured by the administration of vitamin D. Onset during the first year of life. A cell membrane transport defect due to a mutated gene that codes for alkaline phosphatase, and that results in abnormal reabsorption of phosphate in the kidneys, thus producing abnormally low levels of phosphorus in the blood. Deficient calcium absorption in the intestines results in softened bones. Laws of segregation predict that about twice as many females as males will be affected by such XD conditions.

See **dwarfism, pituitary**.

First of a group of chronic disorders that cause ulceration in the intestines. In type 1 (includes Crohn’s disease) the inflammation extends deep into the intestinal wall. Onset is generally between 15 and 35 years of age, with a second peak in the 5th–7th decades. About 1:5 cases of IBD1 are familial. Several genes in the q12 region of HSA 16 appear to be

lines the walls of capillaries, and it is activated by HDLs (high-density lipoproteins) such that it metabolizes LDLs (low-density lipoproteins, the “bad” cholesterol). The enzyme also regulates cell size; certain PLP alleles are expected to contribute to high levels of triglycerides and/or increased cell size (hypertrophy). Simple clinical tests are available to detect elevated HDL, LDL, and triglycerides. Clinical severity is associated with apolipoprotein genotype. AKA Frederickson’s hyperlipoproteinemia, lipase D deficiency, leptin deficiency. Another variant (Hyperlipoproteinemia, Type I[b] (207750, AR, 19q13.2)) causes hypoproteinemia due to Apolipoprotein C-II deficiency. Type I, PLP, LRP5, and apoE variants are also implicated in **type II diabetes**.

A rare X-linked dominant congenital condition characterized by an increase in the number of hair follicles in locations such as the face and upper body, resulting in hirsutism; has been called an atavistic gene (a “reactivated” ancestral DNA sequence). AKA the “wolf man” syndrome. Related conditions include hypertrichosis universalis (145700), and congenital generalized hypertrichosis with gingival hyperplasia (135400). The term hypertrichosis can also refer to the growth of hair along the rim and on the auricle of the ear, or on the elbows. Hypertrichosis is a feature of many other syndromes, including Ambras syndrome, Brachmann–Cornelia–de Lange syndrome, and 14q32.3 deletion syndrome.

Vitamin D resistant rickets; causes a type of bow-leggedness that cannot be cured by the administration of vitamin D. Onset during the first year of life. A cell membrane transport defect due to a mutated gene that codes for alkaline phosphatase, and that results in abnormal reabsorption of phosphate in the kidneys, thus producing abnormally low levels of phosphorus in the blood. Deficient calcium absorption in the intestines results in softened bones. Laws of segregation predict that about twice as many females as males will be affected by such XD conditions.

See **dwarfism, pituitary**.

First of a group of chronic disorders that cause ulceration in the intestines. In type 1 (includes Crohn’s disease) the inflammation extends deep into the intestinal wall. Onset is generally between 15 and 35 years of age, with a second peak in the 5th–7th decades. About 1:5 cases of IBD1 are familial. Several genes in the q12 region of HSA 16 appear to be

Hypertrichosis, congenital generalized (CGH or HTC2; 307150, XD, Xq24–q27.1)

Rare.

079

Hypophosphatasia, familial (307800, XD, Xp22–p22.1)

Incidence is about 1:60,000.

080

Hypopituitary dwarfism

Inflammatory bowel disease I (IBD1; 266600, AR, 16q12)

IBD is reported primarily in populations of Northern Europe, North America, and migrant populations in Australia, New Zealand, and South Africa. Incidence in most of these populations is

081

Table 1. (Contd.)

Trait	Description	Regional variation	Ref.
<p>Jacob syndrome Klinefelter syndrome (-, MCA, XXY)</p>	<p>4—involved in the inflammatory response (CD19, CD11, IL-4), but the condition is generally regarded as heterogeneous. A less severe form of IBD is usually called ulcerative colitis.</p> <p>See Double-Y syndrome.</p> <p>Symptoms of this aneuploid condition (47, XXY) appear at puberty: affected males are tall with long limbs, experience a precocious puberty but lack secondary sexual characters, have hypogonadism (small penis and prostate gland), breast swelling (gynecomastia), a protruding stomach, taurodontism, and irreversible sterility caused by primary testicular failure; mental retardation is apparent in some cases. Osteoporosis is common in later adulthood. Cause is due to the dosage effect of a supernumerary (extra) X chromosome; some individuals are cell mosaics (XY/XXY). Other rare subtypes include 48, XXXY, 48, XYY, and 49, XXXXY. Barr bodies are consistent with the all but one rule. Androgen therapy and subcutaneous mastectomy restore a male phenotype in some milder cases.</p> <p>See XX male syndrome.</p>	<p>8:10,000. Other populations report less than half of this incidence, worldwide. Females appear to be at a slightly increased risk for IBD.</p> <p>Affects 1:500 males; a tendency toward learning disabilities results in mental retardation in many cases with the severity increasing in proportion to the number of supernumerary X chromosomes. Up to 1% of clinically institutionalized males are Klinefelter patients. Most population studies have sampled only Europe or Japan; prevalence is unknown elsewhere.</p>	082
<p>Kuru (245300, AR, 20pter-p12)</p>	<p>Disease characterized by ataxia and progressive dementia accompanied by bouts of inappropriate laughing.</p> <p>Discovered in 1957, kuru was at first thought to be a form of viral encephalitis transmitted only by the ritual ingestion of the nervous tissue of an infected individual during funerary processing that involved cannibalism. Found only among the Fore people of Highland New Guinea, it was next thought to be a sex-limited disease because of its high prevalence in females and children. Carleton Gajdusek won the Nobel prize after he showed that he could transmit chimpanzees with what turned out to be not a virus but a prion. Diseases that appear to be inherited, but turn out to be environmentally caused, are known as phenocopies.</p> <p>Like the other prion diseases new variant CJD, familial fatal insomnia, and Gerstmann–Strausler–Scheinker disease, kuru-affected individuals were found on autopsy to possess a predisposing genotype, in this case a characteristic mutation at position 178 and were invariably methionine homozygotes (MM) at position 129.</p>	<p>Rare; limited to the Fore peoples of New Guinea; no new cases reported since funerary practices were changed.</p>	083
<p>Lactose intolerance, adult Leber's hereditary optic</p>	<p>See disaccharide intolerance type III.</p> <p>One of the maternally inherited mitochondrial myopathies</p>	<p>About 20 allelic mutations are</p>	084

<p>neuropathy (LHON; 535000, -, mtDNA)</p>	<p>in mtDNA characterized by sudden loss of central vision at about the 3rd decade due to optic nerve degeneration. The defective gene codes for a respiratory enzyme. One of the earliest inherited conditions noted, first described in 1871. AKA Leber's optic atrophy.</p>	
<p>Lesch-Nyhan syndrome (308000, XR, Xq)</p>	<p>Heritable condition characterized by spastic cerebral palsy accompanied by involuntary movements, and severe mental retardation coupled with aggressive and self-destructive behaviors; death before puberty. A metabolic disease affecting hypoxanthine-guanine-phosphoribosyl transferase (HGPRT)-mediated guanine conversion; failure to recycle nucleic acids, converting them instead to uric acid that manifests as urinary stones (causes orange "sand" in diapers). Fibroblasts of female carriers exhibit about 50% HGPRT activity due to the random effects of X-chromosome inactivation.</p>	085
<p>Longevity (152430, 502000, MF, -)</p>	<p>Aging is a biologic process marked by the decline of bodily function and individual adaptability that commences at conception and proceeds until the death of an individual. Aging is variously described as the end of growth, or the increasing probability of mortality with time. Longevity refers to the achievement of maturity and to the average life span characteristic of the individuals in a population or species under specific environmental constraints. Much evidence suggests that some portion of the variance of life span (or longevity) is inherited. Studies of adoptees, twin studies, and research with other mammals all suggest that complex organisms, including humans, inherit a tendency for a species-wide fixed longevity. There has been recent interest by gerontologists in certain maternally transmitted genes, and in the TERC locus (telomerase RNA component, 602322, 3q21-q38). See progeria.</p>	086
<p>Long-QT syndrome (LQT, 192500, 152427, 600919, AD, 11q15.3, 7q35-q36)</p>	<p>Congenital, heritable condition predisposing affected individuals to heart arrhythmia, fainting, and sudden cardiac arrest in the presence of loud sounds or during exercise. Defective potassium channels result in the accumulation of potassium in the heart and inner ears, resulting in heart defects and deafness. Mutant gene in LQT1 is KCNQ1; in LQT2, candidate genes have been mapped to a region on chromosome 7. One of the ion channel diseases. Exhibits evidence for genomic imprinting. Genes on chromosomes 3 and 6 may also affect expression of the syndrome. LQT has also been investigated in some Sudden Infant Death Syndrome cases. AKA Romano-Ward syndrome; includes a variant known as the Jervell and Lange-Nielson syndrome.</p>	087
	<p>known. Rare; generally 0.32:10,000 or less in many populations, but as high as 1% in founder populations such as French Canadians.</p>	
	<p>Affects 1:10,000 males.</p>	
	<p>There apparently are no long-lived human populations, that is, populations with a notably high proportion of centenarians. Three candidate populations—the Abkhazians and Osetia people of Russian Georgia, the people of Vilcabamba in southern Ecuador, and the humza of Pakistan—have all been explained by age exaggeration, record alteration, or by unusual demographic phenomena.</p>	
	<p>About 30 alleles of the KCNQ1 gene have been described.</p>	

Table 1. (Contd.)

Trait	Description	Regional variation	Ref.
<p>Major affective disorder 1 (MAFD1; 125480, MF, 18p)</p>	<p>A suite of behaviors characterized by radical mood swings, from euphoria to depression. Two major, distinct modes are recognized: bipolar affective disorder (BPAD, AKA manic depressive illness), and unipolar affective disorder (depression without mania). Onset in the first case is usually the 2nd decade, and in the 3rd decade for the latter. Affected individuals with a family history apparently respond better to lithium than sporadic cases. Differential concordance MZ:DZ twin rates of 57%:14%, and correlation studies of adoptees with biological parents both suggest some contribution of genetic factors, but with incomplete penetrance; MAFD is an ambiguous multifactorial disorder. Families with affected individuals tend to show co-morbidity with schizoaffective disorder, alcoholism, and/or anorexia nervosa, as well. The possibility of genetic anticipation as an additional mechanism has been proposed. Early linkage studies reporting genes on chromosomes 11 and X (MADF2) have been retracted.</p>	<p>About 1–2% of the American population is affected; diagnosis is inconsistent due to cultural perceptions and procedural variation.</p>	088
<p>Maple syrup urine disease (MSUD, 248600, AR, 19q13)</p>	<p>Affected individuals have sugary-smelling urine, lethargy, breathing and swallowing problems, mental impairment, coma, and inevitably, death. A genetic disease of faulty amino acid metabolism. The defective protein is branched chain keto-acid dehydrogenase that results in an inability to metabolize leucine, isoleucine, and valine. AKA branched chain ketoaciduria.</p>	<p>Rare; informative.</p>	089
<p>Marfan syndrome (MFS1; 154700, AD, 15q21.1)</p>	<p>Degenerative disease of connective tissue caused by a defect in fibrillin (FBN1), an elastic tissue protein found in the eyes, aorta, limb, finger, and rib bones. Affected individuals appear tall and loose-jointed with “spindly fingers,” long and slender limbs, hands and feet. A concave chest deformity is also a feature, as are a curved spine, displaced lens, and cardiovascular problems. Manifests in the 3rd decade of life. It is usually a rupture and dissection of the aorta that causes death. MFS is an example of pleiotropy, in which a single gene affects many target tissues in a body. Indications of a paternal age effect. The fibrillin cistron is large (more than 110,000 base pairs spread over 65 exons).</p>	<p>The de novo mutation rate is $4/6 \times 10^{-6}$; about 15% of cases appear to be new mutations. Mutations tend to cluster in “hot spots” in the fibrillin gene. MFS is now considered more common than previously thought: about 1:4,000 live-born infants have Marfan syndrome. MFS has been described worldwide.</p>	090
<p>Mediterranean fever, familial (FMF or MEF; 249100, AR, 16p13)</p>	<p>Rheumatic condition characterized by recurrent episodes of fever and inflammation of the abdomen. The candidate gene, pyrin (MEFV), functions normally in granulocytes to</p>	<p>Affects 1:200 individuals in non-Ashkenazi Jewish, Armenian, Arabian, and Turkish populations;</p>	091

<p>suppress the immune response; several known mutations disable pyrin, and permit an inflammatory reaction.</p>			<p>1:5 may be carriers.</p>
<p>Melanoma, malignant (MM); 155600, AD, 9p, 1p36)</p>	<p>An aggressive form of skin cancer that affects predominantly lightly melanized populations, especially Europeans. First signs are a mole or patch of rapidly growing skin, which metastasizes via the bloodstream. One of the predisposing genes is CDKN2, which codes for a protein named p16, a checkpoint regulator of cell division. MM is also associated with the HLA-B7 haplotype (AKA skin cancer, cutaneous malignant melanoma, CMM).</p>	<p>Highest incidences of MM are in equatorial countries where lightly melanized individuals reside, for example, New Zealand. Lowest (nil) rates are found in highly melanized populations (e.g., Maori in New Zealand, Australian aboriginals). About 40,000 Americans are diagnosed annually with MM.</p>	<p>092</p>
<p>MELAS</p>	<p>See Mitochondrial encephalopathy lactic acidosis syndrome.</p>		
<p>Menkes syndrome (309400, XR, Xq12–q13)</p>	<p>Disorder characterized by cerebral degeneration and atrophy, microscopically kinky gray hairs, abnormal facial features, and bone damage; death in early childhood. The cause is abnormal copper transport; the defective gene is ATPase (ATP7A); (AKA "steely hair disease"). Other diseases such as Ehlers–Danlos syndrome may be allelic variants of this gene. AKA occiput horn syndrome.</p>	<p>The mutation rate is reported to be 1.96×10^{-6}. Prevalence in northern Europe is 1:300,000; in Australia, 1:40,000.</p>	<p>093</p>
<p>Mental retardation, X-linked non-specific (MRX, 309530, XR, Xq22.1–q21.3)</p>	<p>Heritable condition characterized by mental impairment; large testes, ears, and jaw; high-pitched voice, jocular speech. Defective gene also has a fragile site (AKA Martin–Bell syndrome). One of tens of sites, many X-linked, that cause mental impairment. MRX is not the same entity as FRAX, fragile X syndrome.</p>	<p>Common; prevalence of MRX in European males is 17:10,000.</p>	<p>094</p>
<p>Mitochondrial encephalopathy lactic acidosis syndrome (MELAS; 540000, MH, mtDNA)</p>	<p>Adult onset muscular degenerative condition that manifests in the 4th decade. Symptoms include hearing and speech impairment, difficulty walking, memory loss, diabetes, seizures, dementia; fatal. Caused by a mutation in a mitochondrial gene that codes for tRNA. AKA Mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes syndrome.</p>	<p>Prevalence reported at 1.6:10,000.</p>	<p>095</p>
<p>Mitochondrial myopathies (551000, MH, mtDNA)</p>	<p>A group of inherited disorders causing profound muscle weakness and inherited strictly from the mother (maternal inheritance). Mitochondrial disorders include KSS (Kearns–Sayre syndrome), LHON (Leber hereditary optic neuropathy), infantile bilateral striatal necrosis, NARP (neuropathy, ataxia, and retinitis pigmentosa), MILS (maternally inherited Leigh syndrome), MELAS (mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes), PEO (progressive external ophthalmoplegia), and MERRF (myoclonic epilepsy with red ragged fibers, see epilepsy).</p>	<p>Each is rare, but informative.</p>	<p>096</p>

Table 1. (Contd.)

Trait	Description	Regional variation	Ref.
Monoamine oxidase A deficiency (MAOA); 309850, XR, Xp11.23)	MAOA is an enzyme found in the outer membranes of mitochondria, and that normally catalyzes reactions that metabolize the neurotransmitters dopamine, serotonin, and noradrenaline. Due to one of several mutations, affected individuals process chemicals in wine, cheese, and certain Chinese foods differently, increasing the risk of heart attacks. This controversial syndrome has also been described as "borderline mental impairment and abnormal behavior," with familial aggregations of exhibitionism, voyeurism, and arson. Panic disorder has also been linked to the MAOA polymorphism (AKA Brunner syndrome). A second form of the enzyme, MOAB, also exists.	Rare; informative. Behavioral link based on a single Dutch pedigree.	097
Mosaicism, chromosomal (158250, MCA, -)	Normal females are mosaics for the expressed/inactivated X chromosome, with some lines expressing the mother's, and some lines expressing the father's X-linked alleles, such as G-6-PD. Mosaicism proper, however, refers to a somatic mutation during development, so that an individual is a mosaic for, say, Down syndrome in only some cell lines. Another (very rare) form of mosaicism occurs when two embryos fuse very early in development and express in one organism the genotypes of two individuals.	Rare; informative.	098
Mucopolysaccharidosis, type I (MPS1, 252800, AR, 4p16.3)	One of 13 similar mucopolysaccharidoses with a genetic basis. Type I features mental impairment, enlarged liver and spleen, heart disease, bone defects, hearing loss, large tongue, corneal clouding, and coarse facial features; fatal. A lysosomal storage disease in which the defective enzyme is α -L-iduronidase (AKA Hurler syndrome).	Rare; 1:150,000.	099
Mucopolysaccharidosis, type II (MPS2; 309900, XR, Xq20)	Severe symptoms: deformed face, dwarfism, joint stiffness, deafness, mental impairment, heart defects, enlarged liver and spleen; diagnostic heparitin sulfate in urine, fatal in adolescence. Defective gene is iduronate sulphate sulfatase (AKA Hunter syndrome).	Rare; 1:100,000.	100
Multiple births	Multiple birthing in humans is considered clinically to be an exceptional, teratogenic event. Polyembryony is the production of multiple embryos from a single fertilized egg, such as monozygous twins. Most higher-order births (more than two) are mixed sets of identical and fraternal twins. The predicted number of natural births (not induced by hormone therapy) of each kind is the subject of Hellin's rule (or law) of multiple births, which states that if the observed frequency of twins in a population is n , then the expected	Multiple births occur approximately 1:73 births (incidence is 0.02725); of these, the majority are twins (94.4%), 5% are triplets, 0.5% are quadruplets, and one tenth of 1% (0.001) are quintuplets or higher.	

frequency of triplets is n^2 , of quadruplets is n^3 , etc. The so-called "vanishing twin" phenomenon has recently led to a renewed interest in the twin events. See **twins**.

First described by Duchenne in 1868, DMD is caused by a mutation in dystrophin, an essential structural muscle protein, and which results in collapsed muscle cells and produces chronic, progressive muscle weakness. Deterioration of muscle cells causes a secondary immune reaction. Different mutations in the DMD gene lead to several types of null mutations that each have characteristic ages of onset. The DMD gene is the largest known gene in humans. The Becker type features reduced amounts of dystrophin. (Muscular dystrophy can also be a state of malnutrition caused in rodents and dogs by a reversible deficiency [avitaminosis] of vitamin E. The primary cause is a deficiency of the tocopherols, anti-oxidants that retard the rancification of fats.)

Hereditary nearsightedness of severe degree; extreme myopia. Myopia is classified as low, high, and extreme. Myopia is multifactorial and is measured as a metric character, with a heritability of 0.58. There is an apparent high correlation between severity of myopia in urban populations and high performance on certain aptitude tests. MYP is considered a case of pleiotropy.

Myopia 2 (MYP2); 255500, AR, 18p11.31)

The de novo mutation rate is $40\text{--}105 \times 10^{-6}$. Affects about 1:3,500 newborn males; 1:3 are de novo mutations.

101

In general, the categories of low and high myopia are positively correlated with the prevalence of extreme myopia (EM). Prevalence rates of EM are *low* (<0.5%) in Americans, Australian aboriginals, Eskimos, European Australians, Fijians, Finns, French Canadians, Greenland Eskimos, Labradorans, most Native Americans, natives of New Guinea, Yupik Eskimo males; *medium* (0.5–2%) in Chinese, subcontinental Indians, Israelis; and *high* (>2%) in Alaska Native Americans, Icelanders, Danes, Malays, Nigerians, Sioux Native Americans, Yupik Eskimo females. Incidence is 1:8,000 births.

102

Myotonic dystrophy (DM); 160900, AD, 19q13.2–q13.3)

Heritable disease characterized by difficulty relaxing contracted muscles; muscle wasting, cataracts, balding; other defects in gonads and heart; mental impairment. Onset in young adulthood. The defective protein is a muscle kinase, and the trait exhibits evidence for progressive expansion of a trinucleotide repeat that makes symptoms more severe in successive generations, a phenomenon known as anticipation, and there is also evidence for genomic imprinting (AKA Kennedy disease, dystonia myotonica, DM).

103

Table 1. (Contd.)

Trait	Description	Regional variation	Ref.
Neurofibromatosis type I (NF1; 162220, AD, 17q11.2)	Relatively benign inherited disease characterized by mild tumors of muscular, skeletal, and nervous system tissues, especially on nerve endings in the skin, often accompanied by café-au-lait spots and soft tumors. The usual cause is one of several defects in a cytoplasmic protein (neurofibromin, NF1), which normally suppresses the activity of a second gene (p21, the Ras oncogene) that causes tumor formation; the result is uncontrolled cell proliferation (AKA von Recklinghausen disease, peripheral neurofibromatosis). Although the “Elephant Man” has often been suggested as a case of NF1, Proteus syndrome is now a better candidate.	The de novo mutation rate is $40\text{--}100 \times 10^{-6}$, a very high rate; about half of all new NF cases are also new mutations. A paternal age effect is suspected. Incidence is about 1:3,000 births worldwide, although it is 1:1,000 in Israel, 2:1,000 in North Africa, and 1:1,000 in Asia. About 80,000 Americans have NF1.	104
Neurofibromatosis type II (NF2, 101000, AD, 22q12.2)	Heritable condition characterized by tumors of cranial nerves, deafness. The NF2 gene, merlin, normally functions to link cell membranes to cytoskeletal structures. Many mutations to the NF2 gene have been documented (AKA central neurofibromatosis).	Rare; affects 1:37,000.	105
New World syndrome	A constellation of conditions including hypertension, obesity , hyperlipidemia, hyperinsulinemia (diabetes). AKA syndrome X, metabolic syndrome.		
Obesity (OB; 164160, AD, 7q31.3)	Condition characterized by chronic weight gain and retention. Mutations in the LEP gene for the hormone leptin (OB), which functions normally as a fat-regulating hormone; a deficiency dramatically affects metabolism resulting in obesity. OB has been strongly implicated in animal studies and the gene has been identified in the human genome. Obesity, however, is a complex disorder in humans, and genetic factors play only a part. One of the other candidate genes for genetic susceptibility to adiposity, rather than morbid obesity, has been mapped to 3p26-p25; this gene codes for a hormone secreted by the stomach, ghrelin, a circadian molecule that stimulates human growth hormone release from the pituitary and seems to have an antagonistic interaction with leptin in feeding regulation and the perception of hunger. A third factor, lipoprotein lipase (PLP, see Hypolipoproteinemia), has also been the subject of recent research.	Incidence and population genetics in humans is unknown.	106
Osteogenesis imperfecta (166210, 166200, 166260; AD & AR; 7, 17)	A prenatal developmental disease that results in skeletal fragility, osteoporosis, brittle and easily broken bones, blue sclera, poor teeth, and hearing loss. Caused by a defective procollagen gene that affects embryonic collagen formation. The embryonic (congenital) form is usually fatal;	The de novo mutation rate is 10×10^{-6} . Prevalence worldwide is about 2:10,000.	107

<p>a late-appearing (delayed) form is characterized by recurring fractures of the extremities after the first year of life (AKA brittle bones).</p> <p>A protein with a molecular weight of 53,000 daltons; the p53 tumor suppressor normally restrains the proliferation of cells, and is involved in 60% of all cancer types, but especially cervical and colon cancers. "Wild type p53" normally functions as a tumor suppressor or "cancer killer;" by proliferating rapidly in the presence of a nascent tumor. p53 normally activates cell growth inhibitors resulting in apoptosis (programmed cell death); it suppresses DNA transcription until polymerase enzymes can repair DNA damaged by carcinogens. Mutations in p53 can cause cessation of these functions, leading to familial cancers, such as in the Li-Fraumeni families and small cell lung carcinomas. The p53 cistron contains 11 exons; the autosomal location of the p53 gene is on HSA 17p13.3, and consists of 393 amino acids. Most p53 mutations are new (de novo) somatic mutations, however. The p53'R2 is a gene that may mediate the effects of the p53 tumor suppressor gene. p53R2 encodes a ribonucleotide reductase involved in the p53 checkpoint for repair of damaged DNA; a dysfunctional p53R2 enzyme could contribute to tumorigenesis. Cf., Ras oncogene.</p> <p>Neurodegenerative condition characterized by tremors, muscular stiffness, and walking and balance difficulties; Lewy bodies are inclusional in many regions of the brain. Mutations in alpha synuclein (SNCA) cause fragmentation; SNCA fragments are characteristic of some forms of both PD1 and Alzheimer's disease. Not all forms of PD are inherited, however.</p> <p>Chromosomal defect (aneuploidy, 2N = 47) due to three copies of all the genes on chromosome 13, characterized by mental impairment, large triangular nose, cleft lip and other facial deformities, systemic organ defects, and polydactyly (AKA Trisomy 13).</p> <p>Inherited condition characterized by thyroid goiter and deafness. The mutant gene is PDS; normally this gene makes pendrin, a protein found in the thyroid that is involved in sulfate transport (AKA goiter-deafness syndrome).</p> <p>PKU is characterized by an inability to metabolize phenylalanine; the subsequent toxic accumulation of this amino acid can cause mental defects. Symptoms begin to appear at about 4 months of age, and include irritability,</p>	<p>108</p> <p>About 35 alleles have been described, each associated with a specific cancer or variant. Population genetics unknown.</p>
<p>p53 tumor suppressor protein (TP53; 191170, AD, 17p13.1)</p>	<p>109</p> <p>More than 500,000 Americans have one of the several forms of PD.</p>
<p>Parkinson disease, familial (PD1; 601508 163890, AD, 4p14)</p>	<p>110</p> <p>Incidence is 1:15,000 live births.</p>
<p>Patau syndrome (-, MCA, 13+)</p>	<p>111</p> <p>Common, accounts for 10% of all cases of deafness.</p>
<p>Pendred syndrome (PDS; 274600, AR, 7q31)</p>	<p>112</p> <p>Prevalence worldwide is 1:11,000. PKU is most frequent among the Irish (1:4,000 births) and among the Scottish and non-Finn Scandinavians</p>
<p>Phenylketonuria (PKU1; 261600, AR, 12q)</p>	

Table 1. (Contd.)

Trait	Description	Regional variation	Ref.
	<p>depigmented and dry skin with a musty odor, and abnormal EEG patterns; inconsistent phenotypic symptoms. Seizures begin at about a year in one third of cases; as adults many others are diagnosed with schizoid and/or antisocial personalities. There are five types; in classic or type I PKU the defective enzyme is hepatic phenylalanine hydroxylase, PAH, that results in failure to convert phenylalanine to tyrosine due to the complete deletion of exon 12; this causes abnormal myelin formation. PKU can be managed by a phenylalanine-deficient diet but early detection is difficult; after 6 months the neuronal damage is irreparable. The proximate result of recent mass screenings for carriers and dietary management of PKU has resulted in longer lives for many PKU-affected babies. Prior to these interventions, few affected individuals ever reproduced. As more PKU-genotype individuals survived the critical postnatal developmental period during which the nervous system matures, these surviving individuals began to reproduce. The ultimate consequence was an overall increase in the frequency of the abnormal allele, as well as a clinically new condition known as maternal PKU (see below) (AKA Følling disease).</p>	<p>(1:8,000) and their descendants in the United States, where about 1:50 are carriers for the trait. Many populations can be characterized by specific mutations to PAH: Norwegians, French Canadians, Turks, and Yeminite Jews can be so identified. PKU is rare among Asians, southern and eastern Europeans (including Ashkenazim), Finns, and Africans.</p>	
<p>Phenylketonuria, maternal (261600)</p>	<p>See phenylketonuria, above, for clinical symptoms. Adult females diagnosed with PKU who received prophylactic dietary intervention therapy as infants and survived the critical developmental postnatal period without experiencing damage to their nervous systems frequently abandoned the dietary constraints in later life with no ill consequences. However, these females have produced a new generation of PKU-affected individuals. After abandonment of dietary restriction, the serum phenylalanine levels in these individuals increased dramatically (hyperphenylalanemia), but with no directly ill effects. When pregnant, however, their second generation fetuses were subject to the same cumulative effects of PKU on their nervous systems even though the source was their mother's serum. When such mothers are untreated during pregnancy, 95% of the resulting offspring are mentally retarded and/or microcephalic.</p>	<p>Maternal PKU occurs only in societies where PKU has been treated by dietary management.</p>	113
<p>Philadelphia chromosome (Ph¹, 151410, MCA, t9; 22; 9q34 and 22q11.21)</p>	<p>A condition caused by the balanced translocation of a portion of chromosome 9 to 22, and that results in a new "tiny" chromosome, Ph¹. The clinical outcome is a condition characterized by abnormal proliferation of bone marrow cell</p>	<p>Rare; informative.</p>	114

lines, and chronic myeloid leukemia (CML), produced when the Abelson oncogene (ABL) and breakpoint cluster regions (BCR, 151.400) demonstrate a synergistic "position effect," and produce an abnormal "fusion protein" that causes cancer. Patients live about four years until immature WBCs overtake other cells, resulting in death. The breakage on chromosome 22 occurs in the BCR. Cf.,

Burkitt lymphoma.

Failure of the limbs to develop properly, resulting in small limb buds and other dysplasias. The most usual manifestation is the absence of the most proximal bone of a limb(s), for example, the humerus or femur; three forms, all AR (AKA Roberts syndrome). The "thalidomide baby syndrome" is a phenocopy.

Genetic disease featuring fluid-filled cysts in the kidneys, and one of the major causes of renal failure in adults; manifests in the 4th decade of life. The defective gene is polycystin, which functions normally in cellular signal transduction; it is bound to the nuclear membrane and possesses a 225-amino acid tail that projects into the cytoplasm.

A congenital genetic anomaly in which extra fingers or toes, sometimes not completely developed, are present in an individual. There are two common forms of hexadactyly (6-digit polydactyly). In the postaxial form, a single full or partial extra digit is located distal to the little finger. The GLI3 gene has been implicated. In the preaxial form (174700, AD, 7p13), a single full or partial extra digit is found proximal to the thumb. Both forms manifest during prenatal development. There are nine other less common forms, some with more than six digits; these latter are all very rare.

Polyposis of colon, familial

Porphyria variegata (176200, AD, 1q22, 6p21.3, 9, 11, 14)

See Adematous polyposis of the colon, familial.

A less common form of several types of inherited porphyria, the variegata form is characterized by a failure to metabolize the porphyrin ring in hemoglobin and results in obviouse red urine; other clinical symptoms include photosensitivity, abdominal pain, constipation, weak limbs, rapid heartbeat, hoarseness, and mental confusion with periodic stupor. Manifests in the 5th decade of life. Porphyria variegata is an AD, pleiotropic disease that, like hemophilia, segregated in the royal families of Europe. A

Phocomelia (269000, AR, 113q12del)

Very rarely seen as a full-term fetus.

115

Polycystic kidney disease, adult (PKD1, 173900, AD, 16p13.3-p13.12)

Affects 1:1,000 individuals. The de novo mutation rate is high: 60-120 x 10⁻⁶.

116

Polydactyly, postaxial (174200, AD, 7p13)

Postaxial polydactyly has a prevalence of 0.67:1,000 in Spain. The postaxial form of polydactyly is roughly 10 x higher in individuals of Nigerian ancestry than in other populations (18:1,000 for females and 27:1,000 for males). Postaxial polydactyly has a prevalence of 1.5:1,000 in Latin America, presumably due to African admixture in the Caribbean. The prevalence of the preaxial and other forms is much lower, about 5:100,000 in all populations surveyed.

117

Common in Finland and Dutch South Africa. In the latter case, the high prevalence is due to a single founder, a Dutch colonist.

118

Table 1. (Contd.)

Trait	Description	Regional variation	Ref.
Prader–Willi syndrome (PWS); 176270,AD, 15q11–q12)	<p>pleiotropic disease, the symptoms can manifest in various forms, giving the appearance of several diseases; there is also an AR mode. While the variegata form is the most celebrated, porphyria cutanea tarda is the most common form (AKA “the South African malady”).</p> <p>Neurogenetic condition characterized by mental impairment, obesity, small hands and feet, and lack of sexual maturity. Exhibits evidence for genomic imprinting; PWS is caused by a small deletion on chromosome 15, and is transmitted paternally. See Angelman syndrome.</p>	Rare (< 1:100,000); highly informative.	119
Prion protein (PRNP, 176640,AD, 20pter–p12)	<p>In 1996, a new variant of Creutzfeldt–Jakob disease in Great Britain was linked to exposure “years ago” through the consumption of beef cattle that had died from bovine spongiform encephalopathy (BSE, AKA “mad cow disease”). New variant CJD is one of the transmissible spongiform encephalopathies (TSEs). The human diseases in this group include Kuru, new variant Creutzfeldt–Jakob disease (nvCJD), familial fatal insomnia (FFI), and Gerstmann–Strausler–Scheinker syndrome (GSSS). Analogous animal diseases include scrapie, transmissible mink encephalopathy, chronic wasting of deer and elk (wapiti), bovine spongiform encephalopathy (“mad cow disease”), feline spongiform encephalopathy, and exotic ungulate encephalopathy.</p>	Rare; informative. Appears to be limited to regions where certain varieties of sheep reside, and to countries where these same sheep varieties (or, subsequently, cattle) have been exported. The potential for similar prion diseases in humans exists wherever prion-infected animals are consumed, for example, deer and elk.	120
Progeria(s) (176670,AD, -)	<p>The progerias are a small set of accelerated aging disorders. They include Werner syndrome and Hutchinson–Gilford syndrome (the latter is AKA progeria proper). In H-G progeria, children usually die of a heart attack before the age of 12. There are indications of a paternal age effect. Cells from affected individuals display a reduced number of replicative passages and a reduced ability to repair DNA. Recent evidence also suggests an AR mode of inheritance.</p>	Exceedingly rare; only about 20 cases have been described. Informative.	121
Proteus syndrome (176920,AD, -)	<p>Heritable condition characterized by asymmetrical growths (hamartomata), macrocephaly and dysplasia: an amalgam of symptoms from several cases includes lymphangiomas, subcutaneous swelling, cranial hemihypertrophy, limb or digit gigantism, multiple hypertostoses of the calvaria, facial bones and mandible. Asymmetries extend to the postcranial tissues in rare cases. An autosomal dominant lethal allele that survives in tissues of chimeric or mosaic</p>	Very, very rare due to the requirement of two sequential events; informative.	122

<p>individuals has been proposed; hence the rarity. The wide range of symptoms may be due to degree of mosaicism. This syndrome has been proposed as likely in the case of John Merrick, the “elephant man,” rather than neurofibromatosis. AKA elatoproteous syndrome.</p>	<p>Very, very rare; informative.</p>	<p>123</p>
<p>Pseudohermaphroditism, female, with skeletal anomalies (264270, AR, -)</p>	<p>Virilizing clinical signs of these chromosomally XX females include ambiguous genitalia, bony abnormalities of the face and long bones, enlarged clitoris and fused labioscrotal folds. Cf., Androgen insensitivity syndrome.</p>	<p>124</p>
<p>Pseudohermaphroditism, male, with gynecomastia and hirsutism (264300, 264600, 201910; AR, 9q22, 2p23)</p>	<p>Several similar conditions in which an individual with XY chromosomal genotype with an SRY gene present on the Y, and (sometimes) internal male organs of reproduction (male gonadal sex), has a female exterior (female phenotypic sex). Germline mutations can occur which interfere with the production of testosterone and/or DHT are the cause of the condition. In some cases, masculinization can take place at puberty (this variation is known as guevedoces, “penis at age 12,” in the Dominican Republic); in others, not, depending upon the epistatic context. The second most common cause of male pseudohermaphroditism—gynecomastia at puberty coupled with hirsutism—can be caused by 17-beta-hydroxysteroid dehydrogenase deficiency (HSD17B3 deficiency, 264300), 17-ketosteroid reductase deficiency (17-KSR deficiency, 201910), or 5-alpha reductase-2 deficiency (PPSH, 264600, the “guevedoces” mutation), all phenotypically indistinguishable without a serum assay. See also Androgen Insensitivity Syndrome.</p>	<p>125</p>
<p>PTC tasting (171200, AD, 5p15)</p>	<p>Benign ability to taste or not taste phenylthiocarbamide. PTC is a stereolog to many thioureas or goittrins, which have a bitter taste (to tasters) like some alkaloidal vegetables such as the cruciferous vegetables: cabbage, broccoli, brussel sprouts, turnips, kale. Ingestion of large quantities of goittrins interferes with iodine metabolism, producing goiter-like symptoms. The ability is polymorphic in humans. PTC is in fact a more complex trait than a simple AD; probably a two-locus trait with incomplete penetrance at the major locus (AKA taste blindness).</p>	<p>126</p>
<p>Ras oncogene (KRAS); 190070, AD, 12p12.1)</p>	<p>The Ras oncogene functions normally as a switch, relaying signals from hormones, for example at the cell surface receptors into the interior of the cell, causing cell growth. In cases where Ras is mutated, this switch can be permanently “on,” and cell growth occurs even in the absence of receptor activation. The various forms of Ras proteins (HRAS, 190020, AD, 11p15.5 and NRAS, 164790,</p>	<p>About 10 alleles have been well characterized in terms of specific varieties of cancer. Population genetics of these variants is unknown.</p>

Table 1. (Contd.)

Trait	Description	Regional variation	Ref.
Retinoblastoma (RB1); 180200, AD, 13q13.1–q14.2)	<p>AD, 1p13.2) are involved in about 30% of all cases of tumorigenesis. AKA Ras p21 protein activator. Cf., p53 tumor suppressor protein.</p> <p>A rare eye cancer in infants characterized by bilateral tumors in the retina of the eye, and a predisposition to bone cancer. An inherited germline mutation plus a new somatic mutation are both required in the hereditary form. The affected gene is Rb1, portions of which (exons 13–17) are abnormally deleted from chromosome 13 in the cells of an immature retina. The normal function of Rb1 in other body cells is to act as a tumor suppressor by preventing certain regulatory proteins from initiating DNA replication (cf., the p53 tumor suppressor). Retinoblastoma exhibits evidence for genomic imprinting; there are also indications of a paternal age effect. Other mutations to the Rb1 gene cause cancers in other types of cells. Sporadic, nonhereditary, unilateral forms of retinoblastoma also exist, in which two simultaneous somatic mutations are required.</p> <p>Progressive neurodevelopmental arrest disorder characterized by mental retardation, neuronal impairment, reduced muscle tone, hand wringing, autistic-like behaviors, and seizures. RTT is lethal in hemizygous males, so clinical cases are always females. Onset usually between 5th and 18th year. Defective molecule is methyl-CP6-binding protein 2 (MECP2). Evidence of genomic imprinting.</p>	Affects about 1:20,000 children, worldwide.	127
Rett syndrome (RTT); 312750, XD, Xq28)	<p>Progressive neurodevelopmental arrest disorder characterized by mental retardation, neuronal impairment, reduced muscle tone, hand wringing, autistic-like behaviors, and seizures. RTT is lethal in hemizygous males, so clinical cases are always females. Onset usually between 5th and 18th year. Defective molecule is methyl-CP6-binding protein 2 (MECP2). Evidence of genomic imprinting.</p>	Incidence is about 1:10,000 worldwide, and found in virtually all large populations.	128
Rhesus isoimmunization (Rh blood type; 111680, AD, 1p36.2–p34)	<p>Coincidental condition characterized by loss of fetal RBCs due to agglutination in utero by maternal anti-D antibodies, causing jaundice, anemia, hypoxia and CNS damage, and an enlarged liver and spleen (i.e., HDN, see below). The rhesus blood group is a complex system with at least six major alleles at three probable loci; the original terminology of Fisher has been slightly modified. The clinically significant alleles are D, d (111680), found on the surface of erythrocytes. Most antibodies, such as those of the Rhesus system (anti-D), are manufactured in response to specific antigenic challenges from an individual's environment. Unlike the major antibodies of the ABO blood group that are large IgM class immunoglobins, the antibodies of the Rh system are IgG class molecules, and small enough to permeate the placental membrane, creating potentially</p>	The highest RH– (d) frequencies are found in Africa and, especially, Europe; the Basque population is almost entirely dd. The recessive d allele (in the cde haplotype) is rare in Asia and the Americas, and absent in Australia and New Guinea. The CDE haplotype exhibits the complementary distribution.	129

significant problems in certain pregnancies. “Rh– incompatible” matings occur whenever a higher parity pregnant dd female can make antibodies to D antigens present in her Dd fetus. The source of the fetal D antigens is the DD or Dd father. Without intervention, the Dd fetus is at-risk for **hemolytic disease of the newborn (HDN)**. Other major polypeptides in the blood group include the Cc/Ee antigens (111700, AD, 1p36.2–p34), but there are over 40 other antigens in this series, as well. For clinical purposes, Rh phenotypes are reported as Rh+ (DD, Dd) or Rh– (dd), but denoting haplotypes for the three major alleles (e.g., cde, cDe) is more accurate. Isoimmunization also occurs in several other blood groups, including the ABO, **Diego**, **Duffy**, Kell–Cellano and Gerbich blood groups, but Rh incompatibility accounts for more than 90% of cases.

Schizophrenia (SCZD);
181500, 603342, 605210, MF,
5, 1 lq, plus 12 other possible
loci)

Schizophrenia is a constellation of similar disorders characterized by a debilitating loss of the ability to organize thoughts and perceptions, and that leads to inappropriate behaviors and a withdrawal from reality. An increased probability of recurrence among close relatives and a high concordance between identical twins suggests a genetic component of high but unknown magnitude. Schizophrenia is genetically heterogeneous, multifactorial and/or probably polygenic presentation. Alternatively, schizophrenia has been suggested to be due completely to environmental agents, caused for example by maternal influenza during the second trimester, when fetal brain cells are undergoing rapid hyperplastic growth, and are susceptible to the effects of such a virus.

Severe combined immunodeficiency disease, X-linked (XSCID, 300400, XL, Xq13; AKA Swiss type agammaglobulinemia)

One of the primary immunodeficiency diseases (PIDs), SCID is a form of **agammaglobulinemia** that differs from the less severe **Bruton type** by a complete absence of lymphocytes and that results in a greater vulnerability to infections and a consequential death at earlier age. Intravenous Ig administration is not beneficial; hence the designation “severe.” Much of the phenotypic constellation (e.g., absence of thymus tissue) of XSCID is due to infection-induced tissue degeneration prior to the time of presentation. The affected gene is the interleukin–2 gamma receptor chain (IL2RG); about 150 different mutations have been identified. There is also an autosomal recessive Swiss form (SCID; 202500, AR, 8q11). About 50% of all U.S. SCID is XSCID; another 5% is due to **adenosine deaminase deficiency**, and the remaining 35% is either the AR form or of unknown etiology.

Affects roughly 1% of the U.S. population.

130

Rare but highly informative; between 100 and 700 PID cases per country in Europe and the United States. The autosomal form has an unknown but notable frequency among Athabaskan-speaking Native Americans (Navajo, Apache, Dene).

131

Table 1. (Contd.)

Trait	Description	Regional variation	Ref.
<p>Sex-determining region of the Y chromosome (SRY); 480000, YL, Yp11.3)</p>	<p>SRY is among the very few genes that have been mapped specifically to the Y-chromosome. The SRY maps to the middle of the short arm of the Y chromosome in both humans and in mice. SRY binds to DNA, distorting its shape, and alters gene expression at the binding site. The SRY alone is not expected to be the only gene that determines “maleness”; rather it is expected to start a cascade of effects due to genes located on the autosomes; these are then expressed either differently (or only) in males than in females. All Theria (marsupials and placental mammals) have the SRY gene. When transferred into normal XX female mouse genomes using the new genetic technology (creating “transgenic” species), SRY DNA fragments induce testis differentiation in those females. AKA TDF, or testis differentiating factor. See ambiguous genitalia, pseudohermaphroditism, XX male, and XY female.</p>	<p>Found on the Y chromosome of all normal males.</p>	132
<p>Sickle cell disease (SCD); 603903, 141900.0243 [HBB]; AR, 11p15)</p>	<p>Described in the Western literature by Herrick in 1910, SCD is an autosomal recessive genetic condition caused by homozygosity for the mutant hemoglobin S allele (Hb^S). SCD is found in populations where malaria is endemic, and is characterized by anemia due to a culling of red blood cells with an altered morphology due to defective hemoglobin in the RBC wall that crystallizes under conditions of dehydration or low oxygen tension; the deformed corpuscles block capillary blood flow (thrombosis), deforming them into a characteristic sickle shape during sickle cell anemia. Symptoms of a sickling crisis include external manifestations of thromboses and ulceration of limb tissues, but internal lesions occur as well. Other clinical consequences include bone and joint pain, infections and anemia. A substitutional mutation of the amino acid glutamic acid for the normal valine at position six in the beta chain of the more common form (Hb^A) of the adult hemoglobin molecule is the cause of clinical problems. The marrow and spleen are stressed to produce more red blood cells (RBCs); too few RBCs causes anemia and too few white blood cells (WBCs) impairs immunity. Sickle cell disease usually limits life to 10 years or less in countries where incidence is high in the presence of malaria. Under such conditions, SCD-affected individuals are homozygous (SS), with an estimated direct fitness lowered to 10% or less. Carriers of the allele (AS) enjoy the maximum relative</p>	<p>The estimated frequency of this allele (S) in several studies of American populations is about 0.05. In West Africa the allele frequency is usually greater than 0.10, and can exceed 0.20; the incidence of homozygosity is as high as 1:50 in West and Central African tribes. Historically known as <i>ahotutuo</i> among the Twi, as <i>chwechwechwe</i> among the Ga, as <i>nwiwit</i> among the Fante, and as <i>nuidudui</i> among the Ewe. As many as 1:15 Americans of West African ancestry may be carriers of an impaired Hb^S allele, and it remains one of the most prevalent lethal diseases associated with an African ethnic group. Worldwide, however, the Hb^S is also found in South America, in the Australasian and Indian subcontinents, in the Mediterranean region, and in the Caribbean.</p>	133

fitness (100%) due to heterozygote advantage, and are said to carry the *sickle cell trait* (in carriers, 20–40% of total Hb is Hb^S, but carriers should avoid hypoxia and under certain conditions can experience a sickling crisis). Although the cause of SCA is known, prophylaxis is limited to transfusions and, more recently, the stimulation of fetal hemoglobin synthesis by administration of hydroxyurea (AKA Dresbach's anemia, Herrick's anemia, and sickle cell anemia, SCA). See **hemoglobin alleles**.

Situs inversus viscerum
(270100, AR, -)

Heterotaxy (reversed asymmetry) is the result of a failure to establish normal left–right asymmetry during embryonic development; the usual case is complete mirror image of normal internal viscera orientation, with the heart in the right lung cavity, etc. Most cases are familial and segregate as an autosomal recessive, although X-linked forms (306955) have been reported. There is suspicion of a paternal age effect.

SRY

See **Sex-determining Region of the Y chromosome**.

Tay–Sachs disease, infantile
(TSD; 272800, AR, 15q22–q24
[HEXA]; 5 [HEXB])

A lethal autosomal recessive condition characterized clinically in infants by a “startle reaction” due to nervous tissue degeneration; mental impairment, paralysis, blindness (red spot on retina), and inevitable death in infancy. The defective gene, HEXA, codes for the alpha chain subunit of beta-hexosaminidase A, found in lysosomes; the mutant form interrupts ganglioside GM₂ metabolism, causing irreversible problems in the nervous system. Affected individuals are recessive homozygotes (tt). Two common mutations account for more than 90% of all cases. Other variants of TSD exist, that is, mutations in HEXB, which contains three subunits that map to chromosomes 5 (β chain subunit).

Testicular feminization (TF)

See **Androgen Insensitivity Syndrome (AIS)**.

Thalassemia, alpha (141800,
141850, AC, 16pter–p13.3)

An inherited codominant abnormality of blood, caused by an imbalance in the production of the subunits of hemoglobin (Hb). Symptoms range from none to mild anemia to stillbirth (hydrops fetalis) due to lethal anemia, heart failure, and fluid accumulation. Cause is inactivation (deletion) of up to 4 loci (in various combinations) that produce the alpha globin chains of hemoglobin. Some

Rare.

134

Affects 1 of every 2,000 children whose parents are descended from Ashkenazi Jews. As many as 1:30 Jewish Americans of Eastern European ancestry may be carriers of an impaired TSD allele, and it remains one of the most prevalent lethal diseases of childhood associated with an American ethnic subpopulation. The estimated frequency of this recessive allele (t) in several studies (French Canadians in Quebec, Louisiana Cajuns that had been expelled from Canada, and non-Amish Pennsylvania Dutch) ranges from 0.013 to 0.016. In other populations the frequency is equal to the mutation rate, 2×10^{-6} .

135

Highest frequencies of the alpha form are found in Persia, but it is also found in the Mediterranean region, Africa, Southeast Asia, the Philippines, and Japan; in New Guinea and elsewhere in Melanesia, the alpha(+) allele is nearly fixed

136

Table 1. (Contd.)

Trait	Description	Regional variation	Ref.
Thalassemia, beta (141900, 604151, AD, 11p15.5)	<p>variants confer resistance to malaria to adults in the heterozygous state; homozygotes have severe anemia, while heterozygotes have a milder form (AKA Mediterranean anemia).</p> <p>An inherited codominant abnormality of blood, caused by an imbalance in the production of the subunits of hemoglobin (Hb). Symptoms vary from none to severe. Clinically, beta thalassemia is divided into three entities: (1) Thalassemia major is an often fatal genetic disease in which the amount of hemoglobin is decreased by the action of a recessive allele when in the homozygous condition; characterized by severe anemia and defects in bone, liver, and spleen that are ultimately fatal. Caused by defective or inactivation of either one or two of the beta chains in hemoglobin. (2) Thalassemia intermedia, characterized by mild anemia in persons heterozygous for the same autosomal recessive allele that, when homozygous, causes thalassemia major; this deficiency also confers some resistance to malaria. (3) Thalassemia minor (asymptomatic) (AKA Cooley's anemia).</p>	<p>(98%) in most populations.</p> <p>More than 70 different beta chain mutations have been identified. The beta form is found worldwide, and is common in Africa, the Caucasus, and Asia; the distribution is generally explained by suspected Phoenician, Carthaginian, and Greek colonization. It is also found in moderate frequencies in Europe and the Americas.</p>	137
Tourette syndrome	<p>See Gilles de la Tourette syndrome.</p>		
Triplo-X syndrome (-, MCA, 47,XXX)	<p>Features of this major chromosome anomaly include amenorrhea in tall, thin females; otherwise, phenotype is normal; slightly lowered IQ in some reports. All X-polysomic individuals risk the production of gametes with an unbalanced sex chromosome count. Females with 48,XXXX have 3 Barr bodies, 49,XXXXX have 4 Barr bodies, etc., and progressively impaired intelligence proportional to the number of Barr bodies (AKA "super female" syndrome).</p>	<p>Affects 1:1,500 live born females.</p>	138
Trisomy 21 (190685, MCA)	<p>See Down syndrome.</p>		
Turner syndrome (-, MCA, 45,X0)	<p>Clinical symptoms of this non-familial aneuploid condition (2N = 45) include low birth weight, swelling in hands and feet, webbing of the neck, coarse facial features, nail hypoplasia, and a very low hairline in childhood; there is no sexual maturity (gonadal dysgenesis and sterility is nearly universal). Further symptoms include a short adult stature, wide-spaced nipples, broad chest, and pigmented moles. There is an excess of lymphocytes at all stages. Hearing impairment prevalence ranges from 50% to 100% of cases. There is no reported parental age effect. Some hormonal therapy has recently become possible. Rare cases of phenotypic sex discordance sometimes involve male MZ twins with subsequent somatic nondisjunction in one of the</p>	<p>1:2,500 live-born females affected; 1% of all conceptions are 45,X0, but 98% of all X0 conceptions are spontaneously aborted, which indicates that the condition occurs frequently at conception (1:250).</p>	139

<p>pair that produces a 45,X0 female phenotype; the other twin remains a normal male. Turner syndrome exhibits evidence for genomic imprinting; it is usually the father's X chromosome that is lost.</p>	<p>Pairs of individuals produced at one birthing event. One of several types of multiple birth events such as triplets, quadruplets, etc., of which various combinations may be MZ or DZ. Multiple birthing in humans is considered clinically to be an exceptional, teratogenic event. See fraternal twinning and identical twinning.</p>	<p>See multiple births for incidences of higher-order births.</p>	<p>140</p>
<p>Twins</p>	<p>DZTs are thought to be the result of two simultaneous pregnancies such that a pair (or more) of individuals reside in a womb. There are two placentas, and twin pairs can be the same sex or opposite sexed. There is a strong maternal age affect, with the probability of dual conception rising sharply in the latter portion of the 4th maternal decade (AKA binovular twinning). Cf., Twinning, identical.</p>	<p>The DZ twinn rate varies by geographic region: The overall number of DZ twins per 1,000 live births is 2–7; in North America, 7–11; in Europe, 9–20; in Africa, 45–50.</p>	<p>141</p>
<p>Twinning, fraternal (DZT); dizygotic twins, 276400, MF, -)</p>	<p>MZTs are thought to be the result of a single conception, with cleavage occurring (sometimes asymmetrically) while the preimplantation cells of the morula are still totipotent; hence monozygous. MZT pairs are “always” of the same sex, except in very rare cases of discordant gonadal dysgenesis caused by epigenetic factors. There are no demonstrable parental age effects in MZ twinning. Whether MZ twinning is familial is still an open research question (AKA uniovular twinning). Cf., Twinning, fraternal.</p>	<p>The MZ twin rate is about the same worldwide: 3–4 per 1,000 live births (1:240 full-term pregnancies is a frequently cited figure). Of all twin conceptions, however, about 70% result in singleton births, a result of the “vanishing twin” phenomenon; the actual MZ twinning rate may thus be as high as 1:80.</p>	<p>142</p>
<p>Twinning, identical (MZT); monozygotic twins, 276410, MF, -)</p>	<p>Hereditary form of abnormal tyrosine accumulation that causes liver and kidney damage; occurs when the amino acid tyrosine fails to be degraded into p-hydroxyphenylpyruvic acid by a defective enzyme, p-hydroxyphenylpyruvic oxidase.</p>	<p>Rare.</p>	<p>143</p>
<p>Tyrosinemia, type II (276600, AR, 16q22.1–q22.3)</p>	<p>Heritable defect characterized by wide-set eyes, wide nose, displacement of the epicanthic fold, pigment anomalies such as eyes that differ in color, white forelock and eyelashes, and variable hearing loss. Defect is in paired Box gene 3 (PAX3); homeobox genes regulate structural development in embryogenesis. Indications of a paternal age effect. There are several other forms of WS, all inherited in an AD fashion.</p>	<p>Rare; informative.</p>	<p>144</p>
<p>Waardenburg syndrome, type I (WS1; 193500, AD, 2q35)</p>	<p>One of the progerias, or syndromes in which the rate of “aging” is increased, or at least mimicked. In WRN, onset is in the 2nd or 3rd decade of life; by 40 an affected individual has premature wrinkles, baldness, cataracts, muscular dystrophy, and diabetes. Lifespan is truncated. The defective gene is WRN, probably a helicase in the RecQ family that normally unwinds DNA.</p>	<p>Rare; informative.</p>	<p>145</p>
<p>Werner syndrome (WRN); 277700, AR, 8p12–p11.2)</p>			

Table 1. (Contd.)

Trait	Description	Regional variation	Ref.
Wilson disease (WND); 277900, AR, 13q14.3-q21.1)	Inherited condition that manifests by the 2nd decade of life, characterized by liver disease in children and by neurological difficulties in young adults. Other symptoms include headache and stomach ache, loss of balance, gravelly voice, handwriting abnormalities, drooling, and uncontrolled facial expression. Defects in mineral (copper) metabolism cause damage to the liver and CNS, corneal modification (ring around iris), tremors; emotional changes. The defective gene is ATP7B.	Rare (1:75,000); informative.	146
Xeroderma pigmentosum (XP; 278700, AR, 9q22.3)	An autosomal recessive set of conditions (XPA, XPB, ... XPG) caused by deficient genes that are normally involved in DNA excision repair ("cut-and-patch repair"). XP is characterized by extreme sensitivity to ultraviolet light; the radiosensitivity results in unrepaired damage to fibroblast DNA and the formation of multiple pigmented spots that often become skin cancer. Onset in the 1st decade of life. First described by Kaposi in 1870.	Rare, but highly informative regarding DNA repair mechanisms.	147
XX male syndrome (278850, YL, X(Y))	Normal phenotypic males have a 46,XY chromosome constitution. Rarely, an individual with a 46,XX chromosome constitution presents with a male phenotype due to an abnormal translocation of a portion of the Y chromosome that contains the SRY gene to the X chromosome. All such XX sex-reversed males are sterile; some exhibit features of Klinefelter syndrome . XX males may lead normal lives; many marry.	Although rare (1:9,000), several athletes with this syndrome have become controversial public figures. The International Olympic Committee has reportedly ceased testing for this and other exceptional genetic conditions.	148
XY female syndrome (306100, XR, X(X))	Normal phenotypic females have a 46,XX chromosome constitution. Rarely, an individual with a 46,XY chromosome constitution presents with a female phenotype and gonadal dysgenesis, XY type (GDXY). All XY sex-reversed females are sterile. Although sterile, XY females may lead normal lives; many marry; (AKA Swyer syndrome).	Although rare (1:20,000), several athletes with this syndrome have become controversial public figures.	149
Zellweger syndrome (600414, 214100, AR, 12p13.3, 7q)	Absence or defects of peroxisomes that lead to characteristic prenatal defects of skull, face, ears, eyes, hands, feet, liver, and kidneys; fatal. Defective proteins fail to develop surface receptors on peroxisomes. (PXR1, peroxin 5).	Rare; informative.	150

This is a very small sample of the more than 5,000 known gene-based entities. For additional information, see Mai et al. (2004) and McKusick et al. (2004). The *OMIM* was consulted for all 150 entities, and a major portion of each digest was abstracted from that source. Most of the conditions listed here are well-documented one-locus anomalies with a straightforward mode of inheritance and complete penetrance. A few are polygenic or multifactorial, and a few are indicated as controversial. Supplemental data can be found in recent references for each condition as noted in the final column.

NOTES

1. Dedicated to Sir Archibald Garrod and William Bateson, who deduced the Mendelian recessive pattern of inheritance of alkaptonuria, the first *inborn error of metabolism* described a century ago, in 1902.
2. This work is a companion piece to the entry Genetic Disease I.
3. Shakespeare (1611), *The Tempest*, Act IV, Scene I.
4. Locke, John (1690). *Essay Concerning Human Understanding*. London.
5. Italicized terms in the text refer to conditions found in Table 1.
6. Although conventional wisdom sets the prevalence of a “common” disease at 1:1,000, less common conditions have been included here for the reasons noted.
7. Among the diseases or entities that have been excluded from this survey are allergy (but see *asthma*), many forms of cancer (gastrointestinal, lung, reproductive organ), chemical sensitivity (but see *anosmia*), chronic liver disease, clubfoot, congenital dislocation of the hip, several other demyelinating diseases, gluten-sensitive enteropathy, many gynaecological disorders, hairlip (\pm cleft palate \pm ankyloglossia), handedness, congenital heart malformation, several hyperbilirubinemias, hyperlipidemia, essential hypertension, hyperuricemia and gout, several causes of infertility and pregnancy loss, multiple sclerosis, narcolepsy, involutional osteoporosis, otitis media susceptibility, panic disorder, peptic ulcer, premature X-linked ovarian failure, precocious puberty, pyloric stenosis, renal tract malformations, reward deficiency syndrome, rheumatoid arthritis susceptibility, many common skeletal disorders, sudden infant death syndrome (but see *Long-QT interval*), thyroid and parathyroid disease; and—not insignificantly—virtually all of the immunogenetic lines of evidence linking infectious disease susceptibility to MHC/HLA haplotypes.

HIV/AIDS Research and Prevention

Anthropological Contributions and Future Directions

James W. Carey, Erin Picone-DeCaro, Mary Spink Neumann, Deborah Schwartz,
Delia Easton, and Daphne Cobb St. John

INTRODUCTION

As of December 2002, 42 million adults and children were estimated to be living with HIV/AIDS in the world (UNAIDS/WHO, 2002). Approximately 29.4 million of these are in Sub-Saharan Africa. More than 30% of the

adults in some southern African countries are living with HIV infection. Over 3 million AIDS-related deaths have occurred globally during 2002 (UNAIDS/WHO, 2002). The pandemic grows at an accelerated speed, with an estimated 13,000–15,000 new infections occurring each day (Osmanov et al., 2002; UNAIDS/WHO, 2002).

Beyond Africa, expanding epidemics are present in Russia, Eastern Europe, and many parts of Asia. A combined total of more than 5 million people are infected in India and China (UNAIDS/WHO, 2002). In comparison, there were over 816,000 reported AIDS cases, and more than 174,000 reported HIV infection cases among persons who had not developed AIDS in the United States and its territories as of December 2001 (CDC, 2001c). These figures are likely to be underestimates because of undiagnosed and unreported cases. HIV often impacts the most impoverished and vulnerable groups. AIDS-related deaths of parents have left an estimated 14 million children (less than 15 years old) living as orphans in countries across the world (UNAIDS, 2001). While there have been many advances in medical treatment, there still is no cure or effective vaccine. Many persons do not know they are infected until they progress to later stages of disease, and they often learn of their HIV serostatus only after they acquire opportunistic infections. Regardless of their awareness of their serostatus, very large numbers of HIV-infected persons do not have sufficient access to appropriate and affordable medical care.

Morbidity and mortality due to HIV/AIDS has devastated the economic and social well-being of numerous countries. HIV/AIDS differs from many other diseases in that it often strikes adults in the most productive age groups. Even with access to good medical care, the disease is eventually fatal. Economic costs include individual and societal expenditures for medical care, drugs, and funeral expenses. Other costs include loss of productive and well-educated members of society, increased health insurance rates, burdens on hospitals and public social service programs, and care of orphans. The cumulative impact of the disease has had significant deleterious effects on national economies (Bollinger & Stover, 1999; Rugalema, 2000; Rugalema, Weigang, & Mbwika, 1999). In 1997, public health spending on AIDS alone exceeded 2% of gross domestic product (GDP) in 7 out of 16 African countries where total health expenditure from public and private sources on all diseases accounted for 3–5% of gross national product (GNP) (UNAIDS, 2000). Loss of economically productive and vocationally trained persons due to illness or death, and diversion of labor to the care of sick family members, exacerbates food insecurity by reducing the agricultural output and distribution capacity in many less-developed nations. It can impact

other non-agricultural economic sectors as well (Barnett & Whiteside, 2002; World Bank, 1999).

Complex societal, behavioral, and medical factors affect HIV transmission, treatment, and control. Researchers from an array of social and behavioral sciences have worked with public health investigators and practitioners to better understand the conditions that influence HIV transmission. Social and behavioral scientists have played a significant role in developing effective interventions to reduce HIV-related risk behaviors. Psychology, in particular, has made notable contributions to the struggle against HIV/AIDS, especially in the form of behavioral change theories and intervention design. In recent years, other social and behavioral science disciplines, including anthropology, economics, health education, communications, sociology, and many others, also have played increasing roles.

The purpose of this entry is to review some of the major contributions made by anthropology within the larger field of HIV/AIDS prevention research and to identify potential areas for future growth. The HIV research literature is extremely large and complex. Space limitations mean that the entry cannot provide an all-inclusive review. Moreover, because many HIV research studies are implemented by large multidisciplinary teams, it often is very difficult to discern the contributions specifically growing from anthropology, even when prominent individual anthropologists explicitly collaborate on a study.

With these caveats in mind, we discuss a sample of the published literature as a way to highlight major issues and trends and also to show how anthropology fits into the larger HIV/AIDS research context. We begin by providing a summary of key epidemiological and medical aspects of the disease. Second, we discuss an overview of the contributions of the social and behavioral sciences, giving particular attention to the development of theory-based HIV prevention interventions. Third, we examine in greater detail areas where anthropology has made its largest impact to date, especially in the conduct of formative HIV behavioral research, and in the application and development of ethnographic methods for the study of HIV risk behaviors. Finally, we suggest areas where anthropologists should play a greater role in the future, such as more active involvement in the development and rigorous testing of new intervention approaches based on anthropological theories and empirical field studies.

EPIDEMIOLOGICAL AND MEDICAL FEATURES OF HIV/AIDS

History of the Disease

To date, the earliest known instance of infection with human immunodeficiency virus (HIV) is from a blood sample collected in 1959 from a man in the Democratic Republic of Congo, although how he became infected is not known (Zhu et al., 1998). Most researchers believe that the viruses that cause AIDS in humans (HIV-1 and HIV-2) evolved from related viruses found among chimpanzees and sooty mangabey monkeys in Africa (Korber et al., 2000). Korber et al. (2000) estimate that the ancestor of the contemporary HIV-1 virus crossed over into humans, possibly via a hunter's exposure to blood from a chimpanzee infected with a simian immunodeficiency virus, some time between 1915 and 1941. Beginning in the late 1970s and early 1980s, rare types of pneumonia, cancer, and other illnesses that normally do not affect individuals with healthy immune systems began to be reported by medical personnel in Los Angeles and New York among a number of gay male and other patients in the United States (CDC, 1981). In 1982 public health officials began to use the term "Acquired Immune Deficiency Syndrome," or AIDS, to describe the occurrences of these opportunistic infections and illnesses, and the virus itself was identified in the early 1980s. Since that time, HIV/AIDS has become a major worldwide public health problem. It has reached pandemic proportions in places such as southern African nations and Southeast Asia (United Nations, 2001). In spite of enormous international research efforts and expenditure of funds, there currently is no effective vaccine to prevent primary HIV infection (Johnston & Flores, 2001).

HIV Transmission

HIV infection is acquired most commonly through sexual contact with an infected partner and by sharing contaminated injection equipment, often from illicit drug injection (CDC, 2000a). Prior to the implementation of HIV-specific screening procedures in 1985, HIV also was spread through blood transfusions using infected blood or blood-clotting factors. Transmission via accidental needle sticks in a health care setting is rare and post exposure prophylaxis (PEP) is often available in such situations (CDC, 1995). HIV transmission through contaminated blood products or in medical settings may still occur in

poorer countries that do not enforce HIV screening precautions or that re-use needles. Vertical transmission, or the passing of HIV from mother to infant during pregnancy and child birth, can also occur. However, antiretroviral therapy (ART) administered to the mother and to the infant in the neonatal period, results in a major reduction of the overall risk of vertical transmission of HIV to approximately 8%. In some settings, ART combined with cesarean section, has resulted in a further lessening of risk to levels of less than 2% (Andiman, 2002). Nursing HIV-infected mothers can also pass HIV to their child through breast milk (Georgeson & Filteau, 2002; Quintanilla, 1996). While researchers have identified evidence of HIV in the saliva of infected individuals (Levy, 1993; Levy & Greenspan, 1988), there is little evidence to conclude that HIV is spread through contact with saliva. There also is no evidence to show that HIV can be spread through casual contact with the tears, sweat, urine, or feces of an infected individual (CDC, 2000a). The exact probability for transmission via oral sex is not known, although it is likely to be very low (CDC, 2000b).

Immune System Effects

HIV weakens the body's ability to fight disease by damaging the CD4+ cells, a component of the immune system that helps respond to infections (McCune, 2001). Thus, infected individuals with weakened immune systems become susceptible to numerous HIV-related opportunistic infections and other conditions (CDC, 1997, 1999, 2002a, 2002b; Gallant, Moore, & Chaisson, 1994; Levy, 1993; Sulkowski, Mast, Seeff, & Thomas, 2000). Some of the more common of these illnesses include:

- bacterial and mycobacterial infections such as syphilis and tuberculosis
- protozoal and fungal infections such as candidiasis, or *Pneumocystis carinii* pneumonia (PCP)
- malignancies such as Kaposi's sarcoma and lymphoma
- viral infections such as cytomegalovirus (CMV), hepatitis, and herpes simplex
- neurological conditions such as AIDS dementia complex (ADC).

If left untreated, co-infection with HIV and opportunistic infections can lead to rapid deterioration of the individual's health, and ultimately, death. For example, tuberculosis has become the leading cause of mortality among HIV-infected persons worldwide (CDC, 2000b; Cegielski et al., 2002; Rieder, Cauthen, Kelly, Bloch, & Snider, 1989; UNAIDS, 2000). Persons co-infected with

HIV-1 and malaria may be more likely to develop clinical malaria, particularly as the onset of AIDS approaches (Whitworth et al., 2000).

HIV Prevention and Condom Use

The only certain way to avoid risk of sexual exposure to HIV is to abstain or to have sex in a mutually monogamous relationship with an uninfected partner (Novello et al., 1993). However, the risk of HIV infection from engaging in vaginal or anal sex with an infected partner or one of unknown serostatus can be greatly reduced through consistent and correct use of latex or polyurethane condoms (CDC, 2001a; NIAID, 2001). In a European study of 124 HIV serodiscordant heterosexual couples, de Vincenzi (1994) reported that none of the seronegative partners that remained sexually active during the study period and who reported always using a condom became infected. In contrast, among 121 couples who inconsistently used condoms, seronegative partners became infected at a rate of 4.8 per 100 person-years (95% confidence interval = 2.5–8.4). Approximately 15,000 sexual intercourse episodes were reported by the couples in di Vincenzi's study. In another study of seronegative female partners of HIV-infected men, Saracco et al. (1993) reported an incidence rate of 1.1 per 100 person-years among those who always used condoms versus a rate of 7.2 per 100 person-years among those who did not always use or never used a condom. Among Haitian sexually active serodiscordant couples, Deschamps, Pape, Hafner, and Johnson (1996) found an HIV incidence rate of 1.0 per 100 person-years among the seronegative members of couples that were consistent condom users versus a rate of 6.8 per 100 person-years for infrequent or non-condom using couples. Overall, when comparing various studies in a meta-analysis, Davis and Weller (1999) estimated that consistent condom use is approximately 87% effective at preventing HIV infection (95% confidence interval = 60–96%). This estimate is roughly similar to a condom's effectiveness at preventing unwanted pregnancies. However, condoms' effectiveness for preventing infection with other STDs may vary (Manhart & Koutsky, 2002; NIAID, 2001).

HIV Treatment

At present, there are three major classes of anti-HIV drugs (NIAID, 2002a). These include protease inhibitors, nucleoside analog reverse transcriptase inhibitors (NRTIs),

and non-nucleoside analog reverse transcriptase inhibitors (NNRTs). Protease inhibitors work by preventing HIV from being successfully assembled by and released from infected CD4+ cells. NRTIs act by incorporating themselves into the genetic material of the virus, thereby halting the viral building process (Richman, 2001). NNRTs stop HIV production by binding directly onto reverse transcriptase and preventing the duplication of viral genetic materials (NIAID, 2002a, 2002b; Williams et al., 1993).

Treatment generally involves administration of complex combinations of these drugs. Many of these powerful agents have an array of unpleasant side-effects and toxicities. Combination treatment using therapies from each class is necessary to reduce the chance of the virus developing drug resistance (Richman, 2001). Unfortunately, over 90% of HIV-infected persons live in impoverished less-developed countries where most cannot afford the high price of antiretroviral drugs or do not have access to them (Rand Corporation, 2002; United Nations, 2001; Yamey, 2000). This is the case despite reduction in the treatment costs brought on by price competition and international political pressures on the pharmaceutical industry (Garrett, 2000; United Nations, 2001).

SOCIAL AND BEHAVIORAL SCIENCE IN HIV PREVENTION RESEARCH

Importance of Behavioral Theory for HIV Prevention

HIV prevention programs must, by necessity, rely heavily upon strategies to change people's behaviors that put them at risk for infection. Public health personnel should concentrate effort on changing those behaviors that carry the greatest risk for HIV transmission. The design of effective HIV behavioral interventions is highly challenging, in part because of the complex array of individual and contextual variables that affect sexual or drug use behaviors, and also because of the difficulty in getting persons to change behaviors that provide them with powerful and pleasurable rewards.

One of the most important contributions of the behavioral and social sciences to HIV/AIDS prevention has been the development of theory-based behavioral intervention strategies. Behavioral and social science theories are useful because they help guide researchers and intervention personnel to focus their attention on the

factors that promote or discourage HIV risk behaviors (CDC, 2001b). Useful theories identify specific correlates of HIV risk behavior that, if changed, should help bring about reductions in behaviors that put an individual at risk for HIV infection. There is value in designing a mixture of interventions specifically for groups with known elevated risk for HIV infection, along with more general population interventions for groups at lower risk (Sumartojo, Carey, Doll, & Gayle, 1997).

Many of the most prominent theories used to date in HIV prevention research have grown out of the social psychology, health education, and health communication fields. If they are adequately specified, theory-based HIV behavioral interventions can be tested and compared using experimental or quasi-experimental research designs. Theories that stand up to empirical field studies not only have value for explaining patterns and causes of HIV risk behavior, they also have practical utility for guiding prevention interventions. HIV behavioral interventions that have been shown to be effective in scientifically rigorous research provide an essential base for turning HIV prevention research into useful public health practice (CDC, 2001b).

Examples of Theories Used in HIV Behavioral Interventions

After HIV/AIDS was recognized, early work to curb the spread of the disease attempted to promote accurate factual knowledge about HIV transmission risk behaviors and risk reduction (e.g., DiClemente, Boyer, & Morales, 1988; Kelly, St. Lawrence, Brasfield, & Hood, 1989; Kelly et al., 1990; Marin, 1989; Norris & Ford, 1991). These education efforts were successful in encouraging greater levels of understanding that HIV can be acquired through sexual contact or by sharing contaminated injection drug equipment. They also were successful in building awareness that personal risk of becoming infected can be lowered by using condoms during sex, being sexually abstinent, limiting sex to a monogamous relationship with an uninfected partner, and by avoiding injection drug use with contaminated equipment or stop shooting drugs.

In spite of these successes, some groups continue to hold medically inaccurate beliefs and unsubstantiated opinions concerning persons with HIV infection. For example, in a nationally representative survey of adults conducted in the United States during 2000, researchers found that over 40% of the respondents incorrectly

believed that it is likely for HIV to be transmitted through sharing a glass, or by being coughed or sneezed on by a person with HIV infection (CDC, 2000d). Nearly 19% of these survey respondents indicated that persons who acquired HIV through sex or drug use “got what they deserved.” Stigmatizing responses were more frequent among men, European Americans, persons over the age of 55 years, those with only a high school education, those with an annual income less than \$30,000, and those with a poorer self-reported health status. After more than 20 years of efforts to build public awareness, the results of this survey underscore the importance of continuing to dispel HIV/AIDS misconceptions, along with inaccurate and stigmatizing beliefs in many groups, even in economically and educationally well-off countries such as the United States.

While an accurate understanding of basic HIV-related facts is important and necessary, by itself factual knowledge generally is not sufficient to motivate reduction in HIV risk behaviors. More sophisticated theories of HIV risk behavioral reduction are needed that take into account other factors beyond factual knowledge. During the early 1990s, a variety of theoretical models were adapted for understanding HIV risk behavior and to design prevention interventions. One influential example is the Health Belief Model (HBM), which initially was developed in the early 1950s to understand why people were reluctant to participate in tuberculosis screening and other public health services (Rosenstock, 1974; Rosenstock, Strecher, & Becker, 1988, 1994). As applied to HIV, the HBM proposes that six types of variables influence health behaviors of individuals:

1. *Perceived threat* is a person's subjective perception of how susceptible they are to acquiring HIV and how serious the medical and social consequences would be.
2. *Perceived benefits* are a person's beliefs regarding whether HIV risk reduction strategies (e.g., asking sex partners to use a condom) will reduce perceived threats.
3. *Perceived barriers* are the negative consequences persons think may result if they try an HIV risk reduction strategy. For example, economically dependent women may not suggest condom use to an abusive male partner for fear of a beating or eviction.
4. *Cues to action* include awareness of bodily symptoms or environmental features that help stimulate action. For example, if a person contracts an STD or hears a salient media campaign, he or she may be more likely to engage in HIV risk reduction behaviors.
5. *Perceived self-efficacy* was added to the HBM by Bandura in the 1970s (see Bandura, 1986, 1997, for reviews). Self-efficacy is the degree to which a person believes that he or she is capable of executing a specific health-related action.

6. Finally, the HBM also recognizes that a wide array of other variables, such as demographic, social, psychological, structural, and environmental factors, may shape a person's health beliefs and, thus, may influence his or her health behaviors.

HIV risk reduction interventions that are based on HBM would attempt, among intervention participants, to increase their perceived levels of HIV threat, convince them of the efficacy and value of proposed HIV risk reduction strategies, assist them to find realistic ways to overcome barriers they anticipate, increase their level of awareness, and conduct exercises to build the skills they need to implement a strategy.

Another influential theory that has guided a large segment of HIV behavioral research and intervention design is the Theory of Reasoned Action (TRA; see Ajzen & Fishbein, 1980, for an overview and history since the late 1960s). In addition to HIV and STD studies, investigators have used the TRA to study a wide array of other behaviors including smoking, dieting, wearing seatbelts, exercising, and breast feeding (Fishbein, Middlestadt, & Hitchcock, 1994). As described by Fishbein et al. (1994) when applied to HIV behavioral research, the TRA includes the following key components:

1. Define the behaviors of interest as specifically as possible to minimize conceptual ambiguity and include four components: action, target, context, and time. For example, a study might investigate if female commercial sex workers (target) in brothels (context) consistently (time) request that all sex partners use a male latex condom (action).
2. The strength of a person's *prior intention to perform the behavior* is one of the strongest predictors of the performance of the behavior.
3. Strength of intention is thought to be influenced by two major sets of factors: (a) the person's *individual attitudes*, a combination of positive and negative beliefs regarding the outcomes of performing the behavior and evaluations of the consequences of these outcomes, and (b) the person's *perceived norms* of other people's opinions regarding the specified behavior (e.g., safer sex is good) and their willingness to conform to those views.

HIV prevention interventions guided by the TRA would promote one or more specific risk reduction behaviors and would motivate participants' intentions to adopt the behaviors by having them examine the pros and cons of changing and by exposing them to other persons, similar to themselves, who have favorable attitudes toward the new behaviors.

A third influential theory is the Transtheoretical Model of Behavior Change, also known as the Stages of Change (SOC) theory (Prochaska, 1994; Prochaska & DiClemente,

1986). The idea behind the SOC is that people usually alter their behaviors through a series of incremental steps, instead of all at once. The SOC literature names the first of these stages *precontemplation*, defined as the period where the person has not recognized that he/she has a problem (e.g., thinks heterosexuals cannot contract HIV) or has no interest in changing his/her behavior. The second stage is called *contemplation*. Persons in this category are aware that they have a problem and they are thinking about changing their behavior (e.g., are weighing benefits versus difficulties of cleaning their drug injection equipment). The third stage, called *ready for action* or *preparation for action*, includes persons who have decided to change their behavior but either have been practicing the behavior for less than one month or have been practicing it inconsistently (e.g., sometimes forgets to use condoms). The fourth stage is termed *action*, and includes persons who have successfully changed a behavior for a period of one to six months. The final stage, *maintenance*, is reserved for persons who have been practicing the new behavior consistently for longer than six months. The SOC theory recognizes that persons may relapse or oscillate between various stages in the continuum and be at different stages for various risk behaviors. HIV risk reduction interventions designed around the SOC are tailored for each participant and will include identification of their HIV-related risks, as well as their placement in the continuum of readiness to change for each risk. Interventions would employ stage-specific questions, discussions, and/or materials to encourage movement along the continuum of change.

A fourth influential theory is the Diffusion of Innovations Theory (DIT), initially developed to understand the spread and adoption of technological changes (Rogers, 1962). This theory proposes that innovations pass through particular communication channels among members of a social system over time. As with the SOC, the DIT proposes that innovations are adopted following a series of stages. These include: *knowledge*—where persons become aware of the innovation's existence (e.g., female condoms); *persuasion*—a period where persons form favorable attitudes toward the innovation (e.g., recommended by a trusted friend who uses them successfully); *decision*—entailing commitment to its adoption (e.g., purchases condoms); *implementation*—putting the innovation into practice (e.g., inserting condom prior to sex); and *confirmation*—reinforcement based on positive experiences with the innovation (e.g., application of the

condom was easy and partner did not object). The DIT further states that persons or groups vary in their willingness to quickly adopt a new idea or innovation and fall along a continuum of venturesome “innovators” and “early adopters” to more conservative “laggards.” As greater proportions of a social network adopt an innovation, the innovation becomes normative and it spreads more quickly. HIV interventions using the DIT seek to identify sources of information (e.g., respected persons) trusted by the population of interest (e.g., gay men) and to use these sources to inform and persuade other members of the population to adopt the new behavior, often through endorsing or modeling the behavior to demonstrate its value and social acceptability.

Theory-Based HIV Behavioral Interventions

The Health Belief Model, the Theory of Reasoned Action, the Transtheoretical Model of Behavior Change, and the Diffusion of Innovations theory are just four examples of a much larger number of conceptual frameworks that have been used to design HIV behavioral interventions (CDC, 2001b). Some interventions combine principles derived from multiple theories. The following examples illustrate how theories such as these have been used to design successful interventions.

The AIDS Community Demonstration Project was based on the Transtheoretical Model of Behavior Change (AIDS Community Demonstration Research Group, 1999). Its main goal was to assess the effects of a community-level intervention promoting condom use with main and non-main sex partners. The project was implemented in Dallas, Denver, Long Beach, New York City, and Seattle. Intervention settings included street outreach, public sex environments, and other community venues. Trained peer volunteers interacted with persons in these settings, identified their particular stage of readiness to adopt HIV risk reduction behaviors, and attempted to motivate them to change using a strategy tailored for their stage. As part of the intervention evaluation, over 15,000 interviews were conducted with injection drug users, female sex partners of male drug users, commercial sex workers, men who have sex with men, and other members of census tracts with high STD prevalence. By the end of the study, residents of intervention communities were shown to achieve consistently greater

levels of condom use with non-main partners than residents in the comparison communities.

Project RESPECT (Kamb et al., 1998) developed a brief counseling intervention based on a combination of the Theory of Reasoned Action and the Social Cognitive Theory. Their study was conducted in Baltimore, Denver, Long Beach, Newark, and San Francisco. It was implemented by local health department staff trained to carry out the intervention in inner city STD clinics. The goal was to compare the effects of an enhanced four-session interactive counseling approach, and a shorter two-session counseling approach, versus a didactic session typically used in STD clinics. The aim was to learn which approach was more effective in reducing high-risk behaviors and preventing new STDs. A total of 5,758 adult men and women were enrolled. Results showed that participants in both the four-session and two-session study arms reported significantly higher levels of condom use compared with persons in the standard didactic group. Counseling session recipients also developed 30% fewer sexually transmitted infections compared with participants in the standard comparison condition.

Based on hypotheses concerning the role of peer opinion leaders and the Diffusion of Innovations theory, Kelly et al. (1992) enlisted the assistance of bartenders at gay clubs in three communities in Mississippi and Louisiana to nominate popular opinion leaders. These opinion leaders were given intensive education in basic HIV epidemiology and prevention techniques, and in methods for delivering effective HIV prevention messages. They also participated in role-plays, discussions, and practice exercises to learn ways to cope with real-life problems in reducing HIV risk behaviors among gay men in the communities. Each of the trained opinion leaders then were asked to have conversations regarding HIV risk reduction with at least 14 different peers from their own social network at the gay bars. Of the 1,469 gay bar patrons who completed the baseline and post-intervention surveys, men from the intervention study arm reported significantly greater reduction in anal intercourse without a condom compared with the men in the comparison group.

Numerous other examples of effective theory-based interventions designed to reduce HIV risk behaviors can be found in the literature (CDC, 2001b; Neumann & Sogolow, 2000). However, use of behavioral theory alone is not a guarantee that an intervention will be effective. Other factors contribute to the relative success or failure

in reducing risk behaviors (CDC, 2001b; Kelly, 1995). For example, successful interventions typically have clearly defined goals and target audiences. Instead of delivering a series of HIV-related facts via a didactic lecture, intervention recipients should have opportunities to discuss their questions and concerns, as well as practice new skills and solve problems. Successful interventions are well planned, and allow sufficient time for delivery of all the required components. Intervention staff and other key support personnel are well trained, and supervisors carefully monitor and evaluate their work to ensure there is no drift or dilution away from the intended protocols. Successful interventions have sufficient resources, including appropriate numbers of qualified staff, financial resources, and administrative support. Interventions should reflect genuine problems in the target population, be culturally appropriate, and match gender or other special needs when appropriate. Finally, interventions should be feasible and acceptable to community members.

ANTHROPOLOGY IN HIV/AIDS BEHAVIORAL RESEARCH

Anthropology in HIV Behavioral Intervention Research

Despite early calls from within the field to translate their work into risk reduction strategies and behavioral interventions (e.g., Gorman, 1986; Herdt, 1987), there continues to be a noticeably low amount of anthropological influence in HIV behavioral intervention research. The Centers for Disease Control and Prevention (CDC) reviewed over 5,000 HIV reports in its Prevention Research Synthesis project (CDC, 2001b; Sogolow et al., 2002). Virtually none of the effective interventions identified in the Prevention Research Synthesis project's database were based on a theory growing primarily out of anthropology. In reviewing additional literature for this entry, we also found relatively few anthropologists appearing as lead authors or co-authors on publications describing intervention studies, accompanied by rigorous scientific evaluations. To date, the HIV/AIDS behavioral intervention research field appears to have been largely dominated by theories, methods, and perspectives primarily growing out of psychology, social psychology, health education, epidemiology, and medicine.

There are, however, a few intervention studies with a clear anthropological influence, especially in the area of HIV risk reduction associated with drug abuse. One example is a community based HIV prevention intervention designed for out-of-treatment injection drug users and their sexual partners (Weeks et al., 1996). Weeks and her colleagues designed a culturally enhanced intervention approach for Puerto Rican and African American women, and compared its efficacy with a standard drug risk reduction counseling intervention. The enhanced arm was designed to bring about behavior change by incorporating each group's key beliefs, values, and norms. The intervention study arm included discussion of traditional family roles, relationships, group pride, and ways use social resources and cultural values to help avoid HIV-risk situations. The results of Weeks et al.'s study were somewhat mixed. On the one hand, participation in the culturally enhanced arm appeared to lead to drug-related risk reduction for some subgroups. However, extremely high-risk drug injectors tended not to alter their behaviors, and many dropped out of the study altogether. Other examples of HIV and drug risk reduction intervention that incorporate anthropological perspectives include studies by Dushay, Singer, Weeks, Rohena, and Grubar (2001) and Trotter, Bowen, Baldwin, and Price (1996).

Nations and de Souza (1997) provided training to 126 traditional Umbanda healers in seven urban slums in Brazil concerning the biomedical aspects of HIV/AIDS, safer sex practices, avoidance of ritual practices where blood from different individuals might be co-mingled, and in the sterilization of cutting instruments used in rituals. Compared with 100 healers that did not receive the training, healers that participated in the training demonstrated statistically significant lower HIV prejudicial attitudes, along with increases in AIDS awareness, accurate HIV risk behavior knowledge, information about correct condom use, and willingness to use lower-risk alternative ritual blood practices.

As members of diverse research teams, some anthropologists have expanded upon their anthropological training and have used methods and perspectives from other disciplines, such as epidemiology, to conduct large behavioral surveys or to investigate the potential for HIV vaccine trials (e.g., MacQueen et al., 1999; Valleroy et al., 2000). Others have contributed anthropological methods for participant recruitment and for the design of intervention materials as part of larger multidisciplinary team efforts (e.g., Terry et al., 1999; Trotter et al., 1996).

Stall, Paul, Barrett, Crosby, and Bein (1999) evaluated the effects of a safer sex intervention for gay men, conducted at a substance use disorder treatment agency in San Francisco. Stall and his colleagues randomized 82 men into a treatment arm consisting of a safer sex plus treatment disorder experimental condition, and compared with 65 men who received only the standard substance use disorder treatment. Using methods primarily drawn from epidemiology, the investigators found no statistically significant differences in unprotected anal intercourse between the two groups over five waves of data collection. However, they did find statistically significant reductions in unprotected anal intercourse in both groups compared with initial baseline levels.

Ethnography and HIV/AIDS

Compared with intervention studies, anthropology has had a more prominent role in conducting formative cross-sectional research. Anthropologists have used ethnographic methods to investigate a very broad array of topics among diverse populations and geographic settings. The following examples discuss at least seven ways ethnography has been used by anthropologists to contribute to HIV/AIDS behavioral research.

Descriptive Research. Ethnographic studies, which generally employ cross-sectional research designs, can provide information that subsequently is useful for developing interventions or improving programs. Examples include research on sexuality (e.g., Parker, Herdt, & Carballo, 1991; Schensul & Schensul, 1998). Another example is MacQueen, Nopkesorn, Sawaengdee, Mastro, and Weniger's (1996) use of focus group methods to better understand alcohol consumption patterns, brothel attendance, and condom use among Thai military conscripts. Other descriptive studies have documented the effects of AIDS on persons and cultural groups (Herdt, Leap, & Sovine, 1991), have identified factors affecting how cultural groups understand the impact of the disease on their society (Farmer, 1992), and have helped explain cultural issues related to designing education and service delivery for those affected by or at risk for AIDS (e.g., Herdt & Boxer, 1991). Some other examples include studies by Bourgois (1998), Clatts and Mutchler (1989), Feldman (1995), and Varga and Blose (1996).

Studies on Health-Seeking Behaviors. Ethnography has been used to understand health-seeking

behavior related to HIV/AIDS care, stigma, and willingness to reduce HIV risk-related behaviors. For example, Furin (1997) conducted a two-year ethnographic study of HIV seropositive gay men in West Hollywood. Furin reported that the majority (69.2%) of men in the study used some type of alternative therapy. The primary reason for seeking an alternative treatment appears to be dissatisfaction with biomedical therapies, but Furin suggests that other sociocultural factors may also be involved. In particular, AIDS activism in West Hollywood appears to promote the use of alternative therapy. This activism, the author proposes, allows gay men in the community to "become their own doctors" and reclaim power over their treatment and the technical sphere of AIDS.

Ethnography has provided a framework for understanding how HIV/AIDS prevention messages are perceived by intended target audiences (Nicoll et al., 1993). Other studies have described the process through which concerns about family or community response to one's HIV diagnosis has led to delays in seeking treatment. Early in the epidemic in Kenya, for example, AIDS was defined mostly in terms of commercial sex work, and today the disease is still strongly associated with prostitution. Moss et al. (1999) found that women who contract STDs usually are assumed to have participated in commercial sex work, and men who contract such an infection are thought to have been with a prostitute. Presenting oneself to a hospital for treatment of an STD may result in revealing the illness to neighbors and/or family, which can have tremendously adverse impacts on family life. Women who fear being labeled as prostitutes or losing their husbands are less likely to seek treatment.

Correlates of Risk-Taking Behaviors. Ethnography has been used to uncover rationales for both HIV risk and protective behaviors. For example, a number of studies have found that while commercial sex workers may use condoms with their clients, they remain at high risk of being infected with HIV because condom use with their boyfriends and husbands is not considered appropriate (Day, 1988; Varga & Blose, 1996; Waddell, 1996). Based on ethnographic interviews with key informants, Waddell (1996) found a variety of beliefs that affected reluctance to use condoms with the women's non-commercial sex partners. Some of these included the belief that they would be able to recognize if their husband or boyfriend had HIV; a willingness to risk HIV infection for some other desired purpose, such as having a baby or getting married; the belief that life will get better after

they quit sex work; overly optimistic comparison of their HIV risk with that of other women; and resignation to having no alternative. Waddell recommends that interventions address these beliefs and focus greater attention on non-commercial sex partners.

Social Context and Life Circumstances. Other investigators have examined contextual factors that affect HIV risk. Cochran (1989) found that an underlying cause of low HIV risk perception among some African American women appeared to be the existence of more immediate day-to-day concerns, such as survival needs, family demands, and economic pressures. Meyers and Ellen (2001) showed that HIV risk was viewed as just another part of life within an atmosphere of social violence among inner-city adolescents. Stratford, Ellerbrock, Akins, and Hall (2000) used ethnographic methods to study HIV attitudes and misconceptions, contact with commercial sex workers, and low condom use among 71 truck drivers in Florida. They found that risk was exacerbated by long hours driving, loneliness, along with drug and alcohol use. Sterk (1999) used participant observation and various ethnographic interview methods to study low-income urban women who use crack cocaine. She explored the women's circumstances and how they cope with them, including violence, HIV/AIDS, racism, sexism, and poverty. These studies on the context of HIV risk suggest that sex and drug behaviors should not be considered in isolation, but rather should be viewed as factors intertwined with other problems facing members of a community. Interventions should take into account the larger context of HIV risk.

Sterk's (1999) work is a vivid example of what Singer (1994) means when he describes HIV as part of a larger "syndemic" of closely linked health and social problems. The term syndemic is defined as "two or more afflictions, interacting synergistically, contributing to the excess burden of disease in a population" (CDC, 2000c). Examples of problems that commonly interact with HIV include alcohol and drug abuse, violence, joblessness, homophobia, racism, sexism, inadequate housing, insufficient health care, presence of other illnesses, and poor education (e.g., Cochran, 1989; Farmer, 1992; Singer, 1996; Sterk, 1999).

Intervention and Program Evaluation. Ethnography has been used to help evaluate existing HIV interventions, such as Hansen and Groce's (2001) assessment of the Cuban national HIV prevention efforts. Other investigators have used the methods to evaluate needle exchange programs. These efforts allow researchers to

observe what happens to the syringes between the time that they leave the exchange and when they return, something that cannot be completely determined by lab testing of returned needles (Page, 1997). Singer et al. (2000) combined qualitative research methods with epidemiologic surveys and laboratory techniques to assess differences between neighborhoods in access to sterile syringes in three US cities. Their qualitative methods included use of focus groups, ethnographic descriptions of neighborhoods, diaries kept by injection drug users (IDUs) on their drug use and injection equipment, daily ethnographic visits with IDUs, and interviews.

Research with Hidden Populations. For it to be successful, the use of ethnography generally requires a closer contact with communities and respondents, compared with other research methods such as structured surveys. An advantage of this is that ethnographers may develop a more in-depth understanding of subtle aspects of communities and have more time to develop trust with community residents. This makes ethnography a useful tool for research with hidden subpopulations, groups that are not readily identifiable, socially stigmatized populations, or groups that wish to remain hidden (e.g., Latino men who have sex with men, or illegal drug users). Such groups not only may be at significant risk for HIV infection, but also may be under-represented in standard public health surveys and public health surveillance data sets.

For example, ethnographic study of homeless heroin addicts in San Francisco provided detailed descriptions of HIV risk behaviors among a group that would be very hard to reach using traditional survey methods (Bourgois, 1998; Bourgois, Lettiere, & Quesada, 1997). Because of the time invested in developing relationships and trust with the research participants, Bourgois not only was able to identify the risky practices of the subjects but also to discover the reasons behind them. Such understanding is necessary in order to develop effective interventions. Key informants told Bourgois that they often misrepresented their risk behaviors to paying quantitative interviewers who spent less time getting to know the community. These studies show how intensive ethnographic studies with small groups within a community may complement statistically representative structured surveys and epidemiological investigations with large samples (Herdt & Boxer, 1991; Wight & Bernard, 1993).

Society's Perceptions of HIV. Finally, ethnography has been used to better understand how societies view or

portray groups impacted by HIV/AIDS. Farmer's (1992) research on AIDS in rural Haiti clarified how broad social conditions, particularly those related to poverty and political unrest, shaped the national response to the Haitian AIDS epidemic. Farmer also describes how the press in the United States may have exacerbated racism against Haitian immigrants by portraying them using images of "filthy squalor, voodoo, and boatloads of disease-ridden or economic refugees" (Farmer, 1992). Farmer argues that this led many Americans to believe that AIDS was pervasive throughout the Haitian populations, and may have formed the basis of misplaced accusations, particularly that Haiti was the birthplace of AIDS. Other examples discussing society's perceptions of groups heavily impacted by HIV/AIDS include Clatts and Mutchler (1989), Feldman (1995), Murray and Payne (1989), and Singer and Marxuach-Rodriquez (1996).

Development and Improvement of Qualitative Research Methods

Although traditional ethnographic methods have formed the backbone of many anthropological studies, the challenges posed by HIV/AIDS have stimulated the development of new methods. Both traditional methods and newer qualitative research techniques have been adopted by other disciplines to such a great extent that it is now difficult to attribute them as "belonging" to any one field.

One example of these new methods involves "rapid assessment techniques" (see Beebe, 2001, for an overview). Rapid assessment does not refer to a single specific method, but rather to a set of approaches and tools for conducting research under time and resource constraints. As conceptualized within anthropology, these methods are designed to help investigators explore narrowly defined research topics more rapidly than is possible with traditional ethnography (Trotter, 1995). Rapid assessment techniques have been used to conduct formative and evaluative research for national and local HIV programs in settings as divergent as Nicaragua, South Africa, and England (e.g., Carey, 1994; Fenton, Chinouya, Davidson, & Copas, 2002; Weir, Moroni, Coetzee, Spencer, & Boerma, 2002). Researchers from other fields have contributed to the burgeoning rapid assessment methods field in HIV and other areas, including community psychology, epidemiology, international economic development, and sociology (Annett & Rifkin, 1995; Higgins et al., 1996; Scrimshaw & Gleason, 1992; Selwyn, Frerichs,

Smith, & Olson, 1989; Wilson & Family Health International, 2001).

The AIDS Rapid Anthropological Assessment Procedures, authored by Scrimshaw, Carballo, Ramos, and Blair (1991), is an early and well-known example of an attempt to create a set of clearly described procedures for collecting formative data from communities. It provides guidelines for studying sexual behavior, other possible modes of transmission, as well as AIDS-related knowledge, attitudes, beliefs, and practices. Rapid assessment studies often compare data from several different sources (called "triangulation" in the literature). Some of the specific techniques used in rapid assessments include formal and structured and semi-structured interviews, direct and systematic observation, informal conversations with key respondents, personal diaries, and the collection of data from secondary sources.

Various groups have developed rapid assessment manuals using anthropological techniques for specific HIV research needs. Batchelor, Rossman Beel, and Freeman (2001) working with the Texas Department of Health and the CDC, and the California Department of Health Services (1998) both developed rapid assessment methods toolkits to help local jurisdictions conduct HIV needs assessments and to feed the results into local HIV prevention program planning. The World Health Organization (WHO), for example, developed a rapid assessment protocol for planning condom services (WHO, 1991). The WHO also produced a series of rapid assessment documents focusing on maternal and child health, family planning, injection drug use, sexual risk behavior, and psychoactive substance abuse among young people (WHO, 1993, 1998a, 1998b, 1998c). In part modeled from this work, the US Department of Health and Human Services developed the "Rapid Assessment, Response, and Evaluation" (RARE) project to collaborate with metropolitan governments to gather information for improving HIV prevention services among African American, Latino, and other populations disproportionately impacted by HIV in large urban areas in the United States (Needle, Trotter, Goosby, Bates, & Von Zinkernagel, 2000; Trotter, Needle, Goosby, Bates, & Singer, 2001).

Some commentators have expressed skepticism as to the validity of results produced using rapid assessment procedures, largely because of concerns that the short time frames may impose too many shortcuts and superficial understanding of complex issues (Bennet, 1995;

Harris, Jerome, & Fawcett, 1997; Manderson & Aaby, 1992). Replicability and generalizability may not always be possible in rapid assessment studies, especially when dealing with the sensitive topics associated with AIDS research (Scrimshaw et al., 1991). The use of multiple sources of data, however, can help address some of these concerns (Beebe, 2001).

In addition to developing and using rapid assessment methods, anthropologists have refined techniques and software tools needed for the systematic collection and analysis of large qualitative data sets on HIV behavioral research projects. McLellan, MacQueen, and Neidig (2002) describe the steps needed to prepare and transcribe large qualitative data sets. MacQueen, McLellan, Kay, and Milstein (1998) and Carey, Morgan, and Oxtoby (1996) discuss the processes needed to reliably code and analyze qualitative data from multisite research projects. The needs of HIV behavioral research have stimulated further development of a variety of new qualitative data analysis software programs, including "CDC EZ-Text," "AnSWR," and "AFTER," each serving a variety of different qualitative research needs (Carey, Wenzel, Reilly, Sheridan, & Steinberg, 1998; Nova Research Company, 1998; Strotman, McLellan, MacQueen, & Milstein, 2002).

While HIV research needs may have encouraged the development of methodological innovations such as rapid assessment techniques or qualitative data analysis software, these tools have been used for a wide array of other purposes within and beyond public health. In that sense, anthropological efforts within HIV behavioral research have had broader "spin-off" benefits in producing methods and tools useful for investigating other research topics.

DISCUSSION AND FUTURE DIRECTIONS

HIV/AIDS has become one of the most important challenges facing the contemporary world. There is not likely to be an effective vaccine in the near-term future. While anti-viral drugs have greatly reduced AIDS deaths in wealthy countries such as in Europe or North America, HIV medical care is very expensive, complex, does not eliminate the virus from the bodies of infected persons, and is largely out of reach for many impoverished subpopulations and countries. The epidemic has had catastrophic health and humanitarian impacts on the physical, social, cultural, economic, and political well-being of millions of people. The disease strips households and

communities of valuable trained and skilled labor. In places such as Lesotho, Malawi, Mozambique, Swaziland, Zambia, and Zimbabwe, heavy HIV burdens are exacerbating food shortages and increase the likelihood of famine (UNAIDS/WHO, 2002). Regional military conflicts, civil unrest, poverty, racism, gender inequality, stigma, and lack of access to affordable medical care may contribute to the spread of HIV/AIDS (UNAIDS/WHO, 2002). In addition to Sub-Saharan Africa and other countries with long-standing HIV epidemics, other nations, including the former Soviet states, Indonesia, Cambodia, China, and India, show alarming signs of increasing HIV incidence and prevalence (UNAIDS/WHO, 2002). Because persons with AIDS are more vulnerable to opportunistic illnesses, HIV further complicates public health struggles to control different diseases such as tuberculosis, syphilis, and many other conditions.

Researchers from many disciplines have made advances in understanding the biological aspects and treatment of HIV, as well as in illuminating the individual and social conditions that foster its transmission. Taken together, the social and behavioral science disciplines have done a commendable job in helping to better understand the correlates of HIV/AIDS. Some disciplines, such as psychology, have played an especially notable role in developing and testing effective theory-based approaches for reducing HIV sexual and drug use behaviors.

In the past, the most prominent HIV research contributions from anthropology appear to be in the realms of ethnographic studies, and in the development of new approaches and tools needed for conduct of qualitative research. This is not surprising, because ethnography has been a traditional hallmark of the discipline. As applied within HIV behavioral research, ethnographic approaches have been used for a very wide range of purposes, including descriptive or formative research, studies among hard to reach populations, identification of factors associated with risk-taking and treatment-seeking behaviors, program evaluation, and in understanding how society reacts to the epidemic and views HIV-infected groups. Refinement of qualitative methods, such as the development of rapid assessment techniques or creation of new qualitative data analysis software, help researchers to more quickly obtain results needed for pragmatic response to the HIV crisis.

With some exceptions, to date anthropology has done a less impressive job in directly contributing to the

development of actual interventions to reduce HIV risk behaviors. It should be noted, however, that descriptive studies indirectly have helped shape intervention efforts by providing basic knowledge useful for targeting and tailoring interventions to specific populations. Nevertheless, active involvement in the direct design of interventions largely has been left to psychology and other disciplines, whose theories of human behavior often have led to an emphasis on changing individual-level behaviors, beliefs, and personal circumstances. There is a recognized need for theoretical models and new intervention approaches that take into account larger social structural and cultural contexts that shape risk behaviors (Kowalewski, Henson, & Longshore, 1997; Sumartojo, 2000). We recommend that anthropologists should make a much greater effort to develop theoretical bases for designing and testing HIV risk reduction interventions targeting communities, social networks, and dyadic relationships. Anthropology has long been interested in the effects of social norms and cultural values on individual behavior. This is a promising area for future anthropological contributions. Identifying and conducting rigorous scientific evaluations of specific ways to change community values, social structures, and normative behaviors that support reduction of HIV risk behaviors, and identifying the specific community-level variables that most strongly mediate individual HIV risk behaviors, are examples of such potential contributions. This type of work would complement, but not replace, HIV prevention approaches that emphasize interventions with individuals or small groups.

Anthropologists should also seek out new and expanded opportunities to participate on multidisciplinary teams implementing HIV behavioral intervention trials. This includes the design and conduct of theory-based intervention studies that account for social and environmental context, constraints on choices, and potential ways to change risk behavior. They also can seek new ways to help transfer effective, rigorously tested interventions into HIV practitioner settings for widespread implementation. Anthropology faculty in academia should train their graduate students to design, conduct, and evaluate interventions using experimental research designs, in addition to the training they receive on ethnographic methods and analyses. Anthropology students also could profit greatly by seeking supplemental training in other disciplines, such as in epidemiology, psychology, or biostatistics.

It has been argued that the advent of HIV/AIDS was the single most important contributor to the growing role

of anthropology in public health (Heggenhougen & Pedersen, 1997). Although medical anthropology was well established in prior decades, it was not until the mid- to late-1980s that utility of anthropological perspectives and methods became more visible within public health. The HIV/AIDS epidemic led to a return to the study of sexuality in anthropology and the recognition of the value of such research (Tuzin, 1991; Vance, 1991). Roles for anthropologists in public health have expanded. Anthropologists, along with other social and behavioral scientists, now serve a multitude of roles including acting as advisors, policy-makers, health educators, social workers, and administrators within AIDS control programs (Feldman, 1990; Holtgrave, Doll, & Harrison, 1997; King, 2000; Snider & Satcher, 1997; Roberts, Bansbach, & Peacock, 1997; Rugg, Levinson, DiClemente, & Fishbein, 1997). In short, not only has anthropology contributed to HIV research, but the importance of the disease has shaped the directions of the discipline itself. We believe this growth and diversification of roles can continue well into the future.

Malaria and other Major Insect Vector Diseases

Jeannine Coreil

INTRODUCTION

Anthropological research on insect vector-borne disease spans the full spectrum of theoretical and methodological approaches in medical anthropology. Important contributions to both biological and cultural anthropology have emerged in this field. Theoretical orientations reflected in the literature include ecological, ethnomedical, political-economic, feminist and applied/public health perspectives. Research designs include large-scale population studies, community surveys and clinical case studies. This review will focus on malaria, the most prevalent and deadly of the tropical diseases,¹ with selective coverage of other diseases transmitted by insects.

Most of the work cited here was conducted in the past two decades. In 1979, Dunn noted the paucity of any behavioral science research on parasitic diseases and outlined a very general program of research, including anthropological studies (Dunn, 1979). Two decades later, Kendall and Zielinski, (1999) document substantial development of the field, including a prominent contribution of anthropological perspectives and methods. This review covers five major insect vector diseases: malaria, dengue fever, lymphatic filariasis, onchocerciasis, and Chagas' disease. These were selected on the basis of their importance as world health problems and as foci for anthropological research.

The epidemiological characteristics of these diseases are summarized in Table 1. Clinical features of the diseases will be briefly summarized. Malaria produces extreme debilitation from fever, headache, and chills, is recurrent, increases the risk of low birth weight, miscarriage, and stillbirth in pregnant women, and is particularly life-threatening in young children. Like malaria, dengue causes fever, headache, and chills, as well as body pain and skin rash. Unlike malaria it is not recurrent, although persons who have had dengue are at elevated risk for the more serious forms of dengue hemorrhagic fever and dengue toxic shock syndrome. Children are particularly at risk for complications of dengue. The clinical manifestations of lymphatic filariasis are diverse, including lymphedema and elephantiasis of the leg, arm, or genitals. The most debilitating aspects the disease are periodic acute attacks of adenolymphangitis, accompanied by painful swelling of the affected area, headache, and fever. Although the common name for onchocerciasis is river blindness, this form of the disease is less common than onchocercal skin disease, a disorder characterized by lesions and depigmentation. Chagas' disease causes damage to the heart and other organs, and often goes undetected until midlife, when damage to the heart and colon causes fatal complications in 30–40% of victims.

Table 1. Epidemiology of Major Insect Vector Diseases

Disease	Vector	Pathogen	Distribution	People infected
Malaria	Mosquito	Protozoa	Tropics, Subtropics	300–500 million
Dengue	Mosquito	Virus	Africa, Tropical South America	<5,000 per year
Lymphatic filariasis	Mosquito	Nematode	Tropics, Subtropics	120 million
Onchocerciasis	Blackfly	Nematode	Africa, Latin America	17.5 million
Chagas' disease	Triatomine bug	Protozoan	Central and South America	18 million

ECOLOGICAL STUDIES

The prominence of biocultural approaches to the study of vector-borne diseases is well illustrated by anthropological research on malaria. The most notable example of this tradition is the frequently cited case of malaria and sickle cell disease in Africa (Alland, 1970; Livingstone, 1958; McElroy & Townsend, 1996; Wisenfeld, 1967). Many introductory texts use this case to illustrate the impact of culture change (introduction of agriculture) on disease ecology (malaria prevalence) and human biological adaptation (genetic selection for the malaria-protective sickle cell trait). The transition to food production in East Africa about two millennia ago was accompanied by the clearing of land, removal of forest canopy, and the exposure of wet areas to sunlight. These conditions offer ideal breeding grounds for mosquitoes, including *Anopheles gambiae*, the vector for a severe strain of malaria caused by *Plasmodium falciparum*. Mortality from falciparum malaria was high, often killing 25% of its victims. The opportune presence of a genetic mutation in the population led to selection of individuals with the abnormal hemoglobin that causes red blood cells to “sickle” and prevent reproduction of *Plasmodium* organisms, and accounts for the prevalence of this trait in African and African origin populations. The social ecology of malaria in Africa illustrates the interaction of biology and culture in the production of disease patterns.

Understanding of the interaction of biology and culture in relation to malaria was further elaborated in studies of the coevolution of certain cuisines and other malaria-protective hemoglobin variants in Mediterranean populations (Greene & Danubio, 1997). Focusing primarily on G6PD (glucose-6-phosphate-dehydrogenase) deficiency

and thalassemia, researchers have linked the cultural patterning of oxidant-containing plant food consumption to an optimal antimalarial interaction with red blood cell anomalies. In addition, it is posited that therapeutic antimalarial remedies have developed within specific cultural settings to maximize the protective effects of G6PD deficiencies.

Other anthropological work on malaria in the Mediterranean has taken a broad ecological perspective, such as the work of Peter Brown in Sardinia. Drawing upon epidemiologic, geographic, and ethnographic data, Brown describes three levels of cultural adaptation to malaria (Brown, 1998). At the level of human ecology, malaria prevalence shaped settlement patterns as well as the practice of inverse transhumance in the local subsistence system. At the level of social organization, traditional gender roles and social stratification resulted in lower exposure of women and members of the upper social class to the anopheles mosquito vector. Ethnomedical beliefs, on the other hand, prescribed certain behavioral practices that likely reduce the rate of illness relapse among people affected by malaria. Brown extends this multi-level framework to analyze the resurgence of malaria globally (Brown, 1997), identifying economic–demographic, social, and ideological factors involved in its spread.

Ecological approaches focused on a more local level have been applied to other vector-borne diseases such as dengue fever. Unlike malaria, which has a mosquito vector that breeds in large, stagnant pools of water mostly found in rural areas, the dengue vector (*Aedes aegypti*) typically propagates in periurban, artificially created small water containers such as discarded tires and household objects. Understanding the transmission and

control of dengue thus requires a focus on communities and households. Using the concept of ethnoecology, Whiteford (1997) analyzes data from a community study of dengue fever in a poor barrio of Santo Domingo to examine the role of historical factors and political will in shaping local concepts of community participation in disease control. Focusing the analytic lens inside the household of this same community, Coreil, Whiteford, and Salazar (1997) develop a model for studying the household ecology of disease transmission. The model examines risk behavior, transmission behavior, and risk protection within three spheres of influence, that is, the social, bio-physical, and cultural environments.

One of the most comprehensive anthropological studies of a vector-borne disease is Joseph Bastien's analysis of Chagas' disease in Bolivia. Also known as American trypanosomiasis, Chagas' disease is caused by a protozoan and transmitted by the tiny, domestic triatomine bug, locally known as the "kissing bug" because of its proclivity to bite people on their faces during sleep. The disease causes irreversible cardiac and intestinal damage, has no cure, and is fatal to about 30%–40% of its victims. With about 18 million people infected in Central and South America, the disease is a major public health threat. In *The Kiss of Death* (1998), Bastien presents a multi-faceted account of the history, ecology, epidemiology, and control of Chagas' disease, describing his book as an "anthropology of the house" (p. xxiii). Careful attention is given to the ethnophysiology of the disease within the local health culture, as well as traditional preventive and curative practices. Case studies of victims and activists vividly portray the lived experience of the illness and its importance in Andean society and culture. In a chapter entitled "Culture and Political Economy of Homes," the author integrates symbolic and political perspectives on domestic housing and efforts to control the vector. The book concludes with a template for culturally contextualized control strategies that span the micro and macro intervention levels.

ETHNOMEDICAL STUDIES

Ethnomedical studies, broadly defined, comprise a large proportion of anthropological research on vector-borne diseases. Numerous studies have investigated local beliefs and practices regarding specific conditions, including conceptions of etiology, pathophysiology, severity, home management, and treatment. Often such

studies are conducted with specific knowledge utilization goals for planning intervention programs. Because of its global threat, ethnomedical studies of malaria are well represented in this literature. The scope of this research agenda was outlined in a chapter written by Carl Kendall entitled "Social and Behavioral Aspects of Malaria" that appeared in a 1991 Institute of Medicine's report on malaria (Oaks, Mitchell, Pearson, & Carpenter, 1991).

The failure of the 1950s era global initiatives to eradicate malaria through vector control shifted international attention to prevention and treatment (Bruce-Chwatt, 1984), with particular concern for the emergence of drug-resistant strains of *Plasmodium*. Ethnomedical studies have documented that in most endemic areas, malaria usually is subsumed under a broad category of "fever," or it may be incorporated into more than one local diagnostic category (Agyepong, 1992; Miguel, Tallo, Manderson, & Lansang, 1999; Reubush, Weller, & Klein, 1992). Understanding of the role of mosquitoes in malaria transmission is variable, with some localities recognizing alternative forms of the disease, such as a traditional category and a more modern entity involving the mosquito vector (e.g., Ahorlu, Dunyo, Afari, Koram, & Nkrumah, 1997; Lipowsky, Kroeger, & Vazquez, 1992). McCombie reviewed a large number of studies of help-seeking and treatment for malaria to identify patterns and evaluate adequacy of care (McCombie, 1996, 2002). Her review showed that the majority of malaria cases receive some type of treatment, with about half of cases involving self-care only, and about half involving use of traditional or official sector services. Traditional remedies and modern medicines (antimalarial drugs) are often used in combination. McCombie calls for the use of more systematic and rigorous methods to evaluate treatment adequacy in order to inform policy development.

Similar ethnomedical studies have been conducted on local cultural knowledge of dengue fever and its transmission. For example, in Merida, Mexico, ethnographic and survey research found that dengue was associated with mild febrile illnesses such as colds, considered transient, inevitable, and not serious in daily life. Like other mild fevers, dengue prevention was viewed as a matter of taking care of oneself once sick in order to prevent progression of the illness to a more serious state. The researchers suggest that indigenous models of prevention should be taken into consideration when designing community education programs related to dengue control (Winch, Lloyd, Godas, & Kendall, 1991).

Anthropological research on dengue has focused more closely on the organization of cultural knowledge about mosquito vectors. Studies have investigated recognition of different types of mosquitoes, perceptions of their dangerousness, and association of different insect vectors with particular illnesses. Kendall et al. (1990) applied systematic anthropological techniques to “exploratory ethnoentomology,” using consensus analysis to group common household insects into categories and rank order their perceived dangerousness among Honduran informants. These cultural insights were helpful in designing a community-based vector control program. Others have identified the components of an exploratory ethnoentomologic study, including cultural domain mapping of insects, knowledge of the life cycle and ecology of mosquitoes and their association with disease, and local methods of mosquito control (Coreil, Whiteford, Salazar, & Barkey, 1991).

Ethnomedical studies of onchocerciasis and lymphatic filariasis document less awareness of the role of insect vectors in disease transmission than with malaria or dengue, although local cultural models are undergoing rapid change with the implementation of educational and control programs in many areas. In Nigeria, understanding of the role of *Simulium* flies in the transmission of onchocerciasis was very low, with most respondents either unaware of any cause for the disease or attributing the condition to sun exposure, heredity, witchcraft, excessive consumption of cola nuts, or mosquito bites (Awolola, Manafa, Rotimi, & Ogunrinade, 2000). In Ghana and Haiti, similar elements in cultural models of filariasis were found. In both areas traditional attributions of causality favored supernatural explanations, including accidental stepping on magical herbs in Ghana and walking on magical powder in Haiti. Community reactions to the disease were also similar in the two areas, with people avoiding critical comments about affected individuals for fear of getting the disease themselves (Coreil, Mayard, Louis-Charles, & Addiss, 1998; Gyapong, et al.)

COMMUNITY PARTICIPATION IN HEALTH PROGRAMS

A large body of anthropological research on vector-borne diseases fits under the general rubric of community participation in health programs. Like other social scientists,

anthropologists are viewed by health planners as experts on community, culture, family, gender, and other “behavioral” factors in disease. Thus anthropologists often have been engaged to conduct community assessments and ethnographic research to help plan disease control interventions. Early involvement tended to fit the prevailing mode of “troubleshooting” failed programs due to lack of community involvement (e.g., MacCormack & Lwihula, 1983). Beginning in the 1980s, however, it became normative to integrate social science research into the planning process of international health programs. Anthropologists have made important contributions to defining important elements of community participation in control programs for malaria (Manderson 1992a, 1992b) and dengue fever (Gordon, 1988; Gordon, Rojas, & Todwell, 1990).

The role of anthropological research in dengue fever control was expanded substantially by the “Integrated Community-based *Aedes aegypti* Control Project” (1998–90) focused on the Americas and funded by the Rockefeller Foundation (Kendall & Winch, 1989). The goal of the project was to develop model vector control programs in several Latin American countries based on the integration of anthropological, epidemiological, and entomological research. A workshop held at Johns Hopkins University in 1988 (Kendall & Winch, 1988) brought together vector control specialists, anthropologists, and other social scientists to develop an interdisciplinary research agenda for improving the design of dengue control programs. The proposed agenda included studies of the cultural construction of dengue, insects and the physical environment, individual and collective behavior related to sanitation, water and mosquitoes, and factors influencing community participation in control programs. Projects involving a number of anthropologists were conducted in Mexico, Honduras, and the Dominican Republic (Coreil et al., 1997; Leontsini, Gil, Kendall, & Clark, 1993; Lloyd, Winch, Ortega-Canto, & Kendall, 1992; Lloyd, Winch, Ortega-Canto, & Kendall, 1994; Whiteford, 1997; Winch, Kendall, & Gubler, 1992). Results of these studies are cited elsewhere in this entry.

A good example of the application of anthropological concepts and methods to the design of community-based interventions for vector-borne diseases is found in a dengue control project conducted in Mexico. Using ethnomedical findings from formative research (cf. Winch et al., 1991, cited above), investigators implemented a public health communication intervention to increase understanding of dengue transmission, recognition of

mosquito larval production sites, and knowledge of appropriate control methods such as disposal of water-collecting containers. A comparison of intervention sites and a control group showed better outcomes for the former (Lloyd et al., 1992). A detailed discussion of the five-stage process used to develop, implement, and evaluate the intervention illustrates the importance of adapting programs to ecologic, cultural, and social differences between localities (Lloyd et al., 1994).

GENDER, STIGMA, AND TROPICAL DISEASES

Scholarly and programmatic interest in the importance of gender differences in the impact of tropical diseases was bolstered by the establishment of a Task Force on Gender and Tropical Diseases within the Tropical Diseases Research division of the World Health Organization (WHO, 1996). Three core elements characterize gender-focused health research: first, women are viewed as more than productive and reproductive agents; second, women's health is situated in the larger sociocultural and political-economic context of society; and third, particularly in areas where tropical diseases are prevalent, structural factors within society frequently make women economically dependent on men and relegate them to lower social status (Rathgeber & Vlassoff, 1993). In their review of the state of knowledge regarding gender and tropical diseases, Vlassoff and Bonilla (1994) focus on malaria and onchocerciasis to illustrate the impact of a wide range of variables that differentially affect men and women, both as determinants and consequences of disease. For example, women's more frequent contact with water in general tends to expose them more often to the vectors that transmit malaria and schistosomiasis, and they bear harsher consequences from the burden of disease due to their caretaker responsibilities.

Gender research has been conducted on a variety of vector-borne diseases, including malaria, onchocerciasis and filariasis. A study in Sudan documented successful recruitment of women to participate in health education and behavior change activities related to malaria control (A/rahman, Mohamedani, Mirgani, & Ibrahim, 1995). Sociocultural research related to onchocerciasis has highlighted the impact of social stigma, as well as gender differences in stigma for those affected by onchocercal skin disease (OSD), a condition characterized by disfiguring

lesions, nodules, depigmentation, and rashes. The Pan-African Study Group on Onchocercal Skin Disease (1995) documented significant social stigma associated with the disease in several countries, and found a greater degree of perceived stigma among affected men than women. Studies focusing on the impact on Nigerian women, who are more frequently affected by the condition in that setting (Brieger, Ososanya, Kale, Oshinme, & Oke, 1997), show that women believe strongly that onchocerciasis has a negative effect on their fertility (Brieger, Ramakrishna, Adeniyi, Pearson, & Kale, 1987), and women with OSD married later and weaned their children sooner than women not affected by the disease (Amazigo, 1994). An experimental study of the impact of ivermectin treatment for OSD in Nigeria on perceived stigma showed no gender differences but documented a higher level of reported stigma 6 months following treatment, which the researchers attribute to the unexpected effect of having raised awareness of stigma among study participants (Brieger, Oshiname, & Ososanya, 1998).

In many parts of the world, women are more frequently affected by lymphedema and elephantiasis of the leg associated with lymphatic filariasis. This can lead to women experiencing a greater burden of stigma and disability due to enlarged legs, skin disfigurement, and difficulties with mobility, as documented for India (Bandyopadhyay, 1996) and Haiti (Coreil et al., 1998). A support group intervention designed to increase self-esteem and coping among Haitian women with filariasis documented improved quality of life and home management practices among program participants, and examined the process of indigenization of support groups in this cultural setting (Coreil, Mayard, & Addiss, 2003). In men, filariasis is most commonly manifested clinically by urogenital symptoms, including hydrocele (enlarged scrotum), and has been associated with shame and sexual dysfunction (Dreyer, Noroes, & Addiss, 1997).

CONCLUSION

Anthropological research on insect vector diseases, largely conducted over the past two decades, reflects a broad range of perspectives. Biocultural approaches have been applied primarily to malaria, with ecological, ethnomedical, and public health perspectives found across all the diseases reviewed. Much of the research

was stimulated by efforts to implement culturally sound disease control programs. Increased interest in macro social issues is evident in recent attention to gender and stigma in tropical diseases, particularly the physically disabling diseases such as onchocerciasis and filariasis. Future directions for research will likely enlarge the focus on the social conditions underlying vector-borne diseases, following biosocial research agenda for tropical diseases that shifts the focus “upstream” to the politics of policy development, and the organization of prevention and control services (Farmer & Becerra, 2001).

NOTE

1. The delineation of such a disease-focused topic reflects the influence of biomedical nosology in defining specializations within medical anthropology. The continued relevance of the category “tropical diseases,” largely composed of the vector-borne diseases, is a legacy of colonial history as well as scientific interest in exotic infections affecting poor countries. Also, while the review focuses on the work of anthropologists, it is often not meaningful to differentiate the latter from similar research conducted by social scientists trained in other disciplines. Thus, some anthropologically oriented work by non-anthropologists is included.

ACKNOWLEDGMENT

Mental Disorders

Alex Cohen

BACKGROUND

The *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition (or *DSM-IV*) defines mental disorder as a “clinically significant ... syndrome or pattern” in which an individual exhibits behavioral or psychological patterns that are associated with “distress, disability, or increased risk of pain or death” (American Psychiatric Association, 1994).

However, there are several problems with this definition. First, it covers a vast range of conditions. One might reasonably ask whether it is valid for a single definition to encompass the entire spectrum of conditions: from the relatively rare, severe and chronic psychoses to the relatively common, often comparatively mild and intermittent mood disorders. Even if it is valid to speak of mental disorders in such an inclusive way, more precise focusing may be obligatory when formulating and testing hypotheses about the effect of sociocultural environments on human mental well-being. For example, Vikram Patel’s (1998) research in Zimbabwe focuses on the relationship of culture to the manifestation, course, and outcome of depression and anxiety, while Ezra Susser and his colleagues focus on brief psychotic disorders in India (Susser, Varma, Malhotra, Conover, & Amador, 1995; Susser & Wanderling, 1994).

Second, the authors of *DSM-IV* point out that the use of the term “mental” implies a clear differentiation between “mental” and “physical” disorder, a distinction that does not, in fact, exist. For example, tropical diseases such as malaria and sleeping sickness may produce symptoms that mimic those of the psychoses and depression (Weiss, Cohen, & Eisenberg, 2000), and non-specific fevers have been implicated in the etiology of acute brief psychosis in Northern India (Collins et al., 1999). At the same time, physical disorders such as myocardial infarction may be precipitated by emotional states of fear or anger (Kendell, 2001). Low-back pain often occurs in the absence of a distinct physical disorder (Kleinman, 1988). Finally, epidemiological research in 10 countries found that loss of energy, a symptom that is clearly associated with a host of

physical disorders, was a core symptom among most people suffering from depression (Weissman et al., 1996).

Third, the diagnostic categories of the *DSM-IV* were derived from evidence gathered almost exclusively from North American and European populations. If the discipline of anthropology has demonstrated anything, it is that the diversity of human behavior extends far beyond what can be observed within one, albeit broad, cultural group. Applying those categories to people in non-Western societies may result in what Arthur Kleinman has termed a *category fallacy* which he defines as: “The reification of one culture’s diagnostic categories and their projection onto patients in another culture, where those categories lack coherence and their validity has not been established” (Kleinman, 1988). Imagine a South Asian psychiatric epidemiologist conducting a study of semen loss syndrome (known as *sukra prameha* in Sri Lanka) in the United States where this syndrome is virtually unknown (Obeyesekere, 1985). For that matter, imagine investigations of *amok*, *latah*, *nervios*, or any of the other so-called culture-bound syndromes among European or North American populations. On the other hand, Kleinman (1988) suggests that the application of the *DSM-IV* concept of dysthymia, a chronic low-level form of depression, would be just as inappropriate in China. In all of these cases, the psychiatric categories validated in one cultural context would be found to be absent in other contexts, leaving one with the impression that cultural expressions of distress are incommensurable. This is difficult to believe. Yet, is it any more valid to claim that, for example, semen loss syndrome is nothing more than a variety of anxiety disorder; or that *amok* is a type of brief reactive psychosis (Kleinman, 1988)?

Fourth, the *DSM-IV* definition gives no indication of the multiplicity of causal factors (social, psychological, biological) that may alone or in combination lead to a mental disorder. Despite the claims of cognitive neuroscientists that mental disorders arise from dysfunctions in the neural mechanisms of the brain, aside from dementias such as Alzheimer’s disease, no biological diagnostic markers have been identified for any mental disorder (Andreasen, 1997). At the same time, there is a large body of literature

that demonstrates the influence of social, cultural, and economic environments—poverty, gender discrimination, political violence, malnutrition, and poor physical health—on the etiology and epidemiology of all manner of mental disorders (Cohen, 1999; Desjarlais, Eisenberg, Good, & Kleinman, 1995; Dohrenwend & Dohrenwend, 1974; Kessler et al., 1994; Patel, 2000; Patel, Araya, de Lima, Ludermir, & Todd, 1999; WHO, 2001).

Fifth, the process of recognizing, that is, diagnosing, mental disorders represents a social and cultural negotiation. Although it appears that certain clusters of symptoms are universally considered as indicative of madness or insanity (Edgerton, 1966; Murphy, 1976), that is not the case in regard to the common mental disorders (Edgerton, 1969) or mild forms of mental retardation (Edgerton, 1984; Koegel & Edgerton, 1984). For these disorders, sociocultural norms, values, and beliefs, shape perceptions of what differentiates acceptable and normal personality traits from mental disorder.

Finally, the diagnostic system used in the *DSM-IV* is explicitly categorical, meaning that mental disorders are divided “into types based on criteria sets with defining features” (American Psychiatric Association, 1994). Although classification is a fundamental step in making sense of the natural world it is also true that the system used in the *DSM-IV* does not represent, “neatly bounded monothetic categories” (Littlewood & Dein, 2000). That is, diagnostic categories share many common symptoms and cannot be considered discrete entities. The lack of discreteness is also suggested by a high degree of co-morbidity—the co-occurrence of two or more mental disorders in an individual—that is revealed by epidemiological research (Kessler et al., 1994). This categorical model, which is based on evidence from North American and European populations, also presents a problem when looking at mental disorders cross-culturally. Distinct cultural patterns of symptomatology, referred to as “idioms of distress” (Nichter, 1981) by anthropologists, are either relegated to the exotica of so-called culture-bound syndromes, or dismissed as merely cultural variations of an underlying, universal form.

UNIVERSALS AND CULTURE-SPECIFICS

The tension between looking for the underlying universal (and presumably biologically-based) structures of mental disorder and considering culture-specific “idioms of distress” has been at the center of cross-cultural psychia-

try and anthropological investigations of mental disorders ever since Emil Kraepelin went to Java in 1904 and visited the asylum of Buitenzorg (Kraepelin, 2000/1904). There he undertook a study of *dementia praecox* (which later became known as schizophrenia) and manic-depressive insanity among the Javanese and European populations. Comparisons between the groups were difficult. While Kraepelin found that the clinical presentations of the disorders were “broadly in agreement,” the symptomatology among the Javanese was, in general, “much less florid, less distinctively marked.” In particular, Kraepelin noted the relative absence of delusions and auditory hallucinations, and offered the racist explanation that this was the result of a “lower stage of intellectual development” among the Javanese. In regard to the culture-bound syndromes, *amok* and *latah*, Kraepelin suggested that, rather than representing unique disorders, they were merely unusual forms of disorders already known.

The distinction between the universal and the particular was formalized by Kraepelin’s student Karl Birnbaum into the *pathogenic/pathoplastic* dichotomy in which the former represented the underlying, presumably biological causes of mental disorders, and the latter represented the personal and cultural variations that always characterize the presentation of symptoms in individuals (Littlewood & Dein, 2000). To a great extent, this notion determined the nature of cross-cultural investigations of mental disorders for almost three quarters of a century.

The search for universal content was made difficult, however, by the lack of biological diagnostic markers and, therefore, relied on the presentation of symptoms. This worked well in relatively homogeneous European populations, but not so well in populations whose symptoms and clustering of symptoms were quite different (Littlewood & Dein, 2000). In 1977, Arthur Kleinman challenged this approach and offered a radically new vision for transcultural psychiatry and medical anthropology (Kleinman, 1977). He maintained that traditional comparative studies of mental disorders, depression in particular, imposed Western notions of psychiatric nosology and, therefore, obscured the role of culture. He went on to urge that cross-cultural studies begin with “detailed local phenomenological descriptions” of mental disorders rather than assuming the validity of Western psychiatric categories—an approach that he termed, “the new cross-cultural psychiatry.”

Kleinman’s perspective stimulated a host of anthropological investigations that looked at the meanings

and cultural expressions of distress (Good, 1977; Nichter, 1981), explanatory models of illness (Kleinman, 1982; Weiss, 1997), cultural shaping of health-seeking behaviors (Lin, Tardiff, Donetz, & Goresky, 1978), the social course of mental illness (Kleinman, 1988), and clinical studies of course and outcome (Patel, 1998), among others. The result has been a much richer cross-cultural understanding of mental disorders (Littlewood & Dein, 2000; Skultans & Cox, 2000). In particular, this work made three important contributions to psychiatry (Becker & Kleinman, 2000). First, examining different mental disorders in a range of societies has produced “evidence for their syndromal significance and integrity in the absence of biological markers.” Second, an understanding of the importance of explanatory models has led to clinical services that are more culturally appropriate. Finally, understanding the social roots of distress and the social course of mental disorders holds out the prospect of a public health approach that will improve outcomes and, perhaps, reduce the burden of disease associated with mental disorders (Murray & Lopez, 1996).

KINDS OF DISORDERS

Depression

The symptoms of depression include feelings of sadness, hopelessness, and thoughts of death, often accompanied by somatic complaints of fatigue, sleep disruptions, and weight loss, all of which result in functional and social disability. Worldwide, hundreds of millions of people suffer from depression. According to the most recent data, depressive disorder accounts for 4.4% of the world’s total burden of disease as measured by Disability Life Years (DALYs), which makes it a public health problem whose magnitude is only slightly less than lower respiratory infections (6.4%), perinatal conditions (6.2), and HIV/AIDS (6.1) (WHO, 2001). Among people aged 15–44 years, depressive disorders account for fully 8.6% of global DALY, second only to HIV/AIDS (13.0%). Epidemiological surveys have found wide variation in cross-national rates, as well as rates among women that are consistently higher than those found in men (Weissman et al., 1996). Epidemiological research has also determined that, worldwide, about one quarter of all attendees in primary care settings are suffering from mental disorder, most frequently depression or mixed depression/anxiety, but

that few of them are either diagnosed or treated (Ustun & Sartorius, 1995).

It was widely believed in much of the 20th century that African and Asian populations did not suffer from depression (Littlewood & Dein, 2000). Carothers (1953) maintained that Africans were not capable of experiencing depression, because their brains were less developed than those of Europeans. (Note the similarity to Kraepelin’s racist explanation of cultural variation in the symptomatic presentation of *dementia praecox*.) These notions were eventually dispelled by research showing that the peoples of Sub-Saharan Africa suffered rates of depression that were as high, if not higher than those found among European populations (Abas & Broadhead, 1997; Orley & Wing, 1979). Even though rates in Asia have been found to be much lower than those found in Western populations (Kleinman, 1996; Lin, 1953; Weissman et al., 1996), depression is by no means absent entirely in Asia. More importantly, Kleinman’s (1982, 1986) pioneering work on depression and neurasthenia in China suggests that the Western psychiatric conceptualization of depression—positing feelings of sadness and loss as the core symptoms—represents but “a small fraction of the entire field of depressive phenomena” (Kleinman, 1977). Among many populations of the world, somatic complaints, rather than feelings of sadness and loss, are the symptoms most associated with depression (Kleinman & Cohen, 2000). Indeed, cross-cultural research has revealed that the somatic expression of symptoms in mental disorders is common in all societies, and that differences may reflect not only varying idioms of distress but also local health care systems that may neglect or discount mental disorders (Kirmayer & Young, 1998; Raguram, Weiss, Channabasavanna, & Devins, 1996).

Medical anthropologists have played a key role in delineating the cultural construction of depression (Kirmayer & Groleau, 2001; Kleinman, 1986; Kleinman & Good, 1985; Manson, 1995). For example, the anthropologist Spero Manson (1995) conducted research among American Indians suggesting that an understanding of depression must not only encompass symptoms but also take into consideration “the social contexts and cultural forces that shape one’s everyday world, that give meaning to interpersonal relationships and life events.” Although depression is the most frequently diagnosed problem among American Indians who come to mental health treatment facilities, it is easily misdiagnosed (Manson, Shore, & Bloom, 1985). One possible reason for

misdiagnosis, at least among the Hopi Indians in the American Southwest, is that the Hopi language seems to lack a word or phrase for “depression.” Moreover, about one quarter of the clinical sample that was suffering from depression reported a dysphoric mood for one rather than two weeks—two weeks is the duration criterion in the *DSM-IV*. Fully one half of the clinical sample, compared to one quarter in a sample from the general population, was suffering from both chronic and major depression. Finally, depression was secondary to alcoholism in every male subject, a pattern that is not so common in the general population of the United States. In sum, these findings indicate a critical need to recalibrate concepts of depression when looking at distress as manifested cross-culturally.

Arthur Kleinman (1986, 2000), and Sing Lee (1999), an anthropologically informed psychiatrist, have shown how the Western construction of depression overlaps with the Chinese construction of neurasthenia, and, at the same time, how the latter is distinctive and reflects the sociocultural context of China during the past 50 years. But the story does not end there. Neurasthenia is in the process of “disappearing” in China, transformed into depression by “a confluence of historical, political, and economic forces” (Lee, 2002) that include the entrance of China into the global market economy, the dominance of Western academic psychiatry, and the successful marketing of antidepressant medication by international pharmaceutical companies. This transformation has important implications for how the next generation of anthropologists and cross-cultural psychiatrists will define and study depression.

Schizophrenia

Schizophrenia is a severe mental disorder that most frequently begins in late adolescence or early adulthood and is characterized by delusions (fixed, false ideas), hallucinations (either auditory or visual), and behavior that is deemed socially inappropriate (e.g., going without clothes, lack of attention to personal hygiene). It is the mental disorder most closely associated with the terms *madness* or *insanity* and is, in all societies, a highly stigmatized condition, one that may lead to social isolation, neglect, and abuse (Weiss et al., 2000). Schizophrenia is relatively rare; depending on the diagnostic criteria used, it has an incidence rate of fewer than 5 persons per 10,000. But if the disorder is chronically disabling, its prevalence is much higher, about 1–20 per 1,000

(Kulhara & Chakrabarti, 2001). Because of its severity and chronicity, schizophrenia is a leading cause of DALY among persons 15–44 years, accounting for 2.6% of their burden of disease (WHO, 2001).

Cross-cultural research on schizophrenia has a curious history. Kraepelin’s explanation for cultural variation in the presentation of *dementia praecox* strikes us today as embarrassingly racist. About 25 years later, mirroring Margaret Mead’s (2001) culturally relativistic claim that adolescence in Samoa looked nothing like it did in the West, Charles Seligman, a physician and anthropologist, claimed that nothing resembling schizophrenia had existed in New Guinea prior to European contact: “There is no evidence of the occurrence of mental derangement, other than brief outbursts of maniacal excitement, among natives who have not been associated with White Civilization,” and went on to claim that financial debt to Europeans was the sole cause of “fatal instances of insanity” (Seligman, 2000/1929). However, we now question these claims because Seligman did not look beyond the evidence he found in a hospital, an institution whose patients and disorders were surely not representative of the indigenous population in general (Littlewood & Dein, 2000).

Later, some anthropologists thought that shamans were actually individuals with schizophrenia, but that the cultures in which they lived provided them with socially acceptable roles that minimized the functional consequences of the disorder (Devereux, 1980/1965; Kroeber, 1940). Jane Murphy (Murphy, 1976), for one, disputed this claim. She presented evidence that, at least in the case of the Yupik-speaking Eskimo, the behaviors of shamans were different from the behaviors of people defined as being *nuthkavihak* (insane). For the most part, the “shaman/schizophrenic” hypothesis has been abandoned (Good, 1994).

H. B. M. Murphy and A. C. Raman (Murphy & Raman, 1971) were the first to carry out a systematic comparison of the course of schizophrenia in two distinctly different sociocultural contexts. Through a retrospective comparison of hospital records, they concluded that schizophrenia showed less chronicity among persons in Mauritius than among a matched sample in the United Kingdom. However, the study suffered from at least one serious shortcoming: its reliance on hospital data as an accurate reflection of course of illness. The frequency with which people are hospitalized depends on a great number of sociocultural and socioeconomic factors. Individuals with similar levels of schizophrenic symptom

severity will be hospitalized more frequently if they live in societies in which psychiatric resources are readily accessible than in societies without psychiatric facilities. Thus, impressions of course of illness that are derived from hospital data in different societies may only reflect differential access to psychiatric resources and not accurately present actual sociocultural differences in the chronicity of schizophrenia.

At about the same time of the research in Mauritius, the anthropologist Nancy Waxler conducted research on the course of schizophrenia among a group of Sinhalese Buddhists in Sri Lanka (Waxler, 1979). Again, course of illness in this so-called traditional society was found to be better than what was found in the developed societies of the West. Waxler interpreted these findings as evidence supporting social labeling theory, which postulates that cultural beliefs and reactions to schizophrenia either encourage or discourage chronicity. In particular, she maintained that cultural beliefs in external causes and a short course of schizophrenia protected individuals from developing long-term chronicity and disability. However, like Murphy and Raman, Waxler relied on hospital samples and long-term, retrospective follow-up. Furthermore, her conclusions were not based on either close, ethnographic examinations of the lives of people with schizophrenia or even survey data. Therefore, her conclusions more closely resemble conjecture than hypothesis testing (Cohen, 1992).

In much the same spirit of trying to demonstrate that “traditional” cultures are nurturing and “modern,” but Western cultures are pernicious, Nancy Scheper-Hughes (1979) carried out ethnographic research in an attempt to explain high rates of schizophrenia in Western Ireland. Although her work is a fascinating account of life in a small rural community, and she makes a compelling argument that the nature of that sociocultural environment is a cause of the high prevalence rates of schizophrenia, the premise that Western Ireland has a high prevalence of schizophrenia was based on hospital rate statistics that were later shown to be artificially inflated (Cabot, 1990; Ni Nuallain, O’Hare, & Walsh, 1990). That is, Scheper-Hughes may have provided an explanation for a phenomenon that did not exist.

The most compelling evidence of the better prognosis for schizophrenia in non-industrialized societies comes from two cross-national studies conducted by the World Health Organization: the International Pilot Study of Schizophrenia (IPSS) (WHO, 1979), and the Determinants

of Outcome of Severe Mental Disorder (DOSMeD) (Jablensky et al., 1992). The efforts of the DOSMeD project, in particular, represent the most ambitious and methodologically sophisticated cross-cultural study of schizophrenia. The investigators attempted to identify—over a period of two years—all persons suffering from the first onset of schizophrenia in 13 catchment areas located in 10 countries. In brief, the research demonstrated that schizophrenia occurred throughout the world, that its clinical characteristics were more notable for cross-cultural similarities than differences, that the majority of persons with schizophrenia followed a remitting pattern of course over a period of two years, and that the incidence of narrowly defined schizophrenia was essentially constant throughout the world. Perhaps the most important finding was that the research demonstrated “in a clear and, possibly, conclusive way . . . that the course and outcome of schizophrenia was markedly better in the centers located in developing countries. (Jablensky et al., 1992). In particular, differences in the prognosis of schizophrenia may reflect differences in family support, styles of interaction, industrialization, and urbanization.

In general, anthropologists have embraced the findings of the DOSMeD research. It has been cited as the “single most important . . . finding” in cross-cultural psychiatry (Lin & Kleinman, 1988), despite a host of methodological problems including: (1) the absence of ethnographic and sociocultural evidence to support the conclusions (Cohen, 1992; Edgerton & Cohen, 1994); (2) an overwhelming emphasis on universal aspects of schizophrenia rather than cross-national variation in the incidence of broadly defined schizophrenia and cultural differences in the clustering of symptoms (Kleinman, 1988); (3) the use of outcome variables—such as percentage of the follow-up period spent in the hospital or on psychotropic medication—that reflect differences in socioeconomic environments rather than variations in course of illness; (4) extensive evidence of the neglect, abuse, and severe stigmatization of persons with schizophrenia in several of the developing societies in which the DOSMeD research was conducted (National Human Rights Commission, 1999; Odejide & Olatawura, 1979); and (5) indications that, in the West, the long-term course of schizophrenia displays much less chronicity than once thought (Harding, Zubin, & Strauss, 1987, 1992). Even with the questions about the validity of the “developing” and “developed” categories, and the need for “further

study within the ‘black box’ of imputed cultural effects on outcome” (Craig, Siegel, Hopper, Lin, & Sartorius, 1997), the DOSMeD research, and its predecessor, the International Study of Schizophrenia (Harrison et al., 2001; Hopper & Wanderling, 2000), continue to be cited as conclusive evidence of better outcomes for schizophrenia in the developing world (Kulhara & Chakrabarti, 2001).

THE FUTURE

For most of the 20th century, the anthropological study of mental disorders and related phenomena focused on exotic healing rituals, the so-called culture-bound syndromes, and the search for universal features that were hidden by the “noise” of culturally shaped symptomatology (Becker & Kleinman, 2000). With Arthur Kleinman’s (1977) call for a “new cross-cultural psychiatry,” the focus shifted away from universals to the examination of local “idioms of distress” and how the nature of human suffering was shaped into a multitude of forms by cultural processes. At the beginning of the 21st century, the focus of cross-cultural psychiatry and psychiatric anthropology is once again shifting. In a psychiatric textbook article on anthropology and psychiatry, Anne Becker (a psychiatrist and anthropologist) and Kleinman state that the cross-cultural study of mental disorders “provides evidence for their syndromal significance and integrity in the absence of biological markers” (Becker & Kleinman, 2000). Is this an anthropological version of the old comparative psychiatry, a neo-Kraepelinism? Sing Lee (2002) challenges the field, stating that cultural psychiatry must move away from “debates over categories and repetitious studies of reliability” that may have become irrelevant in an era of global change. Research is now questioning the assumption that depression is distinguished in some societies by psychological symptoms and in others by somatic symptoms (see also Kirmayer & Young, 1998). Whether or not depression has distinct forms in different cultural settings, and whether or not idioms of distress are incommensurable, the apparent effectiveness of antidepressants to treat a wide range of disorders challenges some of the foundations of the “new cross-cultural psychiatry.” That is, the dominance of Western psychiatry and its biomedical model of mental disorders, along with the international marketing of antidepressants to treat a

broad spectrum of disorders, has marginalized the notion or utility of the cultural construction of mental illness. Therefore, Sing Lee suggests that the central role for anthropologists and cross-cultural psychiatrists is to become engaged in addressing the barriers to effective care that now characterize international mental health. These barriers include stigma and discrimination against persons with mental illness, lack of resources devoted to the treatment of mental disorders, little critical assessment of mental health and services policies, and virtually no evaluation of mental health programs in low-income countries (Cohen, 2001).

F. John Meaney

BACKGROUND

Perhaps no phrase in any language produces in sum more anxiety, controversy, fear, hopelessness, and stigma, at least in Western societies, as “mental retardation” or a similar phrase for intellectual disability. We live in a world that cultivates and sells perfection, and while this might be

fine for some outcomes of concern, it fosters and reinforces the attitudes of people in many cultures and societies that are less than accepting of individuals with physical and mental disabilities. Although in general most societies have progressed with respect to the concerns of individuals with disabilities, advances in our knowledge and legislated changes have still not overcome the

prevailing sense that differences are not fully acceptable among all in society. Deficits in intellectual functioning place individuals who so vary among the groups in our societies that are marked by such descriptors as race, cultural background, language, socioeconomic status, sexual preference, and body habitus, among others.

More than a decade ago, Groce and Scheer (1990) opened their introduction to a collection of papers on cross-cultural approaches to disability and chronic illness with the statement "Few areas in social science and medicine can benefit more from the contribution of an anthropological perspective than research on physical and mental disabilities" (p. v). This remains true as we move into the 21st century, and perhaps increasingly so with the impacts of such scientific endeavors as the Human Genome Project, the ever-increasing attention to cultural factors in the assessment of disability and the provision of services for individuals with disabilities, and the knowledge that we can no longer think in terms of "nature or nurture" but rather in terms of all diseases and traits reflecting the interplay between the underlying genetic factors and environmental exposures in all their complexity. The unique perspective of anthropology from both the biological and cultural contributors to human variability places the discipline in a position of tremendous utility in sorting through the various viewpoints and policy decisions that confront our society with respect to the future applications of this knowledge base.

Groce and Scheer (1990), among others (Longmore, 1987), stressed that the concept of disability is a sociocultural construct rather than a biological one (and, I might add, is therefore just like the concept of "race"). Thus the approaches of cultural anthropology, and especially medical anthropology, are useful in disentangling the sources of cultural variation in how people view individuals with disabilities and the latter view themselves. From the perspective of the late 1980s, Groce and Scheer (1990) were able to state that ethnographic literature on disability was beginning to emerge, albeit slowly. Furthermore, they added that before the 1970s, references to disability in the anthropological literature were few and far between. Currently we are seeing more attention being paid to the need for culturally competent services for individuals with disabilities, as a body of data has developed to demonstrate marked variability among cultures in their interpretations of disability and the practices that emerge as a result of the cultural beliefs and attitudes (Groce, 1999). At the same time, disciplines other than anthropology are coming to the

fore, such as multicultural approaches in psychology (American Psychological Association, 1990), and in the fields of education, communication, and counseling.

The important point about cultural considerations is that culture pervades all of our thinking about disability, defining the ways we assess intellectual disability, influencing the methods through which we provide intervention and services, and determining the attitudes and behaviors with which we respectively perceive and act with respect to people with disabilities. An emerging literature has developed in the last two decades, particularly concerning differences among cultures in attitudes toward people with disabilities, including mental retardation (Westbrook, Legge, & Pennay, 1993). Likewise, there is recognition of the importance of language as the communication aspect of cultures and therefore correlated with the way disabilities are perceived by society at large and among cultures. The extended recognition is the ongoing need for cultural sensitivity to the variation in terminology for disability over time (Devlieger, 1999) and among cultures today (Fernald, 1995).

Similar to the lack of studies of disability by anthropologists is the neglect by historians in tracing from the historical perspective how people with disabilities have lived and interacted with society at large. Longmore (1987) described the situation, which he labeled the "hidden history of disabled people," as "nearly untouched terrain" awaiting "excavation by historians" (p. 363). By the late 1990s the terrain was being populated with works that in their totality stressed the diversity of experiences through time of individuals with mental disabilities (Brockley, 1999).

DEFINITION AND DIAGNOSIS OF MENTAL RETARDATION

Defining mental retardation (MR) given its sociocultural context is the most difficult of tasks. In an attempt to standardize the way MR is defined and classified in the United States, the American Association of Mental Retardation (AAMR) has published since 1908 a series of volumes defining MR. The 10th edition, titled *Mental Retardation: Definition, Classification, and Systems of Supports* (AAMR, 2002a), has been released recently. The AAMR defines MR as follows: "Mental retardation is a disability characterized by significant limitations both in intellectual functioning and in adaptive behavior

as expressed in conceptual, social, and practical adaptive skills” (AAMR, 2002b). Two of the five assumptions the AAMR considers essential to the application of the definition are of relevance to considerations of the socio-cultural context of the definition. They are that “1) limitations in present functioning must be considered within the context of community environments typical of the individual’s age, peers and culture, and 2) valid assessment considers cultural and linguistic diversity as well as differences in communication, sensory, motor, and behavioral factors” (AAMR, 2002b). In general the definition considers both cultural and linguistic factors. The problem has been in the criteria and decision rules used to assess MR.

Previous editions of the AAMR definition have been lauded on the basis of their having rejected typological thinking with an appreciation of individual differences in intellectual functioning (Gelb, 1997) or having satisfied the view that some ambiguity in the definition supports the notion that there really is no “true” definition of the term (Reiss, 1994). They have been criticized by others (MacMillan, Gresham, & Siperstein, 1993) on the basis of decision rules not being reliable in their employment by researchers and clinicians. Another underlying flaw in such attempts to define MR is the reliance on tests of intellectual functioning, such as IQ tests that are well known to be culturally biased. The aforementioned assumptions attempt to address this shortcoming, but have not been applied consistently in the assessment of intellectual functioning across the broad cross-section of populations of the United States and elsewhere.

The existence of individual variation among individuals with MR, even within a condition such as Down syndrome, is fundamental to the rejection of “typological thinking,” a view that de-emphasizes individual differences within a group and stresses an underlying “unique essence” or “essential type” (Gelb, 1997). Gelb argues that this sort of thinking went by the wayside with the emphasis on “population thinking,” essentially the importance of individual differences, by evolutionary biologists such as Ernst Mayr, among others, during the latter half of the last century. He provides evidence that “typological thinking” continues to persist in certain sectors of the biological and social sciences and pervades the work of investigators in the field of MR. Some of this approach can be attributed to the lack of accurate, objective data on behavioral characters in many syndromes that involve MR and the need to make statistical comparisons among groups using reliable instruments for measuring characteristics

such as temperament (Nygaard, Smith, & Torgerson, 2002). However, given the fact that genetic data have demonstrated for some time that the vast amount of variation is among individuals as compared with groups such as racial populations, there is a need for the application of this knowledge in the study of individuals with disabilities.

There are two areas in the assessment of MR that have received much attention during the past 10–15 years and are of direct relevance to the concerns of medical anthropologists. One is the growing evidence for the influence of sociodemographic factors on the outcomes of assessments of MR among different ethnic and racial populations. The evidence regarding over-representation of children in minority populations among those with MR has been reviewed by Donald Oswald and his colleagues and new data presented (Oswald, Coutinho, Best, & Nguyen, 2001). The studies reported by Oswald et al. demonstrate that the disproportionate representation of African American children with mild MR is reduced (Yeargin-Allsopp, Drews, Decouflé, & Murphy, 1995) or disappears (Halfon & Newacheck, 1999) once sociodemographic variables such as age, gender, race, family characteristics, and socioeconomic level are taken into account. These and other studies reviewed by Oswald and his group suggest that poverty is the major contributor to the differentials in identification rates among ethnic groups. Data from South Africa (Slone, Durrheim, Lachman, & Kaminer, 1998) suggest a similar primacy for socioeconomic contributors to the differentials in referral patterns for assessment of MR. The data from the U.S. Department of Education Office for Civil Rights reported by Oswald et al. offer further support for the importance of both characteristics of individual students and the sociodemographic characteristics of school districts in predicting identification with MR, but the impact may differ according to groupings by gender and ethnicity. These data suggest that this is an area of disability research that is ripe for the input of anthropologists.

The second area is the growing literature on the development of culturally and linguistically competent assessment tools with applicability across cultural groups. Tombokan-Runtukahu and Nitko (1992) reported on an English language instrument used in the United States to measure adaptive behavior in individuals with MR that they had revised for use in Indonesia. The investigators concluded that the instrument could be applied in an Indonesian population and had psychometric characteristics very

similar to the original version. However, the instrument basically addressed only one aspect of Indonesian culture through translation into Bahasa Indonesian, although it was assessed for applicability in Indonesian cultures. Similarly, tests of intelligence and overall functioning have been modified and standardized for usage in testing people with MR in other cultures with reasonable results, such as the Wechsler Adult Intelligence Scale for China (Ryan, Dai, Paolo, & Harrington, 1992) and the ABILITIES Index, a measurement instrument that measures functioning in children with disabilities (Simeonsson, Chen, & Hu, 1995). More recently Gonzalez-Gordon and colleagues have tested a Spanish version of the Psychiatric Assessment Schedule for Adults with Developmental Disability (PASADD-10) and found it to have limitations in terms of predicting psychiatric disorders in individuals with intellectual disability (Gonzalez-Gordon, Salvador-Carulla, Romero, Gonzalez-Saiz, & Romero, 2002). Plank (2001) presents from the view of a psychologist "in the trenches" the problems and potential solutions in testing cognitive functioning in American Indian children and adolescents. The data to date suggest that much work remains to be done in adapting instruments to cultures other than those in which they were developed.

THE EPIDEMIOLOGY OF MR

It is critical at the onset of a discussion of the epidemiology of MR to remind ourselves again that we are dealing with a concept that is culturally based. How we define MR and the tools we use to determine if an individual is considered to have MR are by and large determined by the majority culture in any society. Therefore, when we conduct surveillance and epidemiological research, we are assessing an outcome that is administrative in nature in the sense that we are usually bound by the measurement tools that we know have cultural biases. This is the ultimate limiting factor in any population studies of MR.

Prevalence

Routine surveillance systems for the collection of population-based data from which to estimate prevalence rates for MR are still not abundant across the world. However, advancing computer technology and new possibilities for record linkage and data handling by Internet websites are likely to improve epidemiologic studies of MR in the future (Leonard & Wen, 2002). In the United

States, the only ongoing system has been the Metropolitan Atlanta Developmental Disabilities Study (now the Metropolitan Atlanta Developmental Disabilities Surveillance Program – MADDSP) based in the Centers for Disease Control (CDC) (Yeargin-Allsopp, Murphy, Oakley, Sikes, & the Metropolitan Atlanta Developmental Disabilities Study Staff, 1992). This system has been in existence since 1984 and targets MR as well as cerebral palsy, epilepsy, and vision and hearing deficiencies. The program identifies cases of children 3–10 years of age in a six-county area that comprises metropolitan Atlanta. The CDC summary of data reported from these surveillance systems is that the prevalence of MR in school-aged children is 12 per 1,000 (CDC, 2002). Rates reported by age, race, and sex for the 1991 reporting period have varied from 5.2 per 1,000 children to 16.6 per 1,000 (Boyle, Yeargin-Allsopp, Doernberg, Holmgreen, Murphy, & Schendel, 1996). In these data, severe MR accounted for about one third of all the cases. The National Health Interview Survey Disability Supplement (NHIS-D) of the U.S. Census Bureau uses a household survey method to collect data on individuals with MR and/or developmental disabilities and has produced an estimated prevalence of MR of 12.2 per 1,000 in a slightly older age interval of 6–17 year olds (Institute on Community Integration, University of Minnesota, 2000).

The most comprehensive recent review of prevalence data worldwide by Leonard and Wen (2002) includes data on prevalence of severe and mild MR in children of school age from Roelevard, Zielhuis, and Gabreels (1997) and several recent studies reported after their review. The rates of severe MR in studies reported 1960–2002 suggest a prevalence of 3–4 per 1,000 children, with a range of rates from about 1 to 7 per 1,000 (Leonard & Wen, 2002). Rates for mild MR were much more variable (2–80 per 1,000), with an average prevalence of about 33 per 1,000 for the same time span.

A prevalence of 8.3 per 1,000 in a cohort of children born between 1980 and 1990 has been reported for Western Australia (Bower, Leonard, & Petterson, 2000). Rates of severe MR have been reported in an Italian population of 6–13-year-old schoolchildren at 3.4 per 1,000 (Benassi, Guarina, Cammarata, Cristoni, Fantini et al., 1990) and in a 20–29 year-old cohort in Northern Ireland ranging from 4.07 to 6.37 per 1,000 according to the health district reporting (Mallon, MacKay, McDonald, & Wilson, 1991).

In general, rates will vary with age, geographic location, sex, and ethnic/racial group when studies take these

factors into account. The problem in making comparisons among different populations have to do with varying definitions of and methods of assessment for MR, differences among systems of collecting data, variability in the resources available to do population-based surveillance, and varying capacities in the application of computerized record linkage and databases.

Etiology

Mental retardation has been described in some recent epidemiological reviews as a “heterogeneous group of conditions” or “disorders” (Murphy, Boyle, Schendel, Decouflé, & Yeargin-Allsopp, 1998) or “group of conditions” (Leonard & Wen, 2002). Current thinking about human diseases stresses the need to move away from the old ways of viewing “nature versus nurture” or some disease entity as the result of “genetics or environment” toward a view that emphasizes that all diseases are likely to be both genetic and environmental (Khoury, 1998). This way of thinking gets us away from the typological thinking that seems to beset categorization of MR into groups of conditions of prenatal, perinatal, or postnatal origin as used currently. Applying this current view, perhaps MR is best defined as an outcome of variable causes that can be assessed along multiple dimensions, but is typically evaluated through measures of cognitive or intellectual functioning. In this manner, we can consider MR in general as a multifactorial outcome for which multiple genes and gene complexes are involved and numerous environmental exposures interact with the underlying genetic factors. Mental retardation is associated with numerous syndromes for which genetic causes have been identified and/or environmental exposures that at least theoretically are thought to interact with genetic factors to produce the outcome.

Another aspect to this thinking about MR is that we apply the concepts so eloquently presented by Richard Lewontin and his colleagues several decades ago (Feldman & Lewontin, 1975; Lewontin, 1974). In a series of publications in which the heritability of IQ was considered, Lewontin reminded us that we cannot estimate what percent of a person’s phenotype, such as height, is the result of genes and what percent is environmental. Lewontin stressed that these traits are studied in populations when we are attempting to assess how much of the variation in a trait is the result of variability among genetic backgrounds, namely genotypes, and how much is of environmental origin. Similarly, we cannot say that

the entire deficit in cognitive functioning of a child with Down syndrome is the result of the child’s chromosomal abnormality of trisomy 21. We might expect, however, that a large proportion of the cognitive deficiency in a population of Down syndrome individuals would be the result of the chromosomal involvement and the remainder to environmental factors.

The etiological data on MR are vast and a thorough account of what is known about the causes of and risk factors for MR is beyond the scope of this review. However, brief overviews of what is known about genetic and environmental causes of MR will be presented in the next two major sections.

Population Differences

Whenever population comparisons are made for the prevalence of MR, the methods by which populations are delineated must be carefully considered. Most studies of population differences for MR represent attempts to use existing categorizations of populations, for example racial and ethnic groups, such as those by the U.S. Census Bureau, to compare rates of occurrence. At best these populations represent a mix of underlying genetic and environmental-based factors that are difficult to decipher as to their contributions to the group differences.

Recent studies in the U.S. populations have demonstrated higher prevalence rates of MR for children of African American ancestry than for other groups (Croen, Grether, & Selvin, 2001; Murphy, Yeargin-Allsopp, Decouflé, & Drews, 1995; Yeargin-Allsopp, Drews, Decouflé, & Murphy, 1995), even after taking into account certain socioeconomic and demographic variables in one study (Yeargin-Allsopp et al., 1995). Similar between-population variation in rates of MR have been seen elsewhere (e.g., in Australia—Leonard & Wen, 2002). Explanations for population differences have been summarized by Leonard and Wen (2002) and include the possibility of confounding variables, community factors such as segregation and social disadvantage, cultural differences that result in variable behavior among groups and use of assessments of intellectual function that are not appropriate, and prenatal or postnatal factors such as maternal conditions that could increase the risk of MR in specific groups. When making any cross comparisons among populations, such as international comparisons, issues involving the methods used among systems to obtain data also need to be considered (Durkin, 2002; Leonard & Wen, 2002).

GENETIC FACTORS IN MR

The genetic causes of MR have been reviewed recently in Murphy et al. (1998) and Leonard and Wen (2002). The former consider causes to be “well-defined events or insults to the fetus or child that result in a high probability of MR” and give the example of Down syndrome. Studies vary, but according to several reported by Murphy et al. (1998), genetic conditions account for the largest percentage of known causes of MR (30–40%) and 7–15% of all cases of MR. Up to 30% of severe MR and 4–8% of mild MR in which cause is identified are the result of chromosomal abnormalities according to one study (Schaefer & Bodensteiner, 1992). In several studies reported by Leonard and Wen (2002), Down syndrome is the single genetic condition reported most frequently. Its prevalence is generally considered to be about 1 in 1,000 live births. The study with the largest population base reported that Down syndrome accounted for more than 82% of all chromosomal abnormalities (Hou, Wang, & Chuang, 1998). In the same study, Fragile X syndrome, the most common form of X-linked MR, had the next highest occurrence among the chromosomal conditions. The prevalence of Fragile X is about 1 in 1,000 males and 1 in 2,000 females.

An interesting new line of research into the genetic etiology of MR is the investigation of chromosomal rearrangements in the ends of the chromosomes or telomeres. Genome wide telomere screening with fluorescent in situ hybridization (FISH) probes has been reported for a number of populations of individuals with MR. The frequencies of subtelomeric rearrangements have ranged from 2% to 10% depending on the population studied (Baker, Hinton, Callen, Altree, Dobbie et al., 2002; Rio, Molinari, Heuertz, Ozilou, Gosset et al., 2002). These studies suggest that the role of chromosomal abnormalities as a cause of MR might be substantially larger than has been thought (Chris Cunniff, personal communication).

Less than seven years ago over 500 genetic conditions were reported by Flint and Wilkie (1996) to be associated with MR. A recent search (October 2002) of the Online Mendelian Inheritance in Man (OMIM) for genetic conditions in which MR was observed produced 1,076 entries (<http://www.ncbi.nlm.nih.gov/omim/>). The number of conditions for which genes are identified is likely to grow in light of the rapid pace of discoveries in human molecular genetics and continuing advances in biotechnology and its applications. If anything, the knowledge bases around

many genetic conditions for which information on genetic causes was not clear 10–15 years ago indicate that the genetics is more complex than we had ever imagined. Examples include genomic imprinting in which the expression of genes depends on whether the chromosome of concern is maternal or paternal in origin. This phenomenon has been observed in two conditions, Prader–Willi syndrome and Angelman syndrome, in both of which MR is a major feature. These two conditions were the next most prevalent to Down syndrome and Fragile X syndrome in the study by Hou et al. (1998).

Not only are there more genetic conditions with associated MR, but the number of reported studies for specific conditions is also increasing at a rapid pace (Dykens & Hodapp, 2001). Using the Medline database, Dykens and Hodapp (2001) found that the number of publications for conditions such as Fragile X syndrome and Prader–Willi syndrome doubled from the 1980s to the 1990s. For some conditions, such as Angelman syndrome, there were 3–14 times more publications in the 1990s. The breadth and depth of research is also increasing. Many of the studies reported by Dykens and Hodapp (2001) reflect more detailed investigations of genetic etiologies, but also an expansion of research on genotype–phenotype relationships; detailed evaluation of phenotypes, especially behaviors; interventions in specific conditions; and family issues. The 1990s have also been a period of growth in terms of the development of standards of care for genetic conditions through organizations such as the American Academy of Pediatrics and the availability of information on genetic conditions for both specialists in medical genetics (e.g., OMIM) and practicing physicians (<http://www.geneclinics.org>).

ENVIRONMENTAL FACTORS IN MR

The literature on environmental etiologies and risk factors for MR is vast and can only be touched upon here. This section will concentrate on the data from epidemiology regarding environmental factors and recent work regarding cultural factors as they relate to families coping with MR in a family member and their role in families adapting.

Epidemiological Data

When dealing with the etiologies or risk factors for MR, epidemiologists will generally categorize them by the

time period during which they originated. Murphy et al. (1998) review the etiological data on MR by grouping causes and risk factors according to their having originated prenatally (including genetic factors and intrauterine exposures such as infections), perinatally (including factors such as low birth weight), and postnatally (including environmental exposures such as lead and infections).

Prenatal exposures include those associated with maternal behaviors as well as various environmental exposures during the pregnancy. Several studies have assessed the effect of maternal smoking (Murphy et al., 1998), with one finding increased risk of MR in the child with increasing level of maternal smoking (Drews, Murphy, Yeargin-Allsopp, & Decouflé, 1996). The latter investigators have suggested an effect of maternal smoking independent of its contribution to low birthweight. Alcohol exposure in utero is another well-described risk factor for MR through the research on fetal alcohol syndrome (FAS) or less severe conditions such as alcohol-related neurodevelopmental disorder. A recently published prevalence study suggests that this entirely preventable cause of MR remains at levels previously described (Miller, Tolliver, Druschel, Fox, Schoellhorn et al., 2002). Murphy et al. (1998) suggest that intrauterine infections might be diminishing in importance as a causal factor of MR. However, recently analyzed data from the U.S. National Collaborative Perinatal Project demonstrated the risk of MR or developmental delay is elevated in children of mothers who had a third trimester urinary tract infection (McDermott, Daguise, Mann, Szwejbka, & Callaghan, 2001). And in the low-income nations of the world infection continues to be a major risk factor for MR and other developmental disabilities (Durkin, 2002).

Perinatal conditions for which there are data to support increased risk of MR include infections, asphyxia, low birthweight, preterm delivery, intrauterine growth retardation, and twinning (Murphy et al., 1998). Murphy and her colleagues, and Leonard and Wen (2002), provide comprehensive reviews of the most recent data. Low birthweight is the risk factor that has been studied in the greatest detail according to Leonard and Wen (2002). The most recent study of MR of unknown etiology in a large population demonstrated that low birthweight was the single most predictive risk factor for both mild and severe MR (Croen et al., 2001). Generally the data on perinatal risk factors suggest a complicated network of factors operating to influence brain growth and development, and therefore contributing to risk for MR.

Finally, Murphy et al. (1998) review the data on postnatal risk factors, which include exposure to environmental contaminants such as lead, methylmercury, and polychlorinated biphenyls; infections such as bacterial meningitis; and head trauma as a result of accidents (e.g., motor vehicle injuries, near drownings) or child abuse. The CDC estimates that the occurrence of postnatal causes of MR in children ranges from 3% to 15% (CDC, 1996).

Few of the epidemiological studies consider the contribution of cultural factors into the array of environmental risk factors for MR. One notable exception is the work of Yeargin-Allsopp et al. (1995) who suggest that cultural differences such as culture-based behavioral variation and tests of intellectual functioning that are not appropriate across cultures could contribute to an increased likelihood of mislabeling with respect to MR. More recently, Leonard and her colleagues have attempted to sort out culture-based contributing factors to identification of Australian indigenous children with MR (Leonard & Wen, 2002).

Cultural Factors

Culture is certainly an important factor in how families cope with having a member with MR and eventually adapt through modification of individual and familial behaviors. A rich literature has developed during the last 15 years concerning the stress experienced by families in multiple cultures when a family member has a developmental disability such as MR. Psychological stress and depression, and their correlates, have been studied in Hispanic families (Blacher, Shapiro, Lopez, Diaz, & Fusco, 1997; Magaña, 1999), Chinese families of a child with Down syndrome (Cheng & Tang, 1995), Malaysian mothers of children with MR, including some of Chinese ethnicity (Ong, Chandran, & Peng, 1999), and African American, Hispanic, and European American mothers of children with disabilities (Mary, 1990). These data demonstrate substantial evidence of the influence of cultural values and behaviors in adjustments of families. Mary (1990) reported more feelings of self-sacrifice among Hispanic mothers and more instances of spouse denial in this group. Magaña (1999) showed that some aspects of familism, an array of family caregiving, social support, and obligatory behaviors, were protective of the emotional well-being of Puerto Rican mothers of an adult with MR. Blacher et al. (1997) suggested that it was problems in the functioning of families that were the best predictors of depression among Latino mothers in

Los Angeles. The study by Cheng and Tang (1995) reported that Chinese mothers of children with Down syndrome were more distressed than the fathers. Interestingly Ong et al. (1999) found that Chinese ethnicity predicted stress as did mother's unemployment.

How individuals with MR and their families adjust to the numerous life stresses has been studied in a number of cultures. Frison, Wallander, and Browne (1998) found that cultural factors that measured areas such as identification with one's ethnic group and church support were protective against certain types of maladjustive behaviors for which adolescent African Americans with mild MR are known to be at risk. A study of Hispanic and non-Hispanic families having a member with MR was reported by Heller, Markwardt, Rowitz, and Farber (1994). Family interview data showed that Hispanic families, primarily of Mexican American ancestry, had a decreased sense of burden in caring for a family member with MR and increased acceptance and coping through religious experiences than did the non-Hispanic, European American families. More recently Skinner, Correa, Skinner, and Bailey (2001) reported a more detailed study of religion as a strong coping mechanism among Latino families of Mexican and Puerto Rican origins. Using both qualitative and quantitative data, Rogers-Dulan (1998) has reported similarly positive contributions of personal and familial religious experiences and church support mechanisms among African American caregivers with a mentally retarded child. Finally, Miltiades, and Pruchno (2002) have produced an elegant study in which they have tested a model of how coping through religion relates to caregiving. Interviews were done on African American and European American women of age 50 or more who had an adult child with MR. The two groups were matched on socioeconomic indicators so that racial membership no longer would predict socioeconomic status and any group differences could be interpreted as cultural in origin. African American women had a higher likelihood of using religion as a coping mechanism than did European American women. In addition, the study found a positive association between religious coping and satisfaction with caregiving, but not with the burden of caregiving. African Americans were more satisfied with caregiving but experienced higher levels of burden as a result of poor health.

The importance of these studies is in the application of this knowledge in improving the professional competencies with which service providers deal with families of

individuals with MR. This will be dealt with briefly in the next section.

ISSUES IN INTERVENTION AND SERVICES FOR MR

Several issues concerning intervention and services for individuals with MR have come to the fore during the last 20 years as societal attitudes have changed generally and legislative efforts have worked specifically to eliminate barriers and problems, and ensure quality lives for individuals with developmental disabilities. The following, of necessity, is a brief review of the burgeoning literature on international efforts toward intervention and provision of services as well as research that emphasizes population comparisons and cultural responses to services. An overarching theme is the increased attention that has been paid to cultural diversity in all aspects of intervention and the need to incorporate cultural competence into the delivery of services and supports for individuals with MR and their families and caregivers. What always continues to impress is the continuing need for ethnographic data, especially in the area of disability, to support the education and training necessary to achieve standards of cultural competence among service providers.

Family Supports

The family supports movement has seen great progress in the last 20 years and continues to be a major emphasis in the activities and funding concerning services for families of individuals with developmental disabilities. Evaluation studies of interventions with families have appeared in the literature of the 1990s (e.g., Davis & Rushton, 1991), including evaluation specifically for early intervention programs (Guralnick, 1997). The Davis and Rushton (1991) study is of interest in that it was cross-cultural, including both English-speaking (presumably of British ancestry) and Bangladeshi families in London and used randomly assigned controls. The study demonstrated positive effects for both families and children of a home-based, family counseling intervention, with more marked effects in the Bangladeshi families, who presumably benefited greatly from the counseling by same-culture parent advisors.

A number of studies have appeared that review the experiences of different cultural groups with family support activities. Shapiro and Simonsen (1994) reviewed

the needs and experiences of a family support group for Latino families of Mexican origin who had a child with Down syndrome. More recently Bailey, Skinner, Correa, Arcia, Reyes-Blanes et al., (1999) reported data on interviews with 200 Latino parents of Mexican and Puerto Rican origin who had a child under 6 years old with MR or a developmental disability. These data did not demonstrate a unique “Latino style” (as the authors put it) of needs and supports and a number of predictor variables describing family characteristics did not account for much of the total variance in the domains that reflected needs and supports among these families. Finally, Shin (2002) has attempted to model the variables that contribute to maternal stress among American and Korean families (by location) of children with MR. These data showed that American mothers received higher levels of both informal (e.g., family, friends) and professional (e.g., teachers, healthcare providers) support than mothers in Korea and the latter experienced more stress.

Disparities in Services

It has become apparent that healthcare for individuals with developmental disabilities, as well as other services, is not on a par with services for the non-disabled population. The U.S. Surgeon General’s recent report (U.S. Public Health Service, 2001) highlights the multiple problems in this regard in the United States. The disparities cover the entire lifespan, including in the United States residential care/assisted living and nursing homes (Howard, Sloane, Zimmerman, Eckert, Walsh et al., 2002). The sense among those who work in the developmental disabilities fields in other nations, even those with national healthcare systems, is that there are gaps in the delivery of healthcare services for individuals with developmental disabilities. For example, Bollard (1999) has reviewed the situation in the United Kingdom with respect to primary healthcare delivery and concludes that the community learning disability teams in collaboration with practicing nurses could address some of the gaps in services.

Increasingly there are studies being done regarding the costs of services for individuals with developmental disabilities. A recent analysis of the Hawaii Medicaid fee-for-service program demonstrated that profound MR was among the 10 leading diagnostic categories in terms of payments for healthcare (dollar volume for FY1999), ranking fourth (Loke, Kang-Kaulupali, & Honbo, 2001). Studies like these underscore the sense of cultural dissonance between the developmental disabilities communities

and society-at-large as seems to exist for birth defects between those affected and public health (Meaney, 2001).

International Data

There is a growing literature on key issues in developmental disabilities from an international and multicultural perspective. These issues include such areas of concern as transition to adulthood, social integration, quality of life (QoL), and education, among others. There are many signs of changing attitudes and perspectives on an international basis. New initiatives in the special education system in China toward integrating children with developmental disabilities into mainstream classes in local schools (Deng & Manset, 2000) are a prime example of these changes. Transition from late adolescence to early adulthood is probably an area in need of more research from a multicultural perspective. Recently Blacher (2001) has stressed the need for more research to evaluate successes in this difficult transition period and the variables that provide the strongest prediction of success, including cultural attitudes and beliefs. Social integration of individuals with MR from a cultural perspective has been assessed at both the community (Calvez, 1993) and national levels (Pedlar, 1990). Both studies point to limitations in the achievement of full integration into society. Finally, measures of QoL for individuals with developmental disabilities, including more subjective realms of assessment, have received much attention during the 1990s. An international comparison of individuals with MR from a northern Italian community with a sample from an Australian community as well as samples from the general populations of both communities (Verri, Cummins, Petito, Vallero, Monteath et al., 1999) showed that scores on a standard index of QoL were similar among the groups. The data did confirm that individuals with milder MR could report on subjective QoL quite adequately. More research is needed along these lines, as well as increased international comparisons and multicultural research on important issues in developmental disabilities.

THE SEARCH FOR GENETIC–ENVIRONMENTAL INTERACTIONS

Our thinking about the ancient nature–nurture issue has evolved over the years. Plomin and Petrill (1997) wrote

about swings of the nature–nurture “pendulum” and presented a figure depicting these swings in the direction of nature or nurture as the predominant explanation for human behavior and other traits by the decade of the 20th century in which they occurred. Current ideas in the fields dealing with human diseases have taken us away from “nature or nurture thinking” and replaced this misconception with conceptualizations that see human diseases, as well as all human characters and traits, as the products of the interplay of both nature and nurture, that is genetics and environment (Khoury, Burke, & Thomson, 2000). If we are dealing with the outcomes of human disease, then this becomes even more apparent.

Some of the most exciting current work in genetic epidemiology is the search for and reporting of gene–environment interactions. As Khoury (1998) has put it: “The nature versus nurture controversy is being replaced by systematic evaluation of nature–nurture interaction.” With the work of the Human Genome Project and advances in human molecular genetics in general has come the identification of many new genes and their mutations associated with diseases. This coupled with advances in the collection of environmental data have led to an unprecedented surge in the evidence for gene–environment interactions in such subfields of human genetics as pharmacogenetics and genetic epidemiology.

The search for evidence of specific gene–environment interactions for MR is still in its infancy. A recent Medline search by the author (October 2002) combining MR and the phrase “gene–environment interaction” produced one publication. However, current research suggests that this will be one of the major areas of expansion in medical genetics during the next 15–20 years. Dykens and Hodapp (2001) provide a comprehensive review of research in MR focusing on a number of genetic conditions (Down, Fragile X, Prader–Willi, and Williams syndromes). These conditions are arguably the ones that demonstrate the greatest increase during the 1990s in research that will eventually shed light on gene–environment interactions in health outcomes and health, educational, and other interventions. An innovative example of the latter is the research on Fragile X syndrome reported by Dyer-Friedman, Glaser, Hessler, Johnston, Huffman et al. (2002). This study examines both genetic and environmental factors that predict cognitive outcomes, such as IQ, in 120 children with the full mutation for Fragile X

syndrome. Interestingly both genetic and environmental factors predicted intellectual functioning in these children, but there were clear gender differences in the patterns observed. Among girls, the mean parent IQ was the strongest predictor, with some variation resulting from the quality of the home environment. In contrast, the boys’ home environment accounted for more variation in IQ than it did among the girls, and the levels of a specific gene product, the FMR1 protein, was associated with one measure of IQ (Full Scale). This study provides a model for this sort of research through the emphasis on the interplay between genetic and environmental factors in determining a specified outcome as well as the statistical methods (hierarchical regression analysis) utilized to assess the effects of the predictor variables.

SUMMARY AND FUTURE PERSPECTIVES

The need remains for more research from an anthropological perspective on disabilities such as MR. Current research supports the concept of disability as a sociocultural construct. Progress has been made in recent years in considering cultural variation as a key factor in how families react and cope when a member has MR and how to implement effective interventions and services. Research into the causes of MR continues to make tremendous progress through both epidemiological and genetic studies that promise to contribute to improvements in the prevention and treatment of MR.

Parmenter (2001) has recently contributed an interesting overview of the contributions of scientific studies to developments in community inclusion for individuals with MR. From his assessment of the literature over the last 25 years or so, he perceives “a growth in multiparadigmatic thinking and a less rigid way of conceptualizing the nature of reality” (p. 191). In his view, the challenge to the community of researchers for the next century “is for a greater collaboration between researchers, policy planners, and the people most deeply affected—the persons with an intellectual disability, their families and carers” (p. 191). The call for researchers to collaborate more intensively comes at a time when, if anything, subspecialization in the sciences has intensified and at least within scientific communities the ease with which such collaboration gets done has all but disappeared in some university communities as competition and scarce

resources and time create major difficulties for the scientist who wishes to build broad, collaborative approaches to some problem. However, it has to be accomplished if we are to engage the support of policy-makers in creating the necessary resources for such work and accomplish a true sense of priorities for the people most affected by the science.

It could very well be that the collaborative efforts for which Parmenter calls will come when we have accomplished a revolution in our thinking about developmental disabilities. In this author's view that major step will come when the comprehension of the genetic *and* environmental contributors to disease and outcomes becomes a reality for a broad cross-section of the biomedical, behavioral, and social sciences, as well as the public at large. In this vision, it is not simply a matter of getting across the theoretical underpinnings of what is meant by the interplay between genetic and environmental factors, or gene–environment interaction, but also the notion that “one size fits all” should be totally abandoned in the interventional services such as education, medical treatment, and so forth. This is happening first in the medical sciences through the influences of breakthroughs in pharmacogenetics, primarily, but also through examples of gene–environment interaction in the risk for multifactorial conditions and diseases such as birth defects, cancer, and cardiovascular disease. Such interactions will be increasingly observed for developmental disabilities during the next two decades as the genetics of MR, autism, and other conditions is elucidated. It is predicted that the next phase will then be the application of this knowledge to the evaluation of interventions and services. Only then, when we understand more completely the underlying genetic susceptibilities and gene–gene interactions, as well as the environmental contributors, will we be fully capable of assessing what works best and why. That will be the brightest day for the hopes and aspirations of “the people most deeply affected,” for we will be ever so much closer to really understanding what we are doing when we intervene in their lives.

ACKNOWLEDGMENTS

This work was supported in part by grant # 90DD0532/01 from the Administration on Developmental Disabilities. The author would also like to acknowledge the assistance provided by Mary M. Meaney and Carolyn Henley in tracking down references and commenting on earlier drafts of the paper. The manuscript benefited immensely from the

critical eye of Chris Cunniff, M. D. Any errors in factual knowledge despite the assistance are the sole responsibility of the author.

Sudden Infant Death Syndrome (SIDS or Cot Death)

Infant Sleep, Breast Feeding, and Infant Sleeping Arrangements

James J. McKenna

INTRODUCTION

The sudden death of an infant under one year of age which remains unexplained after a thorough case investigation, including performance of a complete autopsy, examination of the death scene, and a review of the clinical history.

Willinger, 1989, p. 73.

There is no such thing as a baby, there is a baby and someone.

D. Winnicott

For species such as primates, the mother is the environment.

Sarah Blaffer Hrdy, 1999.

In Western industrialized societies pediatric health professionals generally encourage child care practices believed to foster social and biological independence in their infants, as early in life as possible. Birth is commonly viewed as the moment in which the newborn becomes an independent being from the mother, since the mother's body is seen no longer to directly regulate the infant's physiology through the placenta. In these cultures the establishment of early infant/child independence is the developmental goal, autonomy the desired outcome (McKenna, 2002; Trevathan & McKenna, 1994; Young & Fleming, 1998).

An important question raised by anthropological studies, however, is whether historically recent recommended child care patterns that emerge from this view presume infants to be more physiologically independent from their caregivers than they actually are. By ignoring the infant's evolutionary history, such as a human infant's innate need for frequent night-time breast feeds and maternal contact, are critical aspects of the infant's biology being mismatched with rapidly changing patterns of infant care that ultimately deprive the infant of needed if not critical external regulatory maternal stimuli and support (LeVine, Dixon, & LeVine, 1994; Lipsitt, 1981; Lozoff, 1982; Lozoff & Brittenham, 1979; McKenna, 1992, 2001, 2002; Montago, 1978).

Indeed, only relatively recently has the significance of underlying biological regulatory effects induced by maternal contact, caregiving style, and proximity been recognized. The idea that patterns of human contact during sleep (Mosko, Richard, McKenna, Drummond, 1996; Mosko, Richard, McKenna, Drummond, & Mukai, 1997a), degrees of parental emotional responsivity (Kelmanson, 1993), infant sleep positioning (Guntheroth & Spiers, 1992), and method and style of feeding (Gartner, 1997) could significantly affect infant survival is a challenge to the traditional Western paradigm that assumes social care to be, for the most part, unrelated to the autonomy and integrity of the infant's fundamental physiology. Until approximately 20 years ago, for infants living in the industrialized West none of these specific factors was predicted nor thought to play any significant role in affecting infant survival per se (Byard & Krous, 2001; Rognum, 1995). But especially among primate species who are born less neurologically mature at birth than most other mammals, visual, auditory, olfactory, tactile, and movement cues and signals emanating from their caregivers are now described as playing a critical "regulatory" role in how infants breathe, sleep, feed, grow, produce stress hormones, and thermo-regulate (Korner & Thomon, 1972).

[Despite this knowledge, it is not always the case that what the human infant's sensory system is designed ideally by evolution to experience from its parent as, for example, its mother's milk delivered through her breast in conjunction with forms of nighttime cosleeping can be obtained.] This is because learned (culturally favored) patterns of child care are extremely variable and subject to rapid modification and change. Moreover, child care patterns emerge not always from studies of human infant biology or what constitutes empirically validated, *ideal* infant care (assuming there is such a thing), but rather from considerations of how compatible they are with current lifestyles, ideologies, and social values. Moreover,

recommended child care practices generally consider, for example, whether or not particular forms are believed to produce desired adult behavioral or personality characteristics (Super & Harkness, 1982).

The problem is that, despite culture, the infant's biology remains relatively constant (Super & Harkness, 1982). And the most optimal choices as regards infant care (from a biological perspective) are not always the ones encouraged by the societies or families within which choices are made. For example, and independent of culture, for all infants everywhere, method of feeding (exclusive breast, bottle, or mixed), sleeping arrangements (social or alone), and infant sleep position (back, tummy, or side) are known to change neonatal and infant physiology in similar ways. And it appears that the only true micro environment to which a human infant is fully adapted is the mother's body (Hrdy, 1999) and, hence, when deprived of maternal contact infantile deficits may find increased opportunities to conspire therein increasing the chances of a SIDS death (McKenna, 1986; McKenna et al., 1993).

SIDS: HISTORY AND EPIDEMIOLOGY

Since 1962 when the sudden infant death syndrome (SIDS, crib or cot death) was first recognized and defined as a distinct medical entity, approximately 280,000 infants under one year of age (living in the Western industrialized world) have died from this puzzling syndrome. Adding to the sadness and difficulties of having to accept the sudden death of an otherwise healthy-appearing infant, no explanation or description of what actually kills the SIDS victim can yet be offered to grieving parents and relatives. A "diagnosis by exclusion," that is, *death by nothing concluded upon postmortem examination*, is all that continues to qualify a deceased infant to be considered another tragic SIDS fatality.

The most intriguing clue to understanding SIDS remains the unique age distribution of its victims. No other human malady except botulism is so heavily concentrated around such a narrow developmental period. Ninety percent of SIDS deaths occur before 6 months of age, mostly between 2 and 4 months; rarely do such deaths occur beyond 12 months of age (Ariagno & Glotzbach, 1991; Byard & Krouss, 2001).

But the primary causes of SIDS are still unknown. The most compelling general hypothesis is that the fatal

event is related to the control of breathing and/or arousal during sleep. Risks for SIDS, which ordinarily involves infants primarily in the first year of life, and especially between 2 to 12 weeks of life, are suspected to be increased by deficits or assaults to the fetus's nervous system incurred in the womb. Maternal smoking during pregnancy is the most significant risk factor to the fetus prenatally, making the infant susceptible to SIDS postnatally, but maternal smoking cannot explain all infant deaths from SIDS. Smoking during a pregnancy is known to produce low birth weight and/or prematurity, which are confounding factors that also predispose some infants to death.

Other SIDS risk factors include the prone infant sleep position (see below), lack of breast feeding, young maternal age, chaotic lifestyles, membership in an indigenous minority or racially impoverished groups, especially involving mothers who are poor and lack both education and prenatal support (Byard & Krouss, 2001).

Some SIDS victims still seem to differ from surviving healthy babies not so much in kind as in degree (Schwartz & Sagatini, 1988). These SIDS infants appear to suffer from subtle deficits that develop during intrauterine life and are not apparent in the neonate (Valdes-Dapena, 1980, 1988). Researchers believe that the actual expression of the fatal deficit is likely to be influenced by, if not dependent on, a number of co-factors that converge at a vulnerable moment in the infant's life (Barnett, 1980; Byard & Krouss, 2001; Rognum, 1995). Nobody can yet delimit all of the appropriate SIDS co-factors or explain why co-factors seem to have differential effects on infants. But it is extremely likely that certain factors are more relevant to some SIDS victims than to others. For example, for some infants, a contributing SIDS risk factor might be the lack of breast feeding (Fredrickson, Sorenson, & Biddle, 1993; Hoffman, Damus, Hillman, & Krongrad, 1988); while for another it might be sleeping face down (prone) in the presence of an upper respiratory infection that diminishes the potency (muscle tone) of airway passages (Blackwell, Saadi, Raza, Weir, & Busuttill, 1993). In certain predisposed infants, efficient respiratory control might also be jeopardized by infantile hypothermia, induced by atmospheric temperature, humidity, or too much bundling up (overheating) in cold weather (Ariagno & Glotzbach, 1991; Fleming et al., 1996).

One group of researchers suggests that between 28% and 52% of SIDS victims found "faced straight down" may have actually suffocated, especially those who were sleeping on beanbag cushions. Unable to dislodge themselves

from the pockets formed by such cushions, the infants may have been forced to rebreathe lethal doses of their own expelled carbon dioxide (Byard & Krous, 2001; Kemp & Thach, 1991).

Though this may be changing with current recommendations to position infants on the back or supine position for sleep, SIDS occurred most frequently in winter, and infants tended to die in the early morning or evening hours, when the infant is out of sight of the caregiver and presumably asleep. However, SIDS is also known to occur while babies are riding around in strollers, sitting in car seats, dozing in baby carriers, and even sleeping on their mother's chests, following a breast feeding episode (Blair et al., 1999; Fleming et al., 1996; Guntheroth & Spiers, 1992; McKenna, 1986).

The SIDS population is exceedingly heterogeneous. No single, consistent criterion or pathological marker can be used to either predict potential SIDS victims or identify them upon postmortem autopsy. Nor is there an animal model of SIDS; it is not known to occur in any

species other than humans (see Byard & Krous, 2001; McKenna, 1986; Rognum, 1995; for reviews).

In the United States, SIDS rates are highest among both Native American and poor African Americans whose mothers are less than 20 years of age, smoke during their pregnancies, are unmarried, and lack access to prenatal care (Hoffman et al., 1988). SIDS rates are lowest in diverse Asian (see below), Swedish, Finnish, Norwegian, English, and Israeli populations, where mothers tend to be older, do not smoke during pregnancy, and place their infants in the supine (back) or side position for sleep. Especially in Asian cultures where SIDS rates are consistently low, infants typically room share and sleep within arm's reach of the mother, or they sleep as they do in China and Japan in direct contact with their mother's body during the first few years of life while the mothers are breast feeding intensively (Gantly, Davies, & Murcott, 1993; Nelson et al., 2001).

SIDS is virtually unknown in China, Thailand, Cambodia, Vietnam, and Nepal, as Figure 1 indicates.

Figure 1. SIDS rates (1995) and the prevalence of bedsharing >5 h per night across cultures. (Source: Nelson et al. (2001). *Early Human Development*, 62, 43–55.)

In contrast, the rates among Inuit Alaskan Indians can range from 4 to 6 per 1,000 live births, and as high as 9–15 per 1,000 live births among impoverished native Canadian Indians, the Cree (Wilson, 1990).

One study revealed that about 18% of all SIDS deaths involve premature infants. Low birthweight is a risk factor, as is the experience of one or more of an “apparent life-threatening event” (ALTE), characterized by a loss of muscle tone accompanied by gasping or choking, listlessness, color changes, or a cessation of breathing. Approximately 6% of infants who experience an ALTE die from SIDS (Ariagno & Glotzbach, 1991; Byard & Krous, 2001).

Various studies report that before their deaths, some SIDS infants slept for longer periods of time, awoke less often, and had more difficulty awakening or arousing than healthy infants with whom they were compared (Einspieler, Widder, Holzer, & Kenner, 1984; Harper et al., 1988). At birth, some SIDS infants received lower Apgar scores and gained weight more slowly. And some exhibited less frequent but more sustained heart-rate variability, and fewer but longer breathing pauses (apneas) (Harper et al., 1981; Hoppenbrouwers, Hodgman, Arakawa, & Serman, 1989).

In a major study in the United States conducted in the 1980’s funded by the National Institutes of Child and Maternal Health, 756 SIDS victims were compared with 1,600 control infants. The research team found that many SIDS victims had had colds and bouts of diarrhea or vomiting within two weeks of death. A significant number had also exhibited droopiness, irritability, or some form of breathing distress involving a rapid heartbeat 24 hours before they died. However, researchers believe that all these symptoms were acting in secondary fashion rather than as primary causes of SIDS (Hoffman et al., 1988). As few as 10% of all SIDS victims had had symptoms associated with a potential SIDS event before their deaths. This includes full-term infants with clinical histories of apneas as well as preterm underweight babies who experience “apneas of prematurity” (Ariagno & Glotzbach, 1991; Byard & Krous, 2001; Rognum, 1995).

Only a relatively low number of symptomatic infants actually die of SIDS. As a result, the medical community is engaged in a volatile debate about whether or not infants with a history of repeated apneas should be sent home from hospital with breathing monitors. At any given time, between 40,000 and 45,000 monitors are put to use in the United States; yet, no data indicate that

monitors prevent SIDS deaths, and no data suggest how or under what circumstances infants die from SIDS when monitors are in use. At present, the effectiveness of home monitors in preventing SIDS deaths is highly questionable (Byard & Krous, 2001).

SLEEP PHYSIOLOGY RESEARCH AND SIDS

The architecture of infant sleep, breathing patterns, and arousal have been intensely studied by SIDS researchers, as have the neuro-structural, neuro-chemical, and physiological systems that underlie, influence, or control these activities (Mosko et al., 1997, 1996). The possibility of fast-acting bacteria (infections) in the nose and respiratory tract, in combination with environmental factors (prone sleeping on soft mattresses, overheating, and maternal smoking) in addition to infantile internal deficits are known to increase SIDS risks (Byard & Krous, 2001).

Researchers note that SIDS tends to occur after abnormalities of the cardio-respiratory control system have failed to monitor some combination of oxygen levels, breathing, heart-rate rhythmicity, body temperature, or the arousal responses needed to reinitiate breathing after a normal breathing pause or apnea. Essentially, the cardio-respiratory system is thought to collapse (Byard & Krous, 2001; Harper et al., 1981; Hoppenbrouwers et al., 1989; Kahn, Picard, & Blum, 1986; Kinney et al., 1995; McCulloch, Brouillette, Guzzetta, & Hunt, 1982; Rognum, 1995; Schwartz & Sagatini, 1988; Shannon, Kelly, & O’Connell, 1977 for reviews).

The unfolding pattern of sleep itself, including how and when human infants arouse or awaken from sleep, is believed to be controlled by the primitive brain stem, located at the central base of the brain. This area is composed of clusters of differentiated cells that receive and send messages to and from the heart, hormonal centers, lungs, muscles surrounding the ribs, diaphragm, and airway passages, as well as structures that specifically help to balance the proper amounts of oxygen and carbon dioxide (CO₂) in the blood. Also controlled by the brain stem is the amount of time spent in various stages of sleep during any given sleep period—for example, in light sleep, (stages 1 or 2), in deep stages (stages 3 and 4), or in rapid eye movement (REM, i.e., active sleep) (Mosko et al., 1996; Mosko et al., 1997; Harper et al., 1981; Hoppenbrouwers et al., 1989). Sleep architecture,

including the form and timing of arousals, are all influenced by external stimuli as well, such as feeding method and the presence or absence of a co-sleeping partner, and must, therefore, be considered alongside any analysis of internally-based sleeping mechanisms (Mosko et al., 1997).

Kinney et al. (1995) studies an area of the brain (the arcuate nucleus) located on the ventral surface of the brain stem, an important area that monitors the proper balance of CO₂ and oxygen. Recall that when CO₂ builds up in the blood, the respiratory neurons are activated to expel it, thereby causing fresh oxygen to be inhaled, reducing the acidity of the blood. A significant number of SIDS victims compared with control infants had fewer “acetylcholine binding sites” in this area of the brain. This suggests that in a variety of different circumstances, prone sleeping included, infants may not have the optimal or even minimal ability to arouse to reinitiate breathing following some type of apnea or exposure to their own exhaled CO₂ if it is trapped; for example, in a mattress as the baby lies face down, or if the infant is under thick blankets. Or it might mean that infants simply cannot arouse to breathe after particularly long breathing pauses or apneas.

CHILD CARE PRACTICES 2002: INSIGHTS FROM PARENTAL SOCIAL BEHAVIOR RATHER THAN FROM BIOLOGY?

In the past 12 years child care practices have proven to be the single most important set of factors for reducing the chances of an infant dying of SIDS (Guntheroth & Spiers, 1992; McKenna, 2002; McKenna & Bernshaw, 1995). The discovery that merely placing infants in the supine (back), rather than in the prone (belly) sleep position, could reduce SIDS rates by as much as 50%–90% continues to astonish many SIDS researchers around the world. Indeed, the prone infant sleep position is likely as important to understanding the probability of SIDS as are the primary deficits. If SIDS researchers were asked just a decade ago to prioritize SIDS research areas according to how likely they were to yield clues about reducing SIDS risks quickly and significantly, child care practices over which both parents and professionals assert control would not have been ranked very high. Instead, knowledge of brain mechanisms that control breathing likely

would have been considered where the answer to SIDS death would be found. Yet, epidemiological findings across cultures now show consistently that, in the absence of maternal smoking, where child care patterns include the back (supine) infant sleep position, exclusive breast feeding, increased infant holding, maternal emotional responsiveness, routine daily structures (compared with chaotic households), SIDS rates are low (Azaz et al., 1992; Balarajan, Raleigh, & Botting, 1989; Blair et al., 1999; Davies, 1985; Farooqui, Perry, & Beeves, 1991; Fleming et al., 1996; Gantley et al., 1993; Kibel & Davies, 2000; Lee, Chan, Davies, Lau, & Yip, 1989; Mitchell & Scragg, 1995; Nelson et al., 2001; Takeda, Yamashita, & Miyazaki, 1987; Tasaki, 1988).

From an anthropological perspective, which is integrative and holistic, it is not surprising that child care practices in relationship to SIDS prevention should prove to be so important. Several different lines of evidence indicate that the social care of infants is virtually synonymous with physiological regulation (see McKenna, 1986; McKenna & Mosko, 2001). In short, human infants need contact with the mother’s body, and lots of it! Indeed, no skills or capabilities of the newborn make sense except in light of its mother’s body. It is the dyad, and not the infant, that constitutes the major unit for study and analysis. Winnecott’s famous statement. “There is no such thing as a baby, there is a baby and someone” is, from a scientific and cultural perspective, perhaps one of the most profound and accurate descriptions proposed for infants in the last century. This is because at birth the human infant brain is only 25% of its adult brain weight. Human infants are the least neurologically mature primate of all the primates, and subject to the most extensive external regulation and support, for the longest period of time. This suggests that, in order for human infants to survive, and for human (parental) reproductive success to be maximized, natural selection likely favored the co-evolution of highly motivated caregivers on one hand, alongside highly responsive infants on the other—infants designed to respond to and depend on external parental sensory stimuli. From both an evolutionary and developmental perspective, then, parental contact and proximity with infants (while awake and asleep) can be seen to represent a developmental bridge for the infant, extending into postnatal environments the role that the mother played prenatally in regulating important aspects of her infant’s continuing development (McKenna, 1995; McKenna & Mosko, 2001).

Hundreds of laboratory studies from the last 20 years confirm this view. These studies demonstrate, for example, the beneficial physiological effects of mothers holding their preterm and newborn infants using the “kangaroo” method of baby care, or skin-to-skin contact, which has the effects of increasing the infant’s skin temperature, stabilizing heart rates and reducing apneas and crying, and improving sleep and digestion. All of these findings are consistent with an evolutionary perspective on the how human infants develop optimally (Anderson 1991; Field, 1995; Kagan, 1984; Konner, 1981; Konner & Wothman, 1980; Korner, Guilleminault, Van den Hoed, & Baldwin, 1978; Ludington-Hoe, 1990; Ludington-Hoe, Hadeed, & Anderson, 1991; Ludington-Hoe et al., 1992; Reite & Field, 1985). Laboratory studies of non-human primates and other mammals also confirm that even short-term separation of primate infants from their mothers induces deleterious physiological consequences such as loss of skin temperature, cardiac arrhythmias, depressed immune responses, and increased stress involving adreno-cortico-throphic hormone release and, in some cases, a reduction in the number of antibodies in the infant’s blood (Reite & Capitano, 1985, Reite, Harbeck & Hoffman, 1981; Reite, Seiler, & Short, 1978; Reite & Snyder, 1982; Stewart & Stewart, 1991; for a review).

Natural selection appears to have favored infant responsivity to postnatal parental sensory stimuli among primates in much the same way that it favored fetal responsivity to, and regulation by, the mother’s physiological and/or behavioral status prenatally, by way of fetal–maternal physiological exchanges. Thus, it is a reasonable assumption that research into the effects of adult contact on human infant sleep physiology might likely reveal some clues to the SIDS mystery.

All human beings practiced diverse forms of parent–infant co-sleeping up until the last 100 years or so, and contrary to popular thinking the Western societal practice of infants sleeping in social isolation represents an historically and biologically novel sleep environment, the consequences of which (either short or long term) have never been considered, nor experimentally explored (McKenna & Mosko, 2001; Mosko, McKenna, Dickel, & Hunt, 1993). Surveys of contemporary infant sleeping practices reveal that approximately two thirds of the world’s cultures habitually practice mother–infant co-sleeping on the same bed or sleeping surface, and the fraction is much higher if the definition of co-sleeping is extended to include sleeping in the same room (Barry &

Paxson, 1971). Thus, solitary sleeping among infants is a relatively recent and mostly Western innovation.

In fact, compared with quickly changing Western cultural ideas about where and how infants “should” sleep, we have suggested that the mechanisms that control human infant sleep are unable to change as quickly, and, where infants sleep alone, their sleep, breathing, thermo-regulation, and arousal mechanisms are functioning in environments for which they were not designed by evolution (McKenna & Mosko, 2001; see also McKenna, 1986, 2002; McKenna, 1991, 1993). Since pediatric sleep researchers have never explored nor considered the impact of social sleep on early neonatal and infant development, we do not know if the recent shift by some world cultures to solitary sleep environments is beneficial, benign, or deleterious, or under what particular social or physical circumstances the effects of co-sleeping can be altered (McKenna, 1995). The question that must be asked is: Why has Western science never seriously asked if it is safe for human infants to sleep alone?

SIDS RATES ACROSS CULTURES

As reported elsewhere in more detail (McKenna, 1996; McKenna & Mosko, 1991) if natural selection designed the developing human infant’s sleep, breathing, and arousal patterns in association with parental contact, as we contend, this perspective gives us an initial basis for postulating (and possibly for better understanding) how and why related physiological control systems might go awry, or somehow function less efficiently when and if sleep environments diverge from the evolutionarily stable ones. If we assume for the moment that all known SIDS risk factors can be held constant, and that no genetic factors predispose some populations more than others to SIDS, then we should find lower SIDS rate in societies, or in segments within a society, in which parent–infant co-sleeping occurs.

As Figure 1 shows, cross-cultural data from urban, industrial, Asian countries generally support aspects of this prediction, but such comparisons are, admittedly, difficult. In Japan, for example, where infant–mother co-sleeping on futons continues to be the norm (Takeda, 1987), current published rates for SIDS are some of the lowest in the world (0.15/1,000 births in Tokyo, 1978; 0.053/1,000 in Fukuoka, 1986; and 0.22/1,000 births in Saga) (Tasaki et al., 1988). The most recent estimate for

the national SIDS rate in Japan is 0.3 per 1,000 live births (see McKenna, 2002, for data). These data do not, of course, prove that co-sleeping is protective against SIDS. It may well be that SIDS is under-reported in Japan, or that it is misdiagnosed as infantile suffocation. Japanese medical scientists have not participated in international SIDS research studies to the extent that American and European scientists have, so the postmortem procedures they employ to identify SIDS may not be appropriate. Nevertheless, these low SIDS rates deserve explanation and further research.

In 1985, Davies reported on the rarity of SIDS in Hong Kong. He used postmortem diagnostic protocols that, on review for a follow-up study by Lee et al. (1989), were judged comparable with Western diagnostic standards by John Emery, a renowned SIDS researcher from Great Britain. Davies found that even in a context of poverty and overcrowded conditions, where the incidence of SIDS should be high, the rates were 0.036 per 1,000 live births, or approximately 50–70 times less common than in Western societies. This finding is even more surprising because breast feeding is not common (of 175 infants at 2, 4, and 6 months of age, the percentage of infants nursing was 9%, 4%, and 2%, respectively), although co-sleeping and the supine sleep position for infants represent the cultural norm.

Davies proposed that proximity to the parent while the infant is asleep may be one reason why the rates are so low, as well as the typical (supine) sleeping position of Chinese infants. The author asked “whether the possible influences of life style and caretaking practices in cot death are being underestimated in preference for more exotic and esoteric explanations” (Davies, 1985)—a viewpoint not unlike that of Azaz et al. (1992) and Emery (1983), who also implicate, for some English infants, the importance of caregiving environments and other behavioral–socioeconomic factors. A follow-up on Davies’ work by Lee et al. (1989) confirms the relative rarity of cot deaths in Hong Kong, finding a slightly higher rate of deaths per 1,000 live births (0.3, compared with 0.04/1,000 reported by Davies).

A third study confirmed the rarity of SIDS in infants of Asian origin living in England and Wales, particularly infants of mothers born in India and Bangladesh, but also infants of mothers with African origins. As the authors point out, Asian women have few illegitimate births, few births at younger ages, and few of them smoke (Balarajan et al., 1989)—all of which seem to reduce the risks of

infants dying of SIDS. No mention was made of any possible differences in sleeping patterns that could explain the lower SIDS rate among the Asian subgroup, although it is likely that these infants were sleeping in proximity to their parents.

These low SIDS rates continue in Asian ethnic groups even after they immigrate to Western (non-co-sleeping) cultures, where most continue their traditional caregiving practices which include co-sleeping (Gantley, Davies, & Murcott, 1993). One study reports that among five Asian American subgroups living in California, the incidence of SIDS ranged from a low of 0.9 deaths per 1,000 live births to a high of 1.5 per 1,000. The variability was related directly to the duration of residence in the United States: the longer the group lived in the United States, the higher the SIDS rates (Grether, Schulman & Croen, 1990), leading us to ask if the trend toward higher SIDS rates reflects the adoption of more “American” patterns of infant sleep management (i.e., solitary infant sleep), among other things.

Data from other industrial societies, among which at least some general comparisons of SIDS rates can be made, also tend to support the general hypothesis that increased nocturnal contact between the parent and infant may reduce the chances of SIDS among some infants. For example, in cultures in which infants are less likely to have their own room or in which infants are more likely to be in close proximity to a parent during the night, SIDS rates tend to be lower (Blair et al., 1999).

Most recently, the International SIDS Child Care Study reports that some of the cultures in which either no SIDS are reported—or its citizens are unaware of SIDS-like deaths—are those cultures that report the highest bed-sharing rates and other forms of co-sleeping, such as room-sharing with parents, are the norm. Moreover, in that same study, it is clear that many cultures that report the lowest bed-sharing or room-sharing have the highest SIDS (Nelson et al., 2001) (See Figure 1).

Even under the best of circumstances, admittedly SIDS is difficult to diagnose. Because it is relatively rare, and because postmortem procedures for identifying SIDS are not necessarily standardized internationally, it is difficult to interpret differences in SIDS rates across cultures. Since parent–infant co-sleeping is hypothesized to be relevant only to some subclasses of potential SIDS victims, proving the hypothesis becomes even more difficult.

In a series of sleep laboratory studies of mother–infant bed-sharing our research team studied “normal” infant sleep in a context that attempted to match the

context within which both night-time breast feeding and infant sleep evolved: the mother–infant co-sleeping microenvironment. This new paradigm for studying infant sleep emerges from a biocultural and evolutionary perspective on infants, and the mother–infant dyad, which assumes the species-wide (universality) and biological appropriateness of infant–parent co-sleeping. This perspective builds from the premise that under safe sleeping conditions, and for the vast majority of infants, infant–parent co-sleeping should be inherently protective and promote infant survival and, hence, parental reproductive success. For reasons presented in great detail elsewhere, my colleagues and I have hypothesized that the sensory-rich co-sleeping micro environment may change the sleep physiology and architecture of the human infant in ways helpful in resisting some types of SIDS (McKenna, 1986, 1995; McKenna & Mosko, 2001; McKenna et al., 1993; Mosko et al., 1993; Mosko et al., 1997a).

Our studies which have now been confirmed by others show that: (1) co-sleeping mothers and infant exhibit high levels of arousal overlap, both longer (epochal) and smaller physiologically defined transient arousals; (2) infants exhibit more frequent state shifts, that is they move from one stage of sleep to another, or awaken more frequently, while co-sleeping and spent more time, at the same time, in the same state of sleep and wakefulness while in the same bed; and (3) as compared with infants sleeping alone, on average bed-sharing infants spent less time in deep stages of sleep (stage 3 or 4) and co-sleeping mothers intervened during the arousals of their infants possibly prolonging the duration of those arousals (see McKenna, 1986; McKenna & Mosko, 2001; McKenna et al., 1997; McKenna, Mosko, Dungy, & McAnich 1990; Mosko et al., 1993; Mosko et al., 1996b; Richard, Mosko, & McKenna, 1996)

Behavioral analysis of mothers and infants observed from the video tapes taken through infra-red cameras revealed that (1) during the bed-sharing night infants face toward each other (face-to-face) for the vast majority of the night (between 72% and 100% of the time (Richard et al., 1996) especially after nursing; (2) on average, on bed-sharing nights the frequency of breast feeding episodes doubled, average intervals between feeds were reduced by half, while the average total nightly duration of breast feeding virtually tripled on the bed-sharing night compared with the solitary nights (McKenna et al., 1997); (3) on average, mothers induce between 10% and 27% of their infants' total behavioral arousal patterns while

co-sleeping, while in turn, the infant can induce over half of their mother's total arousals although the total number of minutes slept increased for both the mother and infant on the bed-sharing night, contrary to popular conceptions; (4) bed-sharing mothers inspect, re-blanket, reposition, and adjust their infants while sleeping over four times more frequently (on average) than they do when each partner sleeps alone (Barone, 2001); (5) through a combination of active or passive embracing, touching, enclosing, and breast-feeding, bed-sharing infants and mothers are in physical contact ranging from 28% to 99% of the observed period compared with a low of 2%, to a high of 14% on solitary sleep nights (see Barone, 2002; McKenna et al., 1994; Richard et al., 1996).

One additional observation is that when infants sleep in the same bed with mother, the mother almost always places her infant for sleep in the safer supine position; but on the solitary nights, when the same infants are placed in a crib by their mothers in an adjacent room, mothers often placed their infants in the more dangerous prone position, even though on the co-sleeping nights always the supine position was used (Richard et al., 1996). Supine, or back-sleeping makes a great deal of sense when it is observed that the infant cannot breast feed, or control access both to and from the breast if sleeping on its belly. Back-sleeping infants arouse more frequently and have far more control over their universe than do prone-sleeping infants, and supine-sleeping infants experience greater protection from SIDS (Barone, 2001; Guntheroth & Spiers, 1992).

HOW CAN THESE FINDINGS BE RELATED TO SIDS PREVENTION?

At present, five laboratories around the world are currently studying and quantifying both the physiological and behavioral differences between bed-sharing and solitary-sleeping mother–infant pairs. In at least three of these laboratories the findings suggest that bed-sharing, occurring under safe environmental circumstances, could potentially make it more difficult for the range of SIDS defects to find expression. For example, the finding that co-sleeping mothers and infants exhibit synchronous, partner-induced physiological arousals, although not very surprising, is potentially important because of the suspected relationship between infantile arousal deficiencies and some cases of SIDS. As described earlier,

Kinney et al. (1995) found that some SIDS victims had reduced acetylcholine receptor sites in the brain stem, suggesting that arousals may be affected adversely. Bed-sharing, by increasing the type and number of arousals, could potentially compensate for such a deficiency (Mosko et al., 1997a, 1997b). It may be that co-sleeping provides the infant with increased opportunities to practice arousing, thereby becoming more proficient at it. Moreover, these responses increase the overall amount of physiological variation (stage shifting, for example) experienced throughout the infant's night-time sleep period. Overall, co-sleeping partner-induced arousals may facilitate the synchronous maturity and coupling of cardiorespiratory systems and the various central nervous system subsystems involved in arousal and/or the shift from sleep to wakefulness. It is possible that these linkages among the infant's physiological subsystems, which interact during arousals, may not occur as easily, as often, or as quickly if infants regularly sleep alone (McKenna et al., 1994).

Our finding that bed-sharing infants spend less time in deep stages of sleep, that is, stages 3 and 4, and more time in stages 1 and 2 is also potentially important. If these findings are confirmed, it may suggest that solitary sleep environments may accelerate the maturation of deep sleep, possibly before arousal mechanisms are maximally efficient to handle arousals during some physiological crises, such as a prolonged apnea. Less deep sleep, and more light sleep from which arousals to terminate apneas is easier, could be adaptive for infants.

Also, the face-to-face orientation and proximity that occurs often during co-sleeping raises the possibility that the infant's atmospheric CO₂ is elevated enough at times to stimulate respiration (Mosko et al., 1997a). In addition to examining the actual distance between the mother's and infant's faces from the videotapes, we are currently measuring the CO₂ content of air over a range of distances from women's faces (Mosko et al., 1998), and the amount of CO₂ available to the infant when its face is partially covered by a blanket. The concentration of CO₂ measured at distances comparable with those that often separate co-sleeping mothers and infants was within the range shown in steady-state breathing studies to increase ventilation in young infants.

Our finding that in the co-sleeping environment mothers continuously inspect, attend to, and more frequently (visually) "check out" their infants also elucidates another type of arousal occurring in the co-sleeping but not

the solitary sleep environment. At least 6–10 times during the co-sleeping night, mothers lean over and inspect their infants. Often during these periods, mothers reposition their infant's blankets, sometimes repeatedly, as if ventilating. Mothers appear to be ensuring that the infant is not in any apparent danger or distress (McKenna & Mosko, 2000; Young & Fleming, 1998). Though we cannot say for certain what motivates this behavior, it seems reasonable to speculate that these infant-directed behaviors increase the likelihood of a mother discovering and intervening to reverse a potentially dangerous condition or situation. As mentioned above, perhaps these activities induce infant arousals at times when there would have been no arousal had the infant been sleeping alone. Such maternal-induced infant arousals from diverse physiological states may provide the infant with practice in arousal (Mosko et al., 1993).

Finally, that infants exhibit significantly more breast feeding activities while bed-sharing (twice as many breast feeding sessions, for three times the total nightly duration as solitary sleeping infants) is potentially very important with respect to protection from SIDS (McKenna et al., 1997). Two recent epidemiological studies suggest that, indeed, breast-feeding lowers the risk of SIDS (Hoffman et al., 1988; Mitchell et al., 1992), while two others suggest that the extent of protection may be dose specific, that is, the more breast feeding that occurs the greater the protection (Fredrickson et al., 1993). While a protective effect has not been found in every study (Gilbert, Wigfield, & Fleming, 1995) many international SIDS prevention campaigns, including those in the United States, encourage or recommend breast feeding as a way to reduce SIDS.

The positive association found by Scragg, Stewart, Mitchell, Ford, & Thompson (1995) between Maori maternal smoking, bed-sharing, and increased SIDS risk is important, and justifies a recommendation against bed-sharing where mothers smoke. And the data may well apply to the other at-risk populations that Mitchell et al. (1992) cite where maternal smoking, drug and alcohol use, dangerous furniture, and other identifiable bed-sharing hazards, where multiple known risk factors interact with bed-sharing, endanger infants... But the special adverse characteristics of particular populations on which positive statistical associations are found between bed-sharing and infant deaths do not justify sweeping conclusions, namely that under all circumstances and in all families and cultures, bed-sharing, or co-sleeping in

general, in whatever form it takes, causes, or necessarily increases, the risk of SIDS and should therefore always be advised against. Such unqualified conclusions and recommendations increasingly are being rejected by the majority of scientists (see *Mothering Magazine*, Special Issue, Sleeping With Baby: Top Scientists Speak Out, September–October Issue, 2002).

If a scientifically valid understanding of the potential benefits or risks of co-sleeping/bed-sharing are ever to be achieved, anthropologists, forensic pathologists, and epidemiologists must work together. New ethnographically sensitive and appropriate epidemiological variables and categories must be adopted which more precisely capture, describe, and classify the diverse social and physical environmental factors that characterize and differentiate co-sleeping environments and the participants from solitary sleeping environments and participants. Moreover, it is imperative that we re-conceptualize from a biological and not strictly a cultural point of view the biological appropriateness of breast feeding and parents and infants sleeping alongside each other, and that the existence of dangerous co-sleeping conditions is no more an argument against the potential benefits to infants and parents of sleeping together than the existence of dangerous solitary infant sleep environments constitutes a valid argument against the safety of all solitary infant sleep. No environment is risk free (McKenna, 1995).

Finally, just as a SIDS can occur independently of known risk factors in a solitary sleep environment, without solitariness being thought of as a “causal” factor, so too can a SIDS death occur while co-sleeping, just as independently and without any contributory “causal” role played by the parents. The tendency to assume some contribution to the SIDS death by virtue of the parents presence, but not to consider parental absence as a contributory factor in a SIDS death, reflects hidden cultural assumptions and ingrained cultural ideologies and expectations.

CONCLUSION

The causes of SIDS are complex. There is no one type of SIDS death and, hence, there will never likely be just one way to prevent it. While all types of research on SIDS must, of course, continue, I argue here that regardless of whatever the primary causes of SIDS prove to be, they will only be understood alongside and in relation to the

infant’s biologically expectable micro environment, which involves reference to mother’s caregiving behavior and method of feeding. It will be critical to remember that since SIDS occurs when human infants sleep, the species-wide, “normal” and healthy pattern of infant sleep is social. In fact, so entwined is the biology of mother–infant co-sleeping with nocturnal breast feeding, that any study that purports to understand biologically “normal” infant sleep without understanding how these two activities interrelate must be considered incomplete, inaccurate, or both (McKenna & Bernshaw, 1995). That infant–parent co-sleeping represents the evolutionarily stable and most adaptive context for the development of healthy infants is not to say that modern sleeping structures or conditions are always safe. But it is important to differentiate between the act of mothers and infants sleeping in proximity and contact which is adaptive, from the conditions within which they do so, which may not be.

While much research is needed to test the hypothesis that increased parental contact during the night will reduce the chances of an infant dying of SIDS, a recognition of the legitimacy of diverse sleeping arrangements for infants, including diverse forms of co-sleeping, is necessary in order to reach a complete understanding of SIDS, a sleep disorder for which the existing research paradigms have proven inadequate .

Tobacco Use in Medical Anthropological Perspective

Merrill Singer

INTRODUCTION

Tobacco is known to be the one commercially sold product that if used as directed by the manufacturer will lead to certain disease and death. Additionally, unlike a genetically caused disease, the health consequences of tobacco use are directly tied to behavior and to the cultural and social structuring of people's ideas, actions, and relationships. For all of these reasons, tobacco use should be of primary interest to medical anthropology. In fact, however, as discussed below, there have been relatively few focused anthropological accounts of tobacco use in a cultural and social context. This avoidance is noteworthy, reflecting both the fact that topics of study within medical anthropology (like other fields) accord greater or lesser social rewards for researchers as well as the fact that in the West, where most medical anthropologists are found, tobacco use lacks extensive symbolic or other cultural embellishment. However, from a strictly health standpoint, tobacco use is of far greater direct consequence than most topics regularly studied by medical anthropologists. Further, because of the role it has played over time in inter-group social relationships, especially between colonial powers and colonized peoples and between dominant and subordinate social classes, tobacco also has had an enormous indirect impact on human health.

TOBACCO AND HEALTH

The significant health consequences of smoking are now widely known. Three commonly lethal diseases, in particular, have been closely linked to the use of tobacco: coronary heart disease, lung cancer, and chronic obstructive pulmonary disease. Other fatal or disabling diseases known to be caused by or made worse by smoking include peripheral vascular disease, hypertension, and myocardial infarction. Smoking also causes cancer of the mouth, throat, bladder, and other organs. As anthropologists Mark Nichter and Elizabeth Cartwright (1991, p. 237) argue, smoking damages the health of families in three additional ways: it leads to or complicates chronic illness thereby reducing the ability of adults to care for and socialize children; it diverts scarce household resources from healthier items; and it exposes children to secondary smoke, a known cause of disease. Current estimates are that 3,000 lung cancer deaths and 62,000 deaths from coronary heart disease in adults who do not smoke are caused each year in the United States alone by exposure to second-hand tobacco smoke. Among children, second-hand smoke is associated with sudden infant death syndrome (SIDS), chronic middle ear infections, and respiratory infections such as asthma (National Cancer Institute, 1999).

In 1989 the World Health Organization estimated that worldwide 2.5 million people die each year from

diseases caused by tobacco use. This had risen to 3 million deaths by 1994. Put another way, one person dies every 10 seconds as a result of the diseases of smoking. World Health Organization data suggest that if current patterns of smoking continue into the future over 500 million people who are alive today will die of smoking-related diseases and by the year 2030 smoking will be the biggest cause of death in the world. Seventy percent of these deaths will occur in developing countries.

The toll of smoking on health also is felt in industrially developed nations. Americans buy approximately 22 billion packs of cigarettes each year. According to the American Heart Association, these are purchased by the 26.3 million men and 22.7 million women in the United States who are smokers. Of these, tobacco products (primarily cigarettes but also cigars, chewing tobacco, and other items) cause the death of 440,000 Americans per year. This amounts to the death of one person each 13 seconds (Ile & Kroll, 1990; Peto, 1990). Smoking is now a factor in over one fifth of all deaths in the United States, far greater than the death toll caused by automobile accidents, drug use, homicide, AIDS, airplane crashes, and suicide *combined* (Chandler, 1986)!

THE SOCIAL HISTORY OF TOBACCO

New World Origins

“They ... brought us parrots and balls of cotton and spears and many other things, which they exchanged for the glass beads and hawk bells. They willingly traded everything they owned They were well-built, with good bodies and handsome features” (quoted in Zinn, 1980, p. 1). With these words Christopher Columbus recorded his first impressions of the island Arawak Indians that he encountered on his first voyage to the New World. From these people, Europe received the word tobacco (*tabaco* in Spanish), a term used by the Arawak to label the bulky cigars that they smoked with relish. Dried leaves used to make the cigars were among the gifts that the Arawak brought to Columbus. The Arawak explained to the curious Europeans that smoking tobacco soothed their limbs, made them feel less weary, and helped them to fall asleep. Columbus and his crew, seeing an item of potential monetary value, brought stores of tobacco back with them to Portugal. From there use of the substance spread, first to France in 1560 and from there

to Italy in 1561. By the turn of the century, tobacco was being cultivated on European soil and had become a widely used substance. Europeans, in turn, brought tobacco with them to much of the rest of the world, including back to the New World to areas such as the subarctic and arctic where it was unknown prior to Columbus’s voyages.

While the exact New World point of origin of tobacco use remains unclear, botanical research has shown that the earliest cultivation of several species of tobacco occurred in South America. The wild ancestors of domesticated tobacco species are not indigenous to the Caribbean area but are found in Peru, Bolivia, Ecuador, and Argentina. It is likely that tobacco and the cultural knowledge needed for both growing and consuming it passed from South America to the Caribbean along with various other cultivated food plants many years before the arrival of Columbus. The Arawak people themselves had their origin in South America, migrating north to populate the various Caribbean islands.

Some species of tobacco are indigenous to North America, and here too they are popular, being among the most widely cultivated plants grown by the indigenous peoples of what was to become the United States. Commonly, North American Indians mixed tobacco with other plants, such as the leaves of sumac and the inner bark of dogwood trees. Consequently, the Indians of the Eastern United States and Canada referred to the substance they smoked in their pipes as *kinnikinnik*, an Algonquian word meaning “that which is mixed” (Driver, 1969). While the first method of consumption encountered by Europeans became its most common method of use globally, in fact different Indian groups consumed tobacco in different ways. Among the Indians of the Northwest Coast, tobacco was chewed with lime but not smoked. Among the Creek, it was one of the ingredients of an emetic drink. The Aztecs ate tobacco leaves and also used it as snuff. Distinct cigarettes with corn husk wrappings were smoked in the Southwest (although this may not have been an indigenous means of consumption). Smoking tobacco in pipes also was widespread among Indian peoples.

Indigenous uses of tobacco were both religious and secular. Shamans, or indigenous healers, used tobacco to enter into an altered state of consciousness and communicate with spirit beings during healing rituals. During rites of passage, tobacco was used to mark changes in an individual’s social status. Smoking tobacco communally

marked the beginning or continuation of an alliance between tribes or affirmed the establishment of a binding agreement.

As this account suggests, tobacco was deeply rooted in the indigenous cultures of many peoples of the New World. Given the ceremonial controls on the frequency of consumption and the diluted form in which tobacco was consumed, as well as the fact that inhalation of tobacco smoke into the lungs was not emphasized, tobacco may not have been a significant source of health problems among Indian people prior to European contact. However, with the diffusion of tobacco to Europe and with the rise of industrialism, tobacco was transformed from a sacred object and culturally controlled medication into a commodity sold for profit. With the emergence and development of the tobacco industry and the intensive promotion of cigarettes, the per capita consumption of tobacco increased dramatically (especially in the early and middle decades of the 20th century), with significant health consequences. As Barnet and Cavanagh (1994, p. 184) synopsise, “The cigarette is the most widely distributed global consumer product on earth, the most profitable, and the most deadly.”

The Impact of Tobacco on Europe

The pathway from ritual object to commodity was a bumpy road. When Columbus returned from the New World, he presented tobacco leaves and products to his benefactors as evidence of the economic value of his voyage. Tobacco was first introduced to Europeans as a medicinal drug, and it was at first cultivated in Europe for this purpose. European physicians of the 16th century became convinced that tobacco could be used to cure a wide assortment of diseases. Before long, however, people who were treated with tobacco, and probably their physicians as well, realized that tobacco was a powerful mood-altering drug that had recreational value. By 1600, smoking was a common practice of working people in the port cities of England and Ireland (Brooks, 1952).

As tobacco shifted from medicinal to recreational, mood-altering use among the poor and working classes of Europe produced a backlash against smoking by the dominant social classes and the church. Mintz (1985, p. 100), an anthropologist who studied the consumable commodities ensnared in colonial trade, suggests that the reason for this hostile response lay in the distinct “visible, directly noticeable” physical reaction that smoking

produces, especially for the new user. Mintz (1985, p. 100) draws a contrast here with sugar, another colonial commodity that became extremely popular in Europe.

Sugar probably was not subject to the kind of religion-based criticism directed at tea, coffee, rum, and tobacco, precisely because its consumption did not produce flushing, staggering, dizziness, euphoria, changes in the pitch of voice, slurring of speech, visibly intensified physical activity, or any of the other cues associated with the ingestion of caffeine, alcohol, and nicotine. These changes in comportment in working people appear to have been threatening to the wealthier classes, who preferred a more passive, controlled demeanor in socially dominated groups. Mintz also points out that unlike tobacco, tea, coffee, and rum, all of which are dark in color, refined sugar is white, the symbolic color of purity in Europe since ancient times. Racist symbolism of this sort (toward mood-altering products that come from foreign lands with threatening dark-skinned peoples), argues Mintz, may have been an underlying cultural influence on the moralistic opposition to tobacco as well as to tea, coffee, and rum.

The first known antismoking tract was printed and distributed in English cities in 1602. Entitled *Work for Chimney-sweepers: or A Warning for Tobacconists*, it helped to launch a high-minded crusade against tobacco use. The class character of this crusade became clear two years later when another tract, entitled *A Counterblaste to Tobacco*, appeared. Although published anonymously, it was widely known to have been produced by James I, the British king (Best, 1983). In James’s view, smoking tobacco was “A custome lothesome to the eye, hateful to the Nose, harmefull to the braine, dangerous to the Lungs, and in the blacke stinking fume thereof, nearest resembling the horrible Stigian smoke of the pit that is bottome lesse” (quoted in Eckholm, 1978, pp. 6–7). Smoking also was criticized at this early moment in its use by Europeans for being harmful to health, causing insanity, sterility, birth defects, and diverse other diseases. Moreover, critics began to taint smoking as a lower-class habit, “of ryotous and disordered Persons of meane and base Condition” (quoted in Best, 1983, p. 175). Finally, in England, which at this point depended on Spain as a source of tobacco, smoking was attacked because it made the country dependent on one of its rivals in the imperial struggle for empire.

In a concerted attempt to build a moral argument against smoking, King James of England enacted a set

of policies designed to restrict tobacco consumption. In 1604 he imposed an additional duty on imported tobacco, raising the existing state tax by 4,000%. Through this dramatic step, he hoped to put tobacco out of the reach of most people. However, James did not ban tobacco completely for two reasons. First, because it was still being used as a medicine, and second, because (contrary to the antismoking propaganda of the era) addiction to the drug appears not to have been limited to the lower classes. James sought to avoid the wrath of members of the wealthier classes and the nobility, who would have opposed a total ban on tobacco importation.

However, several other European countries, including Austria, Denmark–Norway, France, Bavaria, Cologne, Saxony, Württemberg, Russia, Sicily, Sweden, and Switzerland, did institute criminal penalties to punish smokers. Usually the punishment involved having to pay a small fine. However, Russia, at various times, adopted quite harsh legislation that called for whippings, slit noses, torture, deportation to Siberia, and even death (Brooks, 1952). Despite these efforts, illicit use of tobacco continued to be popular. For example, while King James's tobacco tax led to a drop in the quantity of legal tobacco entering England it did not produce a decline in smoking. Instead, as occurred during the 20th century with other plant-based, mood-altering substances, such as cocaine and heroin, smugglers filled the void and an untaxed black market in tobacco emerged.

Tobacco and the Colonies

Ultimately, both government and moralist efforts to limit or prohibit smoking collapsed. By the end of the 17th century, the drug was legal throughout Europe. Underlying this radical shift was a re-evaluation of smoking. What had been defined as a growing social problem came to be seen as an important source of tax revenue for an expanding state structure. In the English case, colonization of North America played an important role in this process. James had invested considerable sums to launch the British colony in Virginia. The objective was to reap the same kinds of benefits that Spain had in its successful exploitation of the resources of Mexico, the Caribbean, and South America. However, while Spain extracted over seven million pounds of silver from its New World colonies between 1503 and 1660 (Wolf, 1969), in Virginia no precious metals were found, nor was the colony able to produce other desired sources of wealth.

Nonetheless, the colonists did find one item they could produce successfully and export to England in large quantities, namely tobacco. The soil of Virginia proved to be a good medium for tobacco growth. Dried tobacco was lightweight and therefore could be shipped across the ocean at comparatively low cost, and the demand for it in England meant that it would bring a sale price far above the production cost. Consequently, from an initial export of 2,500 pounds to England in 1616, Virginia was shipping over a million and a half pounds of tobacco less than 15 years later, and by the end of the century the amount had grown to 30 million pounds (Price, 1964). Tobacco, in short, emerged as North America's first cash crop.

In time, the shipment of tobacco from the colonies was so great that it even overwhelmed the substantial English demand, causing a slump in the market. The English turned to the other countries of Europe as potential new markets for their surplus colonial production. By the latter part of the 17th century, re-exporting came to account for the largest portion of the British tobacco trade. To open up these new markets, the British government sent delegations to other nations to convince them that it would be profitable to remove existing bans on smoking, import British tobacco, and then tax it. In this way, the tobacco trade became a force in England's foreign policy. Ironically, "the English, who at the start of the seventeenth century led Europe in an anti-tobacco crusade, came to profit immensely by taxing and trading in the drug, and closed the century serving as missionaries of smoking to the other governments of Europe" (Best, 1983, p. 180).

Paradoxically, and as an indication of the impact of tobacco on world history, while the British helped to open the French market to tobacco imports, during the Revolutionary War against England, Thomas Jefferson and Benjamin Franklin put up American tobacco as collateral for French war loans to fight and defeat the British.

Tobacco as a Critical Commodity

Through this process of social, political, behavioral, and conceptual changes, tobacco was transformed from an illegal and widely condemned drug into a legal and economically important force in European, and through Europe, world history, a source of revenue accumulation that helped to fund the transformation from feudalism to capitalist production. Tobacco, in short, gained wide acceptance because of the role it came to play as a

commodity critical to the emergence of a global economy. Additionally, as Mintz (1985) points out, tobacco, like other colonial products, including coffee, tea, chocolate, and sugar, were the “drug foods” that came to serve as low-cost food substitutes for the laboring classes of Europe during the rise of colonialism and the subsequent rise of the capitalist mode of production. Increasing “the worker’s energy output and productivity, such substitutes figured importantly in balancing the accounts of capitalism” (Mintz, 1985, p. 148) by lowering the cost of supporting a manual labor force while increasing production.

This argument is tied also to the recognition that with the rise of factory production, the lives of laboring people were significantly transformed. Work shifted from personal involvement in craft production or production for personal consumption into segmented, often boring, mass production under conditions that were alienating for most workers. Under these circumstances, tobacco, and the other items that formed the complex of “drug foods” were so welcomed by workers they were hard to effectively legislate against, a pattern repeated in contemporary times with the current array of illicit mood-altering substances.

Drug food substitutes such as tobacco also were of critical importance in the colonial control of labor and wealth outside of Europe. As Jankowiak and Bradburd (1996, p. 718) have argued, in the colonial encounter between Europeans and other societies throughout the world, colonialists (e.g., traders, merchants, settlers, and administrators) sought to dominate and expand the labor productivity of indigenous peoples for the economic benefit of Europe. While, if necessary, military force was used to achieve this end, inducing chemical dependence on a substance such as tobacco was “more efficient, economical, [and] ... easier to sustain.”

While, various drug foods were used to extract both trade items and labor throughout the colonial realm, the particular substance of greatest importance in any setting differed. Thus, while alcohol was the dominant drug food used to enhance the flow of goods to Europe from the Indians of North America, in the island societies of the Pacific Ocean tobacco reigned. In a cross-cultural review of 19 Pacific societies, Jankowiak and Bradburd (1996) found that in all but four (where alcohol or opium were used) tobacco was the dominant drug food traded to indigenous people in exchange for local horticultural and other products. Resulting chemical dependence on tobacco fueled subsequent exchange with and subordination to

Europe. Tobacco, in short, was taken from the colonized islands of the Caribbean and was used by Europeans in the colonized islands of the Pacific (and other locales as well), to penetrate production and reshape it to Europe’s advantage, contributing thereby to greater European wealth, technological development, and political dominance.

Ironically, one of the arenas of production penetrated by the emergent capitalist mode was cigarette making itself. Prior to the 1880s, cigarettes were rolled by hand one at a time. However, in 1881, James A. Bonsack introduced the cigarette machine, which was capable of producing more than 200 cigarettes per minute (Tennet, 1950). A problem smokers still faced, however, was how to easily light their cigarettes. A common practice among smokers was to go to a tobacco shop to have their cigarettes lit from a gas or oil lamp, making smoking a planned activity that could only occur at special times and places outside of the workaday schedule. In 1912, however, a safe match was invented, altering forever the way cigarettes were smoked. Now they could be consumed during interval moments during the day, allowing the transformation from smoking from a highly conscious exercise into a rapidly initiated practice that required little thought or effort. These inventions significantly contributed to a major jump in cigarette consumption, from half a billion in 1880 to 2.2 billion in 1888, 18 billion in 1914, and 54 billion in 1919 (Sobel, 1978). By this point, smoking had become an acceptable and socially unremarkable habit, a considerable change from the days of the antismoking crusades of the early 1600s.

By the early 1990s, the largest distributor of cigarettes, Philip Morris, was operating a bank of rapid-fire automatic rollers that together turned out 17,000 cigarettes a second, 24 hours a day. Philip Morris produced 11% of the 5.5 trillion cigarettes sold. However, the largest cigarette manufacturer is the state tobacco monopoly of China, which produces more than 1.5 trillion cigarettes a year, almost all of them consumed in China.

ANTHROPOLOGICAL STUDIES OF TOBACCO USE

Factors in Anthropology’s Limited Focus on Tobacco Consumption

As noted, comprehensive anthropological studies of tobacco use are relatively rare, and the topic often is not

found in medical anthropology texts. Even in general ethnographic accounts of the day-to-day social life and behavior of various societies around the world in which tobacco consumption is common, smoking often is mentioned only in passing and then most frequently with respect to people's (sometimes constant) requests for tobacco from the anthropologist. Black (1984) has suggested that tobacco use is understudied by anthropologists because of the way smoking is handled in Western cultures. For the most part, smoking, unlike drinking alcohol, is not a highly symbolic or heavily ritualized behavior in the West (at least, not since the invention of pre-rolled cigarettes and the safety match). This means that in Western cultures smoking tends to be an individual act, tied to internal states of mind and mood, that does not communicate a lot of cultural information. This is not to say that the act of smoking is devoid of symbolic content. For example, as portrayed in numerous movies, a film character may light a cigarette to convey various states of mind or character to those around him or her, including alienation from conventional society, independence from traditional role constraints, an air of mystery and daring, or sexual interest or satisfaction. The defiance theme associated with smoking may, in fact, be intensified in coming years as a result of the popular movement to ban smoking in public places because of the health consequences of passive or secondary smoke inhalation. Yet symbolic valences are known to change over time, and deviance was not always a theme linked by popular culture to smoking. Earlier in the 20th century, during World War I, in fact, cigarettes were "associated with the positive values of quiet dignity, courage, and dedication of the model soldier and became an essential part of the soldier's life" (Resnick 1990, p. 135). This connection was a product of a massive contribution of cigarettes to the U.S. military by the tobacco industry and the subsequent cognitive connection of smoking with soldiering.

In Robb's (1986) view, smoking in the West now serves symbolically as an *anticipatory rite of passage* for members of subordinated social groups such as youth, women, and ethnic minorities. Unlike socially approved rites of passage, such as a wedding or graduation, in an anticipatory rite of passage members of the subordinate group seek to unilaterally claim passage to a higher status even though this has not been sanctioned by the dominant group. In a somewhat different vein, Eckert (1983) has suggested that smoking may be used by some youth to symbolically express their membership in particular

adolescent peer groups. Several studies show that smoking among adolescents, for example, is associated with perceived approval for smoking in a valued peer network (Green, 1979; Mittlemark, 1987). In her ethnographic study of smoking among Puerto Rican adolescents in Boston, McGraw (1989) strongly emphasizes an important cultural dimension of this behavior. She found that, in fact, the physical impact of cigarette use may be the least rewarding factor motivating consumption. Rather, the primary appeal lies in the use of smoking as a behavioral mechanism to create new friendships or affirm existing social connections.

While these examples are noteworthy, smoking still does not appear to be a behavior especially fraught with complex cultural meanings, especially for adults. Rather, its primary message in everyday life in Western culture appears to be the symbolic marking of either a time-out in the middle of a course of action or work, especially one that may be stressful or demanding (i.e., an equivalent to a coffee break or because of feeling "uptight"), or to mark the completion of a task or segment of the day (e.g., to mark transition into a period of relaxation). Consequently, to follow Black's argument, anthropologists working in other cultures often have not thought to look at smoking as a topic of interest or one that can be tapped to reveal rich cultural information. Of course, in some settings smoking may be quite loaded symbolically and a topic worthy of interest on these grounds, but it does not appear that many anthropologists yet have explored this possibility. This is not to say anthropologists have ignored smoking completely, but only that they rarely have made it their primary focus of research.

Cultural Studies of Tobacco Use

It appears that the first anthropological examination of tobacco use in a cultural context was carried out by Alfred Kroeber, a (pipe-smoking) founder of American anthropology. In 1939 he published an article subtitled "Salt, Dogs, and Tobacco." This essay explored the distribution of tobacco and tobacco use among several Indian groups in the American West. Keenly interested in the relationships among the parts of a cultural system, Kroeber noted that tobacco was used as a ritual offering to the spirit world among those tribes who cultivated the plant. However, among tribes who did not plant tobacco but only gathered wild species of the tobacco family, it was not offered to the spirits. Similarly, he found that tobacco was used by shamans for healing purposes only in those

tribes who smoked it but not among peoples who chewed or ate tobacco. It was Kroeber's (1939) contention that tobacco and particular patterns of consumption tended to diffuse together as cultural packages among Indian groups, thus accounting for the distribution patterns that he found. Another examination of the role of tobacco in shamanism was conducted by Wilbert (1987) in South America.

Perhaps because it is one area in which ritualization of tobacco use is greatest, much of the anthropological literature on smoking comes from studies in Oceania (Haddon, 1947; Hays, 1991). Black (1984), for example, conducted an ethnographic study of the role of tobacco use on the Tobian Islands of Micronesia. Prior to European contact, the Tobian Islanders did not use tobacco. It was introduced to them during the 1800s by trade vessels searching the Pacific for wealth to bring home to Europe. In time, tobacco came to be incorporated socially and symbolically into the web of Tobian culture. Tobacco is highly valued on the islands and heavily smoked. But it still is not grown locally. Cigarettes still are obtained through trading with visiting ships, including U.S. Navy vessels or Asian fishing boats. On the islands, tobacco is an important marker of an individual's social status. Because tobacco is highly sought after and must come from off-island sources, those individuals who control a supply reap the social benefits of becoming centers of social attention. These individuals are noted for having "considerable skill, immense social knowledge, and a good deal of self-control, forethought and social autonomy" (Black, 1984, p. 483). When tobacco supplies on the islands become especially low, social gatherings, such as communal meals, diminish in frequency. One reason for this loss of sociability, according to Black, is that individuals become increasingly irritable and antisocial as they withdraw from their nicotine addiction. To avoid social conflicts, they withdraw as much as possible and wait as patiently as possible for the next shipment of their drug of choice.

In a related study, Marshall (1979) examined the role of tobacco on the Pacific islands of Truk. Like the people of the Tobian Islands, the Trukese did not have tobacco prior to the arrival of European vessels. Nonetheless, this lack of experience did not prevent the Trukese from avidly seeking tobacco early in the contact period. The date at which tobacco first reached Truk is unknown, but, like many other Pacific Islanders, the Trukese seemed willing to do almost anything to obtain it.

This weakness was of course exploited by the traders who eventually moved into the area (Marshall, 1979, p. 36).

By the end of the 1870s, Marshall (1979, p. 36) reports, the Trukese were "hopelessly addicted" to tobacco, holding it to be dearer than food or drink. Christian missionaries who arrived in the area in the late 1800s made giving up tobacco a symbol of Christian conversion.

In the modern period, Marshall notes, beginning at about 18 or 19 years of age all young men in the village he studied begin smoking. Girls, who are more apt to be involved in the church, are much less likely to smoke. In a 1985 survey of 1,000 adults in Truk, Marshall found that only about 10% of women were current smokers, compared with over 70% of men (Marshall, 1990). In Marshall's (1979) assessment, both tobacco and alcohol have been fully incorporated as symbols of masculinity and young men are under considerable social pressure to use them. In another paper, Marshall (1987) describes similar cultural incorporation for the wider Micronesian area of the Pacific.

Elsewhere in the Pacific, anthropologists have described tobacco use in passing in the course of studies on social organization, political conflict, and ecological adaptation. For example, on the Palau Islands of Micronesia, Barnett's (1961, p. 27) brief account of tobacco use shows a pattern similar to Truk (which lies about a thousand miles to the east). Here, too, smoking is "a man's vice" and very few women adopted the practice. Because cultivation practices are not well known, islanders rely on the import of European cigarettes.

By contrast, to the south, in Melanesia, smoking among women is common. A striking example is found in Roger Keesing's (1983) book entitled *Elota's Story*, a life-history account of a local leader in the Solomon Islands. While Keesing gives little mention of tobacco use in the written text, the book is well illustrated with numerous photographs of men, women, and children smoking pipes as they go about their day-to-day activities. Douglas (1955, p. 35), who also conducted research in the Solomon Islands, affirms that these people "smoke almost continually." In the Trobriand Islands, collective cigarette smoking is customary at social events. For example, at the birth of a baby, Weiner (1988, p. 51), an anthropologist who has done fieldwork in the Trobriands, observed people breaking off a piece of thick trade-store tobacco, separating it into tiny pieces, and rolling the pieces in newsprint to make long, funnel-shaped cigarettes. These were passed around the group to smoke. At the same

time, the Trobrianders view tobacco as a powerful substance that sorcerers use to attack their victims. Indeed, almost all deaths are believed to be the work of a sorcerer who has managed to chant magic spells into the victim's betel nut or tobacco. Weiner (1988) has recorded an account of tobacco-related sorcery in which a sorcerer gave an unbelieving Christian convert a cigarette to smoke to prove his rejection of pre-Christian belief. Later that night, the individual fell ill and died, affirming to all the power of indigenous practice. Not surprisingly, people in the Trobriands are very cautious about accepting tobacco from powerful individuals who have knowledge of sorcery. Among friends and relatives, however, smoking together is a common social activity.

Among the Sambia of New Guinea, the largest island in Melanesia, Herdt (1987, p. 71) notes the psychosocial role of tobacco at the end of a day of toil in the gardens: "Smoking and betel-chewing relax people, who turn to gossip, to local news, to stories—the old men always ready to spin tales of war and adventures of the past, the children always ready to hear the ghost stories that make them wide-eyed and giggly with excitement." Communal smoking is not peculiar to the islands of the Pacific. Shostak (1983) describes in some detail the strong desire for tobacco she encountered among the !Kung San of southern Africa, the frequent requests they made of her for the substance, and the predominantly group method of consumption.

In an unpublished study in South India among subsistence farmers of the Sudra and Harijan castes, Mark Nichter (cited in Nichter & Cartwright, 1991) found that tobacco is consumed in almost every household in a variety of ways, including smoking and snuff, and in conjunction with the chewing of betel nut. Among males over 25 years of age, 65% reported smoking cigarettes. People explained that smoking increased relaxation, contributed to sociability, helped to reduce the pain of hunger and toothache, enhanced digestion, and assisted with regular defecation. He estimated that tobacco purchases consumed 7–10% of household income. In another unpublished study from the Middle East, Marcia Inhorn (cited in Nichter & Cartwright, 1991) examined tobacco consumption in Alexandria, Egypt. She found that 151 of the 190 (79%) lower-class male heads of household in her sample had smoked, and 53% of these were smoking at least one pack of cigarettes a day. This expense consumed between one third and one half of disposable family income and was seen by many women as hurting the family's ability to properly feed their children. Addicted to cigarettes,

most men were unable to quit, having begun smoking when they were in late adolescence.

As these accounts reveal, tobacco use is now ubiquitous in the developing world and is integrated with wider cultural complexes. In Micronesia, tobacco smoking is a culturally constituted male activity; in Melanesia it is not gender-typed. Similarly, in some places smoking is continuous, while in others it is limited to particular times and contexts. In either case, many local smokers have become dependent on the international tobacco market and on supplies of cigarettes from the West. Contrary to Western images of traditional primitive peoples leading pristine lives in exotic lands, as these accounts suggest, through their consumption and their labor peoples of the developing world have come to be locked into the global economic system. Indeed, as Stebbins (2001, p. 148) points out, many of the traditional smoking practices described by anthropologists have now all but disappeared having been overwhelmed "by aggressive marketing by transnational tobacco companies."

Tobacco in Critical Medical Anthropology

In more recent years, some anthropologists have been involved in focused studies of cigarette smoking in the Western world. For example, anthropologist Joel Gittlesohn et al. (1999) initiated a study of social influences on the smoking behaviors of African American and European American adolescents in Baltimore, MD. This qualitative study employed both individual interviews and focus group interviews. They found that European American females were more likely to perceive permissive messages from parents about smoking than either European Americans males or African Americans. They concluded that lower rates of smoking among African American youth was tied to desires not to be disrespectful of parents and being "turned off" by parental addiction to nicotine. All of the adolescents, regardless of ethnicity or gender, noted that lax antismoking policies at school contributed to smoking among students on campus. A few anthropologists also have become involved in applied work in smoking, including prevention efforts among youth (Corbett, 1999; Willims, 1991), although this arena too is more notable for its quite limited degree of anthropological involvement.

Since its emergence in the early 1980s, critical medical anthropology has developed a keen interest in the

social origin of disease. This concern has focused critical theoretical attention on the manufacture and promotion of consumer products such as tobacco that are known to be harmful. Several critical medical anthropologists have studied the tobacco industry. Foremost in this regard is Kenyon Stebbins, who has undertaken studies of smoking in Mexico and of the impact of transnational tobacco companies on the health of underdeveloped nations. In addition, until his retirement, he was an anti-industry activist in the heart of tobacco country (Stebbins, 1994, 1997). In 1991, Stebbins and Dennis Willms developed a special issue on anthropology and smoking for the journal *Social Science & Medicine*, the only collection of articles available on this topic.

Of special concern to Stebbins' work has been the effort of the tobacco industry to make up for stagnating sales in the United States by developing markets in underdeveloped nations that are already struggling with infectious, nutritional, and other diseases. He notes that transnational tobacco corporations have found that developing countries are particularly appealing markets because the governments are short on cash and in need of revenue-producing products, laws that restrict consumption are limited, and awareness of the health effects of smoking is not fully developed. Under such condition, Stebbins argues, tobacco industry advertising can be quite effective in recruiting new smokers, especially given the prestige that often is accorded imported items from the West. Thus, the handful of super-rich transnational tobacco corporations have moved ahead quickly to capture new Third World markets, while expending about \$12.5 billion annually on advertising. As a result, worldwide tobacco consumption is increasing at the rate of 1% a year, with Brazil, India, and Kenya leading the way. In underdeveloped nations, sales are growing at least three times faster than elsewhere. In some Third World settings smoking is ubiquitous, Stebbins points out, even among physicians. For example, in some parts of Nepal "84.7% of males and 71.5% of females smoke In areas of Bangladesh, China, and Senegal between 55 and 80% of the males are reported to be smokers" (Stebbins, 1990, pp. 229–230). As a result, rising rates of lung cancer and related disease have been identified in heavy smoking countries such as Pakistan, among South African Blacks, and in Malaysia, Bangladesh, and Brazil. Stebbins also cautions about the serious environmental costs associated with tobacco cultivation and curing, especially from deforestation, erosion, and desertification.

Despite these recognizable dangers, Stebbins' analysis of the actions, power, and monetary resources of transnational tobacco corporations does not leave him optimistic about the ability of the Third World to avoid a smoking epidemic. To do so, he asserts, will require a level of political will by the governments of developing nations that was never demonstrated by the governments of developed nations.

Ironically, at the same time that the United States has pressured the governments of South America to control the production and export of cocaine, U.S. administrations have used their economic and political muscle to open up the markets of South America to the import of U.S. tobacco, a substance that is responsible for far greater levels of disease and death than all illicit drugs combined. Stebbins (2001) has examined the aggressive tactics employed by tobacco companies to gain access to South American markets and to attract new smokers. As he notes (Stebbins, 2001, p. 164), with cigarette imports and advertising rising and smoking levels increasing transnational tobacco companies "have been making a killing (in more ways than one)" in South America. Cigarette companies have successfully fought antismoking legislation in a number of South American countries and have even been successful in getting some smoking-control laws vetoed, such as the 1993 anti-smoking legislation passed in Argentina that was subsequently rescinded by the president. In the minds of many people in Argentina, "the veto was the result of industry bribes at the highest level" (Stebbins, 2001, p. 162).

Also involved in the critical medical anthropology analysis of smoking and the impact of the tobacco industry on health are Mark and Elizabeth Nichter (Nichter & Cartwright, 1991; Nichter & Nichter, 1994). The Nichters note that the United States has played an important role in fostering child-survival (e.g., oral rehydration and immunization) and safe-motherhood programs on a global scale. Unfortunately, the benefits to human health and survival gained through these large-scale efforts will be for naught, they argue, because of the complicity of the U.S. government in promoting cigarette sales in the Third World. Indeed, they maintain, a focus on child health internationally diverts attention from the political and economic dimensions of illness in a world of enforced inequality.

The U.S. government, the Nichters point out, has exerted its influence in developing a world market for tobacco in three identifiable ways. First, since the 1930s, hundreds of millions of dollars of Commodity

Credit Corporation loans and price supports have gone to tobacco growers, enlisting them to grow more tobacco. Because of these subsidies, an acre of tobacco brings in 16 times the profit from an acre of soybeans. Second, in the 20 years following World War II, the government spent one billion dollars buying up surplus tobacco from U.S. distributors and supplying it to Third World countries, thereby helping to develop a craving for tobacco. Third, U.S. trade policy is designed to assist American tobacco companies overseas. Countries such as Japan, South Korea, and Thailand have all been intensely pressured by the U.S. government to begin importing tobacco or face stiff trade sanctions. In fact, the pressure on Asian countries to increase tobacco consumption has been called “a new opium war” (Ran Nath, 1986).

Additionally, noting that 75% of tobacco cultivation occurs in the Third World, the Nichters point out that international lending programs such as the World Bank and the Food and Agriculture Organization of the United Nations actively make loans, extend advice, and provide seed and pesticides to small farmers to help them enter into tobacco growing. Ostensibly committed to the development of Third World nations, these programs will, in the long run, help the Third World to develop a significant health problem. Tragically, because of the limits on what these nations will be able to spend on health care, most Third World victims of tobacco-caused diseases will not benefit from advances in the medical treatment of these conditions. Contributing to this outcome will be the fact that the manufactured cigarettes marketed by transnational tobacco corporations often have much higher tar (the chemical source of health problems in cigarettes) and nicotine (the chemical source of addiction to tobacco) levels than those sold in the West. For example, the Nichters point out, the median tar level in cigarettes sold in the United States is 20 mg per cigarette, while in Indonesia it is almost double this level.

Consequently, the Nichters argue for the development of an anthropology of tobacco use that does not limit itself to the narrow confines of studying the motivations or behaviors of individual smokers but rather pays attention to the actions of governments, international organizations, and the tobacco industry in shaping smoking behavior. They argue as well for the study of the social relations of consumption and the semiotics of consumables (i.e., the social meanings invested by people in consumed items and the communication of meanings enacted through their consumption behavior) within a

broader political–economic framework. In other words, it is the Nichters’ view that it is important to understand how the tobacco industry acquires new markets and with whose help, at the same time that we analyze how people come to infuse tobacco products with particular cultural meanings and to respond to these cultural meanings as if they had the same material reality as the products themselves.

Stebbins (2001, p. 151) stresses that

Fighting Big Tobacco is entirely different from combating most public health problems. Unlike cigarettes, most infectious diseases and maternal and child health problems do not provide profits to transnational corporations and governments. Similarly, most public health problems are not exacerbated by extensive advertising campaigns that promote the cause of the health problems.

Tuberculosis Research and Control

Anthropological Contributions

R Shrestha-Kuwahara, M Wilce, HA Joseph, JW Carey, R Plank, and E Sumartojo

INTRODUCTION

Worldwide tuberculosis (TB) kills more young and middle-aged adults than any other infectious disease (WHO, 1999). Though it is curable and preventable, more than

5,000 people die of TB every day (2 to 3 million people per year) (WHO, 1999). TB often strikes the most vulnerable members of society and, if left untreated, causes its victims to lose weight, weaken, and eventually waste away (Ryan, 1993). TB disproportionately affects the

indigent and other marginalized groups of society in whom unequal susceptibility patterns have long been recognized (Dubos & Dubos, 1952).

Many complex biological and social factors impact TB transmission, progression to disease, and treatment. By identifying and examining the interrelation of these factors, anthropologists and other social scientists have made important contributions toward the control of TB. Anthropological methods and approaches have been especially valuable in understanding and addressing the broad range of sociocultural, behavioral, and structural issues pertinent to TB control. This entry presents a review of TB-focused anthropological and social science literature included in Medline, PubMed, PsycInfo, Gale Business Arts, Web of Science, SocioFile, and Anthropological Index Online. While limited in breadth and scope, the research highlighted here has many implications and applications for TB control practice.

EPIDEMIOLOGICAL AND MEDICAL FEATURES OF TB

Epidemiology of TB

The epidemiology of TB has an unequal global distribution. The highest numbers of active TB cases are found in less developed countries, especially in Southeast Asia, which has 41% of the world's TB burden with over 3 million cases per year; in the African nations that are most affected by HIV, there are 1.6 million new TB cases each year, in contrast with nations having established market economies, which report roughly 100,000 cases. Moreover, one third of the world's population is estimated to have latent TB infection (WHO, 2001). In industrialized nations, although the numbers of cases continue to decline, TB disproportionately affects low-income groups, substance users, persons from TB-endemic regions, the elderly, and residents of congregate facilities, such as nursing homes and prisons (ATS, 1992; CDC, 2000; Grange, 1999).

The HIV/AIDS pandemic has greatly contributed to the continuing threat of TB, particularly in Africa and Southeast Asia. In Africa, the estimated incidence of TB closely correlates with the estimated HIV prevalence (WHO, 2001); worldwide, in fact, one third of the increase in new TB cases in the last 5 years can be attributed to HIV (WHO, 1999). TB is now the leading cause

of death among HIV-positive persons worldwide and accounts for 40% of AIDS deaths in Africa and Asia (WHO, 1999). In the United States, active TB is included as an AIDS-defining opportunistic infection for HIV-infected persons (CDC, 1998).

Adding further urgency to controlling TB, multidrug-resistant TB (MDRTB) has emerged as a serious problem in many parts of the world, including Russia, Latvia, Estonia, Argentina, the Dominican Republic, and the Ivory Coast (WHO, 1999). Up to 50 million people worldwide may be infected with MDRTB (WHO, 1999). In low-prevalence countries, drug resistance is generally more common in foreign-born populations, most likely reflecting inadequate treatment programs and sporadic drug availability in high-prevalence countries (Broekmans, 2000).

Medical Features of TB

TB disease in humans is a communicable disease caused by *Mycobacterium tuberculosis*. Although it can affect any part of the body, generally only active pulmonary and laryngeal TB pose a risk of transmission from one person to another. Like influenza, *M. tuberculosis* is transmitted when a susceptible individual inhales air containing droplet nuclei carrying the tubercle bacilli. Once inhaled, the droplet nuclei eventually reach the lungs and frequently spread throughout the body. In most cases, a competent immune system limits the multiplication of the tubercle bacilli, although some bacilli remain dormant but viable, rendering a condition known as latent TB infection (LTBI) (CDC, 1995a, 2000).

A person with LTBI has an estimated 10% lifetime risk of developing active TB disease. However, certain persons, including children under 4 years of age, persons who have a weakened immune system due to conditions such as malnutrition, HIV/AIDS, diabetes, or certain cancers, and those recently infected with *M. tuberculosis*, have a much greater risk of developing active TB. HIV coinfection is the strongest known risk factor for developing active TB disease. Studies suggest that being coinfecting with HIV and TB places people at a 7–10% *per year* risk of developing active TB (CDC, 1995a, 2000).

Diagnosis and Treatment

The most widely used diagnostic method for TB is microscopic examination of stained smears of sputum, while

sputum cultures usually confirm the diagnosis. Chest radiographs are commonly used to assist in diagnosis. The tuberculin skin test is used to diagnose LTBI (CDC, 1995a, 2000).

In most cases, active TB is effectively treated with a combination of four drugs taken for at least 6 months (CDC, 1995a, 2000). Treating persons coinfecting with HIV and TB is more complicated, as the appropriate treatment regimen must take into account the disease progression of the patient and interaction of drugs if protease inhibitors are involved. Treatment of MDR-TB is also complicated and requires the use of more expensive and more toxic second-line drug regimens (CDC, 1995a, 2000). In developing countries, MDR-TB is more likely to be fatal due to the limited availability and accessibility of effective treatments (WHO, 2000).

LTBI may be treated with one of several drug regimens. In many industrialized nations, treatment is commonly recommended for persons with LTBI at high risk of developing active TB disease (CDC, 2000), such as HIV-infected persons and contacts of TB patients.

HISTORY OF TB

Theories regarding the origins and global spread of TB continue to change as new archeological discoveries are made and molecular technologies evolve (Davis, 2000). Studies have enabled scientists to hypothesize that *M. tuberculosis* evolved from the closely related mycobacteria, *M. bovis*, possibly coincident with the domestication of cattle by humans approximately 15,000–20,000 years ago (Daniel, 2000). Studies have identified TB in mummies from Egypt dating back 5,400 years (Crubézy et al., 1998; Daniel, 1997). Skeletal remains show TB had spread throughout Europe and the Middle East during the Stone Age (Ryan, 1993). Other skeletal remains suggest that TB reached the Americas with the early migrants via the Bering Strait (Daniel, 2000), and remained a major health threat throughout the pre-colonial period.

Sociological and anthropological research has explored the social context of TB over time. Analyses of ancient writings provide amazingly accurate descriptions of persons afflicted with what we now know to be pulmonary TB (Ayvazian, 1993). The high mortality associated with TB was reflected in art, social policy, and science (Barnes, 1995; Bates, 1992; Smith, 1996; Star & Bowker, 1997; Tomes, 2000). Although the wasting pallor

caused by TB became romanticized briefly during the mid-19th century (Ott, 1996; Sontag, 1990), the disease was otherwise overwhelmingly perceived to be caused by poverty, uncleanness, or immorality. Dubos and Dubos (1952) note that even in ancient times, written records and even death records may have downplayed the existence of TB, suggesting negative social stigma.

Notable advances in understanding the pathophysiology and clinical manifestations of TB occurred during the 17th, 18th, and early 19th centuries (Ayvazian, 1993). By linking the disease to its social context, scientists and political leaders advocated for social reform with mechanisms such as better nutrition, improved sanitation, and better housing to reduce the disease. Late in the 1800s, isolation and treatment of TB patients in sanatoria (Feldberg, 1995) and the pasteurization of milk to eliminate the threat of *M. bovis* were highly visible attempts to control TB. General economic development played a further role in the decline of TB mortality in industrialized nations (Fairchild & Oppenheimer, 1998).

In 1882, Robert Koch identified the tubercle bacilli, *M. tuberculosis*, as the biological cause of TB disease and established it as an infectious disease (Ayvazian, 1993). In the 1940s, scientists discovered that the antibiotic, streptomycin, killed *M. tuberculosis*; however, the bacilli had a propensity to develop resistance to antibiotics when only streptomycin was used. By 1950, combined drug treatment was established and, a few years later, isoniazid was introduced as a “miracle” cure for TB when combined with properly chosen drug combinations for sufficient duration (Davis, 2000).

As social scientists observed, the introduction of the first antibiotics to treat TB enhanced the assumption of physicians’ expertise and authority in obviating this major public health threat. Lerner (1997) notes that by the 1950s and 1960s, researchers were using terms such as “uncooperative” and “non-compliant” to describe patients who did not follow physicians’ treatment orders. In the 1970s, social scientists began emphasizing the importance of a patient’s right to be actively involved in treatment decisions (Donovan & Blake, 1992; Stimson, 1974; Sumartojo, 1993; Trostle, 1988) as well as the pejorative implications of the term “compliance” itself, recommending the term “adherence” to better acknowledge the patient role in TB care and treatment (Ogden, 1999; Sumartojo, 1993).

Over the next decades, despite declining TB mortality rates in industrialized nations, TB continued unabated throughout most of the world. Further, the emergence of the

HIV/AIDS epidemic and of MDRTB were cause for serious global concern. The need to use social and behavioral approaches to strengthen the quality of patient care became more apparent. Many programs implemented interventions such as directly observed therapy (DOT), whereby health care workers observe patients swallowing medication.

Subsequently, directly observed treatment, short-course (DOTS), was developed and promulgated by the World Health Organization as its strategy for TB control (Walton & Farmer, 2000). Concurrent with the calls from the medical community for new social and behavioral interventions has been a call in the social sciences for a better understanding of the potential impact of such interventions and to develop new intervention strategies through coordinated, theory-driven research (CDC 1995b; Farmer, 1997; IOM, 2000; Rubel & Moore, 1995).

SOCIAL AND CULTURAL RESEARCH IN TB CONTROL

In reviewing the published anthropological and social science literature on TB, wide gaps in research are apparent. Research into the meaning and social implications of TB has been limited to a relatively small number of cultures. In her recent literature review, Ogden (2000) notes that the limited use of theoretical frameworks to examine behaviors hinders full understanding of the social and cultural factors surrounding TB.

Similarly, Jaramillo (1998) found that many studies are narrow in scope and examine neither the context of TB control programs nor other external factors that may influence behavior. Jaramillo further notes that the use of different study designs and methods sometimes results in contradictory findings. Despite the lack of theoretical grounding and of reliable comparison studies that allow patterns to be identified across cultures, the published social science research provides valuable information on key issues affecting patient outcomes. Issues related to care-seeking behaviors, adherence to treatment, stigma, program structure, and patient-provider relationships are particularly important to TB control. This section has been organized to reflect this applied approach.

Understanding Care-Seeking Behaviors

Studies examining how a local culture interprets TB causes and symptoms helps providers understand why

people delay seeking treatment. For example, in Thailand, research indicates that some people, associating their TB symptoms with HIV/AIDS, delayed seeking treatment for fear of having AIDS (Ngamvithayapong, Winkvist, & Diwan, 2000). In Kenya, patients attributed TB to causes such as hereditary predisposition, consumption of alcohol, smoking, or witchcraft, which often resulted in delayed care-seeking at a clinic specifically for TB patients (Liefoghe, Baliddawa, Kipruto, Vermeire, & Munynck, 1997). Recent work in the Philippines showed that many patients attributed TB symptoms to drinking or smoking, and, thus, delayed seeking treatment for their “harmless” symptoms (Auer, Sarol, Tanner, & Weiss, 2000). Similarly, in a study of the Igbo of Nigeria, TB patients who held rigidly traditional views that TB can be spread by eating beef and other high-protein foods reportedly delayed seeking treatment, often waiting until after they were malnourished (Enwereji, 1999).

In Botswana, TB symptoms are often attributed to hard work in mines or to drinking and smoking (Steen & Mazonde, 1999). Some groups report multicausal models regarding TB etiology. For example, Vietnamese refugees in the United States reported various combinations of 29 separate beliefs regarding causes of TB, the most frequent being hard manual labor, smoking, alcohol consumption, poor nutrition, and germs (Carey et al., 1997). In Malawi, patients believed TB was caused by adultery, germs, alcohol abuse, “wrong” food, stagnant water, dust, and witchcraft (Brouwer, Boeree, Kager, Varkevissier, & Harries, 1998).

Etiologic beliefs may influence how people choose to treat or be treated for their symptoms. A study in Malawi showed that patients thought TB resulted from bewitchment or breaking sexual taboos believed they could only be treated by traditional healers, while TB from other causes could be treated with Western medicine (Banerjee, Harries, Nyirenda, & Salaniponi, 2000). In contrast, other groups express strong preferences for treatment from biomedically trained physicians, with little or no interest in traditional remedies (Carey et al., 1997). In Ethiopia, interview respondents believed TB and all diseases were generally caused by imbalances in behaviors or diet, and were best treated by herbal remedies and healthy foods (Vecchiato, 1997). A study among the Xhosa-speaking people of South Africa found that people often associated TB with a lack of hygiene and also with witchcraft, specifically the lightning bird, *impundulu*, and sought care first from a diviner (de Villiers, 1991).

Only when traditional treatment failed did they seek Western medicine. Similarly, Wilkinson, Gcabashe, and Lurie (1999) reported TB patients' visits to spell casters, faith healers, and those who use plants for healing among South African patients, despite patients' recognition that TB could be cured.

In rural Haiti, while many patients accepted sorcery as a possible cause for TB, their etiological beliefs had no impact on compliance with biomedical regimens (Farmer, Robin, Ramilus, & Kim, 1991). Similarly, Rubel (1993) found high rates of adherence with biomedical treatment among migrant farm workers, regardless of whether they attributed their symptoms to biomedical causes or "folk illnesses." In Tanzania, Wandwalo and Morkve (2000) found no connection between knowledge about TB and completion of treatment. In Chiapas, Mexico, religious movements have increased the acceptance of germ theory and of Western medicine, reducing the attribution of disease to witchcraft (Menegoni, 1996).

While Western medicine offers patients a biological explanation for the biological cause of TB, it cannot provide a spiritual or philosophical explanation of why they have been afflicted with it (Steen & Mazonde, 1999). Traditional, non-Western practice offers patients meaning for their illness as well as emotional support (de Villiers, 1991; Steen & Mazonde, 1999). Further, traditional healers are easily accessible and often paid after the patient is cured (Liefoghe et al., 1997). One study in Nepal reported that women sought traditional health care services before seeking care in government clinics, due in part to the proximity of services (Yamasaki-Nakagawa et al., 2001). In Botswana, traditional healers advised TB patients to attend medical clinics when patients presented certain signs and symptoms (Steen & Mazonde, 1999). In contrast, in Malawi, patients often sought care from traditional healers initially, but were reluctant to disclose these visits to medical professionals for fear of being denied care by Western doctors (Brouwer et al., 1998).

The importance of semantics in illness and treatment is illustrated by Nichter's work in the Philippines. The term "weak lungs" covers a range of respiratory ailments and is used by the lay population and physicians alike, the latter ostensibly to avoid the stigma associated with TB. However, broad use of the term "weak lungs" leads to self-treatment, a practice encouraged by the marketing of isoniazid as a type of "vitamin" for the lungs, considered useful even if taken for a short time. These practices can result in delayed diagnosis and the development of drug resistance

(Nichter, 1994). In a study of Ethiopian refugees in Israel, Chemtob, Weiser, Yitzhak, and Weiler-Ravell (2000) found that the confusing Ethiopian terms used for TB symptoms and related illnesses increased communication problems with health care providers and treatment in Israeli clinics.

Kleinman (1980) studied the indigenous ways in which TB was viewed and explained in China, noting that local terminology merges both the psychological and physical symptoms of the disease. Using Kleinman's explanatory framework, Rubel and Moore (2001) found that working-class Mexicans from similar socioeconomic strata share a humoral explanatory model of TB (i.e., illness categorized as "hot" or "cold") and that women shared much stronger agreement on these humoral qualities than men. This finding could be explained by Mexican women's role as gatekeepers of household health and their consequent greater knowledge of health and illness, suggesting the influence of learned social roles on the distribution of traditional health knowledge.

In industrialized nations, social scientists have sought to better understand the health cultures of subpopulations. Researchers found many misunderstandings about TB among minority ethnic groups in Kansas City (Marinac, Willsie, McBride, & Hamburger, 1998). In New York, interviews with Vietnamese refugees showed misunderstandings related to TB causes and transmission (Carey et al., 1997). Similar findings were reported in a focus group study of Vietnamese persons in California, who nonetheless indicated broad trust in Western medicine (Nguyen, Yamada, Matsunaga, & Caballero, 2000). However, in Manitoba, many refugees continued to use traditional medicines (Peters, Hershfield, Fish, & Manfreda, 1987).

Ailinger and Dear (1997, 1998), working with Latino immigrants in the United States, found that concern for family motivated care-seeking behavior and adherence to treatment. Similarly, social support contributed to adherence and completion of therapy, and thus to a reduction of TB incidence among foreign-born persons in Massachusetts; however, economic and social disadvantages often outweighed protective factors (Mitnick, Furin, Henry, & Ross, 1998). Focus groups with Philippine immigrants showed a continued belief in traditional treatments despite other aspects of acculturation (Yamada, Caballero, Matsunaga, Agustin, & Magana, 1999).

Understanding Adherence Issues

Treatment non-adherence fuels continuing TB transmission and fosters the development of drug resistance, resulting in

serious risks both for the individual patient and for the community. The issue of non-adherence to TB medications has frequently been examined through varied approaches and methodologies, yielding a wide range of findings having no single predominant pattern. Many social scientists have identified patient health beliefs or health cultures as the main “cause” of non-adherence (Barnhoorn & Adriaanse, 1992; DiMatteo & DiNicola, 1981). Thompson, Snider, and Farer (1985), examining adherence rates in seven European countries, attributed differences to the extent to which “cooperativeness” as a community value cut across national cultures. Cultural perceptions of medications, such as the classification of medications into “hot” or “cold” according to humoral theory, may also influence adherence (Ito, 1999; Manderson, 1998).

Taking a broader perspective, other social scientists see the issue of non-adherence as stemming from complex factors both within and beyond the control of patients. These factors include patients’ confusion about the implications of symptoms, social stigma, perception of services and providers, transportation costs, the high cost of medications, and service access and delivery problems (Ailinger & Dear, 1998; Liam, Lim, Wong, & Tang, 1999; Rubel & Garro, 1992; Sumartojo, 1993; Thomson & Myrdal, 1986). Nachman’s (1993) work with Haitian refugees also showed that, despite patients’ trust in Western medicine’s efficacy, lack of information and mistrust of service providers greatly reduced their adherence to care (1993). Researchers in India found a high default rate despite high levels of patient knowledge and care-seeking. This behavior was not determined by cultural factors, but by the operational dysfunction of the local TB program (Juvekar et al., 1995).

Considering the vast socioeconomic inequities that persist throughout the world, Farmer affirms that individuals who do not adhere to therapy are probably “the ones least able to adhere” (Farmer, 1997). A study of Latinos in California demonstrated that, while trust in TB control practices and social connections facilitated patients’ adherence to treatment, access issues most affected behaviors (Poss, 1998, 2000). Similarly, in an investigation of factors affecting medication-taking behavior in central India, Barnhoorn and Adriaanse (1992) found that three socioeconomic variables, not cultural factors, were the strongest predictors of adherence: a family’s per capita income, the type of house in which they lived, and the family’s monthly income.

Virtually all adherence studies note the difficulties encountered in measuring adherence. Even well-designed

studies have failed to find psychological correlates of adherence (Sumartojo, 1995), thus hindering the ability to predict adherence. Given these difficulties, many programs have adopted directly observed therapy as the standard of care (Chaulk & Kazandjian, 1998; Volmink, Matchaba, & Garner, 2000a, 2000b). While effective in monitoring adherence (Chaulk, Moore-Rice, Rizzo, & Chaisson, 1995; Fujiwara, Larkin, & Frieden, 1997), this often costly method of care has raised several questions to which social science has added perspective. For example, researchers questioned the extent to which TB programs have failed to recognize the socioeconomic context in which patients receive services (Diwan & Thorson, 1999; Hurtig, Porter, & Ogden, 1999; Pronyk & Porter, 1999).

The Impact of Stigma

Few would disagree that there is universal social stigma attached to TB (Farmer, 1997). Besides contributing to a worsening of the quality of life for people with TB (Hudelson, 1996; Jaramillo, 1999a), stigma plays a role in most stages of the disease—from acknowledging symptoms and seeking care to being labeled as cured (Rangan & Uplekar, 1999). By identifying the consequences of stigma, social scientists have illustrated the need for effective intervention strategies.

Numerous studies have shown patients’ denial or hesitation to disclose their TB status to family or friends owing to the overwhelming fear of being socially ostracized (Chakraborty, Rangan, & Uplekar, 1995; Johansson, Diwan, Huong, & Ahlberg, 1996; Liefvooghe Michiels, Habib, Moran, & De Muynck, 1995; Nair, George, & Chacko, 1997; Shrestha-Kuwahara, Wilce, DeLuca, & Taylor, 2002). Researchers reported that 77% of the Vietnamese persons studied in New York believed the community would fear and avoid persons with TB, and over 90% stated that having the disease would adversely affect TB patients’ relationships with their families (Carey et al., 1997). Rubel and Garro found that fear of stigma among Mexican immigrants in California significantly influenced patients’ perceptions of their illness and caused them to cease contact with family and friends (Rubel & Garro, 1992). They reported similar findings in Mexico, where patients blamed the social consequences of stigmatization—ostracism—for their long delays in seeking care and their poor adherence to treatment (Rubel & Garro, 1992). In Honduras, Mata (1985) found strong stigma associated with TB, and fear of family rejection and loss of friends led some patients to report preferring

death to social rejection. In Vietnam, researchers found that cultural beliefs related to TB transmission increased stigma and isolation of patients (Long, Johansson, Diwan, & Winkvist, 1999).

Other studies have demonstrated that the shock of being diagnosed with TB frequently sends patients and their families in search of a different diagnosis elsewhere (Dick & Schoeman, 1996; Liefoghe et al., 1995; Uplekar & Rangan, 1996). In a study of Indian patients, Uplekar and Rangan (1996) noted that some doctors avoid disclosing a TB diagnosis out of fear that patients will not return. Strong stigma was similarly noted among South African Zulus who, even after attending a clinic for years, stopped attending after receiving a diagnosis of TB (Rubel & Garro, 1992). In Turkey, even the relatives of TB patients avoided contact with TB dispensaries (Gokce et al., 1991). Stigma can also result in loss of employment, or fear of such, thus delaying care-seeking, diagnosis, and effective treatment (Carey et al., 1997; Jaramillo, 1998; Johansson et al., 1996; Shrestha-Kuwahara et al., 2002; Thomson & Myrdal, 1986).

In societies in which women occupy a lower status, the social consequences of a TB diagnosis may result in undertreatment and increased mortality (Holmes, Hausler, & Nunn, 1998; Hudelson, 1996). Studies in India have shown that married women delay seeking treatment or do not disclose their diagnosis to their husbands out of fear of being deserted (Connolly & Nunn, 1996; Nair et al., 1997; Rajeswari et al., 1999). In Nepal, the low status of women and fear of social ostracism hinder access to adequate TB care (Smith, 1996). In India and Pakistan, single women with a history of TB may face fewer opportunities for marriage (Barnhoorn & Adriaanse, 1992; Jaramillo, 1998; Liefoghe et al., 1995; Rangan & Uplekar, 1999). In Vietnam, stigma has been shown to interfere with provider relationships with female patients and hinder compliance (Johansson, Long, Diwan, & Winkvist, 1999; Long, Johansson, Diwan, & Winkvist, 1999).

Provider Behavior and Service Delivery

The trusting relationships providers form with patients have been shown to strongly influence treatment success (Pozsik, 1995; Salomão, 1999; Sbarbaro, 1990). A review of existing studies addressing provider behaviors suggested that patients respond positively to attention and

encouragement (Boehm, Coleman-Burns, Christensen, & Schlenk, 1995). Similarly, a recent meta-analysis of program-level interventions showed that program success is frequently attributed to good patient-staff relationships and friendly, competent staff (Volmink et al., 2000a, 2000b).

Among the social scientists examining patient-provider interrelationships, Jaramillo (1998) demonstrated that interpersonal relationships are heavily influenced by the negative perceptions of TB patients held by health care workers. By stigmatizing the patients, providers create an unfriendly clinic environment and then blame the patients for failing to complete treatment. In Israel, Ethiopian immigrants experienced condescension and paternalism from physicians (Chemtob et al., 2000). Such unprofessional attitudes of providers exacerbate patients' hesitance to seek or remain in care (Walt, 1999). Patients in other studies reportedly preferred interacting with the more empathetic paramedics or community volunteers, perceiving clinic nurses as authority figures (Dick, Schoeman, Mohammed, & Lombard, 1996; Menegoni, 1996). In a number of studies, researchers found that women sought care from providers they felt comfortable with rather than visiting government-run TB clinics and often delayed obtaining appropriate treatment (Long et al., 1999; Lönnroth, Thuong, Linh, & Diwan, 1999; Thorson, Hoa, & Long, 2000; Yamasaki-Nakagawa et al., 2001).

Cultural and communication gaps between patients and providers have also been explored. Studies have demonstrated that patients and providers have strikingly different perceptions of the barriers to adherence and of the communication that has been exchanged (Rubel & Garro, 1992; Shrestha-Kuwahara et al., 2002). Rubel and Moore (1995) theorized that gaps between patients' and providers' perceptions about interactions and care resulted in the use of poor information for policy planning. Moreover, a lack of understanding of the cultural differences in attitudes can diminish the trust between physician and patient (Grange & Festenstein, 1993).

Fueling patients' mistrust, major deficiencies have been found in physician knowledge, attitudes, and practices in appropriate TB management and in dissemination of information to patients (CDC, 1994; Thomson & Myrdal, 1986; Uplekar & Shepard, 1991). Inaccurate knowledge of TB transmission or appropriate treatment regimens may result in misdiagnosis or mistreatment (Lienhardt et al., 2001; Mata, 1985; Nair et al., 1997; Sumartojo, Geiter, Miller, & Hale, 1997). Interviews with patients in Pakistan confirmed that patients lacked confidence in TB treatment

because of poor service and scarce or inaccurate health information (Khan, Walley, Newell, & Imdad, 2000).

Program Structure

The impact of program structure on patient behavior was acknowledged some 30 years ago when Dr. Francis Curry in San Francisco increased patients' clinic visits via expanded clinic hours and reduced wait times. Although few scientists have examined the overall dynamics of the sociopolitical and economic environment of TB control (Grange & Zumla, 1999; Rubel & Moore, 1995; Walt, 1999), social scientists have shown that program structure and systems organization can have a major impact on TB care.

Although limited, research has shown the effectiveness of comprehensive health service systems that address core issues behind TB risk factors, such as overcrowding, malnutrition, and limited access to health care services. In Haiti, Farmer showed how comprehensive health and social services can successfully reduce mortality and drug resistance (Farmer, 1997; Farmer et al., 1991). In Mexico, policy interventions addressing structural barriers resulted in improved patient adherence (Rubel & Garro, 1992). Similarly, routine provision of a comprehensive array of individualized services has resulted in major decreases in TB cases in New York (Dorsinville, 1998).

The need to integrate patient and community perspectives in TB program structure has been illustrated through a comprehensive review of the social science literature (Porter, Ogden, & Pronyk, 1999) and through Jaramillo's work in less-developed countries (Jaramillo, 1998). For example, "free" TB medicine and care may be extremely expensive to the patient who must incur travel expenses and lost wages to attend the clinic (Jaramillo, 1998; Thomson & Myrdal, 1986; van der Werf, Dade, & van der Mark, 1990). Other economic studies have shown the high financial burden TB places on families (Murray, 1991; Needham, Godfrey-Faussett, & Foster, 1998; Wyss, Kilima, & Lorenz, 2001) and have shown the need for assessing patient costs and acceptability when designing TB programs (Heymann, Sell, & Brewer, 1998). From a policy-oriented perspective, Dievler and Pappas' (1999) research in Washington, DC, showed that racial and class tensions undermined planning processes, resulting in inappropriate and poorly implemented policies. In a comparative case study, Dievler (1997) found that New York, unlike Washington, DC, had community and political will

supporting TB services and that plans were specific and implemented.

CURRENT TOOLS AND APPROACHES

Through the application of research to practice, advances have been made in understanding health cultures and the impact of health systems and have resulted in the development of new tools and approaches to improve the quality of patient care and service delivery. Adopting social science theories and methods, many health care practitioners have applied patient-centered treatment models. These models address barriers to adherence by using a wide range of interventions, including monetary and social incentives, patient education, cultural competency training, supervised therapy, community health worker involvement, and comprehensive services (Banerjee et al., 2000; CDC, 1994; Dick & Lombard, 1997; Farmer et al., 1991; Malotte, Hollingshead, & Rhodes, 1999; Morisky et al., 1990; Pozsik, 1989; Tulsy et al., 2000; Tulsy, White, Young, Meakin, & Moss, 1999). Few of these interventions, however, have been tested using controlled experimental design studies or in diverse cultural settings.

In the area of communication, anthropologists have developed a number of practical tools to enhance the quality of patient-provider interactions. The interview tool developed by Carey et al. (1997) for assessing cultural beliefs and attitudes has helped programs better understand their diverse patient populations. Along the same lines, Qureshi (1994) pioneered the discipline of "transcultural medicine" in the United Kingdom in an effort to avoid problems stemming from providers' ignorance of patients' health cultures and attitudes. Other TB programs have developed manuals to heighten understanding of the cross-cultural issues pertinent to TB (Kalihi-Palama Health Center, 1997; Melendez & Smith, 2000). In addition, social scientists have developed guides and recommendations to facilitate communication between patients and providers and improve service delivery, many of which have been integrated into the CDC Self-Study Modules on Tuberculosis (CDC, 1995a).

Numerous theoretical models and methodologies have been developed to better understand individual and interpersonal health behavior and perspectives on organizational and community interventions (Glanz, Lewis, & Rimer, 1997). One of the earliest models developed to explain health behavior was the Health Belief Model,

originally designed to understand individuals' willingness to seek screening for TB (Becker, 1974). Under this model, it is believed that people need to perceive themselves as susceptible to TB and able to personally benefit from early detection before seeking preventive health screening (Glanz et al., 1997). Researchers have applied this model, as well as others, in the design of educational materials and appropriate interventions (Ailinger & Dear, 1997; Kitazawa, 1995; Kleinman, 1980, 1989; Rubel, 1993; Shrestha-Kuwahara et al., 2002; West, 1993).

Methodologies traditionally used in anthropological research, such as participant observation and discourse analysis, yield rich information regarding health beliefs and behaviors (Ndeti, 1972). Recently, social network methods, which systematically measure the complex interconnections between and among persons, have been theorized (CDC, 2001; Chin et al., 2000; Klovdahl, 1985; Klovdahl et al., 2001; MacQueen, 2000) and adopted to improve the effectiveness of TB contact investigations (Fitzpatrick et al., 2001).

To facilitate and enhance analysis of data collected from qualitative methods, social scientists have developed new research methods and computer software programs, including CDC EZ-text and AnSWR (AnSWR, 2001; Carey, Morgan, & Oxtoby, 1996; Carey, Wenzel, Reilly, Sheridan, & Steinberg, 1998; Carey et al., 1997; CDC, 2001; MacQueen, McLellan, Kay, & Milstein, 1998). Furthermore, to assist decision-makers in integrating social science research into policy planning, Ogden (2000) has defined a framework that can be used at the national and local levels. Recent exploration of TB and gender issues has also contributed to the development of models that enable decision-makers to integrate social and cultural factors into policy planning (Uplekar, Rangan, Weiss, Ogden, & Borgdorff, 2001).

FUTURE DIRECTIONS FOR SOCIAL AND CULTURAL RESEARCH

As this entry has shown, anthropology and other social sciences have brought new perspectives on an ancient disease. While notable contributions have undoubtedly been made, this review has identified wide gaps regarding the theoretical issues pertinent to TB control. Recognizing the broader sociocultural dimensions of TB, many social scientists stress the need to examine the structural barriers hindering the development and sustainability of interventions

(Manderson, 1998). Critics of the purely cognitive or cultural explanations point out that many ethnographic studies have demonstrated that predictors of care-seeking, compliance, and treatment outcomes are fundamentally economic and structural in nature (Barnhoorn & Adriaanse, 1992; Farmer, 1997; Mata, 1985; Sumartojo, 1993).

Anthropological methods can be important tools to identify social forces that impact TB transmission and hinder equitable access to care (Grange, Gandy, Farmer, & Zumla, 2001; Porter et al., 1999). Ethnographic research, such as that conducted by Grygier (1994) on the TB epidemic among the Inuit people in Canada, can help to recapture the human perspective of a disease epidemic such as TB. There is also a continuing need for ethnographic studies of attitudes toward TB at all levels of society, including the perceptions, priorities, and motivating factors at governmental and international levels (Grange & Festenstein, 1993). Additionally, social science research can contribute to a better understanding of the health care environment and how operational and infrastructural factors impact TB control efforts (Brudney & Dobkin, 1991; Farmer et al., 1991; Sumartojo, 1993).

This review has pointed out the dearth of evidence that anthropologists have investigated in developing, implementing, evaluating, and disseminating new interventions to improve the effectiveness of TB control programs. Anthropologists and other social scientists can play a critical role by engaging in systematic, theory-based, multidisciplinary research using scientifically rigorous experimental and quasi-experimental designs to improve specific aspects of TB control programs. With a vast array of theoretical models and frameworks, social scientists should play a greater role in exploring new, theoretically grounded yet pragmatic ways of assisting public health personnel in using social science for strengthening TB prevention and control policies and practices. These changes would be consistent with the expanding roles of other social and behavioral science disciplines in public health over the past two decades (Snider & Satcher, 1997).

TB control experts can learn from their counterparts' experiences battling the AIDS epidemic. HIV/AIDS researchers have advanced the understanding of the relationship between social structural factors and disease and have explored the dynamics of the epidemic in terms of social vulnerability rather than of individual risk (Mann & Tarantola, 1996; Porter et al., 1999). They have also developed frameworks to better understand the impact of structural factors on patient outcomes

(Blankenship, Bray, & Merson, 2000; Sumartojo, 2000). These lessons are equally applicable to the dynamics of TB. Social scientists stress the need to look beyond the current biomedical model of TB control toward a multidisciplinary research framework. Jaramillo, for example, has proposed moving toward a new paradigm of epidemiology that is informed by the debate between “individual agency” and “structure” in explaining patterns of disease. This model is more inclusive of three different levels of causality: biological, health-behavioral, and socioeconomic. This more integrated view of causality asserts that control measures need to come from different levels of organization, and, thus, implies a more comprehensive agenda for research and control activities (Jaramillo, 1999b).

The World Health Organisation (WHO) and the Institute of Medicine (IOM) have emphasized a call made at an earlier meeting (CDC, 1995b) for more social science research in TB control (IOM, 2000). The IOM report articulates the need to understand the determinants of the behavior of providers, patients, and systems and to improve methods for predicting and monitoring adherence to therapy. Other areas needing research are the ethical and human rights issues around the use of directly observed therapy, legal detention of patients, and participation in drug trials.

TB is a serious global public health problem and, unless radical changes occur in TB control efforts, overall prevalence will likely increase (Porter et al., 1999). In most of the developing world, poverty, malnutrition, and overcrowding challenge TB control efforts. In industrialized nations, the risks associated with TB—social marginalization, malnutrition, substance use, unemployment, and congregate living—continue to flourish. Backed by renewed commitment to social and behavioral research, social scientists clearly have a critical role to play in the effort to control and eventually eliminate TB.

Volume II: Cultures

African Americans¹

Eric J. Bailey

ALTERNATIVE NAMES

“Black” Americans, “Blacks”, Afro-Americans and Afro-Caribbeans.

LOCATION AND LINGUISTIC AFFILIATION

In 1996, 53% of African Americans lived in the South, making up 19% of that region’s population. Nationwide, 55% resided in the central cities of metropolitan areas. The 10 counties with the most African American residents on July 1, 1996, were Cook, Illinois (1.4 million); Los Angeles (1.0 million); Kings, New York (900,000); Wayne, Michigan (900,000); Philadelphia (600,000); Harris, Texas (600,000); Bronx, New York (500,000); Queens, New York (500,000); Dade, Florida (400,000); and Baltimore City, Maryland (400,000) (U.S. Census Bureau, 1998).

With regard to linguistic affiliation, African Americans’ primary language pattern is English. English is in the Germanic branch of the Indo-European language family. Yet similar to all American populations, African Americans adapted their language patterns and dialects according to their sociocultural environment. African Americans’ language patterns reflect influences from Africa, Britain, Creole populations, the Caribbean islands, rural, urban, southern regions of the United States, and Canada.

Often identified with such terms as African American English, “Black” English, “Black” English Vernacular, Ebonics, and, most recently, “Spoken Soul,” African American language patterns are a reflection of their dynamic culture. The languages and dialects regularly spoken in the African American community are: Spoken Soul (considered by some a dialect of American English, and by others a language distinct and separate from American English); the U.S. Language of Wider Communication (LWC), a.k.a. “Standard American English”; Non-standard American English; and Arabic, Spanish, Swahili, Creole (and other foreign languages, but these are the main ones) (Rickford & Rickford, 2000; Smitherman, 2000, p. 20).

Depending on time, place, setting, and audience, all or some of the various languages and dialects may be used in the African American community. Most middle-class and professional African Americans speak the LWC, as well as some aspect of Spoken Soul at least some of the time. Most working-class African Americans speak varying degrees of the LWC, Non-standard English, and Spoken Soul (Smitherman, 2000, p. 20).

OVERVIEW OF THE CULTURE

The African American family as a unit has a historical continuity that began not with the American experience but in Africa, long before the intrusion of Europe into the continent. In the process of adapting to their new environments, West Africans merged their cultural traditions with European and Native American traditions. Although some of the cultural traditions have changed or been Americanized, the family unit remains constant.

The characteristics of the African American family today include a bilateral orientation—an equal recognition of the male and female lines of descent but favoring the mother’s kin; extended kin groups; respect for elders; and a high value placed on children and motherhood (Aschenbrenner, 1973; Stack, 1974). Other cultural characteristics include: individual moral “strength” as a human quality; an emphasis on family occasions and rituals; strong belief in spiritualism (Aschenbrenner, 1973; Stack, 1974); reliance upon extended familial network for social, economic, and health care issues; strong orientation toward religious beliefs, activities, and organizations; outwardly expressed emotions; emphasis on nurturing children and participating in many rites of passage; preference for group activities as opposed to individual activities; preference for oral communication and oral history to share news and information; admiration of art, dance, and music; and preference for women and men sharing roles and responsibilities.

As early as the 1500s and 1600s, the ancestors of African Americans were forcibly transported to

South America, the Caribbean, and North America. African Americans are primarily descendants of West African people who mostly shared a common history, place of origin, language, food preferences, values, and health beliefs. With regard to health beliefs and health care practices, African Americans are believed to have retained many of the preventive and treatment practices associated with indigenous West African cultures, primarily because these methods were perceived to be most useful. Jacques (1976), Jordan (1975), Jackson (1985), Baer (1985), Spector (1985), Goodson (1987), Mbiti (1975), Harvey (1988), Tinling (1967), and Tallant (1990) all contend that African Americans continued to utilize folk and herbal medical practices as a result of communication difficulties with Europeans and the fears of European physicians.

There is documented evidence that traditional West African health beliefs and herbal remedies were handed down and maintained by various African American populations throughout North America (Bailey, 1991a; Spector, 1985). For example, oral histories of former slave women from all over the South contain frequent and sometimes elaborate descriptions of the wide variety of plants that constituted the material base from which the slave medical practice operated (Goodson, 1987, p. 200).

Specifically, female African American slave doctors used drugs derived from plants to prevent and cure worms, malaria, croup, pneumonia, colds, teething, and measles. Sometimes, they used the root, and other times they selected the leaf, bark, fruit, or gum resin to boil into a tea or make into a poultice or wear in a bag around the neck (Goodson, 1987, p. 200). Not only did African American slave doctors have this medical knowledge of plants, but also many other slaves knew how to diagnose and treat illnesses. In fact, a number of medicine chests have been discovered filled with the popular preparations of the day: calomel, blue mass pills, castor oil, ipecac, tarter emetic, and various tinctures (Ewell, 1813; Postell, 1951).

During the 1700s and 1800s in the United States, African American health beliefs and practices continued to show similarities with the West Africans' health beliefs and practices. As more African Americans migrated to northern cities during the mid-1800s and early 1900s, they carried a repertoire of health care beliefs and practices. African American health beliefs and practices became a composite, containing elements from a variety of sources: European folklore, Greek classical medicine, modern

scientific medicine, vodoun religion, Christianity, and particularly African folklore (Bailey, 1991a; Hill, 1976).

To better understand the relationship between culture and health care issues associated with the African American population, we must examine the current social, economic, and demographic data from the U.S. Census. Although recently there has been much discussion on the lack of reporting and inaccuracy of the U.S. Census data and the fact that many African Americans are very skeptical of any governmental data agency, the sociodemographic data show some very intriguing and positive trends associated with the African American population.

According to the U.S. Census Bureau (1998) on October 1, 1996, there were an estimated 33.7 million African Americans in the United States, constituting 12.7% of the total population. The African American population is young, with an estimated median age on November 1, 1997, of 29.8 years, nearly 8 years younger than the median for the non-Hispanic "White" population. It is projected that the African American population will grow more than twice as fast as the European American population between 1995 and 2050. By the middle of the next century, the African American population should nearly double its present size to 61 million (U.S. Census Bureau, 1998).

To critically assess the health status and health issues associated with African Americans, one must use a culturally relativistic approach. This entry defines African American culture, highlights the cultural historical origins of their health beliefs and values, examines their cultural health-seeking patterns, and discusses the impact of alternative and complementary medicine on African Americans' ethnomedical beliefs.

The persistence of traditional African American health beliefs and practices provides a meaningful alternative to mainstream formal medicine for many African Americans because of its role in maintaining a sense of ethnic identity. It also indicates a pattern of adaptation to social and economic conditions both within the African American community and in the larger society.

THE CONTEXT OF HEALTH: ENVIRONMENTAL, ECONOMIC, SOCIAL, AND POLITICAL FACTORS

Medical anthropologists are trained to view the health status of each individual and population from a

biopsychosociocultural perspective. Our approach is holistic; that is, medical anthropologists believe that all factors contribute to the well-being or sickness of a person/population. In order to understand how this holistic approach applies to African Americans, I will: highlight the culture of African Americans and then discuss how culture relates to African American health; examine the major cultural, historical, and political issues that may have had an impact on the health-seeking process of the African American population; and examine psychosocial environmental issues such as religion and caregiving and how these factors relate to African American health.

African Americans learn certain health beliefs and practices from their extended familial networks. When a health care crisis occurs, African Americans tend to seek health care information from their extended familial networks or a lay health professional first, and then opt for professional care.

African Americans are acutely aware of nonverbal body language that indicates that a health care provider is comfortable or not comfortable in treating an African American person. If the African American patient perceives the nonverbal language as positive, he or she will most likely return for care. However, if the African American patient perceives the nonverbal body language as negative, he or she will most likely not return for care and not adhere to the prescribed regimen.

Like all Americans, African Americans are connected to the social, economic, political, and health care fabric of U.S. society. Yet once an economic or health care crisis occurs in U.S. society, African Americans often are affected first, primarily because a third of the population is considered the working poor.

Culture adds meaning to reality. African Americans respect and honor those who train, graduate, and serve in the health professional fields. Often, African American health care professionals feel a commitment to serve their community. Because of the low numbers of African American physicians and health care specialists, African Americans frequently choose to work in underserved minority communities as opposed to communities with relatively low numbers of minorities. African Americans' commitment to work and to serve those who are underserved adds meaning to their profession in the health care field.

Culture is differently shared. African Americans perceive health and the health care system differently. Although African Americans have many common traits

and patterns, there remains a high degree of diversity within the African American population. For instance, intragenerational health care issues differ among African Americans as they relate to perceptions of the health care system and health belief system. Additional sociodemographic factors—such as gender, region of the country, income level, and educational level—may also cause differing perceptions of health care issues in the African American population.

Cultural History

Another component of the comprehensive, holistic approach to health is cultural history. The cultural historical approach helps us to better understand issues such as African Americans' past health-seeking process; African Americans' current perceptions of the national and local health care systems; African Americans' lack of participation in clinical trials; and African Americans' alternative medical practices.

The significance of the cultural historical approach can best be illustrated in an article entitled, "African American Suspicion of the Healthcare System is Justified: What Do We Do about It?" Dula (1994) uses historical and contemporary examples of health care issues that contributed to the mistrust and suspicion that many African Americans have for the U.S. health care system. According to Dula (1994), real abuses in experimentation have contributed greatly to the high level of distrust within the African American population for decades.

Suspicion of the medical system in the United States has its origin in slavery medical practices. Dula (1994) states that slaves were sources for medical experimentation and research by doctors, instructional material for medical students, and that enslaved albinos and Siamese twins were displayed as freaks at medical society meetings. African Americans contributed to scientific progress, usually without consent or benefit to themselves, and sometimes without benefit even to science (Dula, 1994, p. 348).

Another cultural historical case is the Tuskegee experiment. Dula (1994) states that the Tuskegee experiment (1932)—in which 400 African American men participated in a government-sponsored study to find the effects of untreated syphilis—was the ultimate proof that European American health policy-makers, indeed, deserved mistrust. Jones (1981) and Dalton (1989)

support Dula's claim. Thomas and Quinn (1991), who stated the following, also support Dula: "The history of the Tuskegee Syphilis Study, with its failure to educate the participants and treat them adequately, helped to lay the foundation for Blacks' pervasive sense of distrust of public health authorities today" (p. 1499).

Religion and Spirituality

Another important factor in the holistic approach to health is the psychosocial component. For the purpose of our discussion, this section refers to psychosocial factors in a broad-based sense, encompassing such issues as mental health, religiosity, and spirituality. In particular, religiosity and spirituality play a significant role in the well-being of the African American population.

The church, one of the symbols of religious involvement, has long been one of the major social and cultural institutions that define how people should see themselves and direct their behavior (Berry & Blassingame, 1982). Taylor and Chatters (1991) emphasize that the teachings of the church regarding human nature and human relationships may foster either mentally healthy attitudes or destructive, neurotic attitudes in its members. Inevitably, a church teaches its members, either directly or indirectly, how to deal with aggression, anger, pride, sexuality, competition, social relations, child-raising, and marital relations (Taylor & Chatters, 1991).

Within the African American community, the significance of the church to community life may be attributed, in part, to the church's position as one of the few indigenous institutions in African American communities—that is, built, financed, and controlled by African Americans. Moreover, African American churches serve as an outlet for social expression, a forum for the discussion of political and social issues, and a training ground for potential community leaders (Chatters, Levin, & Ellison, 1998; McRae et al., 1998; Neighbors, Musick, & Williams, 1998).

In 1991, Taylor and Chatters reported the results from a National Survey of Black Americans ($N = 2,094$) with regard to their religious affiliations. Taylor and Chatters (1991) found results such as: 40 different religious affiliations were reported; one half of the respondents indicated that they were Baptist (52.1%); 11% were Methodist; 6% were Roman Catholic; 3% were Holiness; 2% were Jehovah's Witness; 15% identified one or more of the 35 remaining denominations; one out of ten respondents indicated no religious preference; and eight

respondents indicated that they were either atheist or agnostic.

In a study to examine the significance of religiosity and health outcomes among African Americans, Picot, Debanne, Namazi, and Wykle (1997) conducted face-to-face interviews with 136 African American and 255 European American caregivers of community-dwelling elders. Results revealed that African American caregivers perceived higher levels of rewards from participating in religious services than did European American caregivers. Additionally, the relationship between race and perceived rewards was mediated by comfort from religion and prayer. African Americans are taught to depend on a supreme being, the Lord, and to take their burdens to the Lord and leave them there (Picot et al., 1997). Picot et al. (1997) emphasized the importance of religious beliefs and health outcomes among all groups, particularly the effects within the African American population.

MEDICAL PRACTITIONERS

The types and sources of treatment actions among African Americans are likely to vary according to gender, class, region of the United States, and degree of assimilation into mainstream society. In the United States, most ethnic groups have the option of selecting from a variety of sources: (1) self; (2) alternative or native health practitioners; and (3) formal health professionals.

If the illness is perceived as naturalistic (i.e., due to inadequate rest, poor nutrition, or germs), African Americans tend to use initially one and/or a combination of the following treatment actions: self-care, alternative (indigenous) health practitioner, and formal health professionals (Jackson, 1981; Jacques, 1976; Leininger, 1985; Spector, 1985). A discussion of self-care will be presented later in this entry.

In addition to the variety of home remedies or patent medicines practiced among African Americans, there are primarily two types of alternative indigenous health practitioners serving the African American community: (1) independent practitioners and (2) cultic practitioners (Baer, 1985, p. 327). These two types of alternative indigenous health practitioners operate as individuals or are affiliated with some sort of occult-supply store, either as the owner, an employee, or someone who rents office space. The cultic practitioner is affiliated with a religious group and practices in both public and private settings. The multiplicity of African American alternative

indigenous health practitioners today stems from the role adaptability of traditional African American healers of the past (Bailey, 2000a,b).

For instance, one type of African American alternative indigenous health practitioner, the neighborhood prophet/Old Lady, does not dispense medicine but merely advises clients about concocting herbal medicines. Rather than selling or giving a herbal remedy, the Old Lady tells the client to use it in varying proportions to treat the perceived illness. In addition, she gives advice on various emotional, personal, and domestic problems. She does not receive monetary gifts for her service, only gifts of food or expressions of gratitude (Jordan, 1979, p. 38). The neighborhood prophet/Old Lady treats the individual's mind, body, and spirit in an attempt to return the individual to harmony with nature.

This indigenous alternative health practitioner, as well as many others, have successfully matched their holistic approach to treating illness/disease with the model or perception of treating illness/disease among many African Americans. Although there are no specific utilization data to document the total number of African Americans seeking care from these alternative indigenous health practitioners, their presence and growth within the alternative health delivery network can no longer be denied and overlooked.

Formal health practitioners are referred to as licensed medical doctors (MDs) and doctors of osteopathic medicine (DOs) in licensed allopathic (MD-staffed) and osteopathic hospitals. The U.S. Department of Health and Human Services (1986) regularly documents the number of physician contacts by the general public. Interestingly, the national health care utilization data have always showed a distinctive difference between African Americans' and European Americans' use of formal health practitioners. For example, African Americans sought care from a doctor's surgery less (47%) than did European Americans (57.7%). African Americans were also less likely to contact a doctor by phone (9.2%) than were European Americans (13.4%). Yet, African Americans were reported to have experienced more physician contact in hospital outpatient departments (21.4%) than European Americans (13.7%) and to have more physician contact at home (5.8%) than European Americans (2.5%) (U.S. Department of Health and Human Services, 1986).

Most health care researchers would contend that an obvious explanation for the difference in physician utilization between African Americans and

European Americans is economics. There is no doubt that the cost of seeking care and a lack of health insurance cause many African Americans to delay or not seek care from formal health practitioners. However, some researchers contend that there are other social and cultural factors that have truly caused the disparity in seeking care from formal health practitioners.

In particular, Blendon, Aiken, Freeman, and Correy's (1989) study of 10,130 persons living in the continental United States found that even African Americans above the poverty line have less access to medical care than their European American counterparts. The researchers contend that ethnic-related differences in health care arrangements and lifestyle were the most significant factors in the disparity between African American and European American health care utilization.

For example, African Americans are more likely than European Americans to report that during their last visit, their physician did not inquire sufficiently about pain, did not tell them how long it would take for a prescribed medicine to work, did not explain the seriousness of the illness or injury, and did not discuss tests or examination findings. In addition, fewer than three-fifths of African Americans were completely satisfied with the care provided during their last hospitalization, compared with over three-fourths of European Americans (Blendon et al., 1989). It is apparent that there are differences not only in access but also in the perception of the care provided for African Americans and European Americans. African Americans seem to adhere to ethnomedical beliefs and practices, and they use alternative health care therapies more extensively than do European Americans (Blendon et al., 1989).

Unnatural illnesses are perceived to be caused by a supernatural spirit, magic, sorcery, voodoo or some other personalistic agent (Bailey, 1991a; Hill, 1976; Snow, 1974). The literature on African American illness causation suggests that the African American healing tradition considers the universe a place where the forces of good and evil, God and Satan, struggle for control (Gregg & Curry, 1994, p. 522). Therefore, unnatural illnesses are perceived to be a struggle between the forces of good and evil.

Within this belief system, religion or spirituality is of utmost importance to illness perceived to be caused by unnatural means. Even though religion and spirituality are most commonly reported as important sources of social support for African Americans, they can also be used for dealing with unnatural illnesses in a more

positive way (Ford, Tilley, & McDonald, 1998; Gregg & Curry, 1994; Jackson, Jackson, & Nixon, 1970; Stolley & Koenig, 1997; Taylor & Chatters, 1986). Taylor and Chatters (1986), Stolley and Koenig (1997), and many other researchers have shown that African Americans' use of religion and spirituality for natural as well as unnatural illnesses is their particular method of treating an illness/disease within their health belief system.

Another means of treating an unnatural illness and sometimes natural illness is with voodoo "rooting." As a form of religion, voodoo is a complex of African belief and ritual governing, in large measure, the religious life of African natives (Jordan, 1975). Harvey (1988) states that "as a belief system which combined historical conceptions with practices that were acceptable in a hostile social environment, voodoo is a striking example of a cultural adaptive mechanism used by members of an oppressed group as a survival technique."

The first is the mystic component, which deals with the supernatural such as spells and spirits. The second component is that part of voodoo that deals with psychological support of the individual, and the third part is herbal and folk medicine. African American voodoo prospers, particularly in the South, primarily because it fills a void left by inaccess and denial of medical care by formal American health practitioners (Jordan, 1979, p. 38).

In conclusion, African Americans tend to consult alternative indigenous health practitioners for unnatural and natural causation of illnesses primarily because of their attempt to cope with health problems within the context of one's resources and social and cultural environment; their belief that alternative indigenous health practitioners have some control over the forces that cause illness/diseases in a person's life, whereas Westernized medical physicians cannot heal certain cases of illness and misfortune; and lower monetary expense associated with such treatments (Cockerham, 1986, p. 88; Hill, 1976, p. 14).

CLASSIFICATION OF ILLNESS, THEORIES OF ILLNESS, AND TREATMENT OF ILLNESS

Health

African Americans' perception of what constitutes "healthy" encompasses a relatively high tolerance of discomforts from symptoms (Jackson, 1981). Studies

have shown that African Americans often ignore minor discomforts as backache, upset stomach, or headache until they reach such proportions that they interfere with the business of living (Jackson, 1981). In fact, African Americans, particularly the elderly, often perceive their health status as "poorer" than do European Americans (Manuel, 1985). Furthermore, since one's self-esteem, sanity, and survival are at risk, in a state of health (good or bad), one becomes adaptive, flexible, alert, and able to use a wide range of strategies effectively to endure and reach his/her optimal potential. In other words, until the degree of discomfort impairs daily activities or is acknowledged by the individual's sociocultural network, seeking health care, particularly from mainstream health care facilities, is not warranted.

Illness

Illness is defined as sickness of body or mind; disease is defined as a harmful departure from the normal state of a person or other organism (Green & Ottoson, 1994, p. 697). Illnesses are classified as either naturalistic or personalistic (Snow, 1974). Naturalistic agents identify what caused an illness, whereas personalistic agents recognize who caused the illness (Chino & Vollweiler, 1986). Such impersonal agents as inadequate rest, poor nutrition, and germs cause illnesses. The etiology of illnesses falls into three general categories: environmental hazards, divine punishment, and impaired sociocultural relationships.

In some cases, serious and life-threatening illnesses are perceived to be sent by God (personalistic agent) or some other personalistic agent as punishment for sin (Hill, 1976; Snow, 1974). For example, many African Americans who suspect they have a terminal illness, may delay medical diagnosis. During this delay and/or denial period, many African Americans turn to powers considered greater than themselves to fathom the reason for the disease, thereby accepting terminal illness as "God's will" and believing that nothing more can be done.

Examples of naturalistic and personalistic causative agents are described in the following studies. First, a study investigating the treatment patterns of hypertension among 285 African Americans in the Detroit metropolitan area contended that African Americans' beliefs about the etiology of hypertension were based on naturalistic agents (Bailey, 1991b). Bailey reported that informants considered inadequate rest, poor nutrition, weather disturbances,

and imbalances in hot and cold properties as naturalistic agents affecting their blood pressure. Informants described “richy” foods such as heavily salted greens, pork, and sweets as naturalistic agents. Moreover, cold weather was described as a naturalistic agent that can affect the viscosity of one’s blood pressure (Bailey, 1991b, p. 294). These findings were directly comparable with those of other studies on folk symptomatology (Blumhagen, 1982; Dressler, 1982; Garro, 1986; Snow, 1974).

Second, a study investigating the narratives of 26 African American women with advanced breast cancer found that these women attempted to relate the meaning of their cancer to an indigenous model of health and disease (Mathews, Lannin, & Mitchell, 1994; Lannin et al., 1998). The women interviewed ranged in age from 39 to 83 years, with the majority being over the age of 50.

Cancer was seen by patients to be the worst of all diseases because they believe it is always fatal and is essentially incurable. Consequently, for many of the women interviewed, cancer resembled illnesses that did not respond to conventional categories or cures in the indigenous medical system (Mathews et al., 1994, p. 795). Thus, the only likelihood of finding a cure for cancer was “to turn it over to God.” One of the informants said the following: “Cancer is a horrible disease. It just eats you up. The only one powerful enough to overcome it is the Lord. You just have to trust in Jesus to do battle for you and save you from this horrible affliction” (Mathews et al., 1994, p. 795). Mathews et al. contend that here the battle metaphor is used to portray a struggle between God, as the all-powerful force for good, and cancer, as consummate evil.

Interestingly, Mathews et al. (1994) suggest that too often in the past health care professionals have assumed that patients who delay seeking treatment for cancer or who fail to utilize the screening services available either lack knowledge, are too poor to access services, deny reality, or are excessively fatalistic. In actuality, these patients have well-worked-out ideas about their own health and about their disease (p. 799). Patients, in this case African Americans, also have well-worked-out ideas about treatment strategy depending on whether the illness is perceived as naturalistic or personalistic.

Self-Care

Self-care includes positive steps taken by individuals to either prevent disease or promote general health status

through health promotion or lifestyle modification; medical self-care for the identification or treatment of minor symptoms of ill health or self-management of chronic health conditions; and steps taken by laypersons to compensate or adjust for functional limitations affecting routine activities of daily living.

The use of home remedies or herbs is an example of a self-care strategy. The basic assumption behind the use of herbs/home remedies links the natural organic properties of herbs with the natural healing capabilities of human beings. Herbalists use these organic substances in an effort to neutralize or eliminate one’s body of harmful substances that impair its power to heal itself (Lust, 1974, p. 8). According to herbalists, any herb, if mixed and used properly, can effectively treat any natural illness.

Herbs from the woods are used in many ways. Herb teas are prepared to treat pain and reduce fevers. Sassafras tea frequently is used to treat colds, and placing raw onions on the feet and wrapping them in warm blankets is used to break a fever (Lust, 1974, pp. 196–197).

Spector (1985) has identified some African American home remedies as successful in the treatment of disease. A few selected examples are: a method for treating colds is hot lemon water and honey; when congestion is present in the chest and the person is coughing, the person can be wrapped with warm flannel after his/her chest is rubbed with hot camphorated oil; hot toddies are used to treat colds and congestion (these drinks consist of hot tea with honey, lemon, peppermint, and a dash of brandy or whatever alcoholic beverage the person likes and has available); and Vick’s vapor rub is swallowed.

In general, self-care strategies such as home remedies and herbs are convenient and effective sources of therapy (Davis, 1977). The three major reasons for their continual use in the African American community are that folk remedies may be the only alternatives to costly treatment of acute illness by the health care system; folk remedies have been given the stamp of approval by generations of African American caregivers; and the loving care, attention, and overall nurturance that accompanies the use of remedies cannot be overlooked (Davis, 1997, p. 433).

Furthermore, Davis (1997) states that employing folk remedies in treatment follows closely the culture of a particular group of people and is replete with memories, comfort, and familiarity. In fact, folk remedies may be so enmeshed in tradition that not to perform them is tantamount to sacrilege.

HEALTH THROUGH THE LIFE CYCLE

Pregnancy and Birth

According to the Committee on the Status of "Black" Americans of the National Research Council (1989), birthrates among teenage African American women have been dropping since 1960s. However, because the total number of African American adolescent women has increased by 20%, there were substantial increases in the total births to African American teenagers, despite the declining birthrates. In addition, because birthrates to African American teenagers remain two to three times higher than those for European Americans, a higher proportion of all African American births occur among teenage mothers; in 1984, 20% of all African American births were to teenagers, compared with 11.1% among European Americans (National Research Council, 1989, p. 412). Interestingly, African American teenage women represent only 14% of the U.S. adolescent female population whereas European American adolescent girls have the overwhelming majority of all teenage births.

The higher birthrate for African American teenagers can be accounted for by earlier initiation of sexual intercourse (on average two years earlier than European Americans); less use of contraception; less likelihood of abortion; and the almost universal decision to keep and rear children who are born, rather than offer them for adoption (National Research Council, 1989, p. 412). This pattern of keeping and rearing children is reflected in U.S. Census data.

For example, in 1993, about four in ten African American preschoolers were cared for by grandparents or other relatives besides their fathers while their mothers worked, compared with only about two in ten European American children. Care by grandparents was especially important to African American families, accounting for one-fifth of all arrangements used for preschoolers (U.S. Census Bureau, 1998).

Infancy

In 1991, the mortality rate for African American infants (17.6 per 1,000 live births) was 2.4 times that for European American infants (7.3 per 1,000 live births). Between 1970 and 1991, the mortality rate decreased more for European American infants (59%) than for African American infants (46%), widening the gap in infant mortality between the two populations.

The national average figures for infant mortality do not show all the disparities between African Americans and European Americans in infant mortality rates across the United States. African American infant mortality rates show considerable variation by region. For example, during 1982–1984, the African American infant mortality rate was lowest in the Mountain and Pacific states (15.4 and 16.2 deaths per 1,000 live births, respectively), and highest in the East North Central states (21.7), particularly Illinois (23.3) and Michigan (23.7) (National Research Council, 1989, p. 399).

The marked gap in infant mortality rates between European Americans and African Americans mirrors the more than twofold difference in the rates of low birthweight and very low birthweight between the two groups. African Americans are twice as likely as European Americans to have low-birthweight infants: the African American rate is 12.4 per 1,000 live births, and the European American rate is 5.6 (National Research Council, 1989, p. 400).

Childhood

In 1996, there were 8.1 million African American families, 46% of them married-couple families. The majority of African American families (57%) had children. Families with children averaged two children apiece (U.S. Census Bureau, 1998).

Overall, African American children have benefited from the impressive health gains for all American children since 1950 (National Research Council, 1989, p. 405). The rate of death from all causes for children aged 1–4 was 139.4 per 1,000 live births in 1950 and 51.4 per 1,000 live births in 1985. For children aged 5–14, the comparable rates were 60.1 per 1,000 live births in 1950 and 26.3 per 1,000 live births in 1985 (National Center for Health Statistics, 1997, p. 80). However, African American children have not shared equally in the overall health gains, and their death rates are much higher than those for European American children.

Interestingly, the leading cause of death among children is injury. Accidents cause three times as many deaths than do either of the next two leading causes of childhood death (cancer and congenital anomalies). For African American children, the highest rates of injuries occur in or near the home (National Research Council, 1989, p. 405). The National Research Council states that injuries are related to socioeconomic status: poor children are very likely to live in areas in which heavy

traffic patterns lead to pedestrian injury. Within the house, unrepaired stairwells and inadequate or absent screens or window guards expose children to the risk of falls. Missing smoke detectors along with defective heaters and other household appliances pose fire hazards. Poor homes are also more likely to contain toxic substances, such as chemicals for pest control, or peeling lead paint (National Research Council, 1989, p. 406).

Adolescence

Females. Adolescence is a period of significant life transition, during which children cross the bridge into adulthood (Adams, Scholenborn, Moss, Warren, & Kann, 1995). Behaviors established during this period are often carried into adult life. Adams et al. (1995) state that health behaviors established prior to adulthood can significantly influence health and longevity, both in the short term and later in life.

In 1992, the Centers for Disease Control and Prevention conducted the National Health Interview Survey—Youth Risk Behavior Survey (NHIS—YRBS). The NHIS—YRBS was a collaborative effort of the Division of Health Interview Statistics, the National Center for Health Statistics, and the Division of Adolescent and School Health of the National Center for Chronic Disease Prevention and Health Promotion. Of the 13,789 youth identified as eligible for the NHIS—YRBS, 10,645 completed questionnaires, representing an estimated 77.2% of eligible respondents (Adams et al., 1995).

With regard to weight control, Adams et al. (1995) found that African American adolescent females (36%) were less likely than European American adolescent females (46.1%) to perceive themselves as being overweight. In addition, African American female teens (41.5%) were less likely than European American females (59.5%) and Hispanic females (55.1%) to report any attempt to lose or keep from gaining weight in the past week. Overall, the data show that proportionately, fewer African American female and male youths considered themselves overweight compared with European American female and male youths.

The importance of these national health data on the perceptions of weight control among African American adolescent females relates to the issue of obesity and its health consequences. Obesity rates among African American women are significantly higher than for European American women (Kumanyika, 1994).

Moreover, chronic disease profiles of minority populations indicate that African Americans have higher than average cardiovascular disease-related mortality (Kumanyika, 1991; Otten et al., 1990). These health trends and mortality suggest an urgent need for obesity prevention programs for African American adolescent females.

Males. Much of what has been written and researched about African American adolescent males' health and social behavioral outcomes has been negative and downright gloomy. The health and social data that are often cited in the literature and reported in the media are the rates of homicide and sexually transmitted diseases.

According to the National Center for Health Statistics (1997), the homicide rate for African American males (72.5 per 100,000) were eight times higher than for European American males (9.4 per 100,000) and nearly five times higher than for African American females (13.9 per 100,000) as for European females (3.0 per 100,000). Among African American youth, the homicide rate (77.9 per 100,000) is eight to nine times that for European American (9.6) and Asian American youths (8.8) (National Center for Health Statistics, 1994, p. 29). The cause of this disparity in homicide rates is multifaceted—in other words, factors such as personal situational issues, societal discrimination, cultural historical racism, persistent unemployment, peer pressure, and lack of formal education all contribute to the high rate of homicide among African American adolescent males.

With regard to African American male sexual behavior and the risk for HIV infection, the cause for the high prevalence rate of HIV infection is also multifaceted. Whitehead (1997), for example, found that broader historical and sociocultural issues associated with African American adolescent males and middle-aged men contributed to the disproportionately high rate of HIV infection.

According to Whitehead, adolescent African American males need a masculinity transformation primarily because the existing constructs of ideal masculinity transformation fragment masculinity. In other words, the process of becoming a male in our gender-based society is incorrect. Our society teaches young males inappropriate ways of achieving adulthood.

The goal of masculinity transformation is to achieve a sense of masculine gender identity as a whole (Whitehead, 1977, p. 436). Masculine transformation is a

strategy of empowerment that moves away from notions of masculinity that focus on gaining economic capacity to achieve social (with male peers) or economic status. Furthermore, Whitehead states that masculine transformation emphasizes community service, goal-setting, and discipline in achieving goals, and integrates body, mind, and spirit.

The cultural relativistic strategy resulting from Whitehead's masculinity transformation involves peer training in which older, more mature males, including low-income males, work with preadolescent and adolescent boys and young adult men. It helps men on their road to masculine wholeness and works to help younger men overcome their fragmented masculinity (p. 437). Thus, Whitehead recommends masculine transformation, along with the usual HIV/AIDS materials, to effectively address HIV/AIDS among African American adolescent males in low-income American communities.

Adulthood

According to the National Center for Health Statistics (1997), the 10 leading causes of death (from highest incidence to lowest) for African Americans in 1995 were diseases of the heart; malignant neoplasms (cancers); cerebrovascular diseases (stroke); human immunodeficiency virus infection (HIV); unintentional injuries; homicide and legal intervention; diabetes mellitus; pneumonia and influenza; chronic obstructive pulmonary diseases; and certain conditions originating in the perinatal period (National Center for Health Statistics, 1997, p. 117). African American men and women, however, differ in the order and rank of the leading causes of death.

For example, HIV infection ranked third among leading causes of death for African American men. With regard to African American women, cerebrovascular disease and diabetes mellitus ranked third and fourth, respectively, among leading causes of death. Moreover, ranking ninth for leading causes of death among African American women were nephritis, nephritic syndrome, and nephrosis (lupus).

The Aged

African American elders are a diverse group, and it is important to recognize this group's heterogeneity (Brangman, 1995). No typical African American elder exists. They can vary from an elder living in the rural

South to an elder in an urban area in the Northeast. They may have been born in the northern or southern parts of the United States or be members of a subgroup, as are immigrants from various parts of the Caribbean, such as Jamaica or Haiti. Their history, religious, educational, socioeconomic, and marital statuses, and cultural backgrounds must be taken as a starting point for understanding the individual while avoiding overgeneralizations and stereotypes (Brangman, 1995, p. 16; Mouton, Johnson, & Cole, 1995).

Alzheimer's disease (AD), also called primary degenerative dementia, is a deterioration of mental capacity. AD accounts for over half of all dementias. Death rates from AD increase with age. For Americans aged 65–74 years, the death rate is nearly 10 deaths per 100,000 people (National Center for Health Statistics, 1996). Age-adjusted rates are nearly two times higher for the European American population than for the African American population.

To determine the medical, social, and cultural pattern of AD among African Americans, Gorelick et al. (1994) studied 113 African American AD patients and 79 African American vascular dementia (VaD) patients in Chicago. They found that the typical demographic and background profile of their African American AD and VaD patients was that of a woman born in the southern portion of the United States who had lived on a farm until her mid-teenage years before moving to Chicago. These women currently lived in a house or apartment with other family members, were retired, widowed, and Protestant, and had some form of medical insurance. AD patients were generally older than VaD patients (76.4 vs. 71.8 years) and remained in their state of birth for a greater length of time before moving to Chicago than VaD patients (26.3 vs. 18.8 years). This study represents one of the few research initiatives that exclusively targeted African American patients with AD and VaD. Moreover, Martin and Panicucci's (1996) study of 40 elderly African American women's health behaviors and beliefs highlighted the difference in this study's results versus stereotypical beliefs associated with elderly African American women. Findings revealed that Southern, community-living African American older women generally have a high level of adherence to commonly recommended health promotion/disease prevention habits.

Martin and Panicucci stipulated that the most likely explanation for the high level of adherence may stem from cultural and religious doctrines that discourage

certain unhealthy practices such as excessive alcohol consumption, cigarette smoking, and ineffective coping outlets. Because study findings indicate that African American older women want to maintain their health, increased attention must be directed to the importance of primary prevention behaviors as an assertion of control over one's future health, well-being, and quality of life (Martin & Panicucci, 1996, p. 47).

Martin and Panicucci (1996) suggest that nurses must set into place interventions that enhance perceptions of relevance regarding the lifestyle practice of regular exercise. Regular community-based exercise classes in churches, residential settings, senior centers, or other frequently attended community sites would increase the likelihood of regular participation in exercise.

Finally, it is clear that more and more African Americans are living longer and are in better health. It is imperative that health care administrators develop and plan culturally sensitive health care services for older African Americans from various social and cultural backgrounds.

Dying and Death

Through the legacy of slavery, segregation, and discrimination, African Americans have developed a perspective on death that is unique to this ethnic group (Mouton, 2000). End-of-life decision-making practices draw on religious characterizations of death. The majority of African Americans adhere to a Christian belief system, with 83% claiming a Protestant affiliation (the majority being Baptist) and 14% claiming Catholic affiliation (Ellison & Sherkat, 1990). These religious beliefs recognize a transcendent soul that rises to heaven upon death. African Americans also have a strong belief in a heaven not of this earth. Furthermore, most African Americans subscribe to an African American theology, a religious doctrine that views God as the fighting God of the Old Testament. It is important to realize that not all African Americans view death from a religious construct. However, religion does seem to play a significant role in African Americans view of death and dying (Mouton, 2000, pp. 74–75).

As a whole, African Americans are less likely than European Americans to approve of euthanasia. For example, in a study comparing attitudes toward life-prolonging treatment among 139 patients from a general medicine clinic, only 63% of African Americans approved of

stopping life-prolonging treatments compared with 89% of European Americans (Caralis, Davis, Wright, & Marcial, 1993).

African American attitudes to postmortem issues also are drawn from their shared historical, religious, and social experiences (Mouton, 2000). Overall, African Americans are less likely than European Americans to agree to organ donation. Most have a strong belief in the resurrection of the body, and this belief inhibits their willingness to donate organs because they will need their bodies to be intact on Judgment Day (Mouton, 2000, p. 80).

The effects of history and religious views, combined with individual life experiences and beliefs, influence African Americans' attitudes about the end of life. Clinicians need to bring to the table a degree of cultural sensitivity to eliminate some of the mistrust and fear that some African Americans might have when making end-of-life decisions. Addressing these issues might alleviate some of the apprehension that African Americans feel concerning end-of-life care (Mouton, 2000, p. 80).

Amish

Lawrence P. Greksa and Jill E. Korbin

ALTERNATIVE NAMES

Old Order Amish, Plain People.

LOCATION AND LINGUISTIC AFFILIATION

The Old Order Amish, the focus of this entry, live in more than 200 settlements in over 20 states of the United States and one Canadian province (Ontario). Approximately three-fourths of all Amish live in Ohio, Pennsylvania, and Indiana. The Old Order Amish speak Pennsylvania Dutch (a German dialect) within the group, use High German in their church services, and, with the exception of preschool children, are generally fluent in English. All of these languages are in the Indo-European language family.

OVERVIEW OF THE CULTURE

The Old Order Amish are an Anabaptist religious isolate. The Anabaptist (or Swiss Brethren) movement arose in Europe in the early 16th century. The Anabaptists believed in adult rather than infant baptism and refused to bear arms, both of which resulted in them being severely persecuted. *Martyr's Mirror*, a book found in most Amish homes, documents how hundreds of Amish were brutally executed for their religious beliefs.

In 1693 the group now known as the Amish separated from the Mennonites, one of the early Anabaptist groups, because they believed in a stricter adherence to the doctrine of *meidung*, or a total shunning of excommunicated church members. Following this separation, the Amish migrated throughout the German-speaking parts of Europe. They were highly regarded as farmers, but were severely persecuted for their Anabaptist beliefs.

To escape religious persecution, the Amish migrated to North America between about 1727 and 1860. There are no longer any Amish in Europe. In 1865, approximately one third of the Amish population split off from the more liberal Amish majority. This offshoot minority was given the name Old Order Amish in recognition of the fact that they wished to retain the old *Ordnung* (order of behavior), or set of orally transmitted rules that govern the behavior of the Amish.

There are currently over 150,000 Old Order Amish residing in the United States and Canada. The primary unit of organization for the Old Order Amish is the congregation, or church district, each composed of an average of 30 households and approximately 150 people. Each congregation is led by a bishop, with the assistance of two to three ministers and one deacon. Religious leaders are chosen by lot. Bi-weekly worship services are held in homes, and there is no separate church building. Each church district has its own *Ordnung*, which it reaffirms twice a year during communion. The *Ordnung* consists of both rules that are common to all Old Order Amish and rules that are specific to each congregation. If a member consistently violates the rules of the *Ordnung*, a hierarchy of responses is initiated, with the highest level of response being excommunication in association with *meidung*. At the most extreme, *meidung* requires all members of the congregation (and by extension all Amish), to have absolutely no contact with the shunned individual. However, any shunned person who repents is reincorporated into the community. The severity of the *meidung* has been decreasing in recent years.

Because each church district has its own *Ordnung*, there is variability from church to church. There is no higher level of religious organization above the church district, although church districts may be affiliated with one another based on similarity of their *Ordnungs*. The term settlement is used to describe a group of congregations located within the same geographic region.

Religion is the core organizing principle for the Amish and is embedded in every aspect of Amish life. A distinction between religious and non-religious affairs is meaningless for the Amish. Amish life is guided by several key principles, including adherence to adult baptism; *Gelassenheit* (acting with humility and simplicity at all times); conviction that true grace can only be achieved if one lives in isolation from the non-Amish world; an ethic of absolute non-violence; a belief that mutual aid is a key ingredient in maintaining the integrity of the

church; and a stance that states have no authority in religious matters. Separation from the world is fostered by the utilization of distinctive symbols, such as 18th century European peasant clothing, horse and buggy travel, and rejection of electricity from power lines. The Amish recognize that separation from the world requires the existence of strong community ties and, in particular, providing each other with assistance when needed. One of the better known examples of mutual aid is a communal barn-raising, but in fact, mutual aid is involved in virtually all aspects of daily life. For example, while families are expected to be self-sufficient in paying for usual health care costs, the church will assist in paying large hospital bills.

The Old Order Amish are often thought of as a static society living the lifestyle of 17th or 18th century farmers. They are, in fact, a dynamic society, with a history of carefully incorporating new technology that they decide is essential for economic competitiveness. However, the Amish are selective, refusing to accept anything that they feel might threaten their core beliefs. It must be remembered that this selection process occurs separately within each church district, resulting in variability among Amish communities in the degree of change that has been accepted.

The Old Order Amish have been undergoing a transition over the past 40–50 years from an economic system based primarily on small family-owned farms to one based on wage labor. This transition appears to be primarily due to the joint effects of a rapid rate of population increase in conjunction with an increase in the cost of farm land in the vicinity of the major settlements. The magnitude of this transition varies substantially between settlements. Some Amish wage laborers work primarily with other Amish men, either in Amish-owned shops or on Amish construction crews, but an increasing number of men now work in factories where they have intensive contact with the non-Amish (variously referred to by the Amish as “Yankees” or “English”).

THE CONTEXT OF HEALTH: ENVIRONMENTAL, ECONOMIC, SOCIAL, AND POLITICAL FACTORS

The Old Order Amish originated from a relatively small founding population and each major settlement has

remained largely genetically isolated from both other Old Order Amish settlements and the surrounding U.S. and Canadian populations for a little over 200 years. As a result, a number of distinctive recessive disorders have developed among the Old Order Amish, with some of them being unique to particular settlements. Other than these genetic disorders, the general pattern of illness and causes of mortality among the Old Order Amish are similar to those for the United States as a whole, except that accident rates related to agriculture and other manual labor occupations are probably somewhat higher.

Cost is one of the primary factors considered by the Old Order Amish when making decisions about health care utilization. Two aspects of cost are particularly important in the Amish context. First, because the Amish do not own or drive cars and rely on horse-and-buggy transportation, estimates of costs for doctor visits and hospitalization must include the need to hire a driver. This can be very expensive, sometimes equaling the cost of the physician visit. Second, due to Amish beliefs in self-sufficiency, separation from the world, and mutual aid, the Amish have generally rejected any kind of formal assistance that comes from outside the Amish community, including commercial health insurance. Obtaining commercial health insurance goes against the principle of separation from the world, implies an unwillingness to accept God's will, and operates against the principle of providing mutual aid in times of crisis. However, since most Old Order Amish have no compunction about using modern biomedicine, but at the same time reject commercial health insurance, this means that illness can potentially result in very high medical bills. This is particularly true for chronic physical conditions and for mental illnesses, which often require long (sometimes lifetime) periods of treatment, often in association with expensive medications.

The Old Order Amish traditionally have relied on personal savings and various mechanisms of mutual assistance within the immediate and larger Old Order Amish community to meet their medical expenses. This includes the use of Amish Aid health care plans that were established in the 1960s in response to the rising cost of health care and with the explicit goal of providing an alternative to commercial health insurance. Although the Amish Hospital Aid plans are essentially health insurance plans, they are not viewed in the same negative way as commercial health insurance plans because they involve Amish mutual aid rather than assistance purchased

from non-Amish. Amish Hospital Aid plans are thus acceptable to many, although not all, Old Order Amish. In recent years there has been a trend in some settlements of at least some of the men working in non-Amish commercial establishments to utilize the commercial health insurance provided by employers as part of their benefits package.

At least as important to the Amish in their selection of health care services as economic factors is the ability to obtain services from an agency that they feel can be trusted to respect Amish culture. If a provider is well thought of or makes a positive impression, news of this will spread in the community, and referrals will occur through personal networks.

The role of the Amish bishop in all aspects of Amish life, including the utilization of health care, cannot be overstated. He is the spiritual leader of the church district as well as the mediator between church members and the outside world. The well-being of the community is an enormous responsibility that bishops take quite seriously. Bishops either can be a barrier to or can facilitate access to health care. If a bishop promotes the view that preventive health care, such as childhood immunization, indicates a lack of faith in God and God's will, members of his church will be less likely to seek that care. If, on the other hand, the bishop is not opposed to such care, then individual members of the church are free to follow their own beliefs and preferences. Bishops can be a barrier to mental health services if they believe that mental illness is the fault of the individual, particularly if they believe it is due to shortcomings of the individual in his or her relationship to God, church, and community. Bishops can also be a barrier to specific agencies if they have heard that an Amish person has had unsatisfactory experiences with that specific agency. On the other hand, bishops can be an enormous asset to service delivery if they feel that a particular mental health care center is effective and can be trusted to respect Amish culture.

The most important point for health providers to understand about Old Order Amish society is that it is dynamic and that there is greater heterogeneity between and within congregations than might be expected by outward manifestations of conformity in dress and transportation.

The Old Order Amish diet reflects its Germanic ancestry and is thus characterized by large servings and an emphasis on meats, starches, and a wide array of pastries. Almost all Old Order Amish families, as recently

as 50–60 years ago, produced almost all their food themselves, with the exception of basic staples such as flour, sugar, and salt. All the food produced on the family farm was (and still is) grown with the minimum use of artificial fertilizers, if any at all. The transition from small-scale farming to wage labor appears to be associated with increased dietary diversity (due to the increasing purchase of foods, both raw and processed), but without any substantial change in basic dietary patterns. Most Amish families still have gardens for producing vegetables that will be canned and used throughout the year, but these foods now provide a relatively small proportion of food intake in most families. Instead, most families now purchase a large majority of their foods in the same grocery stores as their non-Amish neighbors. Similarly, whereas eating at restaurants of any kind was rare in the past, generally only occurring on long trips where no other option was available, many Amish families now routinely purchase foods at a variety of fast food and family restaurants.

MEDICAL PRACTITIONERS

Amish individuals rely on a variety of health care practitioners. The Amish obtain health care from biomedical practitioners, from a variety of complementary and alternative medicine providers, and through the use of home remedies. As long as core religious beliefs are not violated, individual preferences for health care providers are allowed and respected. Biomedical care is sought for both mental and physical illness, though the level of acceptance of biomedical care, particularly for mental health, varies across church districts. Many individuals simultaneously consider and utilize both biomedical and one or more different complementary and alternative (CAM) treatments for virtually all illnesses. There is also a reported tendency for the Old Order Amish not to utilize preventive health services to any great extent, although there is some suggestion that this is changing with increased access to insurance and recognition of the benefits of some preventive care, for example, childhood immunization.

CAM health care is sought either because it is believed to be efficacious or because of its lower cost. Practitioners ranging from reflexologists to chiropractors to herbal and vitamin practitioners may be consulted for health problems. A unique practitioner found in the past

(but apparently no longer used) amongst the Amish was the *braucher*, whose healing was based on repeating secret verses and charms that were passed on orally from braucher to braucher. Brauching was performed by both men and women and the braucher did not need to be in the same location as the ill person. Although many options are available, when an illness persists, recourse is usually toward biomedical care. Individuals may travel substantial distances, across states and to Mexico or Canada, to seek care from practitioners, both biomedical and CAM, whom they believe will provide a cure and/or who are more affordable.

CLASSIFICATION OF ILLNESS, THEORIES OF ILLNESS, AND TREATMENT OF ILLNESS

Health among the Amish is generally associated with an ability to perform one's work and the ability to eat well. Biomedical paradigms, classifications, and theories about illness and treatment are widely accepted among the Amish, keeping in mind that there is both individual variability and variability across church districts. Biological causes generally predominate in etiological explanations of physical illness. With respect to mental illness, most Old Order Amish distinguish between mental disorders that have a biological basis, and therefore can be treated with medication, and those that are not rooted in biology, and therefore require counseling. Amish families are very likely to accept biomedical treatments, regardless of cost, that restore normal functioning, but are likely to strongly resist treatments primarily designed to extend life when there is no hope of restoring normal functioning. The latter, but not the former, is seen as interfering with God's will by most Amish.

SEXUALITY AND REPRODUCTION

The fertility patterns of most populations, and certainly most modernized populations, are strongly influenced by parity-dependent behaviors that limit family size, particularly the cessation of fertility (stopping behaviors) once a couple has attained its desired family size. Populations whose fertility patterns are not influenced to any great extent by such behaviors, but are instead

primarily a function of the biological capacities of individuals to reproduce (fecundity) are referred to as “natural fertility” populations. The Old Order Amish possess very strong religious proscriptions against birth control and thus qualify as a natural fertility population. Unlike most natural fertility populations, however, the Old Order Amish are a healthy and well-nourished population that fully utilizes the available biomedical health care system. As a result, Old Order Amish females tend to have very high fecundities, resulting in very high fertility rates, with an average completed fertility (births to women who have completed the reproductive life span) of 7–8 children. Although there is no evidence that the Amish practice stopping behaviors, there is some evidence that at least some couples practice behaviors that influence the length of birth intervals (spacing behaviors). Such behaviors could eventually have an impact on total fertility rates but are not having a measurable impact at the present time. The transition to wage labor has thus far only resulted in a minor decrease in fertility.

Those few adults who either do not marry or are biologically incapable of having offspring (about 3%, similar to other populations) are considered unfortunate and sometimes have a hard time accepting this reality but are not stigmatized by Amish society. Fertility treatments and medical intervention are sometimes sought by infertile couples.

HEALTH THROUGH THE LIFE CYCLE

Pregnancy and Birth

Children are considered a gift from God. The Amish understand biological procreation, but view God’s will as involved in the number, gender, and health (including miscarriages) of their offspring. Abortion is strictly prohibited. Use of prenatal care varies by parity. In general, prenatal care in the biomedical sector is initiated earlier with first pregnancies and later with subsequent pregnancies. If, however, the pregnancy appears to be problematic (for example, if it involves bleeding), biomedical care is sought without regard to parity. Some Amish communities have created free-standing birth centers, generally staffed by a nurse with a physician on call. Birth centers were established to limit the cost of childbirth so that young couples would not limit family size due to the high cost of hospital births. Birth centers also provide an

atmosphere congruent with Amish preferences for minimal intervention in birth and cost considerations. Women and families are free to decide whether to use birth centers or hospitals for childbirth. The use of midwives, once common, is now rare.

Amish families are not opposed to the use of biomedical technology in childbirth, as long as it is congruent with Amish values and lifestyles. Fetal monitors are accepted, for example, because they may facilitate a better outcome for infant and mother. Prenatal tests, on the other hand, are considered a wasteful use of funds because all children will be accepted, regardless of any problems identified prenatally.

Infancy

Infants are both breast- and bottle-fed, with both types of feeding usually occurring on demand. Breast-feeding remains the ideal or preferred method of infant feeding, though women who elect to bottle feed are not criticized for this decision. There are no data on the length of breast feeding, but exclusive breast feeding seldom lasts for more than 3 or 4 months, at which time Amish families begin to provide soft supplementary foods, such as mashed potatoes, to infants from the dinner table. There are some reports that Amish babies often sleep in the same bed as their parents for the first few months but the frequency of this behavior is not clear. However, most Amish parents do move their babies’ cribs into their bedrooms for the first several months after birth, to facilitate infant care and feeding.

Infants are viewed as not yet having the ability to distinguish between right and wrong, and therefore, they should never be punished in any way for any act. Crying is a sign that an infant needs comfort and is never cause for discipline. Amish infants are primarily cared for by their parents, but older children, particularly older female children, will generally play an important role in child care, even in infancy.

There has been resistance in the past, particularly in the more conservative Amish groups, to child vaccinations, in the belief that vaccinations are attempts to thwart God’s will. This has occasionally resulted in outbreaks of disease within Amish communities. There may still be some resistance to vaccinations (as well as biomedical health care in general) in the most conservative groups, but the majority of Amish parents recognize the value of vaccinations. Additionally, while the Amish have their

own schools, some parents elect to send their children to non-Amish schools or to kindergarten prior to beginning Amish school in the first grade. These parents comply with immunizations that are mandatory for school attendance.

The attitude of Amish parents toward pediatric care for their children largely reflects their attitudes about preventive medical care for themselves. In other words, most Amish parents would not hesitate to take their child to the family doctor or the local emergency room for any disorder that they or their community recognized from past experience (e.g., respiratory disorder) could most effectively be treated with antibiotics or other medical treatments. On the other hand, few Amish parents would probably feel it necessary to take their child to a pediatrician for an annual health exam.

Childhood

Amish parents recognize that one of their most important functions is to raise their children to accept adult baptism and lead a good Amish life. Parents recognize that they must provide a good model of behavior for their children at all times and believe that they must be constantly vigilant to correct the behavior of their children whenever it deviates from the expected norms of the Amish community. Amish parents see the road to becoming Amish (and thus to salvation) as being straight and narrow. It is their responsibility to keep their children on this track. In particular, children are taught to be obedient, to respect authority, to work hard, and that the well-being of the group always takes precedence over their own well-being. The latter belief is summarized in a saying found in many schools: "JOY: Jesus first, Others second, Yourself last".

Amish parents believe that it is their moral obligation to firmly and consistently correct their children. This sometimes is viewed as requiring physical punishment (spanking). Spanking is seen as a necessary (even if disagreeable to the parent) tool for teaching obedience and raising good Christian children. However, any corrective action, including spanking, must not be performed in anger. Amish parents recognize that any corrective behavior performed in anger will not be an effective learning event, which should be the only goal of such behavior.

Toilet training generally begins at about 2 years of age and is approached like all other stages of life for children. Children are gently and calmly told what should

occur. They are not blamed for failing but rather are praised for succeeding. The general attitude is that this is what all children do, so you will too.

Since work is seen as central to both good health and being a good Christian, Amish children are assigned age-appropriate chores from an early age. Children are thus incorporated into the work ethic of the family and community, and are seen by others, as well as by themselves, as contributing to the general family welfare. There was never any difficulty assigning useful and meaningful tasks when most Amish were family farmers. Some Amish are concerned that one negative consequence of the transition to wage labor has been the loss of meaningful chores for the young, leading to potentially dangerous idle hands.

Adolescence

Amish children attend school through the 8th grade. The Amish have their own schools, but families may choose whether to send their children to public or Amish school. Upon completing school, all boys and many girls enter the workforce. Boys with fathers who farm will often assist with farm work, but many boys now work in Amish shops or on construction crews, or for non-Amish businesses. Girls generally work as domestics in both Amish and non-Amish homes. Sometime within in their late teens or early twenties, Amish youth must decide if they will accept adult baptism to join the Amish church.

Adolescence is often a difficult time for parents and youth. This is the stage during which youth must decide if they will make a lifelong commitment to join the Amish church, and during which they locate their spouse for life. During this period, a small proportion of Amish youth develop problems with alcohol, drugs, and tobacco. Although the parents of these youth are often portrayed as passively allowing their youth to misbehave, this is not an accurate description of what generally occurs. In the vast majority of cases, these problems resolve and the youth become baptized in the church. Currently over 80% join the Amish church. For a small, but unknown number of youth, these problems persist into adulthood.

Adulthood

There are no special health or medical issues that arise during adulthood for most Amish. However, due to the unique genetic history of the Amish, there is a high

prevalence of a number of genetic disorders whose symptoms often include a reduction in both cognitive and physical functioning. Given the Amish belief in self-sufficiency and in taking care of their own, such adults are very rarely placed into a medical or alternative care setting. They are instead cared for at home. As a result, it is not at all unusual for an Amish family to have an adult child living at home who cannot take care of him or herself. This adult child will be cared for by the parents until they are no longer physically capable of doing so or, frequently, until they die. At that time, the adult child becomes the responsibility of his or her siblings. Such an adult is only placed into a nursing or other medical facility if the family cannot provide adequate health care.

The Aged

Elders are accorded respect by the Amish. Elder individuals try to live as independently as possible, often moving into a small but separate house connected to one of their children's homes (*grossdawdy* house). In the past, this move would occur when the parents turned over their farm to one of their children, often the youngest male. Once the elderly person is no longer capable of living independently, they will generally either move in with one of their children or their children will take turns taking care of them. In very rare cases, the elderly are placed into a health care facility. Such cases generally only occur if the family is convinced that appropriate care can only be obtained in a nursing home.

Dying and Death

The Amish have well-established rituals associated with death, which is seen as an expected life transition, and associated with eternal salvation. As a result, death appears to be associated with less stress than in many societies. Life should not be prolonged by the use of heroic measures, and family members should be allowed, if at all possible, to die at home. If a hospital death is unavoidable, the dying person should be surrounded by family and church members. Once death occurs, family members are supported and relieved of their usual tasks and obligations. For example, neighbors prepare the home by clearing one room for a viewing and the other rooms for benches (which are normally used for church services) for those who come to pay their respects. If death occurs in the hospital, these preparations will

generally occur before the family even returns home. Neighbors and church members also perform all necessary household and farm tasks. Viewings and funerals are clearly recognized as symbols of community togetherness and are thus generally well attended, so much so that it is sometimes necessary to hold memorial services simultaneously at more than one location. There is generally an open-casket viewing for 1–2 days after death, after which the individual will be buried in one of the local family cemeteries. Non-Amish morticians prepare the body for burial and deliver it to the home, but the actual burial is performed by the church and community.

Argentine Toba

Claudia R. Valeggia and Florencia Tola

ALTERNATIVE NAMES

There are no current alternative names for the Toba, although Spanish colonizers used the collective term *Guaycurú* to refer to many indigenous communities inhabiting the Gran Chaco. The name *frentones* (“large foreheads” in Spanish) was in widespread use for eastern Toba bands in the early centuries of contact. The Toba call themselves *Qom* or *Qom’pi* (people).

LOCATION AND LINGUISTIC AFFILIATION

The Toba have inhabited mostly the southeastern and central areas of the Argentine Gran Chaco. The Gran Chaco is a vast region spanning 1,000,000 km² through Western Paraguay, Eastern Bolivia, and Northeastern Argentina. It is characterized by a patchwork of savannah grasslands and semi-arid forests, with forests along riverbanks. A marked East–West gradient of rainfall makes the western area considerably drier than the eastern. Seasonal changes in temperature are pronounced. Minimum daily temperatures below 10°C, with occasional frosts, can occur between April and September, whereas maximum daily temperatures above 33°C are frequent and are concentrated between September and March.

At present, Toba communities are found mostly in the provinces of Chaco and Formosa, although peri-urban

settlements around major cities in the provinces of Santa Fe and Buenos Aires are increasing in population numbers as well.

The Toba belong to the Guaycurú linguistic family, which also encompasses the Pilagá, the Mocoví, and the Mbayá (Caduveo) (Mason, 1963). However, the number of languages and dialects in what is collectively known as the “Toba” language is still controversial (Braunstein, personal communication). There are at least four mutually unintelligible languages spoken by Toba groups in the Gran Chaco. For example, even when sharing the same Guaycurúan language root, eastern and western Argentine Toba do not understand each other when they meet (Mendoza, 2002).

OVERVIEW OF THE CULTURE

European soldiers wrote about the Gran Chaco Indians as early as the mid-1500s (Schmidel, 1970). However, it was not until the early 1900s that ethnographic work began to be published on the Gran Chaco Indians (Boggiani, 1899; Karsten, 1926; Métraux, 1937; Nordenskiöld, 1912). All Gran Chaco indigenous groups used to share similar subsistence economies despite considerable language variation. The groups were traditionally nomadic or semi-nomadic hunter–gatherers, showing occasional horticulture (Braunstein & Miller, 1999; Mendoza & Wright, 1989). Division of labor was manifest among the Toba (Karsten, 1967). Female

gathering played a major role in Chaco economies, complementing the almost exclusively male activities of hunting, fishing, and honey collecting (Braunstein & Miller, 1999; Gordillo, 1995).

The Toba organized themselves in bands composed of groups of extended families. Traditional leadership was limited to extended family heads (Miller, 1980). Shamans stood out as healing specialists and intermediaries between the natural and the supernatural worlds and often also acted as leaders (Métraux, 1946; Miller, 1967, 1980). Monogamy was the main mating pattern. Toba women have had an independent and influential position in their society as a consequence of their central role in the family economy (Braunstein, 1983; Karsten, 1967).

The Gran Chaco Indians successfully resisted Spanish colonization and Argentine expansion policies until the late 1800s. Until the 1930s most communities still relied on foraging for their subsistence. During the last century, disruptions to their traditional lifestyle and ecological deterioration of the habitat forced many communities to migrate to urban centers and become sedentarized. At present, indigenous communities in the Gran Chaco fall along an acculturation continuum ranging from the more traditional, living in rural, isolated areas, to the more Westernized, living on the periphery of most non-indigenous towns in the Gran Chaco and in the cities of Rosario and Buenos Aires (Miller, 1999).

THE CONTEXT OF HEALTH: ENVIRONMENTAL, ECONOMIC, SOCIAL, AND POLITICAL FACTORS

Social, Economic, and Political Context

The Argentine Toba are experiencing a dramatic transition from their original lifestyle to the one offered by non-indigenous communities. The severe degradation of their original environment, together with overpopulation and overwhelming socioeconomic pressures, have considerably diminished the possibility of retaining the traditional subsistence model. The Toba have been described as “an egalitarian society with an immediate-return economy” (Mendoza, 2002). Nowadays, Toba communities present varying degrees of economic

dependence on the non-indigenous sectors. Rural communities, located in isolated areas by the Pilcomayo and Bermejo rivers, still rely heavily on the forest and wetlands for their subsistence. Hunting, fishing, and gathering items represent up to 75% of their diet during the wet season (Gordillo, 1995). During the dry season (winter), they rely on temporary jobs in nearby towns and on subsidies to large families from the provincial government. Families settled in peri-urban or urban communities only hunt, fish, and gather opportunistically, when they have access to transportation to the forest or the river. They subsist on the wages of the few men with public employment, on the unstable salaries of temporary jobs, and on governmental subsidies. Older women, usually accompanied by young children, may gather food and other goods from the non-indigenous population by asking door to door or simply sitting on the doorsteps of markets and food stores. Most women do not work for a salary and their activities revolve around childcare and household chores. Some women weave baskets or string bags, which they sell as handicrafts in the non-indigenous towns. The percentage of Toba families, both rural and urban, with unmet basic needs varies between 75% and 100%, depending on the province (Costanzó et al., 2001; Delucchi, Fontan, Grichener, & Wassner, 1996).

Integration of the Toba into Argentine social and political life has been extremely difficult. Education policy, as a basic premise of social equity, has not achieved much success. Schools are not integrated, even in urban settings. Furthermore, in the province of Formosa, some schools follow the “aboriginal modality.” In these schools, non-indigenous teachers teach a shorter version of the “regular” curriculum, while bilingual indigenous teachers offer native language writing and reading courses. Although this schooling modality was intended to bridge the language gap in the classroom, it is being seriously criticized by Toba delegates, who argue that their children’s opportunity to an equal education is being radically curtailed (Alegre & Francia, 2001). Up to this date, no Toba person in the country has achieved a professional (or equivalent) degree.

The political participation of all Chacoan Indian groups has been reduced to negotiation of their vote. Voting is compulsory in Argentina. Around national and local election times, political parties gain votes by offering food and clothes. However, there is an increasing tendency in urban settlements to form civil associations that can legally request community development funds

from national and international organizations. For example, a civil association formed in a Toba village in the province of Formosa is devoting its efforts to enforce the implementation of the *Ley Integral del Aborigen* (Aboriginal Integral Law), sanctioned in 1984 but never properly enforced (Alegre & Francia, 2001).

Health Situation

There are no current demographic statistics on the Toba, but the Institute of Aboriginal Communities of Formosa estimates a total of 70,000 Toba people living in Argentina. As recognized Argentine citizens, the Toba have access to free medical services at public hospitals and health centers. However, it is a common complaint that indigenous people are constantly discriminated against at these places. Complaints from Toba people range from being ignored at hospitals to being abused and mistreated. The provincial governments have acknowledged the lack of communication between indigenous and non-indigenous sectors in the arena of public health. In order to alleviate this situation they implemented a plan that includes training health agents at the local communities. These agents are in charge of monitoring the health of a given number of families in their own villages, reporting illnesses and new pregnancies, administering medicines, and promoting health education. The success of this strategy remains to be evaluated, but preliminary results seem very promising.

Epidemiological statistics for each life cycle stage are given below. Briefly, the current health situation of the Toba is that of poor communities in developing countries. Infant and child mortality are high and mainly a consequence of preventable causes, such as diarrhea, dehydration, and respiratory infections. Tuberculosis is prevalent across all ages and its incidence is more pronounced in rural communities. Cardiovascular problems and obesity-related diseases are becoming increasingly common among sedentarized, urban Toba.

MEDICAL PRACTITIONERS

Among the Toba there are different specialists who are in charge of restoring health (Karsten, 1932; Métraux, 1946, 1967). The main figures associated with medical therapy in the larger part of Toba communities are the shaman (*pi'oGonaq*) and the "curandero" (*ratanaGaq*).

Nevertheless, this distinction is somewhat artificial because the functions fulfilled by both often coincide in the same person.

In general terms, the shaman has the capability of curing and killing through the invocation and collaboration of his auxiliary spirits (*nataq*). The shaman's techniques include sucking out the illness that has materialized in an object, blowing on the area of the extraction, and praying to auxiliary spirits. The shaman's calling is restricted to those who have inherited from their father or grandfather the power that allows them to contact non-human entities from different spaces of the cosmos. However, certain people can develop ties with non-human beings who later endow them with the power to cure and kill and, therefore, to become a shaman (Métraux, 1967; Tola, 2001; Wright, 1997).

In contrast, the "curandero" is not characterized by the "cure-kill" ambivalence of his therapeutic powers. His knowledge allows him only to cure with plants, whose medicinal powers are known by the Toba through experimentation. In general, this category of medical practitioners includes persons that participate in the Toba Evangelic cults present in the communities (Miller, 1967; Wright, 1990). Their healings are often done by the extraction of evil spirits out of the sick body through collective prayers.

There are other specialists whose knowledge is more limited and who carry out only the healing of specific illnesses, such as those affecting infants and children. These practitioners acquire their knowledge after a personal experience related to the illness and the proximity to death. The acquisition of curative faculties often relates to the presence in dreams or in moments near death of some non-human being who gives to the ill person the power of curing one specific illness. Unlike shamans, the "curandero" and these specialists had at some time a relation with powerful non-human beings, but they are not in permanent contact with them neither in dreams nor when the healing takes place.

CLASSIFICATION OF ILLNESS, THEORIES OF ILLNESS, AND TREATMENT OF ILLNESS

Sources of illness include spells attributed to the will of shamans, non-human entities, or sorcerers, as well as to

the violation of restrictions imposed during specific moments of the life cycle (Métraux, 1937; Nordenskiöld, 1912). Illnesses caused by shamans can only be cured by other shamans. The healer extracts from the body of the victim the object sent by the aggressor shaman. Once the source of evil has been eradicated, the shaman introduces the object into his own body by friction, transforming it to a source of power for him. The non-human entities can generate illnesses in people by materializing in the forest, in dreams, or during the night. The type of illness varies depending on the entity. In general, if the illness is not cured by a shaman whose spirit can talk to the insulting entity, the ill person dies (Métraux, 1967; Wright, 1997). Sometimes, the illness is related to “natural” conditions (e.g., a cold, the flu, or a cough) or to visible causes (e.g., a cut or a wound). These problems do not need the immediate consultation of a shaman. However, if they persist, they are attributed to the actions of shamans, non-human beings, or sorcerers regardless of their initial empirical cause.

When the traditional therapy fails to restore health, the person or his/her relatives may resort to Western medicine physicians or to collective prayer at their local Evangelic church. The general scheme of consultation consists in alternating between the shamanic, evangelic, and biomedical therapies. Physicians often complain about the delay in presenting the sick person to the health center or hospital, and the consequent advancement of the illness. They also consider visits to the “curandero” or to the shaman obstacles to the biomedical treatment. Toba people see illnesses as the result of an intentional damaging action of human and non-human origin. Their view rests on a perception of the person in relation to others (humans and nonhumans) and of the body as an entity that is permeable to symbolic actions. In contrast, the physiological and anatomical knowledge on which occidental medicine is based consecrates the material body and the subject’s autonomy. These differences in the representations of illness and the body often cause confrontations between the shamanic and biomedical therapies and produce a constant conflict of interpretations and representations for the present-day Toba.

SEXUALITY AND REPRODUCTION

The concept of sex and sexuality among the Toba cannot be dissociated from more general social rules and

beliefs such as pre- and post-partum taboos, the social consequences of violating restrictions, the importance of the gestational process in the infant’s health, and ideas concerning family responsibility. After their first menstruation, girls had to submit to a ritual of initiation after which they waited some years before starting families of their own. This waiting period did not mean sexual abstinence, but rather was a time without childbearing responsibilities. Sexual freedom was, and still is, the hallmark of this period (Karsten, 1932; Métraux, 1946). In the past, adolescents who became pregnant without having a stable partner resorted to abortion or infanticide. Since these practices cannot be carried out nowadays, it is common to find a very high number of young unmarried mothers.

Gestation is considered a gradual process in which, through successive semen depositions into the woman’s body, the couple begins to engender a new offspring (Karsten, 1932; Métraux, 1946). In order to start a pregnancy, the woman has to receive a *baby spirit* from nonhuman beings (nowadays summarized by the image of God). During the first 4 months of pregnancy, the fetus is formed by the union of sperm and intrauterine menstrual blood. In fact, the same menstrual blood that was not discarded (because menstruation was interrupted by conception) contributes to the fetus’s formation in the womb (Idoyaga Molina, 1976/77; Métraux, 1937; Tola, 1999, 2001). This representation of conception and gestation illustrates the idea of reproduction as a process requiring the participation of both parents. This model also emphasizes that conception is only possible through the intervention of a nonhuman element, the presence of the *baby spirit*. The absence of this spirit is one of the causes of infertility, which is considered to be mainly the woman’s fault.

HEALTH THROUGH THE LIFE CYCLE

Pregnancy and Birth

Records from prenatal visits to local health centers indicate few pregnancy complications. The most frequently recorded pathologies are pre-eclampsia, eclampsia, and severe anemia, although no quantitative analysis of these problems has been undertaken. An analysis of weight gain during pregnancy in one Toba community indicated an adequate weight gain (mean = 9.9 ± 4.0 kg, range = 5.0–27.2 kg) (Valeggia & Ellison, n.d.).

The majority of births (72–95%, depending on the community) occur in hospitals. Official statistics indicate that in the most remote areas this percentage decreases to about 54% (Programa NacyDef, 2000). However, there are rural communities where all births take place at home with the assistance of experienced midwives. Post-natal records indicate that the incidence of pre-term births among Toba women is as high as among non-indigenous women in the area.

Information about changes in fertility patterns among Toba people is extremely scarce. A survey of reproductive histories of peri-urban Toba women indicated that age at first birth has been declining steadily during the last few decades (Valeggia & Ellison, n.d.). The mean age at first birth declined from 21.5 (± 4.5) years for women born in the 1930s and 1940s to 15.5 (± 1.0) years for women born in the 1980s.

Abortion and infanticide were common (Karsten, 1967; Vitar, 1999). Abortion was more frequently practiced among unmarried or widowed women and was provoked by mechanical means; that is, by striking the abdomen until the miscarriage occurred (Karsten, 1967). Since abortion is illegal in Argentina, the incidence of this practice at present is difficult to assess. However, hospitalizations due to incomplete abortions are among the most frequent reasons for hospitalization, mainly among women 25–34 years of age (Departamento de Información y Estadísticas, 1999). Women also drink herbal teas that are said to “make a delayed menstruation come right away.” The effectiveness of these herbs is unknown. Infanticide was practiced when infants were small, weak, or had an obvious birth defect. The second infant of a twin birth was also put to death, alleging evil intervention. At present, since most Toba follow a Christian religion in which infanticide is interdicted, direct infanticide is virtually unheard of. Yet, as in other societies, some child neglect cases that eventually lead to child death are suspected to be covert forms of infanticide (Gelles & Lancaster, 1987).

Interestingly, interbirth intervals, which now average 28 months (Valeggia & Ellison, 2001a), do not appear to be significantly shorter than those reported in early writings (Karsten, 1967). The Toba respect a postpartum sexual taboo by which couples do not engage in sexual intercourse until the child is able to walk by him/herself, which occurs around the 13–18 month postpartum (Tola, 2000). Given that they have, on average, 10 months of postpartum amenorrhea (Valeggia & Ellison, 2001a),

this taboo may represent a social mechanism to space births.

Infancy

Birth weight is within normal ranges in both urban and rural villages. A study of infant growth found that only 3% of infants born in a peri-urban village weighed less than 2,500g, while 85% weighed between 2,500 and 4,000g and 12% weighed more than 4,000g (Valeggia & Ellison, n.d.). The mean birth weight for this population was $3,380 \pm 498$ g (range 2,025–4,400g). A summary of vital statistics for the year 2000 showed that in the more rural communities, 8% of infants were born weighing less than 2,500g, 80% were born between 2,500 and 4,000g, and 12% weighed more than 4,000g at birth (Programa NacyDef, 2000).

There are no gender preferences among the Toba and both girls and boys receive much attention during their first year of life. The growth of infants is very good during the first year of life. In fact, the mean weight-for-age falls above two reference curves until 11 months of age, showing a peak around 4 months (Faulkner, Valeggia, & Ellison, 2000; Valeggia, Faulkner, & Ellison, 2001). Growth slows down progressively during the second year.

All infants are breastfed from birth until 2–3 years of age or until the mother becomes pregnant again. Breastfeeding can be defined as “on demand.” On average, babies are put to the breast three to four times per hour, even during their second year (Valeggia & Ellison, 2001a). Supplements to breast milk are introduced around the fifth month of life and typically consist of broths, noodles, and rice. In urban settings, formula feeding is starting to replace semi-solid food as the first supplement of choice. The mother is the principal caretaker during infancy (Cohn, Valeggia, & Ellison, 2001). On occasion and for brief periods, the father and older siblings can act as surrogates.

Infant mortality during the first year of life varies from 18.6 per 1,000 in peri-urban villages to 61.8 per 1,000 in rural communities (Programa NacyDef, 2000; Torres, Cabutti, & Palatnik, 1973). The most commonly cited causes of infant death in peri-urban settings are upper-respiratory infections and gastrointestinal infections (diarrhea and dehydration). In more isolated areas, peri-natal deaths appear to be the main cause of infant death (Costanzó et al., 2001).

Childhood

The Toba do not have set ceremonies to mark the beginning and end of childhood. Once children are weaned they are considered to be independent and they are no longer in permanent physical contact with the mother. Girls begin to perform some light household chores and child caretaking when they are 3 years old. However, most helping activities are performed when the girl is between 7 and 15 years old. Girls' helping behavior includes involvement in domestic work (e.g., cooking, cleaning, tending the fire, washing), economic work (e.g., weaving baskets, selling handicrafts), or child caretaking. Young boys are not expected to help, neither in household chores nor in childcare (Bove, Valeggia, & Ellison, 2002).

Toba parents have a very permissive attitude toward children. Children are seldom reprimanded or scolded and are encouraged to learn through experience. As soon as they start walking confidently, they join mixed-age peer groups. Play is unsupervised and children usually play at different locations within the village.

Early childhood (1–3 years old) is the life stage in which Toba children are most vulnerable to problems of malnutrition. A survey carried out by a pediatric hospital in the province of Santa Fe indicated a worsening in the grade of malnutrition in Toba children in successive hospitalizations for other pathologies (Gomez, Morales, Aride, Balonchar, & Jofre, 1998). During the second year of life the mean weight-for-age declines and it falls significantly below Argentine growth reference curves (Faulkner et al., 2000). According to Faulkner et al.'s study, a sharp increase in the percentage of malnourished children occurs around 15 months of age. The authors suggest that this dramatic weight loss may be due to a delay in introducing supplements, coupled with the unavailability of appropriate, nutrient-rich weaning foods.

In 1994, the Department of Epidemiological Surveillance of the Province of Formosa evaluated the nutritional status of indigenous children in the province (Ranaivoarisoa & Ventura, 1998). Compared with non-indigenous children and with national growth curves, Toba children 6–9 years old showed considerable growth faltering. Of the surveyed children, 11% were one standard deviation below the national average and 8.5% were two standard deviations below that average. The authors also pointed out that Toba children in rural communities were in better nutritional status than their urban counterparts, suggesting better diet quality in rural settings.

In the year 2000, mortality rates for children 1–4 years old averaged between 9 per 1,000 and 50 per 1,000 among communities (Programa NacyDef, 2000). The main causes of death for rural communities were tuberculosis, other acute respiratory infections, and malnutrition (Costanzó et al., 2001). In peri-urban settings, early childhood deaths are associated with acute respiratory and gastrointestinal infections. Among the most frequent reasons for medical consultation for young children are acute diarrhea and gastroenteritis, upper respiratory infections, and skin infections, mainly pyoderma resulting from scabies (Stevens, personal communication).

Adolescence

Adolescent girls start their reproductive lives at approximately 15 years of age. Vital statistics reports show high rates of adolescent pregnancy. In certain Formosan villages, as many as 44% of the Toba women giving birth in the year 2000 were 19 years old or younger (Programa NacyDef, 2000), with 3% being younger than 15 years old. These rates were similar regardless of the location and mode of subsistence of the community. Usually, adolescent mothers and their infants remain in the maternal home until the second or third child. The custom of fostering away children born to young girls is fairly common, particularly in urban settings.

Adolescent prostitution is common in peri-urban and urban settings. As many as 20% of the adolescent girls participating in a reproductive history survey conducted in a peri-urban village indicated that they worked as prostitutes in a nearby truck stop (Valeggia, unpublished data). During this survey, the girls indicated that they seldom used condoms during their sexual encounters. Prostitution, although illegal in Argentina, is not stigmatized among the Toba and it is taken as a temporary job.

Health information on adolescent boys is very scarce. With the traditional customs of hunting and fishing severely curtailed, and integration into the non-indigenous society being difficult, many adolescents turn to alcohol. Alcoholism, in turn, leads to violent accidents and death. Violent deaths were, in fact, one of the main causes of adolescent mortality in the last few years in the province of Formosa (Departamento de Información y Estadísticas, 1999). In some villages, adolescents and young adult men find support in the Evangelic church, where they participate actively in ceremonies. School

attendance is still very low among adolescent boys, although it is higher than that of girls. While girls are rapidly incorporated into a strong and supportive female network, boys tend to be left by themselves.

Adulthood

There are virtually no written reports on the health of adult Toba before Spanish colonization. In general, they were described as strong, robust people. Early writings by physical anthropologists noted that the Toba, together with the Patagonian Indians, were among the tallest South American Indians, with an average height of around 169 cm for men and 156 cm for women (Lehmann-Nitsche, 1908; Paulotti, 1948). Interestingly, current adult height is not significantly different from these figures.

At present, very few hospitals discriminate health reports based on ethnicity. The data presented here were obtained from districts in which the indigenous population represents the majority of people (Departamento de Información y Estadísticas, 1999). Still, the data should be regarded as tentative.

Tuberculosis is widespread among Toba adults, particularly those living in more isolated communities. The incidence of Chagas' disease increases east to west in the Gran Chaco, favored by the dryer climate and the prevalence of traditional mud and palm huts in rural areas. Among the urban Toba, the main morbidity causes include hypertension, urinary infections (mainly women), gall bladder calculi, and gastrointestinal infections. As many as 80% of adult members of a rural community in the province of Chaco presented with pterygium and hypervascularization of the ocular conjunctiva (Torres et al., 1973).

Although the incidence of gonorrhea is known to be high among Chaco indigenous groups, other sexually transmitted diseases are dramatically underreported. In a survey conducted in 1998, 75% of the adult women in a Toba community of Formosa reported current or past symptoms of vaginitis and other urogenital infections (Valeggia, unpublished data). Records from city hospitals in Formosa and Chaco show a very low incidence of HIV infection among Gran Chaco indigenous people (Cravero, personal communication), but HIV tests are not performed routinely and underreporting might be significant.

The Aged

Aged people had an important role in Toba society in the past. They were the ones teaching traditions to the young and all important community decisions, including marriages, had to be approved by a council of elders. Post-reproductive Toba women also contributed considerably to the community economy, carrying most of the burden of forest-gathering. Today, changes in lifestyle are also accompanied by a change in the role of elders in the community. It is a common complaint of old people that the young no longer respect them and that that is the cause of a gradual loss of their ethnic identity.

It is difficult to accurately assess the age of older Toba people. Even though most have identification documents, these are not reliable sources of dates of birth. In any event, demographic data from some villages show a dramatic drop after age 55 for both men and women. The main cause of hospitalization for older Toba is pneumonia and other respiratory infections. Mortality records from the Formosan Ministry of Human Development indicate that the main causes of mortality among older Toba adults are tuberculosis, pneumonia, and various types of tumors.

Dying and Death

The Toba do not consider illness and death as natural processes of the living organism, but rather think they are related to the intentional action of another human being or of some nonhuman entity. These actions cause a degeneration of the body that leads to death if they are not countered by the therapeutic methods of shamans and healers (see above). At a corporal level, death is produced when the image-soul of the person (*lki'i*) definitively leaves the body. After this moment and during a variable period of time (from 1 month to several years), the *lki'i* remains on earth near the person's family and his/her body. During the first month after the death of a relative some rules and restrictions must be respected to avoid the spirit of the dead person appearing in dreams or during incursions to the forest. This spirit might attempt to take away the spirit of a member of his/her family. For this reason, when a person dies, the closest relatives often appear oblivious to the death of the person. The dead person's belongings are buried or burned after the burial and the house in which he or she died is destroyed. Moreover, relatives avoid even talking about the dead, pronouncing his or her name, or crying for them. These attitudes or actions are observed by the spirit of the dead,

who—even if they are physically dead—have the power of deciding and acting in relation to the existence of the living persons.

CHANGING HEALTH PATTERNS

The Toba are undergoing a rapid nutritional transition from a hyperproteic diet to a hypercaloric one. Entire communities that used to rely on foraging or home-based cultivation are now depending on the processed foods available in city stores. Their diets are based on what is relatively inexpensive, such as processed sugars, starches, and fats. In addition, these changes are occurring together with an increasingly sedentary lifestyle. This pattern has become increasingly common in all of Latin America (Peña & Bacallao, 1997; Uauy, Albala, & Kain, 2001).

A serious consequence of these lifestyle changes is an increase in the rate of obesity in urban and peri-urban communities. Forty percent of the adult women in a peri-urban setting were overweight or obese (Body Mass Index >26 kg/m²) in 1998–99 (Valeggia & Ellison, 2001b). Although there is no systematic data on changes in incidence of cardiovascular disease or diabetes in this population, hypertension, and gall bladder problems are ranked high within the 10 most-cited reasons for doctor's appointments at local health centers and hospitals (Departamento de Información y Estadísticas, 1999). As is the case in many Native American groups in North America, the Gran Chaco Indians may be more sensitive to the metabolic derangement associated with obesity. The presence of obese adults and undernourished children in the same household represents a serious public health challenge that will require a review of nutrition intervention programs and a culturally sensitive health education plan (Valeggia & Ellison, 2001b).

Badaga

Paul Hockings

ALTERNATIVE NAME

Burgher (early 19th century only).

LOCATION AND LINGUISTIC AFFILIATION

The Badagas are peasant farmers only found on the Nilgiri Hills, a small district in the northwest of Tamil Nadu State, India, where they have lived for the past four centuries. They inhabit over 400 villages which are

not multi-caste; these are mainly between 5,500 and 6,800 ft in elevation, and lie about 11°N of the Equator. The people speak Badaga, a language of the Dravidian family closely related to Kannada (Kanarese) and Kurumba; all three are in the South Dravidian subfamily.

OVERVIEW OF THE CULTURE

A community of refugees from the plains to the north, the Badagas had to cut fields and village sites out of the forests,

mainly during the period 1565–1800. Some swidden cultivation continued until the 1870s. In fields near the villages they grew millets, barley, wheat, and various European vegetables; also cows, buffalo, and poultry were kept. During the 20th century potato, cabbage, and tea became major cash crops, and many educated Badagas moved into urban, professional jobs. Today, except for some 3,000–4,000 Christians, the Badaga community consists of about 150,000 Hindus (2003), of whom a small minority are Lingayats.

Most villages have only several hundred inhabitants, some much less. Each village is surrounded by fields, and usually includes one or two Hindu temples in addition to the several rows of houses and a few cowsheds. These usually lie along the slope of a hill on its leeward side, as protection from the westerly monsoon. Most villages have piped water coming to communal taps, but not long ago the water supply was a nearby stream or at best an open channel running into the village from a stream. Recent water shortages caused by irrigating fields for the first time have led to some villages depending on water trucks. Each village has a green, used for grazing calves and as a danceground or playground, and for certain ceremonies.

The Badaga society was traditionally a chiefdom, and they are still nominally under a paramount chief. This is a hereditary position, always held by the chief of one particular village. Below him are four regional headmen, each traditionally in charge of all the Badaga and Kota villages in one quarter of the Nilgiri Plateau. At the most local level a village has its own headman, and a number of contiguous villages make up a commune with its headman too. At each level—village, commune, region, and Nilgiri Plateau—there is a council for Badaga affairs, its juridical authority now greatly undermined by modern lawcourts and the Indian legal system. Prior to the 20th century disputes would have been settled at one or another level of this council system; major land disputes, ceremonial improprieties, and cases of murder probably reaching the Nilgiri-wide council.

The community is divided into a number of ranked phratries which are mainly endogamous. A conservative Lingayat group forms the top phratry, the Wodeyas, while the headmen's former servants, the Toreyas, are at the bottom. Between these two extremes there are one other phratry of vegetarians and three more of meat-eaters. The Christian Badagas, springing from the first conversion in 1858, now constitute a separate meat-eating phratry. Each phratry is made up of several exogamous clans, which in turn are made up of various lineages.

THE CONTEXT OF HEALTH: ENVIRONMENTAL, ECONOMIC, SOCIAL, AND POLITICAL FACTORS

A modern biomedical listing of the most prevalent diseases among Badagas recently would include pneumonia, typhoid, dysentery and diarrhea, diphtheria, smallpox, rickets, intestinal parasites, tuberculosis, anemia, food deficiency diseases, conjunctivitis, and various skin diseases.

There is now an urbanized middle class consisting of educated Badagas who work in a wide variety of professions. Thousands of Badagas have graduated from South Indian colleges and universities, including medical schools. Modern biomedicine, practiced at several local hospitals and numerous clinics, is only one attractive profession, for doctors and nurses: many other graduates have been drawn toward law, teaching, administration, banking, plantation agriculture, and other specialized professional callings. As well as a hospital in each of the four neighboring towns, large villages have clinics staffed by the Tamil Nadu government medical department. Family planning campaigns have reached into most villages in the past 30 years. The relatively high rate of literacy in the late 20th century meant that thousands could and did read medical advice columns in regional newspapers or magazines, either in Tamil or in English.

MEDICAL PRACTITIONERS

Although today the only practitioners found in the Badaga community are likely to be doctors and nurses trained in biomedicine and working in the state's health-care system, until perhaps 25 years ago there were therapists still functioning in an indigenous, mainly herbal system. While most of these were unschooled general practitioners, there were also some specialists in many of the villages. The commonest was the midwife, always an experienced older woman; a big village might have several. In addition one could encounter exorcists who were necessary in instances of ghost possession; bone-setters; and some specialists who only handled one type of illness, such as fevers. Although by the end of the 20th century the therapists had disappeared, some of the other specialized practitioners remained, for their services might still be needed. These

thus included midwives (now with some medical training), exorcists, and perhaps specialists handling a particular kind of illness.

CLASSIFICATION OF ILLNESS, THEORIES OF ILLNESS, AND TREATMENT OF ILLNESS

Since there are no Badaga medical colleges and no textbooks (this having been a non-literate society until the late 19th century), there has been no formalization of medical theory except by the present author.

Indigenous belief was based on a lack of knowledge of the internal organs, especially in the vegetarian phratries where nobody had ever butchered an animal. As a consequence, it was not known that the heart existed, and other anatomical knowledge was similarly inadequate. The following outline of human physiology was given to me by an elderly male therapist who had never been to school.

The chest contains one organ, the *nenju* (which would in biomedical terms encompass both heart and lungs), which is of no great importance in the Badaga understanding. For them the central organ is the belly. There are some 16 organs in the body and nearly all are somehow connected with the belly: this is responsible not only for digestion but for blood circulation, reproduction, breathing, smell, even sights and speech. Food goes through the mouth into a tube, and then passes down to a stomach. As with cattle (!) there is a second stomach adjoining it, where the body stores liquids, which reach it from the mouth by a separate tube. A third tube links the two stomachs. The mixing of food from these two stomachs occurs in the belly, which lies around and below the navel. Here blood is prepared from the mixed food and liquid, and is sent to all parts of the body through arteries. The actual digestion is assisted by worms about the thickness of a pencil, which live in the belly and eat the food there. They are essential to keep a person alive. An important unit within the belly is the colon (*karu*), which must remain erect, otherwise the person will die. When breathing occurs, the air passes through the nostrils, the mouth, the eyes, and the ears, by a single tube to the *nenju*, and then on to the belly, where it is needed by the worms for digestion. The evidence for this state of affairs is in

flatulence, and in the occasional discovery of worms in someone's stool. The head is important for sense and understanding, and it is recognized that the brain does the thinking. It is not, however, linked with the eyes, ears, mouth, or any other organ. Speech originates in the belly, and the tongue helps in forming the words. The larynx has nothing to do with speech, being simply the gateway through which the several tubes pass carrying air, food, and liquid. The existence of a skeleton is recognized, and it is seen as God's gift to help people stand upright and work.

A biomedical model would recognize heuristically several rather separate subsystems: the nervous system, the reproductive system, the digestive system, the circulatory system, the skeletal system, the lymphatic system, etc. The Badagas in general only see one system operating, but there is a somewhat separate subsystem for reproduction. God has distinguished between the two sexes by giving facial hair to men, breasts to women, etc., and semen only to men but menses only to women. Inside the belly of women, but not men, there is a bag where the baby grows. The fetus is formed entirely from a man's semen, and so copulation is essential for a woman to conceive. After digestion has occurred in the pregnant woman's belly, blood goes to the fetus and it grows on this. After birth milk flows from the belly to the breasts, and it is sucked out through the nipples, which are thought of as the outer part of the *nenju*.

Badagas do not recognize any particular god as causing all disease, or being able to cure it. Five diseases, however, are brought by five "sister goddesses." These include the dreaded smallpox, as well as measles, chicken-pox, rubella, and acute conjunctivitis. Cholera is also caused by an angry god, but is thought to be contracted in the plains. Mental illness, like a form of hysteria, is caused by an ill-intentioned ghost or bad spirit getting into the patient, usually a woman. Non-Badaga sorcerers or shamans, commonly said to be Kurumbas, can cause an evil spirit to enter a person. Other mental problems may also result from the sins of one's ancestors. People sometimes think of "bad blood" in parents as causing abnormalities in their children. Some illnesses are caused by personal uncleanness, or bad diet. Eating too quickly, or having insufficient dairy products, are thought to cause the body to "over-heat" and thus bring illness; buttermilk is a common cure. Over-exertion, including sexual excesses, can bring illness, usually because the colon or an artery gets dislodged, it is said.

Among unweaned infants, the odor that accompanies coitus, or the “bad wind” that emanates from a corpse or from childbirth, can bring sickness and even death. Bites, stings, and burns are recognized as being caused by obvious external agents; but depigmentation of the skin is thought to be caused by “the bite of the blindworm” (which is actually harmless). Some more modern theories of causation may have their origin in scientific medicine. For instance, some people recognize that tiny germs cause tooth decay; and in the case of plague it is thought that mosquitoes carry the disease from rats to people. (This may be the effect of a mosquito eradication program on the lower slopes of the hills.)

As with any medical system, the techniques of treatment depend on the diagnosis. As there are many dozens of recognized ailments, there are dozens of distinct treatments, usually involving the swallowing of a herbal medicine made up by the therapist from freshly gathered wild herbs from the neighborhood. The general term in Badaga for “a medicine” is *maddu*, but it should be understood that this word also encompasses “magical potion,” “opium,” or “poison.”

SEXUALITY AND REPRODUCTION

It is by God’s grace that only women produce milk. Semen is likewise produced by the belly, whence it passes to the penis during coitus. The function of the testicles is simply to act as a sort of counterweight to aid with the erection. Since the fetus is formed from the father’s semen, copulation is essential before a woman can conceive. Her subsequent role is to nurture the developing fetus with blood from her belly.

Adolescents may engage in some premarital sexual behavior, for example in cowsheds or in the forest, but modern requirements of schooling tend to reduce the opportunities for this. In previous times young people might spend much of the day watching the fields or the herds, and many opportunities for casual sexual relations occurred. Today girls expect to retain their virginity until marriage. At the same time, the usual age at marriage has increased from about 12–13 for girls to around 20 or more, and young men now marry in their early 20s too. The latter are now likely to have their first experiences with urban prostitutes, or sometimes with their elder brothers’ wives.

HEALTH THROUGH THE LIFE CYCLE

Pregnancy and Birth

If a woman has not menstruated for 40 days she will be taken to a midwife or other therapist, who will tell from the breasts whether the woman is pregnant, as the nipples become darker. Other signs are if she feels lazy about work, even about walking, experiences nausea, does not want to eat, or requires unusual foods. If pregnant, she should have no intercourse during the first 3 months, and thereafter seldom. The above signs tend to disappear after 60 days. Thereafter there are certain restrictions on the couple. The man should grow a beard and moustache, but should not kill a snake lest its spirit enter the fetus. The woman should not eat red onion or garden marrows, or the baby will have itches when born. The woman must not wash her clothes or put on clean ones, must not cross any large river, or the hamlet boundary, must not go to any festival where she might see something interesting. These restrictions only last till the 90th day. After that time the woman can become active again and eat what she likes. By now, she can feel something in her stomach. From the start of the fifth month the fetus moves occasionally.

In the fourth, sixth, and seventh months the woman can be carefree, and in the even numbered months, the fourth, sixth and eighth, she may cross the hamlet boundary and visit her father’s house (Badaga villages are exogamous). If her eyes turn red, she gets diarrhea, feels uneasy, and her lips itch, then these are signs that the body is “heating”: excess of “heat” may cause a stillbirth in the seventh or eighth month. Therefore the woman is given buttermilk or butter. Buffalo milk freshly milked into a pot in which there is some lime juice is another cure, if drunk immediately. This is given to her every morning for two or three weeks before breakfast.

In an odd-numbered month of the first pregnancy, generally the fifth or seventh, the couple go through a thread-tying ceremony on an auspicious day that confirms their marriage. The relationship has become stable with the pregnancy, although this is not mentioned during the event. Thereafter divorce becomes more difficult. Supposedly the couple sleep side by side that night, with a stick between them to symbolize the coming child, and they have coitus.

In the ninth month the woman is usually at her father’s house, and this is where birth should occur. In the ninth or tenth month she will give birth in the presence of

a midwife and a few other women, including some young ones interested in learning the craft. (Small girls are usually not invited.) If the pregnancy takes longer there may be twins; one of these is likely to be a weaker child. But both are cared for. In cases of a particularly difficult birth the woman is given a mixture of dried ginger, pepper, cumin, clove, crude sugar, sweet flag, coffee powder, and clarified butter, mixed in particular proportions with water. It is said that long ago a cesarian section might be performed sometimes, using the small knife with which the umbilicus is cut. Some midwives also know how to reach into the womb and remove a dead fetus. Should the woman die in childbirth, the fetus must be cut out before her funeral.

Male relatives, including the husband, must wait outside during the birth. If there are difficulties they will offer advice or go and fetch other women. Because the act of birth was considered impure it would not occur traditionally inside the house but on the veranda. Now it generally does occur in one of the outer rooms, but almost never in a hospital. The door is kept closed: the woman's body is naked during delivery, though a cloth may be draped over her shoulders for warmth. In earlier times the grindstone was in front of the woman, to hold onto. Now it is not unusual for the woman to lie down to deliver, in the modern way. Commonly the woman kneels on the floor, with a girl in front to support her. Her legs are apart, and the midwife is behind her to catch the newborn before it touches the floor. Gingelly oil is sometimes applied to the vagina to ease the delivery, and the midwife will check to make sure the umbilical cord is not around the baby's neck. Some can put a hand inside to help the baby out, but only as a last resort in a difficult case. If the feel of the stomach surface tells the midwife the baby is in the wrong position, then the mother is made to place her head on the pounding stone, which is set into the floor, and five or six women support her as she balances there, upside down with her legs in the air. The knowledgeable midwife then shakes the woman's legs until the baby comes into the right position for birth.

The newborn is laid on sacking on the floor. The umbilicus is tied with a piece of string (formerly a thread lampwick) some 8 cm from the belly. This curtails bleeding, and then the cord is cut with a penknife or razor blade, or formerly with a reaping blade. A couple of handfuls of cold water are poured on the infant's shoulders or dabbed on with a cloth. In particular the left shoulder is wetted if a boy, or the crown of the head if a girl, to make the child

strong for carrying loads. It is then bathed in very hot water. Groundnut oil (formerly castor oil) is put all over the body. The mother also takes a bath in very hot water, and then sits to drink some cold milk. Some women now take a sip of brandy. A little opium in a cup of tea or coffee is a cheap alternative. A further dose of opium may be given on the following two days (it was a traditional Badaga product). The new mother is also given a little palm jaggery (crude sugar) and three or four cloves of garlic; one piece is put into each of her ears. The child is then given back to the mother, its face to her right breast (right is the auspicious side). It is given a drop of groundnut oil to drink, and then begins to suck. A lime is then cut in half, and on each cut surface someone puts fresh cowdung, a blade of Bermuda grass, and some clarified butter. An old lady takes the first half and runs it down the right side of the baby, not quite touching it, as she says: "This child belongs to both the father and the mother" (who remain unnamed). Thus the joint parentage is asserted. The half lime is sucked by the mother, touched to her child's mouth, and thrown away. The same thing is done with the other half lime, running it down the left side of the baby. Lime juice is thought to ward off evil spirits. The after-birth comes half an hour later. In modern practice, some midwives, if properly trained, pull the afterbirth out. It is carried outside and buried somewhere distant from the village. A man may dig the hole but would not touch the polluting afterbirth.

Infancy

After the child has sucked the breast for the first time, he or she is given a small piece of bezoar. After a few days some burnt rhizome of the sweet flag is also fed to the baby. After a year or two the infant might be taken on a pilgrimage to a nearby temple, where during an annual festival mendicants were given consecrated pieces of banana mixed with crude sugar. This they chewed a little, then spat into the hands or mouths of devotees, who either ate it themselves or fed it to their children because it was believed to cure all disease. The main food of the infant is mother's milk, but the child will be weaned at about one year. If the mother eats too many sweet things, she may transmit small worms to her baby through the breast milk. She avoids going near any corpse, or the smell of another woman's birth, or the odor of anyone other than her husband in the early morning, or hearing any frightening story, for fear that any of these "bad winds" may

cause her flow of milk to stop. Anyone who comes to look at the baby just after having had coitus, and without bathing first, puts the baby at severe risk; as does someone who has just come from a great distance, if he does not first rest outside the house for awhile.

Three or four days after the birth the mother begins to bathe her baby, perhaps with help from her own mother. The baby is bundled up in old rags, and always kept warm. Care is taken about keeping the face clean, mainly so that a cat will not harm the baby in some way. During the first few weeks the cranium is elongated by manipulation, using oil, though the practice is now rare. Early anthropologists, not knowing of this, commented about the anomalous dolichocephaly of a people whose origin was known to be among the mesaticephalic and brachycephalic peasants of Mysore.

Until the ninth day a baby is thought to have no understanding, though it has vision. After the 40th day mothers try to make the baby laugh, and also take something away to make it cry: this to determine that the child will not be dumb. While a child might be born dumb it cannot be born deaf; so until the fifth or sixth month people are careful not to make a loud noise near the child which could induce deafness. After the third month of its life, the mother will resume her normal work duties.

Childhood

At about the fifth month the child is made to sit up, surrounded by blankets. In the sixth or seventh month he will start to crawl, and will then be allowed to sleep on the floor. People encourage him to crawl, stand, and walk. At around 12–18 months children begin to talk. For common things like sleep, mat, rice gruel, etc. there are baby words that people use. It is primarily the old people in the household who educate their grandchildren and great-grandchildren. The parents may be out working in the fields much of the day. Now that most children are going to school, this interaction with the elderly mainly occurs in the evenings.

Small children are given relative freedom in their actions, and are usually disciplined with threats: the coming of sorcerers, ghosts, mendicants, demons, or vaccinators to take them away are common threats. Otherwise kindness and outright bribery are lavished on small children. Now between the ages of 5 and 7 years they find themselves being sent off to school. Virtually every village larger than a hamlet has at least one; some have several,

and recently private English-language elementary schools have sprung up here and there, as Badagas place much stock in good education today. Children become enculturated partly through school activities, partly through doing things in the village with their friends, and partly from tales their elders tell them. As elsewhere in India, small children look to their older siblings for guidance and advice. Outdoor group games are popular with the very young, including hopscotch, string figures, and board games.

The progress of childhood is marked by a series of ceremonies: naming, before the 40th day of life; head shaving in a temple, within a year of the birth; ear boring, often done at the same time; the first tooth ceremony, if a boy gets his first tooth in the upper jaw; nostril piercing, done in a girl's ninth, eleventh, or thirteenth year on an auspicious day; tattooing, formerly done on girls at about the start of puberty; milking initiation for boys, which is no longer done now that most people have no cattle; and initiation for those boys who are of the Lingayat sect. Otherwise there is no observance for a boy's puberty, but complex ones for a girl's.

Adolescence

Menarche usually comes at the age of 14 or 15, sometimes earlier. Girls at about puberty used to be tattooed on the brow, shoulders, and forearms with distinctively Badaga patterns. The tattooing was done, without any ceremony, with a thorn from one of two local plants or, more recently, with pins or needles, using soot scraped from the bottom of a pot for color. Traditionally, a girl's initiation into adulthood was essentially her marriage ceremony, which would occur at about menarche. Nowadays, child marriages do not occur. There are no maladies recognized as specific to the period of adolescence, and no bodily mutilations mark any male initiation ceremony.

Adulthood

Adult women might add further tattoos to the shoulders, forearms, or back of the hands while they were in the menstrual hut. Each village of adequate size would have its own hut, or several small hamlets would share one, until the mid-20th century. There is no theory of why menstruation occurs: it is simply God's will. A woman should be segregated from food preparation activities for six days.

The Aged

Old people are shown respect, but Badaga proverbs suggest that people are well aware of the infirmities that come with advanced age: "A man above sixty years is said to have half-sense"; "If the lord speaks, the whole village quakes; if an old man speaks there is a sound of babbling"; "The activity of a 20-year-old is pleasure-loving; the activity of an 80-year-old is that of old age." Cynical though all of these may sound, respect is enjoined: "If a person cannot see, hear or walk, as he is such an old man, you must first ask his permission to do anything." It is believed that if a man wears gold his lifetime will lengthen; whereas if he sees two crows in sexual congress then he will die within a year. If he feels he is too young to die, then he can countermand the omen by going up a hill near his home and shouting out to the villagers that he—mentioning his name—is dead. (A woman might also persuade a man to do this for her.) Making sure no one sees him, this act will have the effect of persuading some neighbors to go to his house to pay respects to the corpse; and this process of misleading the mourners is supposed to prolong life.

Dying and Death

When death is thought to be approaching, messages are sent out to other villages inviting relatives and friends of the dying person to come and bless him or her. They bring gifts of grain and milk, offer their blessings, and hope to receive some from the dying person too. Only very close relatives will wait there for death to occur.

Once a person has died, the village headman is called, and a senior member of the family tells him, "This corpse is for you." Accordingly, it is the headman who arranges a communal funeral for the deceased and not his own family, though they will meet much of the expense. Another noteworthy feature of the Badaga funeral is that priests are not involved ceremonially. Most Badagas cremate their dead, but the high-status Lingayat groups and the Christians bury their dead in cemeteries.

The funeral is the most complex of all Badaga ceremonies, and sometimes used to take several days to complete. Now it is always done in one day. It has to symbolically handle the public-health problem of a corpse in the house; the emotional trauma felt by still living members of the bereaved family who must all adjust their lives; and

the social trauma occasioned by the loss of a usually elderly village resident. A full account of the Badaga mortuary rites and their symbolism is included in Hockings (2001).

CHANGING HEALTH PATTERNS

Although several hospitals have been in the district since the mid-19th century, Badagas rarely went near them unless a patient was clearly dying and beyond all hope. Until the discovery of antiseptics in the 1870s, such hospitals were themselves a serious threat to health anyway. By the time this Badaga system was studied by the author during 1963–1972, only a handful of elderly practitioners remained alive in the Badaga villages. Once the prime informant, K. Sithamma, died (July 25, 1976), there were scarcely any other active general therapists, as Badagas were generally availing themselves of biomedical procedures in the local clinics and hospitals, or in some cases using Ayurvedic (q.v.) medications and therapists, and their midwives were going through a short program of training. But for the one book published on Badaga medicine, the system would quickly have become forgotten.

BIBLIOGRAPHY

Note: There are only one book and one article on the Badaga medical system:

Bangladeshis

Darryl J. Holman and Kathleen A. O'Connor

ALTERNATIVE NAME

Bangladeshis are often called Bengalis.

LOCATION AND LINGUISTIC AFFILIATION

Bangladeshis make up the largest ethnic group of The People's Republic of Bangladesh, located in Southern Asia. Most Bangladeshis live in the Bengal Basin, an alluvial plain of the Jamuna River, the Padma River, and the Meghna River. Bangladesh shares borders with India to the west, north, and east, and a small southeastern border with Myanmar (Burma); the southern border is the Bay of Bengal.

The term *Bangladeshi* refers to both a national identity (a citizen of Bangladesh), and a member of the Bengali-speaking majority of Bangladesh. The latter use excludes about 250,000 Biharis and about a million tribal people located in hilly regions along the eastern borders of Bangladesh (Bertocci, 1984). A defining characteristic of Bengali culture is the language Bangla (or Bengali), so that a *Greater Bengal culture* (Basu & Amin, 2000) includes West Bengal, India, and parts of Assam, India.

Bangla is the second largest language spoken in South Asia, after Hindi-Urdu. The language falls on the Indo-Aryan branch of the Indo-European family of languages. Bangla is closely related to other South Asian languages such as Assamese, Hindi, and Nepali. Written Bangla is derived from Sanskrit (Maloney, 1974).

OVERVIEW OF THE CULTURE

The Bangla-speaking majority of Bangladesh numbered about 126 million in 1999. About 87% of Bangladeshis are Sunni Muslims, 12% Hindu, and 1% Christian, Buddhist, and animists (Bangladesh Bureau of Statistics, 2001).

Bangladeshis share deep cultural roots with many other people in South Asia. These shared ideas and traditions transcend the major religions that have swept

through the Bengal Basin, including Hinduism in the first millennium BC, followed by Buddhism, and finally Islam beginning about the 12th century (Maloney, 1974).

European trade with the region began at the end of the 17th century. By the mid-18th century, the British had taken political control of the region, and a period of colonial rule began that lasted through the mid-20th century. Colonial rule brought about large-scale political and economic reorganization. The region changed from being a producer of export goods to a producer of raw materials used by the industries of Great Britain. The transportation infrastructure underwent substantial development, but political changes, agricultural policies, and land reforms drained the region of much of its prosperity (Bose, 1967).

British political rule ended in 1947, when India and Pakistan attained independence. Pakistan was formed as a single Islamic nation that included present-day Pakistan and present-day Bangladesh (formerly, East Pakistan). The 2,000 km separation between the two regions, along with linguistic and sociocultural differences, led to political tensions, and finally secession of East Pakistan in March 1971. A brutal war between the two regions followed that led to the formation of Bangladesh (Islam, 1978). The new country was under military rule from 1975 to 1990, and has been under civilian rule, with considerable political unrest, since.

A male-headed family is the basic social unit for Bangladeshis. Patrilineally related households are grouped into a common homestead called a *bari*. The extended family that makes up the *bari* functions as a single economic unit, headed by a senior couple, their sons, daughter-in-laws, and unmarried daughters. The senior male has authority over members of the *bari*, and his wife maintains authority over her son's wives. Newly married couples usually establish a new household within the male's father's *bari* (Maloney, Aziz, & Sarker, 1981; Rob & Cernada, 1992).

Muslim Bangladeshis practice *purdah* (literally, veil or curtain), including the seclusion of women from public observation, wearing of concealing clothing, and use of screens or curtains to hide women within the *bari*.

The degree of observance varies widely by region, education, and socioeconomic condition. The practice of *purdah* is believed to protect women from evil and maintains family respectability. Some adherents see *purdah* as a symbol of piety and purity, that provides religious fulfillment. On the other hand, *purdah* can severely restrict women's mobility, and limits access to education, occupational opportunity, and health care (Maloney et al., 1981).

Bangladeshi Muslim society is not highly stratified, in accordance with the egalitarian principles of Islam. The Hindu caste system, while present, does not figure prominently in Hindu communities because most Bangladeshi Hindus belong to lower castes or outcaste groups. Additionally, the generally low socioeconomic conditions in rural areas have led to a reduction in caste consciousness (Maloney et al., 1981).

The country of Bangladesh ranks 73 out of 90 in the United Nations Human Poverty Index (UNDP, 2001). The population density of the region was 900 people per km² in 2001, making it the most densely populated non-island area of the world. Economic development over the last 50 years has been hampered by frequent natural disasters and political turmoil (Begum, 2001). Roughly, 7% of the urban population lives in slums; 79% of Bangladeshis live in a rural setting (Bangladesh Bureau of Statistics, 2001), where most households have small plots of land or are landless (Turner & Ali, 1996).

People in rural areas typically are involved in agriculture through sharecropping or wage-labor on larger farms. The primary crop is rice (77% of cultivated land), wheat (6%), and jute (4%). Agriculture makes up about one third of the employment; about 8% are employed in manufacturing, 9% are employed in the business sales sector, and 20% are employed in other service industries. Something over one third of Bangladeshis are unemployed. Children from ages 10–14 make up 12% of the total labor force. Government statistics indicate that almost half of Bangladeshis were below the poverty line in 1996 (Bangladesh Bureau of Statistics, 2001). Independent estimates suggest a figure closer to 87% (Turner & Ali, 1996).

Six years of primary education is compulsory for Bangladeshi children. Even so, economic need results in many children dropping out of school early. Recent government-sponsored Food for Education programs raised primary school retention rates to 70% (Mputu, 2001). Government statistics place literacy at 68% for males and 51% for females. Begum (2001) places literacy at 32%, and

suggests the proportion functionally literate is probably lower. A study that tested people for basic skills found 28% could read, 13% could write, and 37% had oral mathematical skills (Greaney, Khandker, & Alam, 1998). Literacy among people living in slums was less than 15% in 1997 (Bangladesh Bureau of Statistics, 2001).

THE CONTEXT OF HEALTH: ENVIRONMENTAL, ECONOMIC, SOCIAL, AND POLITICAL FACTORS

An important consideration in understanding the health literature for Bangladeshis is that a single organization, the International Centre for Diarrhoeal Disease Research, Bangladesh (ICDDR, B), produces most of the health-related research from Bangladesh (Rahman, Laz, & Fukui, 1999). The ICDDR, B has been conducting intensive demographic and medical research since the early 1960s. Most of the research has taken place within Matlab *thana*, a rural administrative unit located about 55 km southeast of Dhaka, with a population of about 210,000 people. A continuous demographic surveillance has recorded all demographic events (births, deaths, marriages, divorces, and migrations) within Matlab since the late 1960s (van Ginneken, Bairagi, de Francisco, Sarder, & Vaughn, 1998). The area is subdivided into two regions for research purposes. The first is a Maternal, Child Health, and Family Planning (MCHFP) area in which numerous health, nutrition, disease, and family planning interventions have been implemented, beginning in 1977. Many of the interventions have had significant effects on health, fertility, and mortality, so that statistics from the MCHFP area cannot be considered representative of rural Bangladeshis. The second region within Matlab is a comparison area where individuals receive limited diarrhea-related health services but otherwise are not part of the health intervention studies. Findings from the comparison region are more representative of rural Bangladeshis, although they may be affected by diffusion of ideas and knowledge from the MCHFP area.

Bangladeshis have been a high-fertility, high mortality population for at least the last 50 years. The annual growth rate was 2.0% from 1978 to 1998 (WHO, 1999); in 1998, the growth rate was 1.5%, reflecting a recent dramatic decline in fertility (Bangladesh Bureau of Statistics, 2001). The total fertility rate in 1999 was 3.0 children compared with 6.7 children in 1978 (WHO, 1999).

The life expectancy at birth was 60 years (rural) and 62 years (urban) in 1998. By contrast, life expectancy was 51 years in 1966 (Strong, 1992). In both urban and rural settings, males had a slightly greater life expectancy than females. The infant mortality rate in 1998 was among the highest in the world at 6.6% (rural) and 4.7% (urban). Twenty one percent of Bangladeshis do not survive to the age of 40 (UNDP, 2001).

The alluvial ecosystem of the Bengal Basin provides both moisture and rich soil necessary for intensive agriculture. The ecosystem may have ample capacity to support the population, and some suggest that the widespread poverty largely results from sociopolitical conditions (Hartmann & Boyce, 1979). The wet, tropical conditions, as well as frequent natural disasters, contribute to high rates of infectious diseases such as cholera and shigella (Siddique et al., 1992). Cholera is endemic and is the leading single cause of mortality in Bangladesh, accounting for about 11% of deaths annually. Untreated surface water has traditionally been used for all household functions. Since the 1970s, major efforts have been undertaken to install tubewells to provide safe drinking water. By 2000, an estimated 80% of people had access to non-surface sources of drinking water. By 1998, 40% of rural households had installed sanitary toilets, compared with only 6% in 1991 (Bangladesh Bureau of Statistics, 2001).

Bangladeshis have endured repeated natural disasters over the last 50 years. Most of the deadliest cyclones in history have affected Bangladesh (Frank & Hussain, 1971), including a single cyclone in 1970 that killed half a million Bangladeshis (Chacko, 1991) and one in 1991 that killed 130,000 Bangladeshis. Flooding occurs annually in Bangladesh during the rainy season, causing property damage from erosion (Haque, 1988), an increase in diarrheal disease, respiratory infections, and deaths (Siddique, Baqui, Eusof, & Zaman, 1991).

The primary health infrastructure in rural areas consists of traditional medical practitioners with little formal training. Access to allopathic physicians is limited. One registered physician for every 8,600 people was reported in 1981 (Bhardwaj & Paul, 1986), and one physician for every 5,000 people in 1996 (Begum, 2001). The entire country had 91 general patient hospitals in 1997 (Bangladesh Bureau of Statistics, 2001). The overall health system ranking for Bangladesh in 1997 was 131 out of 191 (WHO, 2000).

The health-care system has improved since the 1970s, but overall health remains poor (Vaughan, Karim, &

Buse, 2000). The present poor health conditions seem to result from a complex of factors including high population density, poor sanitation infrastructure, inadequate health care, inadequate education, multiple natural disasters, the war with Pakistan, and political instability since 1971. Military spending by the government of Bangladesh, until recently, exceeded health sector spending (Begum, 2001; UNDP, 2001). The government has recently reorganized the health care system and prioritized health (Vaughan et al., 2000).

MEDICAL PRACTITIONERS

Medicine is practiced at many levels in Bangladesh, including self-care, care from a non-practitioner who has gained some medical knowledge, care from paid and unpaid practitioners without licenses, and licensed professionals. A number of specialties exist, such as midwives, bone-setters, and dental practitioners (Ashraf, Chowdhury, & Streefland, 1982). Additionally, health advice and remedies are available at local "chemists" (pharmacists).

Practitioners of a number of medical traditions coexist in Bangladeshi society. Traditions are sometimes combined so that a practitioner may draw from elements of indigenous traditions and particular religious practices. Frequently, allopathic treatment is used simultaneously with traditional cures (Stewart, Parker, Chakraborty, & Begum, 1994).

A study of health practitioners in Matlab *thana* in the late 1970s enumerated 1,300 nongovernmental health practitioners, 1,500 traditional midwives, and three physicians in a government hospital (Sarder & Chen, 1981). *Kobiraj* practitioners accounted for 15% of health practitioners. These practitioners follow *Āyurvedic* medical tradition based on Sanskrit texts belonging to Hindu scriptures dating to before the second century AD (Basham, 1976; Gupta, 1976). *Kobiraj* are unlicensed and trained by apprenticeship. Combinations of herbal medicines, minerals, and dietary restrictions are used to cure disease and for such things as preventing conception (Aziz & Maloney, 1985). Just over half of the practitioners are men; over half have no formal education. Only 10% practice full time (Sarder & Chen, 1981).

Allopathic practitioners made up about 15% of practitioners in the Sarder and Chen (1981) study. Only one in ten allopathic practitioner was licensed after formal training in medical school. Unlicensed practitioners usually

acquired their skills by apprenticeship. Most allopathic practitioners were men, and about half practice full time.

Homeopathic practitioners made up 3% of the health practitioners. This system is based on an 18th-century German medical tradition, but is often viewed as an indigenous medical system because of spiritual elements and concepts that are analogous to some indigenous systems (Leslie, 1978). In the Sarder and Chen (1981) study, one in five practitioners was registered, all were male, about half practiced full time, and most had formal education. Practitioners were typically trained by apprenticeship, although some registered practitioners had attended medical school. Homeopathic practitioners have increasingly been prescribing antibiotics and other Western medicines (Maloney et al., 1981).

A small percentage of practitioners follow the Yunani (or Unani) system (Sarder & Chen, 1981). The Yunani system is based on Aristotelian medicine, codified in Arabic and Persian texts, and was brought into the culture by Islam (Leslie, 1978). The practitioners are called *hakim* which is Arabic for "a learned man" (Basham, 1976). *Hakim* usually are men.

The most abundantly practiced system of medicine (61% of all practitioners in Sarder & Chen, 1981) was *totka*. This system is a mixture of Āyurvedic, Yunani, and shamanistic schools with no single uniform concept of illness, although supernatural causes are common. The practitioners (*totkas*) are not licensed and have no registration requirements; they train through an apprenticeship system. Two thirds have no formal education, and most practitioners are women. A practitioner specializes in one or two types of illness, and only a small percentage practice full time (Sarder & Chen, 1981).

There are other more specialized medical practitioners in Bangladeshi society. A tradition called *boneji* is practiced by elderly women as an art of concocting medicines from herbs and other substances such as honey and fruit juice (Mushtaque, Chowdhury, & Kabir, 1991). The *Badhi* are a low-caste Hindu people who sell herbal medicines out of boats. A *hāzām* specializes in performing circumcisions on boys. *Hazurs* are ritual healers associated with Mosques (Zeitlyn & Rowshan, 1997). Hindus may consult an ascetic saint (*saādhu*) for health problems. Muslims and Hindus may make use of mystic healers (*fakīr*) or magic healers (*ōjhā*) (Maloney et al., 1981).

Traditional birth attendants (*dhorunis* or *dais*) make up one of the largest groups of "health specialists," outnumbering all other health practitioners enumerated in

the Sarder and Chen (1981) study. The traditional *dai* is an older women in the community, often a widow, with little formal education (Croley, Haider, Begum, & Gustafson, 1966). The term *dai* is sometimes used to denote a midwife that is associated with government family planning efforts (Islam, 1982). Rozario (1995) argues that the role of the traditional birth attendant is not one of a medical practitioner. Rather than managing and facilitating a birth, the birth attendant's role is limited to the removal of pollution associated with the placenta and blood of childbirth.

In addition to assisting with births, *dais* may also provide abortion services, provide contraceptive services, and assist women with fertility problems. Indigenous abortion practices are well known in Bangladesh. Most traditional practitioners are *dais* with no allopathic training (Bhuiya, Aziz, & Chowdhury, 2001; Rozario, 1995).

In the absence of a practitioner, medical services may be sought from any person who has some knowledge of healing skills. Aziz (1977) reports that a medical specialist was not consulted prior to death in Matlab 35% of the time.

CLASSIFICATION OF ILLNESS, THEORIES OF ILLNESS, AND TREATMENT OF ILLNESS

Nearly all Bangladeshis, regardless of religion, believe that disease occurs according to the will of a God or gods (Ashraf et al., 1982). Additional awareness of illness involves elements of pathogenicity, evil supernatural forces, environmental exposures, personal behavior, and, to some extent, heredity.

Some diseases are thought to be caused by exposure to "cold" in the environment. One source of respiratory illnesses, for example, is exposure to cold temperatures, prolonged exposure to cold water, or even cold mud (Stewart et al., 1994). Bangladeshis classify food as being intrinsically hot (e.g., meat, fish, eggs) or intrinsically cold (e.g., rice, many vegetables) (Maloney et al., 1981; Sarkar, 1982). Additionally, foods can turn cold when they become stale or are leftover. Some foods are believed to play a role in disease promotion, particularly cold foods, which are considered to cause respiratory disease (Stewart et al., 1994). Hot foods are often associated with health, vitality, and sexuality (Maloney et al., 1981).

The concept of a disease pathogen is not widely recognized by Bangladeshis without formal education. Some traditional explanations for disease approximate a pathogenic explanation. For example, some forms of diarrhea are believed to be caused by eating inappropriate substances (e.g., mud) or rotten food. Breast milk is recognized as a disease vector. A mother who is exposed to "cold" can pass the disease on to a breastfeeding child (Stewart et al., 1994). "Polluted" breast milk is understood to be the cause of diarrhea in breastfeeding children (Mushtaque et al., 1991; Zeitlyn & Rowshan, 1997).

Bangladeshis recognize heredity as playing a role in some illnesses such as asthma (Stewart et al., 1994). An important category of hereditary effects is the behaviors of a child's parents. Behavior of both parents can influence a child's health prior to conception, during conception, and throughout pregnancy. Parents' behavior can result in illness of the child, overall bad health, or a defective personality. The moral behavior of a mother, for example, is a common explanation for a child's respiratory illness (Stewart et al., 1994).

Evil influences are a common source of illness for rural Bangladeshis. The sources include *bhut* (ghosts), the "evil eye," and "bad spirits (or winds)" (*batash*). These influences are held responsible for many maladies such as tetanus, preeclampsia, and spontaneous abortion (Ashraf et al., 1982). Daily life includes numerous ritual practices designed to prevent attacks of *bhut* (Stewart et al., 1994). Zeitlyn and Rowshan (1997) provide several examples of rituals that protect a mother or her child from evil spirits. Mothers may express a few drops of breast milk before the baby suckles. A box of matches or the bone of an animal sacrificed in a Muslim festival may be placed underneath the bedding of an infant. Another treatment involves a healer cutting a mother's arm in several places and then "sweeping" a mother and her child from head to toe. Amulets (*tabij*) are widely used by both men and women as a means to improve bad health, preserve good health, influence fertility, or ward off evil influences. The practice transcends religions and is probably of ancient origin. An amulet requires a religious functionary to initially empower it; Muslims can recite verses to temporarily bolster the amulet's effectiveness (Maloney et al., 1981).

SEXUALITY AND REPRODUCTION

Bangladeshi beliefs about sexuality and reproduction reflect ancient cultural traditions that precede the major

religions of the area. These include proscriptions and prescriptions for pregnant mothers, beliefs about colostrum, and rituals for newborn babies. Additional beliefs and practices shared with groups in South Asia are based on Āyurvedic texts including ideas about sexuality and ritual pollution (Maloney, 1977; Maloney et al., 1981).

The blood of menstruation is considered polluting, and is believed to negatively affect crops, animals, and the health of individuals. Hindu women are barred from the kitchen, their husband's bed, and religious performance while menstruating (Sarkar, 1982). Muslim women will not enter the fields, come near farm animals, visit the sick, serve food, or participate in religious activities while menstruating (Aziz & Maloney, 1985). Following menstruation, a woman must bath before resuming religious activities. We found in 1993 that some women utilized injectable contraceptives at the start of Ramadan as a means to prevent menstruation during the holy month (unpublished data).

Semen is believed to be made of blood (Muslim) or cerebral tissue (Hindu), so that it should not be wasted. Excessive intercourse is discouraged; masturbation is considered unnatural and believed to damage physical and mental health. Excessive depletion of semen (including female "semen") is believed to have negative consequences such as impotence, weakness, loss of sexual drive, and to cause venereal diseases (Maloney et al., 1981; Sarkar, 1982).

Coital frequency shows a strong age-related pattern from about 11 episodes per month for married individuals less than 18 years old to five episodes after age 40 (Ruzicka & Bhatia, 1982). Couples will not engage in sexual intercourse during menstruation. Coitus is also taboo throughout the third trimester of pregnancy. Following a delivery, couples are expected to practice abstinence for 40 days (Muslim) or a number of days based on caste (Hindu) (Hadi, 2000; Sarkar, 1982). Breastfeeding does not seem to limit coital frequency to the extent seen in other cultures (Ruzicka & Bhatia, 1982). Both Hindu and Muslim Bangladeshis are expected to abstain from coitus on certain religious holidays. Bathing is a requirement following coitus for both religions (Sarkar, 1982).

Premarital sexual activity is prohibited by social ideals and religious beliefs. Even so, Aziz and Maloney (1985) estimate that half of all youths have premarital sexual intercourse. These activities must be hidden from others, as Islamic law provides for severe punishments

for couples that are caught. Likewise, sexual relations outside marriage are not permissible in Bangladeshi society (Sarker, 1982). The frequency of the practice is difficult to determine, but males apparently have more opportunity than females for such activities. Punishment for individuals discovered having an illicit relationship is more severe for women (Aziz & Maloney, 1985).

Bangladeshi culture is strongly pronatal. Children are essential for continuing a patrilineal descent group, and required as part of religious duty. For Bangladeshi men and woman, parenthood is a fundamental part of marital life (Sarker, Rahman, Chowdhury, Nasrin, & Tariq, 1996). Traditionally, fate or “dependence on God” was invoked in response to questions about the ideal number of children. The increased use of contraception and the lower total fertility rates seen through the late 1990s suggest that this cultural ideal has been undergoing significant change.

The birth of at least one son is important to Bangladeshis. Son preference arises from the patrilineal social organization and patrilocal household structure. Sons perpetuate the lineage, maintain an economically viable *bari*, provide for their parents in old age, and arrange for funerals and spiritual welfare of the parents after their death (Aziz & Maloney, 1985). Son preference shows in the pattern of child mortality, which deviates from most other societies in that boys have slightly lower mortality rates than girls. Son preference is clearly observed in fertility differences and contraceptive practices that change according to the sex composition of the offspring (Chowdhury & Bairagi, 1990). Infanticide does not appear to be commonly used as a means of ensuring the birth of a son (Maloney et al., 1981).

At least through the last half of the 20th century, Bangladeshis have had high fertility. The total fertility rates (TFRs—estimates of average family size for women who survive to menopause) were 8.6 children for 1960–62, and 6.9 children for 1966–68 (Sirageldin, Norris, & Ahmad, 1975). The trend continued as TFRs dropped from 6.3 children in 1975 to 5.1 children in 1989. Beginning in the 1990s fertility declined sharply, reaching 3.3 children by 1997 (Basu & Amin, 2000). The causes of this decline are manifold, and include health improvements, improvements in education, and the success of family planning programs. Basu and Amin (2000) argue that the sharp fertility declines seen through the 1990s can be understood as a series of historical, cultural, and political circumstances in Greater Bengal that left the region amenable to such change.

Bangladeshis have long known about and used various contraceptive methods, although the extent to which traditional methods have been used in the past is not known. Maloney et al. (1981) provide a list of 23 herbs and substances recommended as contraceptives by indigenous medical practitioners. By 1981, more women were using modern contraceptive methods than traditional methods (including rhythm and withdrawal) (Kabir, Uddin, Chowdhury, & Ahmed, 1986). Bangladeshis use contraception to space births as well as to stop reproduction (Khan, Smith, Akbar, & Koenig, 1989).

Induced abortion is well known in Bangladeshi society. One estimate is that 800,000 induced abortions were performed in 1978, about one in eight pregnancies (Measham et al., 1981); another study found that induced abortion was used to terminate one in 20 pregnancies (Maloney et al., 1981). Some forms of induced abortion are illegal in Bangladesh. Early menstrual regulation, defined as any chemical or mechanical process used to induce menstruation within a few weeks of a missed period, was decriminalized and condoned as an acceptable practice by the Bangladesh government in 1979 (Dixon-Mueller, 1988). Most Bangladeshis consider induced abortion morally and socially wrong; many Muslims believe it to be contrary to Islamic principles (Maloney et al., 1981). Menstrual regulation has wider acceptance, and may not always be considered abortion; rather, it ensures “non-pregnancy” by inducing menses (Dixon-Mueller, 1988). Additionally, menstrual regulation is consistent with some Islamic interpretations that fetal life begins after the fourth month (Aziz & Maloney, 1985).

Traditional methods of induced abortion involve insertion of plant material, usually a root, into the uterus (Islam, 1982). Bhuiya et al. (2001) observed this for 85% of traditional abortions; the remainder were homeopathic remedies. Maloney et al. (1981) list 44 plants, drugs, and other materials used by homeopathic, *Āyurvedic*, and *kobiraj* practitioners to induce abortions. Allopathic abortion practitioners have become more common in recent years. Bhuiya et al. (2001) found that 44% of all induced abortions were performed by menstrual regulation and 27.5% by other allopathic procedures.

HEALTH THROUGH THE LIFE CYCLE

Stages of the Bangladeshi life cycle can be classified under a number of schema, reflecting different cultural

and religious traditions that have been practiced in the region. Aziz and Maloney (1985) documented nine stages in the Bengali life cycle. Stages are largely determined by an individual's age, although behavior and physical characteristics may play a role in defining an individual's stage. Except for a few stages, rituals of passage are not commonly used to denote or celebrate a transition from one stage to another. Alternative systems of life stages come from Bengali religious traditions. Islamic stages of life that pertain to ideals of training, religious duty, and spiritual well-being are recognized by Muslims. Likewise, stages of life based on ancient Sanskrit texts are part of the Hindu tradition.

Pregnancy and Birth

Pregnancy is viewed as a natural state, rather than a medical condition. Fetal life is recognized as a formal stage by Islamic tradition and the Āyurvedic texts. The life of the fetus begins at 4 months, corresponding to the time when the fetus begins movement (Aziz & Maloney, 1985). This stage is understood to be a period of high vulnerability. The nature and future health of a newly conceived individual is closely tied to the behavior of parents prior to, during, and after coitus. Children conceived on certain days, during certain times of the day, or phases of the moon are believed to take on particular (usually negative) personality traits, deformities, or blindness (Maloney et al., 1981).

Bangladeshi women experience food aversions, smell aversions, and cravings during pregnancy. Pregnancy-related nausea and vomiting occur in about half of all pregnancies. Rates are highest (62%) among young women and lowest (36%) among older women. Symptoms occur any time of the day, but are most frequent in the morning and least frequent in the evening. The most common food aversions during pregnancy are fish, rice, and goat (O'Connor & Holman, unpublished data).

A number of foods are prohibited or avoided during pregnancy because of possible health effects on the fetus. Some fish are believed to cause epilepsy or malformation in a child. Pineapples are avoided because they are considered an abortifacient. Excessive salt, ginger, and chilies are believed by some to be unhealthy for the fetus. The most common cravings are sour foods such as unripe mango or lemon (Maloney et al., 1981), which by Āyurvedic tradition also eliminate toxic substances and the unwanted heat of pregnancy (Nichter, 1989).

About 12% of recognized pregnancies terminate spontaneously prior to birth (Ruzicka & Chowdhury, 1987). This rate is higher than those in well-nourished populations, and depends on a woman's age, nutritional status, and the season of conception (Mostafa, Wojtyniak, Fauveau, & Bhuiyan, 1991; Pebley, Huffman, Chowdhury, & Stupp, 1985).

Infancy

Bangladeshis recognize infancy as a life stage from birth to roughly 5 years of age. Infancy is a dangerous phase of life. In 1978, nearly 14% of Bangladeshi infants died in infancy compared with 1.4% in the United States. By 1998, the proportion had dropped to 8% of Bangladeshi infants dying in infancy, compared with 0.7% in the United States (WHO, 1999). The most common causes of death for infants (Matlab comparison area from 1995 to 1999, ICDDR, B 1996a, 1996b, 1998, 1999, 2000, 2001) were neonatal complications (other than tetanus), respiratory infections, and diarrheal disease. Factors associated with elevated postneonatal mortality (deaths from 4 to 54 weeks of age) are households that do not use a latrine and households with more than 10 individuals (Rahman, Rahman, Wojtyniak, & Aziz, 1985). Infants born to teenage mothers, mothers of low socioeconomic status, mothers with low education, and first-born infants experience higher neonatal and postneonatal mortality (Alam, 2000). Mortality by age 5 is 11.2% (rural) and 6.2% (urban) (Bangladesh Bureau of Statistics, 2001).

Breastfeeding is almost universal in rural Bangladesh, but following birth, an infant may not breastfeed for several days. During this spell, the infant is given prelacteal foods such as rice water and honey (Rizvi, 1993). In the past, delayed initiation of breastfeeding came out of the belief, found throughout South Asia, that colostrum is harmful to the infant. Recent public health programs have promoted early breastfeeding out of concern over disease transmission from contaminated prelacteal foods and to ensure infants receive the health benefits of colostrum. These programs may be responsible for recent decreases in the time to initiation of breastfeeding (Holman & Grimes, 2001).

Nearly all Bangladeshi infants are breastfed (Holman & Grimes, 2001; Huffman, Chowdhury, Chakraborty, & Simpson, 1980; Khan, 1980). The duration of breastfeeding exceeds an average of two years (Ahmed, 1986; Huffman et al., 1980; Mannan & Islam, 1995; Mulder-Sibanda & Sibanda-Mulder, 1999). Urban women,

women with higher education, women whose husbands have higher education, and younger women tend to have a slightly shorter duration of breastfeeding (Huffman et al., 1980; Mannan & Islam, 1995). Most studies find no gender differences in breastfeeding patterns (Greiner, 1997). In Bangladesh, an important consequence of breastfeeding is reduced morbidity and mortality from diarrheal disease (Mulder-Sibanda & Sibanda-Mulder, 1999); this is particularly so for unsupplemented breastfeeding (Shahidullah, 1994).

Childhood

Childhood is recognized as a life stage that begins about the time a child starts school (age 6) and continues through about 10 years of age. Aside from a ceremony for the child's first school attendance, there are few rituals associated with the transition to childhood. Boys are usually circumcized during early childhood. The occasion is marked by a feast; the boy's status changes to that of a "senior" child. Most girls have an ear pierced between the ages of 1 and 9 (Aziz & Maloney, 1985).

The overall effects of poverty and malnutrition are reflected in 1996 statistics on stunting showing that 56% (rural) and 39% (urban) of children are more than two standard deviations below height-for-age standards. Likewise, 58% (rural) and 42% (urban) of children are more than two standard deviations below weight-for-age standards (Bangladesh Bureau of Statistics, 2001).

Adolescence

Adolescence encompasses three Bengali stages of life: *pre-adolescence*, *early adolescence*, and *late adolescence*. The pre-adolescence stage begins with the growth spurt around age 9–11. The stage ends around menarche in girls, but is less demarcated for boys. During this stage, a girl begins to adopt the dress of adult women. Both boys and girls start taking on gender-specific adult roles within the family. Individuals are expected to take on more responsibility for their behavior, especially in limiting their contact with individuals of the opposite sex. Pre-adolescent individuals are expected to sleep with same-sex kin (Aziz & Maloney, 1985).

The early adolescence stage begins around puberty or near the peak of the growth spurt. Boys remain in this stage until their facial hair begins to grow, and their voice changes. Menarche is considered private; it entails no

rites or ceremony, although a girl will begin wearing a *sari* all the time. Girls will begin shaving pubic and underarm hair. Late adolescence begins around age 16 and continues through the early 20s or until marriage. During this time, males will either continue in their schooling or begin to work for the family. Females who are not in school will spend most of their time in the *bari*. Muslims believe that an individual has become morally mature at this stage (Aziz & Maloney, 1985).

Age at menarche was examined in a 1976 study that found a median age of just less than 16 years. The study was on the heels of the 1971 war and a famine in 1974, which may have delayed menarche on average. Heavier girls at a given age were more likely to have reached menarche (Chowdhury, Huffman, & Curlin, 1977). The girls were shorter and weighed less than same-aged U.S. girls, in part reflecting a later growth spurt (Riley, 1990).

Mortality is at its lowest during adolescence. Records from 1994 to 1999 in the Matlab intervention and comparison areas (ICDDR, B, 1996a, 1996b, 1998, 1999, 2000, 2001) show that only 2 per 1,000 individuals die between 10 and 20 years of age. For males, the leading causes of death are accidents (other than drowning, 25%), infections (other than tetanus or diarrheal disease, 9%), suicide (7%), gastro-intestinal disease, and cancer (5% each). For females, leading causes of death are suicide (14%), accidents (other than drowning, 13%), obstetric-related (10%), diarrheal disease (6%), and cancer (5%).

Adulthood

Bangladeshis recognize two stages of pre-senescent adult life: *young adulthood* and *middle age*. Young adulthood begins with marriage and lasts until the late 30s or early 40s, when one's children have grown. Following marriage, a woman moves into the household of her husband's family. Her role in young adulthood is to bear and raise children, and she helps maintain the household (Aziz & Maloney, 1985).

Middle age begins with maturation of one's children and continues into the 50s. At this stage, males may assume a leadership role in the community, and some women work outside the *bari*. Couples will avoid bearing children during this period, as it is considered embarrassing or shameful to reproduce when one's children are reproducing (Aziz & Maloney, 1985).

Adult mortality is highly gender-specific. About 24% of deaths to women aged 15–45 are from obstetric

causes (Matlab comparison area, 1994–1999, ICDDR, B, 1996a, 1996b, 1998, 1999, 2000, 2001). The second leading cause of death is suicide (8%). Next are chronic obstructive pulmonary disease (6.5%), cancer (6%), TB (5.6%), and cardiovascular disease (5.6%). The leading cause of death in adult men is gastro-intestinal disease (14.0%), followed by accidents and drowning (12%), TB (8.5%), cancer (6.2%), and suicide (5.8%).

The ill health of adults can have significant consequences for their children. Deaths of rural adults put their dependent children at significantly increased risk of death, particularly girls (Strong, 1992). The effects of a mother dying are more severe than for a father dying. Older children are likely to have their education interrupted, girls are likely to leave the household earlier, and marry earlier (Roy, Kane, & Barkat-e-Khuda, 2001).

Women have traditionally had little say or control over reproductive decisions. Repeated cycles of reproduction followed by intensive breastfeeding combined with poor nutrition and bouts of diarrheal disease result in declining health with age for rural Bangladeshi women (Ahmed, Adams, Chowdhury, & Bhuiya, 1998).

A Bangladeshi woman usually gives birth in her husband's home or her natal home. Births are rarely attended by trained medical practitioners. Instead, they are attended by female family members, neighbors, or by traditional birth attendants (*dais* or *dhorunis*). Nearly one third of births are delivered by the mother alone (Croley et al., 1966). Social norms associated with *purdah*, shame, and family honor usually prevent male medical practitioners from performing gynecological examinations, even during obstetric emergencies (Rozario, 1995).

Maternal mortality, defined as deaths resulting from pregnancy or childbirth, occurs in about 5–6 out of every 1,000 live births. Increased risk of maternal mortality is associated with higher parity and mothers over 35 years (Alauddin, 1986; Khan, Jahan, & Begum, 1986; Koenig, Fauveau, Chowdhury, Chakraborty, & Khan, 1988; Rochat et al., 1981). About one quarter of all maternal deaths result from complications of induced abortion (Rochat et al., 1981).

Sexual violence occurs within and outside of marriage. In rural settings, women infrequently leave their homesteads, and ethnographic accounts suggest that rapists are likely to be known by the victim. Marital rape is tolerated in Bangladeshi society as a part of a husband's rights to his wife, even though the topic itself is taboo, making it difficult to study (Yasmin, 2000).

One study found that 27% of Bangladeshi women reported at least one instance of marital rape over a one-year period of recall. Marital rape most frequently occurred during taboo times (postpartum, third trimester of pregnancy, and menstruation). Prevalence was lower at older ages, for more educated women, and for women with an independent source of household income (Hadi, 2000).

Another form of sexual violence that has received widespread attention in the international media is the practice of “acid throwing,” where men throw sulfuric acid on women. The crime is usually associated with refusals of sexual or romantic advances. Victims are permanently disfigured, and some are blinded, disabled, or die from their wounds. About 100 cases are believed to occur each year (Faga, Scevola, Mezzetti, & Scevola, 2000; Yasmin, 2000).

The Aged

Old age is recognized as a stage of life that begins in the mid to late 50s. Elderly parents are cared for by their sons, usually the oldest, although in urban settings elderly women may live with a daughter (Kabir et al., 1998). Care for the elderly is considered a beneficial responsibility, rather than a burden. The elderly are respected for their wisdom; they command a near religious reverence (Aziz & Maloney, 1985).

In the late 1990s, there were about 7 million elderly Bangladeshis; about 17.5 million elderly are projected for the year 2025 (Kabir et al., 1998). Men tend to live longer than women, but because of the age difference at marriage, women tend to outlive their husbands (Ellickson, 1988). Mortality risk for elderly men and women is lower while their spouse is alive. Mortality risk is also reduced while living with a son (Rahman, 1999, 2000). Older women report significantly more limitations in their daily activities, and have more physical performance limitations than do their male counterparts (Rahman & Liu, 2000).

Dying and Death

The final stage of life (*acal* or *marankāl*) begins as an elderly person becomes disabled and is reliant on caregivers for basic needs. Care-giving is intensified as an individual becomes progressively more disabled. All attempts are made to fulfill the wishes and needs of the individual. The oldest old are believed to recapture the mental disposition of children (Aziz & Maloney, 1985).

Funeral rites are important to both Muslim and Hindu Bangladeshis. A Muslim corpse is ritually bathed before burial and wrapped in a shroud. The body is placed in a plain wooden box and carried to the burial place by male family members. Women do not attend funerals (Gatrad, 1994). Hindu funerals involve elaborate ceremonies, including the cremation of the body (Maloney et al., 1981).

CHANGING HEALTH PATTERNS

Efforts to reduce diarrheal disease by establishing widespread tube-well sources has had unintended health consequences. In the mid-1990s, high concentrations of naturally occurring arsenic were discovered in the ground water in many regions of Bangladesh and West Bengal. Arsenic-related health conditions include skin lesions, skin cancers, cancers of internal organs, and neurological disorders, but the onset of many conditions has a 10-year latency period, so it is still too early to evaluate the long-term health effects. Because of the enormity of the problem—areas with high-concentration wells may include half of the population of Bangladesh—arsenic poisoning is being treated as a public health emergency (Smith, Lingas, & Rahman, 2000).

Another public health crisis is the re-emergence of malaria in recent years. Malaria had been almost eliminated from the region in the mid-1960s, primarily through heavy use of DDT. The practice was halted during the war of independence from Pakistan. Since the mid-1970s, cases of malaria have increased steadily, and reached a peak of nearly a million cases by 1997. Additionally, a higher fraction of cases involves the more severe and deadly falciparum malaria. The most heavily infected areas are difficult to access and lack surveillance infrastructure (Bangali, Mahmood, & Rahman, 2000).

HIV has not been a serious problem for Bangladeshis, although there is growing concern over the potential for a serious epidemic. As of 1999, about 13,000 individuals are believed to be HIV positive (UNAID, 2001); but only 17 cases of AIDS have been reported (Ministry of Health and Family Welfare, 2002). The infection has only recently made in-roads into vulnerable groups. Prevalence among sex workers is under 1%, but there is a low frequency of condom use among commercial sex workers. Female sex workers have an average of two to five clients a day and the number of clients is estimated to be half a million men daily. The high rate of other sexually transmitted diseases

(STDs) in sex workers suggests that HIV could spread rapidly. The rate of HIV infection is about 2.5% among the relatively small injecting drug community. Needle-sharing is widespread in this group (World Bank, 2000). Blood screening in Bangladesh was initiated in 2000 (Ministry of Health and Family Welfare, 2002).

Baliem Valley Dani

Leslie Butt

ALTERNATIVE NAMES

The Baliem valley Dani are also known as the Dani and the Grand Valley Dani. The term Dani used here does not include the neighboring Western Dani, the Lani, or the Yali, who have been called “Dani” in the past.

LOCATION AND LINGUISTIC AFFILIATION

The Dani live in the 50 km-long Baliem valley, Jayawijaya district, Papua (also known as West Papua, or Irian Jaya), Indonesia. The valley is located 1,500 m above sea level in the middle of the mountain range which cuts through the center of the island of New Guinea. New Guinea was divided by colonizers in the 19th century; the Baliem valley sits on the western side and was part of the Dutch East Indies colony. Since 1969, the former Dutch colony has been incorporated into Indonesia. The Baliem valley Dani are speakers of the Papuan language, Dani, which falls into the Greater Dani language family.

OVERVIEW OF THE CULTURE

The Dani are well known because of the excitement that accompanied the discovery of their complex culture, terraced gardens, and densely populated communities in a mountainous region previously thought to be uninhabited. In 1938, an American pilot spotted from the air the valley’s tracts of symmetrical gardens and circular dwellings. Excitement over this New Guinea discovery was intense, and the press dubbed the valley “Shangri-La.” In the early 1960s, Harvard University organized a large expedition to the region. The well-known film *Dead Birds* (Gardner, 1963) and now-classic ethnography (Gardner & Heider, 1968; Heider, 1970, 1979; see also van Baal, Galis, & Koentjaraningrat, 1984) from this period have helped to fix the Dani as central to the global imagination about “primitive” populations and integral to the study of tribal cultures within the field of anthropology.

The outside world may not have known of the Baliem valley, but people have settled there and cultivated gardens for at least 7,000 years (Golson & Gardner, 1990). At present, the patrilineal Dani number some 60,000, and display the highest levels of cultural intensification and political integration of any group in the New Guinea highlands (Shankman, 1991). For their food staple, the Dani rely on root crops such as the sweet potato, introduced about 300 years ago, and the indigenous taro, which women cultivate in gardens on the valley floor and mountainsides. Women also raise pigs, which men strategically exchange to promote their status, and to strengthen their political alliances. People identify themselves by membership in a totemic clan. In the past, clans grouped into multi-layered political units, and large-scale pre-contact warfare dominated political activities (Heider, 1970). Even after pacification in the 1970s, clan groups still align to form large political alliances. Leadership is achieved through prowess in politics and exchange relations.

Dani men use their influence in the public arena to try to regulate the lives of women. The Dani are polygynous, and most men seek to acquire more than one wife, with between 36% (Aso-Lokobal, n.d.; Peters, 1975) and almost 50% (Butt, 1998; Heider, 1979) of men having at least two wives. Dani society is divided into two moieties, *weta* and *waya*. A person may not marry within his or her moiety. Marriage occurs ideally within a six- to seven-year cycle, culminating in a big pig feast, the *ebe akho*. In this feast, young girls either choose their marriage partner or have their partner arranged by their parents. The big pig feast is the climax of several ceremonial cycles which also include funerals and boys’ initiation (Heider, 1972; Peters, 1975).

Dani gender roles are strongly demarcated. The strict division of labor appears to favor men, for women do most of the hard physical labor in gardens, and do not engage in the male-only rituals that give political power. Household compounds are divided into men’s houses (*pil-amo*) and family spaces. Women are forbidden to enter the *pilamo*, where sacred objects are stored. However,

women expect support from husbands and male kin in domestic matters, and will run away or refuse to marry an unappealing suitor. About 30% of married women have ever run away from their husbands or former husbands (Butt, 2001c; O'Brien, 1969). As Peters (1975) summarizes, women are subject to men in this society, but they are by no means subservient.

Inroads into long-standing gender and social roles began in earnest when the first mission floatplanes landed in 1954. Although neighboring societies underwent mass conversion to Christianity, with many burning all their sacred ritual objects (O'Brien & Ploeg, 1964), the Dani remained uninterested. Instead, the Dani attacked police, resisted schooling, and refused to wear clothes (Peters, 1975). More rapid acculturation processes began in the late 1960s and early 1970s, as the former Dutch colony was handed over to Indonesia in 1969 in a contested vote. Under Indonesian rule, large-scale Dani warfare was stopped. Authorities further prohibited the custom of cutting off portions of the fingers of young Dani girls to commemorate a dead ancestor during a funeral. Government officials also implemented a process of "Indonesianization." A new lingua franca, a national education curriculum, and increased exposure to other Indonesians were meant to assimilate Papuans into the broader nation (Gietzelt, 1989). In 1971, "Operation Penis Gourd," for example, air-dropped clothing into the Baliem valley as part of an effort to "civilize" the Dani, who normally only wore penis gourds and grass skirts. Despite these efforts, the Dani were and remain largely self-sufficient, rejecting many aspects of modernization, Christianity, and Indonesian rule.

Since the 1960s, there has been overt, active resistance by the Dani and other indigenous groups to incorporation into Indonesia. However, up to 8,000 Indonesian migrants have moved to the Baliem valley, and most of them live in Wamena, a prosperous town built alongside the airstrip. Immigrants mostly run the government offices, businesses, and the military. The valley has many police posts and military barracks; these, along with racist and inequitable policies, have heightened resentment among the Dani. In 2000, in partial revenge for political deaths from the past four decades, and following police intervention into an independence rally, Dani activists massacred several families of Indonesian migrants. This tragic incident brings home the extent to which an imagined "Shangri-La" is in fact a contested territory enmeshed within the complex politics of a militarized state. Health and healing needs to be understood as much from the

context of these political realities as from the cultural perspective of the inward-looking, self-interested Dani.

THE CONTEXT OF HEALTH: ENVIRONMENTAL, ECONOMIC, SOCIAL, AND POLITICAL FACTORS

Health challenges in the highlands of Papua are numerous. There are three major impediments to Dani well-being: environmental challenges; changing disease patterns; and unequal access to poor quality allopathic health services.

For most highland New Guinea populations, abundant rainfall, high altitude, and inhospitable terrain make horticulture a constant challenge. Populations living below 1,000 m must battle with endemic malaria. Above 1,800 m, misting from clouds limits agriculture. In contrast, the Dani live at 1,500 m, an altitude with more moderate rainfall, and in a region that favors dense cultivation. The Dani are self-sufficient in food production, with the sweet potato forming 90% of their diet. Pigs form an important supply of protein. Thus, the Dani are taller, more husky, and overall healthier than their neighbors, many of whom picture the Baliem as "a sort of paradise, where pigs abound" (Peters, 1975, p. 72).

Nevertheless, Dani health is affected by environmental constraints. Infant mortality rates are high. Ethnographic and local estimates range between 110/1,000 and 250/1,000 (Butt, 1999; WATCH, 1994), although government figures cite lower rates (cf. World Bank, 1991). The biggest health risks are pneumonia and other upper-respiratory infections, which cause over 50% of recorded infant deaths (WATCH, 1994). Smoke-filled traditional dwellings contribute to high rates of respiratory infection among children and adults.

Birth rates are low; the average number of children per family is around 1.5 children (Butt, 1998; Lokobal, 1992). Almost no mothers have more than three children. Women cite the risks associated with childbirth and the arduous work of caring for both garden and children as reasons for limiting family size. Women also lose autonomy if they have a second child, for it is harder to find a new husband if they have many children.

An overall low-protein diet takes its toll on growth patterns. Malnutrition rates increase as children grow. At 36 months, 7% of Dani children weigh less than 11 kg, and at 5 years, over 25% of children have poor nutrition

(WATCH, 1994). Fifty percent of children's growth patterns fall below established norms for Indonesia (Muslim, 1995).

Among adults, upper-respiratory infections remain a serious cause of illness. Smoky huts, combined with almost universal cigarette smoking of indigenous tobacco, make pneumonia and tuberculosis major health problems throughout the valley for adults of all ages.

Disease patterns are changing but most health problems remain acute. Malaria has gone from being absent in the valley in the 1950s to becoming a major killer of adults. Cerebral malaria, a fatal form, became a serious local concern after an outbreak in 1987 (Sudjito, 1987). Malaria Tropicana, in a 1998 outbreak, also claimed many deaths (Hanevik, 2000). Seven cases of HIV have been recorded from a random sample of 195 adults (Ingkokusumo, 2000). Actual rates of HIV infection are almost certainly higher. Within the valley, sexually-transmitted diseases have become a serious problem. In 1995, 50% of commercial sex workers in Wamena (including Dani and non-Dani respondents) tested positive for gonorrhea, 36% had chlamydia, and 25% had syphilis (Ingkokusumo, 2000). A survey in 1991 showed that 8% of adult hospital patients (including Dani and non-Dani respondents) had gonorrhea (Senis, 1995).

The last factor inhibiting higher standards of Dani health is poor-quality health services. There have been some successes. Since 1954, missionaries in some areas have carefully trained indigenous nurses in basic diagnosis and treatment, and still supply medicine and equipment. Two early campaigns successfully eradicated endemic health problems. The first controlled the incidence of endemic goiter by widely distributing iodized salt. The second campaign reduced the suffering caused by yaws (also known as framboesia), a chronic infectious skin disease. Among the Dani, yaws often progressed to the stage of open skin ulcers, at times eating away flesh, muscle, and joints (Gajdusek, 1961). Missionaries gained an early foothold in Dani communities by publicly curing known yaws cases with a single shot of penicillin.

Most other health interventions, however, have been markedly less successful. Indonesian health care programs put in place in the 1970s implement national health goals, often at the expense of local health needs. This format has been successful in reducing mortality rates in other parts of Indonesia (Yahya & Roesin, 1990). In Wamena, the government runs a hospital that is clean and comfortable, and the Dani will use it under certain

conditions. At most smaller health centers and clinics run by trained Dani workers, however, medicines are unavailable, out of date, or improperly administered (Hartono, Romdiarti, & Djohan, 1999; Ingkokusumo, 2000). The health bureaucracy is controlled by Indonesian migrants who are perceived by the Dani as inaccessible and often racist (Butt, 1998; Hull & Hartono, 1999). Knowledgeable health advocates focus on increasing maternal education as a way to improve the health of women and children, yet they recognize that these aims often contradict Dani values, which do not privilege the education or autonomy of women (Hartono et al., 1999; Sрни, 1999). Nonetheless, many women have been reluctant to bring their children for immunizations, in part because diseases prevented by the injections are not yet present in the highlands. Many women also reject Indonesia's family planning efforts, which promote the use of the long-term contraceptives Norplant and Depo-Provera, because they already have low birth rates.

MEDICAL PRACTITIONERS

There are three kinds of people with specific healing skills who contribute to the well-being of the Dani: part-time healers with specific practical skills, sometimes known as *hathale*; ritual participants, who seek to control the sacred realm; and trained health workers called *mantri*.

First, *hathale*, or part-time healers, span several realms. Many *hathale* are women. Some women have expertise in assisting with childbirth. Other women are experts at performing abortions. Others know herbal remedies or can perform small curing ceremonies. Certain individuals, mostly women (Heider, 1979), are known to be powerful practitioners of the arts of magic. They can cast spells and can sometimes cure the sick. Overall, there is no special status accorded to these healers.

An important healer role is played by participants in rituals designed to control sickness, food, and the threat of enemies. Political leaders have "to be able to involve the ancestral ghosts in the affairs of the group" (Ploeg, 2001, p. 34) and one way of demonstrating this is by bringing about good health through successful ritual practice. Most of these rituals involve killing a pig, cutting it up, cooking it, and eating it in a systematic manner (see Aso-Lokobal, n.d.; Lokobal, 1994; Peters, 1975). Pig sacrifices are intended to placate ancestors, thus ensuring

fertile gardens, fecund women, and a healthy and prosperous population. Failure to carry out the rituals in their correct time and order can explain misfortune, sickness, and misery. The most important of these rituals is the *kaneke hakin*, but Aso-Lokobal (n.d.) tallies 94 distinct rituals related to Dani health. In sum, political leaders produce Dani well-being, not by directly healing the sick, but by the successful execution of rituals.

Lastly, some Dani have undergone two years of nursing training, and are called *mantri*. For a small fee, *mantri* working in government clinics will dispense some medicines, treat wounds, and promote government health programs such as family planning. *Mantri* often find themselves in a position of conflict. On the one hand, all *mantri* believe in the power of Dani rituals to provide physical well-being through mediating social and spiritual relationships. On the other hand, they also dispense with confidence the medicines that they believe will heal their sick patients. Discretion in mediating two often competing belief systems is key to their success. One *mantri* summarizes a common strategy: "Never tell a patient you know he believes in spirits. Never tell them what disease they have. Just give them the medicine" (Butt, 1998, p. 199).

CLASSIFICATION OF ILLNESS, THEORIES OF ILLNESS, AND TREATMENT OF ILLNESS

Traditional beliefs about ancestor spirits or supernatural powers are intricately interwoven into Dani imaginings about why and how people become sick. The rich world of Dani *wesa* (the supernatural) includes ancestor spirits, magical powers, and forest and animal spirits. These intersect with the natural world, contemporary medical services, and individual illness in complex and often idiosyncratic ways. In the main, "illness and death are always considered to be more or less directly caused by ghosts" (Heider, 1970, p. 227).

One belief common to all Dani is the importance of "soul matter" or *etai-egen*. Each person who is born needs to grow an *etai-egen* over the course of his or her lifetime. The *etai-egen* is an immaterial substance that rests lodged just beneath the sternum. Throughout adult life the *etai-egen* is continually subject to potential disturbance or weakening, particularly through the work of

malicious ghosts. Explanations for illness causation often refer to a weakened, shrunken, or disturbed *etai-egen*.

Another widespread belief is that ancestors, sorcery, and malicious spirits cause the majority of serious illnesses. Sometimes ancestors cause sickness directly (Lokobal, 1994). At other times, an individual's actions can cause another person to become sick. Theft, laziness, or disobedience on the part of one person can make a close relative sick. A man who has engaged in extramarital sexual relations, for example, might explain his wife's subsequent reproductive problems as punishment for his errant behavior.

Another form of illness can be brought about when an individual manipulates the spirit world. Vengeful sorcerers or jealous competitors can make another person sick. For example, *imak* sorcerers can cause small crab-like animals to leap into a man's penis if he urinates in a dangerous place. Sorcerers can poison food using a fine, white powder invisible to the target's eye (Gardner & Heider, 1968). Sorcerers often try to poison people from enemy alliances. Lastly, certain illnesses are always caused by angry spirits or sorcery. These include uncontrollable seizures, "inner heat" (*panas dalam*), mental disability, a high fever, and dry cough.

For the Dani, diagnosis of disease is an important art. Sickness will not leave the body, they believe, until a correct diagnosis has been made. Depending on the diagnosis, the sick person or his or her relative will choose from an array of treatment options. The hierarchy of resorts normally follows this pattern: (1) do nothing; (2) use herbal remedies or engage in bloodletting; (3) consult clan *hathale* who may use one of several diagnostic techniques, including blowing on the head of the sick person, dissecting a rat, eating a ritual pig, or preparing protection for the patient's *etai-egen*; (4) pray to the Christian God; or (5) consult a healer from outside the clan.

Most Dani look to the realm of the spirits to diagnose sickness and place clinics and Christian prayer a distant second. A "devout" Christian might immediately seek help from a healer to diagnose sickness, and only resort to prayer once the treatment begins to work. One informant summarized the trend of using allopathic medicine not as a treatment resort, but as a diagnostic tool for understanding the effects of ancestor spirits:

Government clinic medicine is just play medicine, not really important at all, just pills. Government clinic medicine is a test to see whether a sickness is really ancestors and magic or not, not a real treatment resource at all (L. Matuan cited in Butt, 1998, p. 193).

SEXUALITY AND REPRODUCTION

Dani sexuality has been a topic of active debate in anthropology, beginning with Karl Heider's (1976) argument that the Dani had a "low energy" sexual system. Heider had observed a seeming disinterest on the part of Dani men and women to engage in sexual relationships during his 1960s fieldwork. Their willing adherence to a four- to five-year post-partum taboo, low birth rates, and low rates of extra-marital sex, were interpreted by Heider as evidence of a general disinterest in heterosexual intercourse.

There is some data to support Heider's hypothesis. As with most other highland New Guinea societies, negative symbolic constructions about women and their reproductive capacities can make sexual intercourse an activity fraught with tension and uncertainty for men. Menstrual blood can poison men's bodies, food, and pigs, according to the Dani, and men consider vaginal sex toxic and potentially debilitating. Metaphors of poison and contagion continue to be employed to strengthen assumptions about male superiority. Women also fear men's bodily substances. Semen, in particular, can poison women's inner organs if it is ingested orally. Semen must never be scattered on the ground, for it can kill plants and poison the earth. A recent survey (Butt et al., 2002) suggested that Dani men and women continue to limit their location and kind of sexual activities in order to protect bodies and gardens from the debilitating effects of bodily fluids.

Another practice that lends support to Heider's argument is that Dani women continue to attempt to space their children so they are born every four to five years. One way they do this is by not having sexual relations with their husband. Parents of a newborn child are expected to refrain from having sex with each other until the woman has stopped breastfeeding, typically around the child's fourth year. Post-partum sexual abstinence is rooted in the conviction that semen is a highly dangerous fluid to an infant, whose body is weak and unfinished. If a couple has sex while the woman breastfeeds, semen can travel up through the woman's internal organs and come out in her breast milk; this can make the child sick or die.

However, other data substantially challenge Heider's claim of Dani "low sexual energy." Peters (1975) describes intense flirting and a high level of sexual knowledge among adolescents. Pre-marital sex was seen as commonplace in the 1960s (Hayward, 1980; Heider, 1976). Courting parties were common, and Hayward (1980) describes couples leaving parties

together to spend a night in intimacy. Van der Pavert (1986) describes a ritual that cleanses people if they have engaged in sexual relations with members of their own moiety. Lastly, men say they expect to seek sex elsewhere while their wives are breastfeeding (Butt et al., 2002).

Explanations for low birth rates also challenge Heider's assertion that low rates of sexual relations result in small families. Pontius (1977) suggested that low birth rates were possibly due to tight scrotum strings holding the penis gourd in place, which reduced the transmission of spermatozoa. A further report describes the bark of a cinnamon tree being used as a contraceptive (Kostermans, 1969). Butt (1998; see also Peters, 1975, p. 31) records women obtaining abortions as standard practice.

There is, in sum, little evidence to support Heider's (1976, p. 189) claims of an "extraordinarily low level of sexuality" among the Dani. In a manner similar to most societies, the Dani do have a reasonably systematic set of beliefs about the negative effects of non-reproductive and extra-marital sex. Evidence suggests that stringent efforts were made in the past to regulate sexual practice. However, the Dani live out a complex esthetics of sexuality, based as much on ideas about beauty, desire, and entitlement, as on fears about poison and prohibitions.

HEALTH THROUGH THE LIFE CYCLE

Pregnancy and Birth

A number of Dani ideas about conception and birth draw on observed regularities in bodily growth and development. For conception to occur, the Dani believe that couples have to have sexual intercourse around 10 times. The fetus grows because semen from the man helps build the bones and blood from the woman helps build the flesh. When the fetus moves inside the womb, at approximately 20 weeks, couples abruptly stop having intercourse. Some women describe the fetus as roaming around the mother's body at will, drinking milk from the inside. The fetus is always protected by the placenta, termed *opase* (grandfather, or elder male kin), which looks after the baby in the mother's womb.

Most Dani women decrease food consumption in the final month of pregnancy to prevent their child from being too big at birth. The ideal newborn weight is around 2.5 kg. Women usually give birth alone or with a close relative or experienced assistant. Women like to hold themselves

in a standing position, grasping onto the rafters of the cookhouse or the sleeping house roof. Giving birth inside the family compound is essential, as infants are perceived to have so little *etai-egen* that they cannot protect themselves from the spirits that constantly roam the forests and paths. Once the child is born, a relative or the birth assistant wraps the placenta carefully and take it down to the river where it can be disposed of safely. The mother and infant do not leave the site of birth until after the umbilical cord falls off, at around 10 days after giving birth.

Infancy

Dani women are skilled at transforming small, healthy newborns into large, plump infants. The newborn spends the first 4 months of life in a soft, smooth, and cool netbag. Women surround the infant with soft banana leaves or cloth bedding in the netbag, and carry the infant in the bag slung across their lower backs. The infant comes out of the bag only to change soiled bedding, or partially to breastfeed. Once the mother starts garden work, she takes special care to enclose her baby under 10 or 12 netbags to protect the child from the sun, and from being startled. The baby's vulnerable body, which is "still wet," with "closed eyes" and "soft skin," needs extensive protection from the spirit world (Butt, 1998). Infants grow very fast in these conditions. By 4 months, most babies have more than doubled their birth weight, and at 5 or 6 months almost all infants are plump and healthy.

Infant health deteriorates once mothers begin giving supplementary foods at around 6 or 7 months. Bananas, mashed sweet potatoes, and, increasingly, mashed noodles or crackers, are some of the first foods the baby eats. The protein levels of these foods are adequate, but many infants get sick because they are exposed to bacteria on the spoons that women increasingly use to feed their children. At 7–8 months, many infants experience their first bout of diarrhea. Growth rates slow over the first year, and by the age of 18 months, many children show signs of inadequate nutritional intake.

Infants and young children also suffer from numerous chronic skin problems, including infected insect bites and scabies. Scabies are endemic because many women have begun to use pieces of cloth instead of the more sanitary netbag to hold their babies. Intestinal worms plague significant numbers of young children. However, upper-respiratory infections are the biggest concern (see Figure 1) and many infants who get pneumonia die of it. The death

of a child traumatizes parents, and blame usually falls on ancestor wrath brought about by poorly conducted rituals, or on errant behavior by the mother or the father.

Childhood

Dani childhood is carefree and pleasant. Children roam forests and fields, and do so in age sets distinguished along the lines of gender. Complex gender distinctions between boys and girls come into play as the child achieves more independence at around age 6 or 7. Bodies of boys are seen as more "soft" than those of girls, and are less likely to grow fast and well. Girls, in contrast, grow faster, mature faster, and are seen as hardier than boys. Despite claims to the contrary, the Dani exhibit preferential gender behavior. Boys are more likely to receive formal education than girls. Boys are also more likely to be recipients of medical care than girls. Boys under the age of 5 were taken to clinic one-third more often than girls (Butt, 1998). In ritual situations, boys over the age of 10 or so receive larger pieces of pork than do girls, and they are also fed before girls. Women compensate in part by slipping secret bits of food to their girl children.

Adolescence

There is little ritual importance attached to the transition from child to adolescent. Only young boys whose fathers are from the *waya* moiety undergo a ritual to be "made *waya*" (Heider, 1972). At this ritual, which occurs during the big pig feast and lasts about two weeks, boys have dangerous *wesa*, or sacred power, drawn from them. They are then purified through a series of rituals that involve some deprivation, hunting, eating ritual taro, and painting a ritual red stripe on their nose (Heider, 1972; Peters, 1975).

For girls, once a young woman has begun to menstruate, in most regions of the valley her clan holds a formal, public rite-of-passage event in which her reproductive capacities are extolled. This ceremony is known as the *hotalimo* (Peters, 1975). The girl cooks sweet potatoes and distributes them, and women dance non-stop to protect the young girl, for "the spirits of the dead want to kill people at moments of crisis, like menstruation or sickness" (Peters, 1975, p. 37). Young women also undergo a skirt-ing ceremony, which usually happens during the big pig feast. Changing a grass skirt to the low-slung thread *yokal* worn by grown women signifies the girl's maturity and

Figure 1. Waiting at the clinic for the *mantri*, the 9-month-old infant on the right has attained the Dani ideal of plumpness. In contrast, the worried mother on the left holds her 2-year-old son, who is little bigger than the other baby. He has suffered from a respiratory infection for several weeks and is mildly malnourished. This was his first trip to the clinic to receive penicillin.

readiness for marriage. The skirting ceremony is still practiced, even though few women now wear the *yokal* skirt on a daily basis.

Adulthood

At the point where a girl begins to menstruate, she may already be married. Early Indonesian officials and missionaries were horrified to see girls aged 9 or 10 married off during the big pig festival, but they did not realize that the time between public, ritual marriage and consummation of marriage ties is often delayed by several years before the bridegroom's family fully pays off debts to the bride's family (Heider, 1972). Nonetheless, early age at marriage is common, and most young women give birth before the age of 20. This increases the chance of them contracting sexually transmitted diseases early in their reproductive years.

For men, adulthood is achieved later in life, at the time when assiduous attention to social and exchange relations with kin and alliance members begins to pay off.

Both men and women in the present run new health risks. The desire for money and material goods encourages young men to migrate to other parts of the province, in search of the success that cannot easily be attained through traditional routes of leadership. Mobility increases the risk of contracting sexually transmitted diseases. Wife abuse has increased as couples find themselves far from the regulating relations of village life. Youth regularly drink moonshine (made of bananas or pineapple), illegally imported whisky, and occasionally, distilled rubbing alcohol. Some young men and women in Wamena sniff glue every day.

Commercialized sexual relations are on the increase throughout the province, and in Wamena migrant Indonesian and indigenous women offer sexual services to both Indonesian and indigenous customers. Dani sex workers and their Dani clients are young, with most under the age of 21 (Yasukhogo, 2000). Women from the highlands find themselves at the bottom end of the sex work industry, where health risks are greatest. Dani women offer sexual services in insecure, often dirty, locations.

They are poorly paid, at around Rp. 25.000 (U.S. \$2.50) per transaction. Dani women from across the valley have experienced coercive sexual relations with soldiers. Overall, their clients are more likely to be violent, and to refuse to wear condoms. Condom use among indigenous sex workers is almost nil (Butt, 2002).

For many Dani, health is an extension of politics. The use of metaphors of illness and sexuality to explain broader power relations recurs often in Dani political discourse. Many Dani believe that AIDS was deliberately brought in to the province by infected Javanese sex workers in order to render Papuans powerless and enable Indonesian takeover of the valley. Rape of indigenous women by members of the Indonesian military in other parts of the province is also understood as a political tool and contributes to negative Dani assessments of Indonesian rule (Butt, 2001a; Coomaraswamy, 1999; see also Kirsch, 2002). Promoting birth control is also easily understood as part of a broader political effort to control, or eradicate, indigenous Papuans (Butt, 2001b).

Dying and Death

Dani life expectancy is almost certainly lower than the Indonesian average. Contemporary observations suggest that women and men age rapidly, and often die after they become grandparents. Older people, whose *etai-egens* have become small, often refuse to eat or drink in their final days.

It has been said that the Dani are obsessed with death. The transition from the world of the living to the world of ancestor spirits is a critical time, for spirits are at their most vengeful right after death. The funeral of an important Dani man or woman can last for days. People bring their largest pigs as gifts, which are killed, cooked, and distributed in a highly ritualized fashion. After one to two days of mourning and feasting, the family lifts the corpse high onto a log pyre which has been set on fire. The corpse becomes engulfed in flames. Crying women now all raise their voices in a massive wail and men join in. As the smoke rises into the air and the crying voices cut through the night sky, the message carried to those ancestors, wood spirits, and humans lurking outside the compound is that this dead person has been fully honored, and has no cause to seek revenge after entering the world of ghosts.

Dani health is inextricably linked to broader cycles of life and death. Yet, while groups in other parts of the highlands abandon old ways of life, the Dani retain ritual as core to their ideas about healing. One reason for this might be because development and “Indonesianization”

do not appear to have resulted in measurably improved standards of health. Infant mortality remains high, chronic illnesses such as scabies or sexually transmitted diseases have increased, and medical care is inadequate, both in basic quality and in cultural sensitivity (Hartono et al., 1999; Hull & Hartono 1999). For wider political reasons, as well as to protect their cultural strength as a self-interested society, Dani elders continue to insist that health and prosperity can best be achieved not through clinic medicines, but through properly executed rituals, through fecund women and fertile gardens, and through honoring the ancestors and spirits that roam the valley alongside the living.

British

Ian Shaw and Louise Woodward

ALTERNATIVE NAMES

Great Britain, United Kingdom—component countries: England, Scotland, Wales, and Northern Ireland.

LOCATION AND LINGUISTIC AFFILIATION

Britain is an island nation geographically separated from France (and the rest of Europe) by the 22-mile stretch of sea called the English Channel. The dominant language is English, but Welsh is now enjoying a revival assisted

by a recent devolution of government and the formation of a Welsh Assembly. Celtic is still spoken in a few remote parts of Scotland. Also there are some identifiable parts of major cities (linked to immigration) where the English may be a second language of use. Britain is a part of the European Union.

OVERVIEW OF THE CULTURE

The population of the United Kingdom is estimated at 58 million (the 2001 Census began reporting findings in

November 2002). Population density is toward the Midlands and the south-east of England with some areas in the north of Scotland very sparsely populated. However, there are some demographic drifts back to the countryside, particularly by the affluent middle class. Historically, England “annexed” Scotland, Wales, and Ireland into a United Kingdom by the 18th century, though much of Ireland gained independence in the 1960s. The British have been described as a “martial race,” though this may be more a reflection upon Britain’s history of Empire than an accurate description of current culture. Football (soccer) is the national sport.

Religion is predominantly protestant with the established Anglican Church of England and the Presbyterian churches of Scotland and Wales. However, Catholicism is a minority religion, and immigration has raised the profile of the religions of the Indian Subcontinent. Religious tolerance is high, with tolerance generally being cited as a cultural trait—though this does break down from time to time. For instance, the current influx of asylum seekers is seen as a major social and political problem. The influence of religion generally has weakened since the 1960s, which marked a rise of secularism, though there are links between Catholicism and nationalist politics in Northern Ireland. The economy has moved from predominantly manufacturing to predominantly service-based, with the main period of change and restructuring taking place during the 1980s. Globalization has had an impact on family and community ties, with particularly the middle class becoming more mobile, not just within Britain, but globally.

THE CONTEXT OF HEALTH: ENVIRONMENTAL, ECONOMIC, SOCIAL, AND POLITICAL FACTORS

There are four main demographic trends in Britain: a decline in fertility; an increase in dependency of the population; changes in family structure; and increased labor mobility.

A post-war “baby boom” occurred in the late 1940s and 1950s, which was followed by a “baby bust” in the late 1960s (Rimmer & Wicks, 1985). The present birth rate is less than half that of the “boom years.” There has been a dramatic increase in the number of people over the age of 65 in the United Kingdom. Between 1901 and 1991 this number grew from 1.8 to 9 million (Shaw &

Shaw, 1993). There is longer life expectancy for all age groups. Improvements in nutrition, medical services, housing, and work conditions have all contributed to this. The population of those over the age of 75 increased by a factor of 4 over the period 1901–1991 (Shaw & Shaw, 1993). The proportion of the population that is elderly (and the dependency ratio) is not set to “peak” until 2024. The elderly are the major consumers of health and social services and there is concern about how to fund state welfare, which is funded on a “pay as you go” basis, financed through general taxation. As an example, since 1983 state pensions have been linked to the cost of living rather than the average wage.

There have also been substantial changes within marriage. One in four will end in divorce on current trends. One third of all new marriages involve at least one partner who has been married before. One of the consequences is a rise in the population of single-parent families. The current estimate is 1.5 million single-parent families in Britain, and there are concerns about the issues arising from this for child poverty (poverty is used here as a relative rather than an absolute concept). The generally improving social status of women is recognized as important in determining their health outcomes. Also, women are more likely than men to invest the household’s economic resources in their children’s health and education.

Another key demographic effecting health within the United Kingdom is that of labor mobility. In 2000, approximately 84% of the British population lived in England. The years 1981–2000 have seen significant changes in geographical migration. Geographically, people have moved away from their homes for employment, subsequently reducing their available social capital. With the transition to the “nuclear family,” people no longer have the traditional “family” as an institution of care. In contemporary society, people move geographically, which means it is unlikely that an individual will see the same doctor (general practitioner—GP) over a long period of time. The concept of the “family doctor” no longer exists, and unlike years gone by where the doctor was traditionally viewed as both a medical practitioner and also a friend, visiting a GP nowadays is strictly a consultation process. Accompanying these changing social and geographical conditions is a process of self-medicalization of individual problems. The role of medicine in society is now part of an ongoing social process in which health and illness are made relevant for aspects of

everyday life. Personal problems are seen as becoming more medicalized with, for example, an increase in the prescriptions for anti-depressants.

Improvements in life expectancy in Britain have been attributed to access to clean water; effective sanitation systems; waste disposal services; safety precautions in food preparation and storage; increasing nutrient intake, especially following improvements in agricultural technology and productivity, for example; nutritionally fortified and higher-yielding crops; and environmental management. One issue affecting life expectancy is inequality between social classes. There is a significant relationship between social and economic position and health. People in unskilled occupations and their children are twice as likely to die prematurely in comparison with professionals. Similar gradients in mortality by social class are apparent for nearly all causes of death (Fox & Benzeval, 1995). Men in social class 5 lost 114 years of potential life per 1,000 of the population against 39 years in class 1. Such differences are not so marked amongst the elderly (Butler & Calnan, 2000). Data on social variation on patterns of morbidity show similar gradients. For example, age standardized long-standing illness rates for people who are unemployed are over 70% higher than for those who are employed. Also, various indicators such as body mass index, lung function, and blood pressure vary according to social class (Fox & Benzeval, 1995). This situation is mirrored across much of the Western world; however, economic inequality appears to be growing more quickly in Britain than in any other advanced industrial society (Butler & Calnan, 2000).

Britain has a National Health Service (NHS) that was formed on July 5, 1948, to provide a public health service “from the cradle to the grave.” This service is organized and financed in ways that promote the values of equity and fairness and has been described as “the jewel in the crown” of Britain’s welfare state. At the heart of this is the belief that good healthcare is a fundamental determinant of people’s capacity to succeed in life and that as such, it should be free to those who need it. The NHS has been funded predominantly out of general taxation and based upon the principle that access to services should be determined primarily by medical need. A part of the role of the NHS is to combat health inequalities by improving access to those who most need it and by working with local authorities to improve environmental and other determinants of health. There is a strong commitment to the NHS by the Labour Government. The cost of the NHS

is currently around 7.4% of gross domestic product (GDP). The target is to increase its budget to 10% of GDP over the next five years, to bring health spending in line with that of the United Kingdom’s European neighbors.

Environmental issues within Britain also have an impact upon health. In the last 15 years, concerns have been raised regarding pollution, for example, hazardous waste, pollution in rivers and bathing waters. In more recent years, public concern about health has expanded to incorporate the importance of quality food production. Traffic congestion, noise, fumes, climate change, and air pollution have also increasingly become issues closely linked to health in the public mind. Economic conditions affecting health are significant in terms of access to formal healthcare and provision of services. An aging population is a key characteristic of the United Kingdom and has significant economic implications. Subsequently, as the population is living longer and birth rates are lower, there are fewer people in employment. The number of people in the tax base has consequently reduced, impacting on the economic resources available for health, though not public and political commitment to the NHS.

MEDICAL PRACTITIONERS

Medical practitioners in the United Kingdom are overwhelmingly employed and trained by the NHS. The service is organized into two sectors: primary and secondary care. Primary care includes health professionals such as GPs, who receive clients from within the community with undifferentiated and undiagnosed problems. The GP will, in many cases, be the first contact an individual has made regarding his or her condition. GPs serve the entire local community in their areas. Nurse practitioners serve the local community in a similar way to GPs. Primary care nurse practitioners decide upon the priority of patient needs by performing a full assessment of healthcare needs, thereby determining a patient’s health status. Some patients may simply need to remain under the care of the nurse for treatment, whereas others will require consultation with the GP. Here, the patient has the opportunity to consult with either a GP, a nurse practitioner, or both. The role of the nurse practitioner is set to be given full consideration in extending his/her role to reflect that of the GP. However, while the nurse practitioner has a wide range of skills, knowledge base, and ability to deliver specific aspects of care at present, they may need

to be supplemented by a specialist. This may be a district nurse, health visitor, another primary health care nurse, community psychiatric nurse, counsellor, or clinical nurse specialist working in an acute care setting. Essentially the expertise of the primary care nurse practitioner is becoming more akin to that of a GP. They have the ability to operate as a specialist generalist offering care to patients with a wide range of needs.

Secondary care is a specialized service. Patients are generally referred by their GP to a secondary service for continued more specialized care. The number of secondary services provided is vast and covers a plethora of specialities, ranging from adult intensive care, blood disorders and diagnostic hematology, to disability medicine, healthcare of the elderly, and mental health. This service is generally hospital-based, although not in all cases, such as the Community Outreach service that serves people suffering with long-term and enduring mental health difficulties. Essentially, this is a mobile service that offers treatment and service provision within the client's home.

Secondary care services are led by specialist consultants within given medical areas, but the largest group of practitioners within this service is nurses. In recent years, a blurring of professional roles has developed. For example, nurses now are seen to take on more clinical responsibility. This includes professionally autonomous decision-making; screening patients for disease risk factors; developing, with the patient, a care plan; and he/she has authority to admit or discharge a client from his/her own caseload to other healthcare providers. Nurse prescribing is under consideration.

CLASSIFICATION OF ILLNESS, THEORIES OF ILLNESS, AND TREATMENT OF ILLNESS

The biomedical paradigm and its classification of and theories about illness and treatments is dominant. However, this approach has been "modernized" with increasing acceptance amongst health practitioners of the more behaviorally oriented multiple-risk-factor model. This emphasizes the interaction between behavioral risk factors and biological/genetic factors in the causation of disease. The importance of structural and environmental factors is also becoming increasingly recognized in etiology and classification (Butler & Calnan, 2000).

There is strong medicalization in some areas, particularly childbirth and unhappiness. Births are increasingly taking place in a hospital environment, with the incidence of cesarean sections showing a sharp increase in recent years. The incidence of depression in the United Kingdom has also increased from virtually nil in 1950 to "epidemic proportions" today, with one in four people visiting a GP said to be suffering from depression (Shaw & Middleton, 2001). This also illustrates that "lay beliefs" in Britain are heavily influenced by professional (often biomedical) paradigms—namely, that people may seek medical responses to social problems. Common sense understandings are imbued with professional rationalizations. In British society, biomedicine not only has provided a basis for the scientific study of disease, it has also become Britain's own culturally specific perspective on disease; that is, its folk (common sense) model (Engel, 1977). "Lay beliefs" are tied up with the certainty of diagnosis and the legitimacy afforded by taking on medical rationality. It has even been argued that there are no indigenous cultural developments in Britain that are not informed by an expert (if not biomedical) conceptual framework (Shaw, 2002). This can lead to increasing demands for healthcare services as new improvements in technology and pharmacology lead to increasing public expectations of health services. The use of "complementary medicine," particularly herbal medicine, aromatherapy, and Chinese medicine (such as acupuncture), which is not available as a part of the NHS and has to be purchased privately, is also on the increase.

SEXUALITY AND REPRODUCTION

In the 1870s in Britain, two-thirds of women would have had five or more children. In the 1920s, two-thirds of women would have had two or fewer children. The proportion of families with two children has almost doubled over the last century. Now, less than one family in six has three or more children. The proportion of childless marriages has also continued to grow (Parker, 1990). This illustrates a long-term decline in fertility in Britain, despite a "baby boom" in the decade following World War II. Reasons for this decline include: women are having children later in life, many for career reasons; greater availability of birth control and a widening of the legal grounds for abortion since the 1960s has given women more control over conception; more women are working and may find difficulties in looking

after children; marital breakdown is increasing; job security is decreasing (there may be a reluctance to have children in an insecure lifestyle); and women's attitudes have moved away from their traditional image of mother and housewife. An increasing number of live births are taking place outside of marriage (31% in 2001—about a half of these to cohabiting couples). Also, two groups of women have had an increase in fertility—middle-class women in their 30s, and teenagers of working-class parents. This latter group is the cause of considerable concern and the focus of current social policy.

HEALTH THROUGH THE LIFE CYCLE

Pregnancy and Birth

There are social class differences in attitudes toward pregnancy. For those in the “middle class”, it is becoming increasingly the norm for a first pregnancy to take place in the woman's 30s. This is less the norm for lower socioeconomic groups, and teenage pregnancy is becoming less unusual in areas of the cities where there are high rates of unemployment. Abortion is legal up to 24 weeks unless the fetus is regarded as having a severe impairment, in which case it can occur at any time with a supportive medical judgment. People regard miscarriage as a “loss” and a time for expressions of sympathy and support. Pregnancy and childbirth are heavily medicalized in Britain. The development of in-vitro fertilization (IVF) and other fertility treatments has led to service demands upon the NHS. Such services are viewed as a right of citizenship (Shaw, 2002). There is still stigma associated with infertility, but this has reduced significantly in recent years. Similarly, pregnancy and childbirth are regarded as times of risk, both by the medical professions and by many women themselves. Pregnancy is monitored regularly by health professionals, both by midwifery services in the community and by regular ultrasound scanning of the developing fetus and examination in a hospital setting. Smoking and drinking alcohol are regarded as activities that put the fetus at risk and there is a strong stigma associated with any engagement in such activities during pregnancy. Friends and family can be particular agents of “social order” in this respect. Indeed, there has been some work suggesting that such restrictions on the activities of the pregnant woman lead to a sense of losing control over her own life (Bowen, 2001).

The vast majority of births, 98%, take place in hospital. Less than 8% of births in Britain are without any medical intervention and a higher percentage of these are associated with home births. There is government concern over the increasing number of cesarean births in recent years (Lane, 1995). Healthy newborn babies delivered in hospital are generally allowed home after 2–3 days, though mothers can opt to stay in hospital for longer if they wish.

Infancy

Infancy is not a clearly defined category in Britain. However, there is a general view that infants are those between the ages of birth and 5, at which point they start primary school. Infancy is generally broken down in the public mind into three categories: baby, toddler (from taking first steps to developing the ability to run, skip, and jump—the term is derived from the “toddling” walk of the child), and childhood. Health Visitors monitor the initial development of the baby. Health professionals heavily promote breastfeeding, and most mothers will breastfeed for the first 18 weeks (the period of paid maternity leave allowed from work, though many employers offer additional unpaid leave, some up to a year). Subsequent development is monitored by GPs, who carry out immunization. Infants are immunized at the ages of 2, 3, and 4 months against tetanus, diphtheria, whooping cough, hemophilus influenzae type B (HiB), and polio. At 12–18 months they receive vaccination against measles, mumps, and rubella (MMR), which they are also vaccinated against a second time at between 3 and 4 years when they will also receive additional vaccinations against diphtheria, tetanus, and polio. Vaccination take-up is high, over 80%, although the MMR take-up has dropped below this level in some areas in the last year over fears of links between the combined vaccination and autism. This has resulted in isolated outbreaks of measles during 2002. If taken ill, children will usually expect to receive separate specialist secondary care services.

There is little government support or provision of day care for children under the age of 3 in Britain. Childcare facilities do, of course, exist, and are run by private individuals, companies, and by local authorities. Extended families, where in existence locally, may also play a part. The cost of day-care varies across Britain, but £25 per day—2002 prices—(approximately US\$36) is a good guide. This means that the low-paid or those with more than one child not living in an extended family relationship

where there is support from those retired, may be financially better off if one parent remains at home. Labor mobility has reduced the number of available family members locally who could take on a childcare role. The main caretaker is usually the mother. The state does provide free preschool (during the school term only) for children aged 4 (or aged 3 if in an area defined as having poor educational performance). Children start full-time education from age 5.

In post-modern Britain, many of the social contacts that parents have may be other parents whose children attend the same day care.

Childhood

Childhood in Britain is a period of both protection and exclusion. Children's lack of competence in the highly specialized differentiated world of adult activity in this country provides an explanation for children's exclusion and the protectiveness that accompanies it (Mayall, 1996). It is true to say that the daily lives of children are structured through the organization of their parents' time (particularly when both parents work), although childhood is also a time when there is protection from the world by social and economic provision. Schooling from the age of 5 has the dual role of providing the education to enable them to function in the adult world and to protect them during the day while their parents are at work. Childhood is also seen as a time for developing interpersonal skills and relationships as well as providing creative space of their own. Particularly in early childhood, children's imagination is actively fostered by adults—Santa Claus really does come down the chimney and Mickey Mouse really does live in Disneyland. There is a desire amongst parents to extend this period of innocence as long as possible.

Adolescence

There is no legal definition of adolescence in Britain. The Children Act of 1989 covers everyone from birth to age 18, the legal age of consent. Legally, children are deemed to have the capacity to tell right from wrong from the age of 14. However, this age of legal responsibility was recently reviewed following concerns raised by the murder of the toddler Jamie Bulger by two children who were 10 and 11, and by other cases (including a rape committed by an 11 year old). There is still a presumption of incapacity for children between the ages of 10 and 14 in Britain. However, legally, children in this age bracket can be

deemed to have, what is quaintly termed, "mischievous discretion." Here it is for the court to decide in individual cases whether the child knew the consequences of his/her actions and knew right from wrong.

In the mind of the general public the "lay distinction" between children and adolescents is in some sense distinguished by the direction of protection. Children need to be protected from dangers in society, whereas society needs to be protected against the dangers posed by adolescents. This is in part a perceptual, rather than a real issue as groups of adolescents playing or moving around the streets is not uncommon. However, in some, particularly inner city areas, school truants have been linked to crime and vandalism, particularly in the popular press. Mugging and theft for/of mobile phones, in particular, has strong links with adolescent age children (mainly adolescents stealing from other children), as does "joy riding" (fast driving in stolen cars). As a policy response the government has re-enforced the principle of parental responsibility. Parents are liable for fines imposed upon their children, and recent proposals have been made to impose reductions on the receipt of state benefits for parents whose children are truant from school.

Inoculation continues into later childhood, with children aged between 13 and 14 years receiving a Heaf test for tuberculosis and a BGC (Bacillus of Calmette and Guerin) vaccination if indicated. Also, children aged 15–18 receive a booster inoculation to protect against tetanus, diphtheria, and polio.

Adulthood

Health-related issues in adulthood are varied, and in recent years a shift in emphasis has taken place to a demand for the right to be healthy. As society has become adept at problem-solving within the medical realm, a discourse has developed in which health is seen as a basic human need and medical care is perceived as a basic human right. Related to this is the notion of individual responsibility, which is partly reflected nowadays in the attention given to self-help and complementary therapies; aromatherapy, massage, shiatsu, yoga and relaxation, and acupuncture, for example, have all become popular alternative forms of therapy. Within adult mental health creative therapies, such as art and horticultural therapies, are a developing area. In conjunction with this is the increasing number of fitness centres within the United Kingdom and increasing numbers of people attending them. Gender-related issues

include concern about menopause and hormone replacement therapy (HRT), which has received mounting attention. Concerns have also been raised regarding the over “medicalisation” of this natural change within a woman’s body, whereby women are seen more sexually and socially obsolete, and medically and emotionally out of control. Studies show that HRT prevents osteoporosis and may significantly reduce the risk of coronary artery disease, but they also indicate that HRT may increase a woman’s risk for breast cancer.

Domestic abuse in the United Kingdom, either physical or verbal, is becoming recognized as a health issue for a significant minority of women and children. Most women experiencing domestic violence are not identified in medical records. Abusive relationships are still very much seen as a “private” affair, one where intervention has unclear boundaries. Women’s services within mental health is a developing area, concentrating upon a service that identifies the unique needs and demands of women, including safety within in-patient and residential settings. In particular, motherhood and mental health is now a recognized area of need, including post-natal depression. Men’s health has, in recent years, been receiving attention both in the media and in the academic literature. The demarcation between the health of a man and that of a woman, however, is that men’s health is more closely associated with culture (and work) and women’s, with nature (and health). Prostate cancer has become an area of concern for men; 22,000 men in the United Kingdom are newly diagnosed with this each year. The incidence of testicular cancer has doubled in the past 20 years. Depression also is widespread but more often goes unrecognized as a condition in men than it does in women. Furthermore, the effects of alcohol on the body are becoming an increasing medical concern within both genders; young women now drink more frequently than ever. Unequal access to medical care within society tends to be the experience of those individuals suffering from a mental health condition, rather than being unequal in terms of gender. Inequalities exist also in terms of social, economic, and environmental disadvantage. Despite overall improvements in health, the gap between socially disadvantaged and affluent sections of the population has widened. A significant movement within healthcare taking place at present is the recognition and need to involve users at all stages of their care. This spans the whole NHS to ensure the needs of clients are met, and a more pro-active role in their treatment is taken by clients.

The Aged

“The aged” are structurally defined in Britain with mandatory retirement at age 65, when the state retirement pension is also payable. However, those aged 65 in Britain often do not see themselves as elderly and generally reserve that phrase for those aged 75 and over. Life expectancy and general health have increased for all age groups and the numbers aged over 80 is increasing every year. Because of the good health of those in their late 60s, the government is currently considering introducing flexibility on retirement age. This is important because a longer retirement means that more resources are required to fund it. A more flexible retirement age would also provide more scope for individual choice in this respect.

Income in retirement is linked to income in working life. Although there is a state pension, it provides a very basic income and the expectation is that this will be used to supplement a private or employment-based pension scheme. The current focus on “welfare to work” itself tends to exclude those who have retired. Quality of life in retirement, and social status, is still linked strongly to income.

The elderly are the major consumers of Britain’s NHS. There is an association between incapacity and increasing old age; those over 80 consume 27 times the health and social care resources as those between the ages of 14 and 44. Those over 75 are also heavy drug users, with an average of 12 prescriptions per year (Glennister, 1997). The major medical problems of the elderly are related to their age: age-related hearing and visual impairment, cognitive impairment, and cerebral vascular diseases and associated dementia. There are also skeletal problems resulting from arthritis and osteoporosis, which give rise to mobility issues. Some of these diseases and problems can be found in those younger than 65, but the incidence increases with age and concerns with mobility are particularly focused upon those over the age of 75. Labor mobility has meant that there is less likelihood of the children of the elderly living locally to them, and consequently, there is only limited practical support that the elderly can expect to receive from family members. This places increasing reliance upon primary health and social care services.

Dying and Death

Attitudes toward death within Britain have undergone something of a change over the years. Now viewed less

as part of the natural birth–life–death cycle, death is increasingly viewed as the result of a pathological condition, caught up in medicine and disease. Although the dominant religion in Britain remains Protestant, the rise in secularization and the decline in religious influence and practice has led to an increased fear of death as an “end.” This may be linked to the increased value placed on health in British society. Regardless of what condition a human is suffering from, attitudes toward death mean that it must be fought at all costs. The concept of euthanasia is an extremely political area. Although voluntary euthanasia is illegal in the United Kingdom, there are conflicting views concerning this. GPs are allowed to administer a potentially lethal dose of pain killing drugs to relieve pain and suffering, but with no intention to kill. This has been both a political and moral high ground in recent years. Public concerns sway between accepting voluntary euthanasia as a personal choice, and freedom to help people die in dignity and pain free. Other attitudes raise concerns that any system of legalized killing would be open to abuse. This sits very closely with treatment of those suffering from long-term, life-threatening illnesses, such as cancer and HIV/AIDS. Hospice or palliative care services are offered to the individual, which for some may mean living in a cared environment whilst “waiting to die.” The type of care offered by these services is predominantly focused upon pain control to develop a quality of life for the person during the final stages of the illness. Included within hospice care are family support and bereavement services.

Bereavement within Britain is taken as an expected process a person will enter after losing someone to death, and is an acceptable process for an individual to experience. This is often a long and complex ordeal, especially with the loss of children or unexpected loss, and is often dealt with over a period of time, and for some, with the aid of supporting voluntary organizations. There are also now specialized services, such as the National Association of Widows, the Gay Bereavement Project, and Jewish Bereavement counseling. The attitudes toward the loss of a child are seen as the most traumatic and profound of all losses. Parental loss of a child is seen as psychologically

and biologically the same following the death of a child at any age, from miscarriage to adulthood.

Suicide within Britain is seen not as an act of will but rather as influenced by an individual’s mental capacity. Someone who attempts suicide is in need of help, and there are services available to help address this.

The body is treated respectfully following death. It will be taken to a chapel of rest, either at the hospital (if that is where the person died) or to a funeral director. The body is then subsequently transported for purposes of cremation or burial. Cremation is becoming the more usual means of disposal of remains in Britain. A religious service will be held at the chapel and/or church prior to cremation or burial.

Burmese

Monique Skidmore

ALTERNATIVE NAMES

In 1989, Burma was renamed the “Union of Myanmar” by the newly constituted State Law and Order Restoration Council (SLORC). The “Burmese” were renamed the “Myanmarese” or “Myanmars”, and the Burmese language was similarly changed to the Myanmarese language. Minority groups in Burma were renamed “National Races,” with “Myanmars” used to designate Burmese citizens of all ethnicities residing within Burma. The United Nations recognized the name change but pro-democracy groups use the older terms, especially “Burma”, “Burmans”, and “Burmese” as a way of protesting at the undemocratic nature of the name changes.

From 1885 until 1937, Burma was designated a province of India as part of the British Raj, and literature of the period regarding Burma is found in Indian manuscripts and journals.

Several armed groups have claimed independence from the military government and insurgent-held areas often publish literature referring to their territory as an independent entity. The chief example is publications from Manerplaw, Kawthoolei, a self-designated independent homeland of the Karen people (and the Karen National Union rebel headquarters) from 1971 until its capture by Burmese military forces in 1995 (Hail, 1995).

LOCATION AND LINGUISTIC AFFILIATION

Shaped like a kite, Burma is the largest country in mainland Southeast Asia. Burma covers 671,000 km² and borders the Andaman Sea, the Bay of Bengal, Bangladesh, China, India, Laos, Thailand, and Tibet. Most of these borders are flanked by mountain ranges, including the Himalayas in the north. The central riverland plains are the agricultural heart of the nation with the major north-south river, the Ayeyarwady, flowing to the large delta area that spills into the Gulf of Martaban. The Thanlwin River forms much of the border with China, and the Mekong likewise forms the border between Laos,

Thailand, and Burma (The “Golden Triangle”). The Shan Plateau is a rugged, mountainous area bordering China, and tropical jungle covers much of the area bordering Thailand. The eastern borders of the country are home to the Arakanese (Rohingyas), Chin and Naga groups, who are ethnically similar to neighboring populations in India and Bangladesh.

Over 135 minority groups reside in Burma and the range of languages spoken is correspondingly large with over 100 linguistic groups and sub-groups (WOB & NCGUB, 2000). Burmese is the lingua franca, and since the military coup of 1962, the language of internal colonization. It is the language spoken by the majority ethnic groups, the Bamars or Burmans. Karen, Shan, Kachin, Chin, Arakanese, Kayin, Palua, Hindi, Mandarin, and English are just a fraction of the languages one can hear spoken in contemporary Burma. Burmese is a member of the Tibeto-Burman family of languages. In addition, there are members of the Mon-Khmer, Austro-Thai, and Karennic language families. The many different minority groups in Burma are described by the State Peace and Development Council (SPDC) as falling into seven “National Races”: Chin, Kachin, Kayah, Kayin (or Karen), Mon, Shan, and Rakhine. The Central Intelligence Agency (CIA) estimates the population to be broken down into the following percentages: Burman, 68%; Shan, 9%; Karen, 7%; Rakhine, 4%; Chinese, 3%; Mon, 2%; Indian, 2%; and “other”, 5% (including Thais) (CIA, 2002).

OVERVIEW OF THE CULTURE

A primarily rice-based agricultural society practicing dry rice, wet rice, and swidden agriculture as well as aquaculture, Burmese society was monarchical until the Third Anglo-Burmese War in 1885. The deposing of King Thibaw ended governance by the monarchy and official patronage of the only other significant institution, the *Sangha* (monkhood). Education was in the hands of the monasteries, villages comprised approximately 500 people, and headmen in the central riverland plans were part

of a complex political system of reportage, all the way up to the monarch. After British colonization, the complex political units of various groups within Burma (including the *gumlao* and *gumsa* systems of the Kachin, as documented by Edmund Leach) (Leach, 1970) was overlaid with a British administrative system. General Aung San, the founder of the Army, was the architect of Burmese independence. Independence was granted in 1948, one year after Aung San and his parliamentary cabinet was assassinated in a bomb blast. U Nu was elected Prime Minister. A devout Buddhist, U Nu reasserted traditional relationships between lay authorities and the *Sangha* and was seen by some members of the military as being too "traditional" and non-embracing of modernization. In 1962 General Ne Win launched a successful military coup and only resigned in 1988. This period, known as the "Burmese Road to Socialism," turned Burma from the largest rice exporter in Asia, to a UN-declared "Least Developed Country." Following Ne Win's resignation, country-wide pro-democracy demonstrations forced the new dictator, Sein Lwin, to resign. The bloody suppression of the democracy movement birthed the State Law and Order Restoration Council (SLORC), whose name was changed in November 1997 to the State Peace and Development Council (SPDC). Tertiary institutions have remained largely closed since 1988 due to student pro-democracy activism, including the December 1996 student demonstrations. Small technical and rural tertiary institutions opened in 2001. The pro-democracy leader, Aung San Suu Kyi (secretary of the National League for Democracy (NLD)), was released from house arrest in May 2002, but then arrested in May 2003.

Two-thirds of the population are agriculturalists, with 10% employed in industry and 25% in the service industry (CIA, 1999, estimates). Economically, the country is in a perilous condition, with inflation estimated at 50% per annum and a thriving black market. Sanctions by the European Union and the United States against investment in Burma killed a building and land speculation boom in the mid-1990s, a boom that screened the laundering of profits from the production and sale of heroin. External debt for 1999/2000 was estimated at US\$6 billion, and Myanmar received US\$99 billion in economic aid in 1998/99. The official rate of kyat per dollar in January 2001 was 6.6, as compared with the unofficial rate in 2002 of 1,000 kyat/dollar. The government does not publish economic data, but the CIA estimates the percentage of the population below the poverty line at 23% in 1997 (CIA, 2002). The Burma

Freedom and Democracy Act, signed into law by the U.S. President in 2003, applied further sanctions and effectively closed down garment factories and other export industries, further imperiling the formal economy.

Burma vies with Afghanistan as the world's largest supplier of heroin and methamphetamines. The highest levels of the military regime are directly implicated in the sanction and control of the drug trade, as is the Wa State Army, and are, until recently, the Shan State Army and various other military groups operating in the Golden Triangle region. Profits from the heroin trade in part also fund the 40-year insurgency against the military regime as well as providing hard currency for some military officials.

Kin terminology emphasizes age groups rather than vertical linkages and there is no ancestor worship in Myanmar. Women do not take the names of their husbands when they marry, and anyone may change their name as often as they like without any formal procedure, although this is rapidly changing with the increased control local security offices have over the recording of significant life events. There is no division of Burmese names into first names and family names. A Burmese name usually consists of several syllables or words. "Tint Tint Khine," for example, means literally "strong but elegant."

Kin terms are self-referential. A man older than oneself is designated *U* (uncle) and someone younger than oneself is referred to as *Maung* (younger brother). A male of approximate or slightly older age is referred to as *Ko* (or elder brother). Older women are designated *Daw* and younger women *Ma*. Residence patterns are most commonly matrilocal, with extended families living in the same house or in separate houses within one compound. Inheritance is bilateral and kin ties are not of importance unless relatives wish to emphasize the bond (Henderson et al., 1971, pp. 67–68).

The Burmese are overwhelmingly Theravada Buddhist (89%), with small populations of Christians (4%) (Baptist 3%; Roman Catholic 1%), Muslims (4%), animists (1%), and others (2%). Astrologers are common, and Hindu temples, mosques and Jewish synagogues are also in evidence. There is an almost unanimous belief in animism in the *Nat* cult a vibrant system of spirit propitiation. *Nat* spirit wives have in recent years been largely replaced by transvestite men who find an acceptable social role in spirit mediumship and dramatic performance. The relationship between animist nature spirits, *Nat* spirits, and Buddhicized figures is complex and changes over time. Theravada Buddhism is strongest in Burma,

where a mass lay meditation movement practicing *vissipana* meditation seeks to reform the monkhood and eventually social and political life, from below. Charismatic monks and various sects and cults (*gaings*) exist in Burma where a strong belief in the miraculous and millenial beliefs hold significant sway in social life and strategies. Astrology, alchemy, magic runes (*in*), spirit propitiation, soul flight, reincarnation, karma, witchcraft, visions and portents, *samatha* and *vissipana*, are but some of the rich store of religious, cultural, and magical knowledge that inform Burmese people's worldviews.

Drama, dance, puppetry, music, painting, and poetry are central to Burmese life and to cultural, religious, and artistic expression. Comedy, political satire, romantic and nationalistic themes, and Buddhist and spirit universes and powers are all expressed through these media. In recent years popular magazines, DVD/video and karaoke huts, and movie theaters have fostered an indigenous movie and rock star scene.

Women's roles in society are limited due to the military hierarchy of the nation and their exclusion from monastic roles other than as donors, administrators, and nuns. Whilst many Burmese women will claim that they are equal because of shared property rules, lack of dowry, and the general ease with which women may enter and leave marital arrangements, human rights groups draw attention to the atrocities and suffering of Burmese women in war zones and in relocated areas where structural and domestic violence, sexual bartering, and prostitution are serious problems.

THE CONTEXT OF HEALTH: ENVIRONMENTAL, ECONOMIC, SOCIAL, AND POLITICAL FACTORS

In the World Health Organization's (WHO) ranking of the health status of individual countries, Burma ranks almost last, 190 out of 191 nations (WHO, 2001). This statistic represents a spectacular fall in health standards (and living standards more generally) over the last four decades, the period of military rule.

The birth rate in 2001 is estimated at 20/1000 population (CIA, 2002), and the infant mortality rate in 1995 estimated by the WHO to be 50/1,000 live births and under-5 mortality at 101/1,000 live births (compared with the 2001 estimate of the CIA of infant mortality at 74/1,000). CIA health indicators are consistently worse

than WHO and Burmese Government figures because they are based on estimates of deaths due to HIV and other future health estimates. The CIA estimates the total fertility rate to be 2.3 children per woman.

The 2002 health statistics issued by the Myanmar Ministry of Health put government expenditure on health at approximately US\$278 million and capital investment in health at US\$13.5 million. The reported number of cases of some childhood diseases has decreased in the past decade, with reported cases of diphtheria dropping from 204 in 1990 to 38 in 2000, and neonatal tetanus falling from 189 reported cases in 1991 compared with 61 in 2000. Similarly, since oral polio vaccine (OPV) coverage began in Yangon in 1982, the number of reported poliomyelitis cases has fallen from 390 to 50 in 2000 (Ministry of Health, 2002).

Burma has two major psychiatric hospitals, one in Rangoon [Yangon] and one in Mandalay. Qualified psychiatrists are rare in Burma. In 1994 there were 130 medical officers and 260 regional officers trained to identify five psychiatric conditions. There is very limited psychiatric training offered by Burmese medical institutes (Skidmore, 1998). There are four medical institutes in Burma, and since 1978 postgraduate training in psychiatry has been possible in Burma. From 1993, consultant psychiatric health services have operated in the 14 state and division hospitals (Sein Tu, 2002). The inadequate government wages mean that doctors working at the psychiatric hospitals operate their own private clinics in the afternoons or evenings. Medication consists almost solely of barbiturates and Thorazine (chlorpromazine). Differential diagnosis is very limited, with dramatic changes in the frequency of diagnostic categories occurring over the last 30 years (Skidmore, 1998).

Mandatory arrest, incarceration, and detoxification of people suspected of heroin and methamphetamine use occurs in Burma. Throughout the country a number of Buddhist detoxification centers exist. Withdrawal is managed with either no medical assistance or with a tincture of opium. Incarceration occurs for approximately 6 weeks. Two hospitals for drug addiction exist (in Putao and Myitkyina), six "major therapeutic centers," and 22 "rehabilitation" centers (Sein Tu, 2002).

Food shortages have been recorded across 10 of Burma's 12 provinces and inflationary pressures continue to push up the price of basic commodities such as rice, oil, and fish (People's Tribunal, 1999). Government quotas on rice production also assist in malnourishing

Burmese villagers. In peri-urban settlements ringing Rangoon and Mandalay, two meals per day consisting of rice with *ngapi* (fermented fish sauce) and a very small amount of protein (fish, meat, or legumes) is the norm. Malnourishment of children occurs when women do not have enough breast milk and feed their children the water in which the rice has been cooked. Many Burmese people in peri-urban and rural areas use rice-water and betel nut as appetite suppressants or as food substitutes (Skidmore & World Vision International, 1997a, 1997b).

The Ayurvedic humoral system of “hot” and “cold” foods has become irrevocably muddled in Burma. An enormous amount of indigenous medical knowledge was lost upon British colonization and in the subsequent decades of poverty and civil war. Indigenous medical practitioners trained through the apprenticeship system are now rare, with the new generation being trained in government traditional medicine institutes, hospitals, and clinics. Among the lay population, humoral medical concepts are used in non-consistent and often harmful ways. Pregnant women, for example, often refuse to eat foods that provide adequate dietary protein and fat because of beliefs related to harm of the fetus. In addition, the strong belief in *Nat* spirits means that foods favored by *Nat* are eaten only occasionally. These most ubiquitous of commodities, coconuts and bananas, thus provide a form of dietary proscription that further reduces the available foods to people only occasionally receiving adequate nutrition.

Medical hospitals provide excellent medical care for military officers and their families. Public hospitals are subject to routine theft of equipment and pharmaceuticals, and patients purchase their own medicines at pharmacies or market stalls for use in both biomedical and indigenous medical hospitals.

MEDICAL PRACTITIONERS

Medical and medico-religious practitioners are utilized in Burma for a range of emotional, supernatural, mundane, and psychiatric problems. Biomedical physicians are trained at the government institutes of medicine, including training in many biomedical specialties. Overseas training is a common route to specialist training. Private diagnostic services such as X-ray and ultrasound exist in cities and large towns. Opticians and dentists are also common. Specialized nursing institutes also exist and

government-trained midwives work in well-populated areas and also provide rural outreach programs.

Community healers (*yankus*) span the spectrum from charlatans to indigenous medical practitioners who practice a variety of traditional and biomedical procedures. This can often mean that medicine is given inappropriately and without regard to side-effects. Illegal trading of medicines from China, Thailand, and India means that Burma’s markets are stocked with illegally packaged, misleading products, without cold storage, and often many years past their use-by date.

Indigenous medicine is the first recourse for most Burmese when self-diagnosis of the great majority of daily illnesses occurs in the home. Indigenous medicine is practiced privately by practitioners trained through apprenticeship, and officially, as managed by the traditional medicine department of the Ministry of Health. Utilizing the five tastes, Buddhist principles, knowledge of medicinal plant properties, and the preparation of dried and powdered compounds, traditional medicine is the primary form of medical care in the 40% of the country not covered by basic biomedical healthcare (IPPF, 2002). In addition to traditional medicine practitioners, *lethes*, or traditional midwives, practice delivering babies and the care of pregnant women, and care for women for 6 weeks after the birth. They also practice “massage” and a variety of other methods to abort unwanted fetuses. *Lethes* who specialize in abortion become known as abortionists, but the government will often arrest such women. Abortion is illegal in Burma but poverty and domestic violence lead many desperate women to abortionists.

Astrologers, white magicians, alchemists, wizards, *Nat* spirit mediums, and magic monks are among the medico-religious specialists (*daq sayas*) that Burmese people turn to for emotional, psychiatric, and economic aid. Among the rural population who present to psychiatric hospitals, a variety of these practitioners are sequentially utilized, with psychiatric personnel being used only as a last resort and usually without the patient’s consent.

CLASSIFICATION OF ILLNESS, THEORIES OF ILLNESS, AND TREATMENT OF ILLNESS

The most consistent finding arising from the author’s fieldwork in peri-urban Burma is that the regularity and

volume of blood at menstruation and childbirth is the fundamental indicator of health and well-being for women. Being in good health is contingent upon harmony in and between the body and the universe where the latter includes the socioeconomic and political dimensions of everyday life. Blood flow is the key symbol by which Burmese women's beliefs and practices concerning their well-being can be understood. This generic Burmese pathophysiology is used in the forcibly relocated peri-urban townships to experience and express the experience of illness and being unwell. Abortion, childbirth, madness, and "weakness" are the major domains in which understandings of the way that blood flows through the body are elaborated, and these lay diagnostic categories give coherence to women's illness, treatment, and local etiologies. Burmese women's health as articulated at the levels of pathophysiology, interpersonal relations, and the local peri-urban environment, necessarily include the wider political and moral economies of Burma. All of the women interviewed by the author are adamant that the body, mind, and soul cannot be well if the physical, political, and spiritual domains are not aligned in harmony. The moral economy of military dictatorship and the enforced economic impoverishment of the majority of peri-urban Burmese are understood by Burmese people to be the underlying causes of ill health in general, and of peri-urban "women's diseases" in particular (Skidmore, 2002a).

Well-being is divided into gender and age categories, with familial and sympathetic causes of illness understood as possible contributing factors to illness. A belief in the contagious spread of leprosy by family and friends of people with the virus leads, for example, to the stigmatization of entire families and social networks and their inability to find or keep employment if there is evidence of a member of the group with leprosy (Skidmore, 1997a).

SEXUALITY AND REPRODUCTION

Hepatitis, HIV, and other sexually transmitted diseases flourish for a variety of reasons. These include the prevalence of men using prostitution, the practice of polygamy, the rate of heroin addiction in Myanmar (4% for men, 2% for women) (UNDCP, 2001), and other unsafe practices such as re-use of syringes in medical clinics and penis-enlarging procedures common in Burmese jails and among fishing communities. Carrying condoms is widely believed by the police and military forces to constitute

evidence that a woman is engaged in prostitution, and has been legal only since 1993 (Smith, 1996). In addition, men refuse to buy small- or medium-sized condoms, and a majority of both wives and women working in the sex industry argue that they cannot make their sexual partners use condoms. Most state that it is an inappropriate subject to discuss between the sexes.

HEALTH THROUGH THE LIFE CYCLE

Pregnancy and Birth

Women's health is divided into three life periods that correspond to three types of illness categories. *Miyet sa* covers all those illnesses believed to occur because of menstruation and up to the period of motherhood. *Miyet leh* refers to illnesses of the "middle years," specifically related to childbirth, breastfeeding, and women's health during their years of raising children. *Miyet so* refers to illnesses that occur around the time of menopause and continue on into old age for women. Each of these stages is concerned with blood flow, especially lack of adequate menstrual flow at puberty and leading up to menopause. "Weakness" is a major diagnostic category believed to result from too little or too much blood flow, but also arising from the use of contraceptives. Emmenogogues are used extensively to increase blood flow and also as an attempt at aborting unwanted fetuses. Many Burmese physicians translate weakness (*thwe aah neh*) as anemia but the category is broader and refers as much to social and material aspects of living as it does to physiological imbalance. The national nutritional program gives the statistic of 89% of pregnant women to be at risk from iron deficiency anemia (WHO, 2002), and the major reason for young women to present to traditional medicine hospital and clinics is amenorrhea (Skidmore, 2002a).

Too much bleeding during and immediately after childbirth and abortions is also a major cause of concern. Childbirth is seen as a particularly dangerous time, but a belief in potential harm to fetus and mother also marks pregnancy as a period when a large number of taboos concerning food and mobility come into play. Abortion is illegal in Burma, but it is not stigmatized in the community. In addition, marriage and divorce are easily achieved, and illegitimate children are not considered different from other children (Skidmore, 2002a).

Infancy

Burmese midwives deliver babies and perform abortions, primarily through abdominal massage. The postpartum period, *me-dwin*, is marked by sequestration of young mothers, dietary taboos, and attempts to stop the body from losing heat. This means that the body is not bathed in cool water (sometimes no bathing occurs for 6 weeks), and “cold” foods are not eaten. Burmese women usually breastfeed exclusively for at least 2 months, with the water that rice has been cooked in usually given as the baby’s first supplemental food. Infants are carried and cuddled by mothers, and rocking cots, hammocks, and swings are used by mothers, sisters, daughters, and grandmothers to continually keep the child in motion when awake (Skidmore, 2002a). In urban, peri-urban, and regional centers, many mothers use antenatal care, but infant mortality remains high, as does maternal mortality, primarily from incomplete abortions. Maternal mortality is as high as 500–580 per 100,00 live births (WHO, 1997). Women present to regional hospitals on a daily basis with hemorrhage from incomplete abortions. Studies conducted throughout Burma indicate somewhere between 33% and 60% of maternal mortality is directly attributed to abortions (Ba Thike, 1997; Khin Than Tin & Khin Saw Hla, 1990; Ministry of Health & UNFPA, 1999). Two studies have found abortion to be the leading cause of maternal mortality in Myanmar (Krasu, 1992; UNICEF, 2000).

Vasectomy is illegal but there is a thriving trade by urban surgeons. Cesarean rates are very high in some areas and many women opt for a hospital birth, especially a cesarian birth so as to also have sterilization following the birth of their second child. Cesarean births are very expensive and there is no uniformity of charge across the urban and peri-urban areas (Skidmore & World Vision International, 1997a, 1997b). These difficult conditions for childbirth mean that infant mortality rates are almost 400% higher in the 40% of the country where no basic biomedical health services exist (IPPF, 2002).

Childhood

Twenty-nine percent of the population is aged 0–14 years (CIA, 2002). Thirty-eight percent of children aged 6–11 had, in 1994, recognizable signs of goiter (WHO, 2002). In 1994, 31% of children under three years of age had unacceptable weight-for-age ratios (WHO, 2002).

Children are traditionally allowed to run free until the age of 12, when they are sent to monastic centers for

education and discipline. Many children attend government schools and are teased, mocked, and told parables to teach appropriate social behavior and norms. Children are regarded with great affection and as the embodiment of a family’s happiness and wealth. Children have a keen sense of duty to their parents and teachers and may become monks or nuns for short periods of time to repay their parents’ love by making merit for them in their coming lives.

Adolescence

The *shinbyu* (for boys) and ear-boring ceremony for girls traditionally mark, for Burmese Buddhists, the coming of age of adolescents and bestows upon them responsibilities of family and personal welfare. For impoverished families this means adolescents must earn money to contribute to family income. For wealthier families it means following Buddhist precepts and being respectful of monks, parents, and teachers, as well as trying to excel at school. In these ways, adolescents prove that they are worthy of the care that their parents have invested in their childhood. Many adolescents feel a fierce sense of duty toward their parents. As young adults, adolescents are required to dress in culturally appropriate ways and to be mindful of Burmese cultural norms and traditions, especially with regard to appropriate gender behavior. For young girls this includes having a chaperone in public.

Adulthood

Domestic violence, sexual bartering, sexual torture, and death from incomplete abortions are all facets of everyday life in the poorest of Burma’s townships, especially those townships that have been forcibly relocated from central urban areas to paddy fields on the outskirts of the major cities. Alcohol use is very high in these areas as men’s powerlessness becomes apparent in their lack of employment and social status that has resulted from their forcible removal from previous townships (Skidmore, 2002b).

Domestic violence, polygyny (due to the highly mobile nature of the young male workforce), and other forms of marital disharmony have led to a very high divorce rate, paralleled by an almost equal rate of remarriage. This means that families in the relocated townships frequently consist of many step-relations. Incest has been reported by girls and young women when step-brothers, step-fathers, and step-uncles take financial responsibility for the household. Fear of incest and marital rape is widely reported in these townships. Forcible relocation

meant smaller land plots and splitting up of extended families which in turn meant less controls over male household leaders (Skidmore, 2002b).

Drug abuse is a significant problem in Burma. Nicotine, betelnut, codeine, and cough mixtures containing codeine, methamphetamine, opium, benzodiazepans, and, especially, heroin are all common substances easily purchased in urban and regional areas. It is relatively rare for women to be addicted to substances other than betel and opium, although alcoholic female patients do present to the psychiatric hospitals and the smoking of cheroot cigarettes is common among older women (Skidmore, 1998). The 1994 WHO smoking survey found that 47% of people aged over 15 are regular smokers (WHO, 2002).

Heroin is available in several grades in Burma, but the most common grade is known as No. 4 heroin and is highly refined. It is available on street corners, in schoolyards, in “shooting galleries,” and via “courier” or “delivery” systems where regular deliveries are made to individuals’ homes. Benzodiazepans are used as a form of self-medication when heroin is not available or as a form of slow withdrawal from heroin, although the recent availability of large numbers of inexpensive metamphetamines means that multiple drug use strategies are increasingly common (Skidmore, 1998).

The partial payment of government workers with palm oil has led to an enormous increase in heart attack, stroke, and hypertension as evidenced by both non-government organizations (NGOs) and by the presentation of patients at the traditional medicine hospitals (Skidmore, 1998).

The HIV/AIDS adult prevalence rate was estimated by the CIA in 2001 to be 1.99%, with 530,000 people living with HIV/AIDS and 48,000 deaths from HIV/AIDS (CIA, 2002). The explosion of prostitution in the forcibly relocated townships coincided with the narcotics-fueled building boom in the capital cities in the mid-1990s. Nightclubs, karaoke bars, and other venues for prostitution proliferated in this lawless atmosphere.

The 40 years of insurgency in the border areas means that trauma is a prevalent medical problem for patients presenting to biomedical hospitals, clinics, and psychiatric hospitals. Such trauma is not confined to adults and is prevalent among soldiers who have seen active service, insurgent fighters, and all adults and children caught up in war zones within the country’s borders. In addition, landmines and unexploded ordinances pose grave risks to combatants and residents of contested territory. Finally, forced portering for the army, forced labor, the incarceration of political prisoners, and the existence of remote

work camps all further endanger the health of Burmese people (Skidmore, 2002b).

The Aged

Life expectancy rates are low, there is no welfare system in Burma, and aged people have always been cared for within the extended family unit. Wealthier Buddhists may purchase a small home within the grounds of a monastery and so retire there. These Buddhist retirement communities are generally happy places with small garden patches, devotional and volunteer activities that revolve around the monastic cycle, and preparations for the next life. For destitute older people, cataracts and arthritis are major impediments to mobility and no help exists, outside of the charity of monasteries and neighbors.

Within family units, aged people command great respect and continue to wield power over the occupations and living arrangements of their children and grandchildren. They continue to control the family finances although they may spend increasing lengths of time at monasteries. Infrastructure for disabled people is non-existent and most roads are unpaved, making mobility difficult for aged people. They tend to stay home and “guard” the house against theft. When a family member becomes frail or incapacitated, other family members worry that they must stay on their own during the working day, afraid that unscrupulous people will take advantage of their aged relatives.

Dying and Death

As with all major life cycle events, death is managed for Burmese Buddhists by a series of religious proscriptions and practices that center upon the release of the soul, or butterfly spirit, from the corporeal body. Attachment to the body is not encouraged, but proper management of the enduring spirit is necessary to ensure an auspicious rebirth and avoid being trapped as a ghost.

Green deaths occur when a spirit is unable to leave surviving relatives. This can occur when women and babies die during childbirth, or when husbands die leaving their wives with several children to feed and raise alone. In the peri-urban townships ringing Rangoon and Mandalay, where infant and maternal mortality is high, several hospitals are known as “green hospitals.” This term refers to the number of green deaths and resulting ghosts of babies who reside around the hospitals. Women, especially pregnant women, traveling home at dusk or at night, tie yellow ribbons around themselves or their bicycles to ward off these ghosts.

The CIA puts the death rate at 12 deaths per 1,000 population and life expectancy at 55 years. The WHO puts the death rate at 8.6/1,000 population and life expectancy at birth of 60 for men and 64 for women (WHO, 2002). Burmese people aged 65 and older constitute approximately 5% of the population (CIA, 2002).

Cree

Naomi Adelson

ALTERNATIVE NAMES

Eeyou (singular); *Eeyouch* (plural); person, the people. The term Cree is only used when spoken in English and is not the term the people use for themselves.

LOCATION AND LINGUISTIC AFFILIATION

The entire population of Cree in Canada spreads from the province of Alberta to the province of Quebec. Historically ranging from plains-dwellers to woodland

and northern sub-Arctic hunters, the many Cree nations are the most widely distributed geographically of First Nations in Canada. All of the Cree dialects derive from the Algonquian language family. The eastern Cree of the James Bay region of Quebec, the population highlighted in this entry, speak Cree as their first language and English, French, or both after that (96% have Cree as their mother tongue, 90% speak it at home; 77% speak English, 29% speak French in addition to Cree, 20% speak neither French nor English [Schnarch, 2001]).

OVERVIEW OF THE CULTURE

The James Bay Cree or *Eeyouch* of *Eeyou astchee* (the people's homeland) have been living in, traversing through, and sustained by the sub-Arctic region for over 5000 years. Historically, small family bands navigated vast territories of *Eeyou astchee* over the course of a year, hunting, fishing, trapping, and harvesting the plant and animal resources required for food, clothing, shelter, and tools. These hunting territories remain a salient aspect of the lives of the Cree today, as people continue to hunt and consume the game of the region and define themselves through the lands that their ancestors marked as theirs by usufructuary right and on which they still hunt, trap, and fish. Animals of the sub-Arctic such as caribou, hare, beaver, and porcupine, as well as the fish and the fowl of the region, such as Canada goose, duck, grouse, and ptarmigan, were the principal diet of this hunting population and remain important foods today. Summer fruits such as blueberries and cranberries supplemented the meat diet. With contact, and especially the fur trade, came what are now considered staples of traditional fare: flour for bannock (soda bread), tea, and sugar.

The land and its resources are intrinsic to the rich animistic traditions of the *Eeyouch* whereby, most significantly, a successful hunt is the result of a system of mutual respect between the hunter and the animal and its spirit force. Indeed, the culmination of that alliance between animal and human is when the animal chooses to give itself to the hunter (Feit, 1986; Tanner, 1979). With animate spirit imbued in each and every element of the land, the nutritional or healing properties of plants and animals are enhanced. Life and spirituality are inseparable, and both are linked in innumerable ways to the places of *Eeyou astchee*. Thus, *Eeyou astchee* is not only a physical resource, but the source of spiritual and cultural heritage. For example, in the Cree language, specific sites are identified as often by their

topographical features as by a significant experience that occurred there, such as burials, where individuals were born or where a particular spirit resides.

Christian influences on the *Eeyouch* have been both significant and complex ever since the earliest days of Christian missionary activity on *Eeyou astchee* and deserve mention here. Indeed, organized religion continues to demarcate certain boundaries of affiliation and identity among the people. More specifically, the Anglican church introduced Christianity to the Cree region in the mid-19th century. The early missionaries denounced all that they deemed to be heathen practices (especially drumming and the shaking tent ceremony) and those early resolutions resonate to this day. On the one hand, for many, Christianity was an extension of their familiar practices of humility on the land, respect for all living things, and deep love and commitment to their families. Thus, many were readily able to meld traditional practices with this new Christian faith, although strategically chose to practice indigenous ceremonies well outside of the purview of the missionaries. On the other hand, others were—and remain—less inclined to practice anything that was originally forbidden by the church. In some communities, too, evangelical Christianity has a growing and loyal following and it, too, separates indigenous spiritual practice from the more common activities of hunting and trapping. Moreover, there is a surge of interest among many *Eeyouch* in traditional spiritual beliefs and practices and a resurgence of ceremonies once thought lost to the younger generations. Thus, the church, as a symbol of organized religion, remains a complex influence on people's lives as they negotiate their contemporary cultural identities as sometimes part of and sometimes counter to its influences and authority.

Now numbering over 13,000 the *Eeyouch* live in nine communities, many of which originated first as summer gathering places and then as trading post sites. These sites became official villages when the Canadian federal government took over the management of the aboriginal communities in the early part of the 20th century. The nine *Eeyou* communities include four inland (Nemaska, Mistissini, Oujé-Bougoumou, Waswanipi) and five coastal (Waskaganish, Chisasibi, Wemindji, Eastmain on James Bay, and Whapmagoostui on Hudson Bay) settlements. The communities range in population size from about 500 to over 3,000. This is a young and growing population, with only 4% of the total population 65 and over and approximately 34% of the *Eeyouch* under 15 years of age. As well, with a crude birth rate of approximately 24%, the current trend suggests that the population will double

between 1999 and 2027 (Schnarch, 2001). The income security program, set up under the James Bay and Northern Quebec Agreement, provides a cash income to those individuals who choose to spend the greater part of the year living in the bush and actively trapping and hunting. Recent figures indicate that for all nine communities, 37% of the population is registered in this program. Other forms of employment are largely community based and are divided almost exclusively between local administration, Cree entities, and community enterprises (approximately 12% employed in each of these sectors). The unemployment rate for those 15 and over in *Eeyou astchee* is approximately 17% (compared with 10% in Canada) and among those employed, only 39% had full-time, year-round jobs in 1995. The average total income for the *Eeyouch* in their territory is less than half that of non-Aboriginals living in *Eeyou astchee* (approximately \$17,000 versus \$40,000) (Schnarch, 2001).

The *Eeyouch* are represented nationally by the Grand Council of the Crees (GCC) of Quebec, a legal corporation of the Cree nation created in 1974 (GCC, 1996). The GCC originally arose out of political necessity in the early 1970s. In 1971, the *Eeyouch* found themselves in a dire struggle for their lands. The Quebec provincial government, without consultation with the *Eeyouch*, was planning to divert vast waterways on *Eeyou astchee* in order to construct one of the world's largest hydro-electric projects. After a long, grueling, and bitter legal battle with both governments and Hydro-Quebec, the *Eeyouch* finally—but reluctantly—agreed to exchange the rights to over 600,000 km² of land for specific benefits, payments, and land rights. This modern treaty, known as the James Bay and Northern Quebec Agreement (JBNQA), was signed between the *Eeyouch*, the Inuit of Quebec, and the federal and provincial governments. The Agreement provides the context for a form of (delegated) self-government, control of wildlife management, input into environmental impact assessments, an innovative program of guaranteed income for men and women who trap on a full-time basis, as well as administrative control over education, health, local justice, and local and regional governments. The Cree Regional Authority was created to act as the regional government responsible for the administration of the JBNQA. Programs and services provided to the communities are co-ordinated by the Cree Regional Authority with the collaboration of the Cree Housing Corporation, the Cree Regional Boards of Health and Social Services, and the Cree School Board. The now self-governing *Eeyouch* are an established nation due to a large extent to the success of the assertive and, at times,

uncompromising leadership of GCC of Quebec. The GCC rightly boasts consultative status on the UN Economic and Social Council and has had tremendous impact internationally, nationally, and regionally as an efficient, well-organized, and active government (Marville, 2001).

It is important to remember that prior to 1975 and really until about the early 1980s, the *Eeyouch* were organized into “village band societies,” administered locally but according to the dictates of the federal Indian Act; their homes were substandard as were the facilities and services available to them (Salisbury, 1986). The JBNQA brought not only administrative control to the people and income security for full-time trappers but also improved housing and facilities, a voice in the administration of the lands and resources of *Eeyou Astchee*, and control over education and health services. The JBNQA, in other words, was viewed as progressive at the time of the signing. It was, however, never fully implemented, leaving the *Eeyou* leadership engaged in endless legal wranglings with the provincial and federal governments for alleged breaches of the Agreement. In 2001, the new leadership of the GCC agreed to drop all the outstanding lawsuits. In what must be seen as a pragmatic plan to accommodate future generations of the burgeoning population of *Eeyou astchee*, the current leadership of the GCC not only put a moratorium on the legal battles but, more importantly, has agreed to allow further extensive hydro-electric development on *Eeyou astchee*. In exchange, the new Rupert–Eastmain Accord will—if it passes environmental review—see the Quebec government paying out a large cash settlement over the next 50 years to be used for community and business development, job creation, and resource management (Dougherty, 2001; Macpherson, 2001). The signing of this new Accord did not come without dissent from some members of the *Eeyou* communities. The current leadership is attempting to plan for the future, however, and that future must include some form of guaranteed employment for the growing number of young people who have fewer and fewer opportunities to sustain themselves through traditional hunting or trapping activities.

THE CONTEXT OF HEALTH: ENVIRONMENTAL, ECONOMIC, SOCIAL, AND POLITICAL FACTORS

Beyond a simple dichotomy of health or ill-health, being healthy (*miyupimaatisiun*) for the *Eeyouch* is the definitive

expression of core cultural values. Being healthy has traditionally meant a balanced relationship between individuals and their social, spiritual, and natural worlds. In particular, it implies proper hunting practices and hence a respectful relationship between humans and the animals of the land: a successful hunt means healthy eating and appropriate social relations means that the hunted foods will be apportioned amongst oneself and one's kin. If, too, the hunted foods, the land, and the hunting traditions are all integral to *miyupimaatisiun*, then the exploitation of the land would logically be the most profoundly felt impediment to being healthy for the *Eeyouch*. Thus each imposition upon the people and their lands—from the incursions of the earliest traders to internal colonization and present-day disputes to retain control over their territory—magnifies the meanings of *miyupimaatisiun* as well as the direct and indirect impediments to health (Adelson, 2000).

The earliest days of contact brought an onslaught of infectious diseases to the indigenous peoples of the Americas. Diseases such as influenza, typhus, diphtheria, measles, smallpox, and whooping cough took a tremendous toll and wiped out generations directly, through death, or indirectly through the loss of hunting manpower or women's weakened ability to reproduce (Waldram, Herring, & Young, 1995). The more isolated Cree populations likely had comparatively fewer losses from these early infectious diseases because many simply were not in direct contact with the traders and other travelers to the region. As families began to live for longer periods of time near the trading posts, however, infectious diseases began to take a greater toll on the *Eeyou* population. Because of a decline in the fur-bearing animals vital to the trade economy, and subsequent real hunger, or job opportunities, or later to allow children access to the first elementary schools in the *Eeyou* north, by the early decades of the 20th century many more people were living in and around the trading post, swelling them into rudimentary villages. Living at the post, however, was no guarantee of health. Indeed, it was here that the second wave of infectious diseases, including influenza and tuberculosis, took their toll on this population. With large families living in small, inadequate housing facilities infectious diseases spread through these early settlements. Conditions had to reach an extreme before federally based health services were extended north to the people. In one *Eeyou* community, permanent health care personnel only arrived with the armed forces in the 1950s, as this one small, isolated post was an ideal site

for the early distance radar warning systems that were integral to the Cold War. It was not until 1958, and after the federal government deemed the village to be a permanent settlement, that a clinic was established and a nurse available year-round.

Through the JBNQA the Cree Regional Board of Health and Social Services was established as an autonomous body overseeing the full range of health and social service needs of the *Eeyouch*. The Health Board administers all of the health care services in *Eeyou astchee*, including village nursing stations and one hospital (located in Chisasibi) and has worked hard to mediate between traditional therapeutics and biomedicine, always ultimately committed to offering locally meaningful, appropriate and efficacious care (see, for example, Bobbish-Rondeau et al., 1996). The contemporary health care and funding challenges faced by the Health Board, however, frustrate many of these efforts. A recent special assembly on health and social services in *Eeyou astchee* pointed to a host of issues that community members said need greater attention, including high staff turnover and burn-out, to language problems between English or French-speaking staff and Cree-speaking clients, the rise of chronic diseases such as diabetes and asthma, increased family violence, and the current housing crisis (Roslin, 1999). In the end, however, it is important to remember that the problems faced by the Cree Regional Board of Health and Social Services are a composite of the growing health care and social needs of the population, limited financial resources, and the constraints of a relatively new system of independent regional management that must contend with all these issues at once.

MEDICAL PRACTITIONERS

Historically, the *Eeyouch* traveled in small family groups and, hence did not develop any large, formal medical tradition. This does not mean, though, that there were no established healing practices or practitioners. There were those who had expert knowledge of the plant resources of the region, while others were gifted spiritual practitioners, employing sweat lodges or other healing ceremonies as required. As well, some women excelled as midwives, a practice that has all but disappeared with the hospital-based births now requisite in the north. See the next section for a summary of treatment practices.

CLASSIFICATION OF ILLNESS, THEORIES OF ILLNESS, AND TREATMENT OF ILLNESS

Illnesses are most broadly classified as either those that are historically known to the *Eeyouch* and those that came with the influx of non-Native peoples and influences, known colloquially, as “white man’s” diseases.

Traditional illness theories are reflections of the land-based cultural knowledge and practice of the *Eeyouch*. Traditional therapies, in turn, draw directly from people’s intimate knowledge of the land and its resources combined with a sense of the inherent spiritual force of all animate and inanimate beings as well as a healthy dose of pragmatic realism. Indeed, to this day, there is a general consensus that—regardless of treatment modality—there is a greater spiritual force, derived either from Christian or animistic roots, that ultimately decides one’s fate. There were (and remain) individuals who were recognized for their healing abilities and it is this blending of healing power along with a sound knowledge of the indigenous pharmacopoeia which would lead to the greatest treatment success. Whether treatments would or would not work ultimately depended on the fate of a particular individual.

Indigenous therapies were used primarily for the kinds of injuries that one might sustain while traveling or working on the land, such as bone fractures, snow-blindness, burns, or lacerations. There are treatments, too, for common ailments such as toothache, boils, and stomach complaints as well as for post-partum bleeding. Treatments include therapeutic sweat lodges, either when the person is immersed entirely within the lodge or more localized heat treatments (such as around the abdomen or leg), to the specific use of the tamarack or spruce tree inner bark and gum, animal fats and especially rendered bear fat, gallbladder or lung, beaver castoreum, as well as breast milk, tobacco, and meat broth. The abundant bog plant, Labrador tea (*Ledum groenlandicum*), remains a vital part of the contemporary indigenous pharmacopoeia. Labrador tea is regularly harvested and used as a general tonic as well as for a range of pulmonary conditions. Not surprisingly, given the degree to which one depended in the past on mobility, there were a range of therapies devoted to walking disorders, sore muscles, and getting chilled or cold. In particular, feeling cold and lacking an appetite are viewed to this day as precursors to future illness and are treated immediately and with grave concern.

Bush food, and meat in particular, is a source of physical and symbolic strength, vitality, and health and hence not only nutritious but a therapeutic resource, too. There is a hierarchy of strength in bush foods so that the meat, fat, and broth of larger animals, such as bear or caribou, are considered to be especially “strong” whereas wild fowl (goose, ptarmigan, grouse) and fish are somewhat “weaker” foods. So, for example, whereas bear fat is a potent remedy for a number of ailments, the less potent fish broth is considered a sound treatment and an appropriate first food for those who have gone without or have lost their appetite. Most importantly, hunted foods are fundamental to well-being and thus, health, in the *Eeyou* sense of the term; good health is impossible without consuming a full range of (weaker and stronger) traditional foods.

White man’s diseases are more readily classified as they cluster as all those that have come with contact, internal colonization, and its lingering and persistent influences and effects. White man’s diseases follow, to a large extent, a trajectory common to many other indigenous peoples with similar histories of contact (see above). Today, white man’s diseases are predominantly chronic (such as diabetes, cancer, and asthma) but also reflect some of the social ills of the communities that, one might argue, are part of the lingering effects of a system of internal colonization (see below).

White man’s medicines are considered appropriate remedies to white man’s diseases. Thus, even the most rudimentary biomedical services (such as treatment by 19th-century missionaries or their wives for infections or other ailments) was always accepted as part of the range of treatment options available to the *Eeyouch*. For the coastal dwelling Cree, the annual X-ray ship was oftentimes the only contact with biomedicine in the early half of the 20th century. Community members would line up for their annual exam when the ship arrived at the post site and anyone who was found to have tuberculosis was taken or later sent south to a sanatorium, sometimes for years at a time. By the 1950s, nursing stations, run by the federal government, were set up in the villages and were generally well-used by the *Eeyouch*. If a case required medical consultation, then a physician in an urban hospital center would be contacted by telephone and, if required, the patient would be evacuated by plane from the village. Today, the Cree Regional Board of Health and Social Services maintains all the nursing stations and the hospital in Chisasibi (see above). As throughout the rest of Canada, all medical care is provided free of charge; in

addition, members of the communities also receive free all allied health services and required drugs. Despite any concerns about the quality or availability of care through these nursing stations, they are a vital aspect of each community, offering daily and emergency clinics, well-baby clinics, a host of medical information, and the only available pharmacy in the more remote communities.

HEALTH THROUGH THE LIFE CYCLE

Pregnancy and Birth

Each and every child born is a welcome member of the *Eeyou* community. By extension, abortion is considered anathema, whereas miscarriages and stillbirths are fully acknowledged. There is, for the most part, tremendous familial support extended to pregnant women and their infants. With a younger population having babies today, however, there are some basic constraints limiting the degree to which those who would, in the recent past, have cared for the young. Younger mothers, for example, are either still in school or employed and their support network shrinks as grandmothers, also still young, are themselves working outside of the home and unable to offer day-time care to their grandchildren. Child care facilities are now being created in communities where the need for them simply did not exist to this extent a decade ago. By extension, too, all children, regardless of any physical disadvantage, are incorporated into the community. Social stigma of any sort is rare and children are accommodated in whatever way necessary.

Just under 50 years ago all births took place in the family dwelling and, more often than not, this meant on the land. Traditional midwives attended these births and there remains a host of post-partum treatment practices that attest to the skill and knowledge base of these women. By the mid-20th century, most nursing stations were run by nurse-midwives who would regularly assist deliveries. More recently, standard practice is for pregnant women to leave their home community in order to deliver in a hospital. With a small hospital now permanently based in Chisasibi, many of the more northern dwelling *Eeyou* women at least remain in *Eeyou astchee* and do not have to travel late in their pregnancies to an urban center to have their children.

Approximately 70% of women breastfeed their children and while many still consider an extended duration

of breastfeeding normal practice, one study has shown that between 1988 and 1993, the percentage of infants still being breastfed at 6 months had gone from 60% to 40% (although this is still higher than the general provincial target figure of 30%) (Schnarch, 2001). Again, the contingencies of work and family may be playing a large role in this overall reduction in breastfeeding, amongst the younger mothers in particular.

Infancy

Infancy begins at birth and ends with a formal “walking out” ceremony held at about the time when the child takes its first steps. From the time the child is born and right up until this ceremony, the infant is swaddled for warmth, protection, and comfort and is exceptionally well-bundled to protect it from the elements whenever outside. An additional protection used in the past, but cautioned against more recently, was a small necklace made of netting string that was used to “trap” any cold before it entered the infant’s body and hence to shield it both physically and spiritually from the cold.

Many parents will prevent their infant’s feet from touching the earth or ground until he or she has “walked out.” The “walking out” ceremony, traditionally held at the break of dawn on a day soon after the child is just old enough to walk, is a celebration of the symbolic and social transformation of the infant into a future *Eeyou* man or woman. Little boys hold a carved wooden gun, symbolizing their future roles as hunters; little girls hold a carved axe, signifying their roles in maintaining the hunting camp. The young future *Eeyouch*, beautifully and ornately dressed, are assisted out of a ceremonial dwelling by a parent and, witnessed by family and community, can touch the ground for the first time. Symbolizing entry into the communal and natural worlds, the “walking out” ceremony remains an important part of contemporary cultural practice. The ceremony is complete only after a large feast is held, honoring the child as well as the community elders.

Unfortunately, infant mortality rates remain high—almost three times that of the province of Quebec (14.9 vs. 5.3 per 1,000 live births)—despite a significant reduction in infant deaths with improved pre-natal health services over the last 20 years (Schnarch, 2001). One infant disease is worthy of particular note. Cree leukoencephalopathy is a neurological disorder that occurs exclusively, albeit rarely, in Cree infants from northern Quebec (and Manitoba). This is a uniformly fatal disease of

genetic origin that is triggered by a viral infection and has been found only in this population (Black et al., 1988).

Childhood

Children, and especially the youngest child in the family, are doted upon and given a fair degree of freedom outside of the age-appropriate tasks required of them. Children are not strictly disciplined and, traditionally, are taught primarily by example and by observing and listening to their parents and grandparents. This is especially so when learning about hunting-related activities such as the proper maintenance of firearms, hunting gear, and equipment, as well as weather patterns and other vital bush and camp skills. Children are always dressed warmly and their feet properly protected in order to safeguard them from the harsh sub-Arctic elements, as cold or a chill entering the body is viewed as a precursor to future illness.

There is some disjuncture for some parents between the more rigid processes of school-based learning and investing the child with the proper knowledge base and skills to live and work on the land. This is part and parcel of the contemporary tension between development and traditional practices that permeates so many aspects of the lives of the *Eeyouch*. In an attempt to balance these sometimes divergent objectives, the Cree School Board has implemented a formal Cree language program through to the high school years, instruction only in Cree in the first years of school, and a cultural program that ranges from craft production to land-based activities as part of the general curriculum. With control over education, the Cree School Board continues to work toward a reconciliation between the basic provincial educational requirements and the cultural needs of the children, and more and more children are not only completing high school locally but are traveling out of their communities to complete college and university degrees.

Adolescence

Adulthood symbolically begins for boys when they successfully kill their first large game animal. This has been known to happen when boys are between 8 and 10 years old. Thus there is, historically, no particular period of adolescence. And, given the number of pregnancies and young relationships and marriages today, there remains, for many, virtually no time between childhood and the responsibilities of adulthood (almost 25% of births in *Eeyou aschee*

between 1985 and 1998 were to women under 20 years of age [Schnarch, 2001]). A growing concern is the rise in sexually transmitted diseases and, in particular, chlamydia, with a rate of 813/100,000 (compared with 87/100,000 for Quebec), occurring mostly in those between the ages of 15 and 30 (Schnarch, 2001). There has, to date, been no case of AIDS reported, although it is clear that unprotected sex is taking place and is a persistent concern for the public health community serving *Eeyou aschee*.

Adolescence, as something that has evolved with settlement living, is most clearly visible amongst the growing number of youth who are completing a secondary (high school) education, but are increasingly bored with what is for them the drudgery of village life, who see no particular future in their communities as jobs are at a premium and, perhaps through social networks, travel to urban cities or the media, such as satellite television or the internet, are discovering myriad, and oftentimes harmful, ways to alleviate their boredom. Many are smoking (a survey conducted in 1991 found that 77% of those between 15 and 24 years of age were either regular or occasional smokers [Schnarch, 2001]) and there are persistent concerns about substance abuse, vandalism, and accidental injuries and deaths in this young age group.

Adulthood

This stage of life, as mentioned in the previous section, often begins early as young men and women start having children and take on full familial duties while still in school or early on in their lives. The focus here, though, is on the older adults who have experienced dramatic transformations in the course of their lives. Many of the older adults today were born and raised to a young age on the land, then moved into sometimes squalid and certainly under-serviced settlement communities as children. They are the first generation to have had access to a formal educational system (some in more southern communities were placed in residential schools, which had profound effects, both negative and positive, on their future lives) complete with its formal structures and regimented classroom environment. This generation became, too, the first to lead the *Eeyouch* into their new relationship with government, moving out from under a paternalistic system of governance and into an historic, if uncharted, form of self-government. This generation, too, moved from predominantly land-based labor and resources to a substantially more sedentary and stable lifestyle as the village became

a permanent home to so many. Foods, and especially those high in sugar and carbohydrates, have become the mainstay in many households whereas fresh fruits and vegetables, exorbitantly priced in the north and often blemished from long travel, remain both unpalatable and unaffordable to many. Many of these social and environmental changes in the adults' lives are directly reflected in their health statistics. Most telling is the shift in mortality and morbidity from infectious to chronic disease. Over the last decade, for example, mortality rates for circulatory disease, diabetes, and cancers overshadow all other causes of death except for those resulting from accidents and injuries. Obesity is a chronic problem for many and diabetes is taking a greater and greater toll on the population, with 11% of the total adult population and almost 30% of those over 50 now diagnosed with the disease (Bobbish-Rondeau et al., 1996; Schnarch, 2001).

Older adult women may now see, during their menopausal and post-menopausal years, the surfacing of a range of joint ailments that result, the elders say, from having been exposed to cold when young. Women are warned throughout their lives to keep warm, and especially so when menstruating. Any diversion from this practice in one's youth will now bear out in sore joints and, especially, sore legs. This is a time too, though, of positive transitions for women: from mothers to grandmothers and future elders. Once past menopause, for example, women may partake in certain symbolically powerful foods that they are prohibited from eating while still in their child-bearing years (e.g., fetal caribou).

The Aged

Older *Eeyouch*, or the elders, are the most highly respected members of the community. The elders were all born and raised on the land and their generation is viewed as the last ones who truly know the physical, spiritual, and symbolic contours of *Eeyou astchee*. They are referred to as grandparents to all of the children, which means, too, that they have a certain degree of authority in the social management of the community's children. The elders are provided with the most and the choicest parts of any hunted foods, are respected authorities on most issues, and are looked after as best as any community is able (given the constraints of the relative availability of adequate housing or other chronic care facility). The elders constitute a very small proportion of the total *Eeyou* population and are now living into their seventies.

The life expectancy for men is 74.8 (compared with 74.5 for Quebec) and 75.5 for women (81.1 for Quebec).

Dying and Death

While any death is always traumatic, the death of an elder is viewed as an especially significant loss given their status in the community. The rituals of death, for many *Eeyouch*, are an amalgamation of both Christian and traditional spiritual beliefs. Whereas prior to Christian influence the dead were buried near where they passed away, today burial takes place in the community cemetery immediately following a church service. With the range of spiritual and religious influences in communities today, there is a concomitant range of beliefs about life after death, including those that adhere most strictly to the Christian paradigm of a heavenly afterlife to a traditionalist belief in the transformation of spirit from this life to the next as one proceeds on one's sacred journey.

Czechs

Zdenek Salzmann

ALTERNATIVE NAMES

The Czechs call their culture *česká kultura* (Czech culture). To call it “Bohemian culture” would be misleading because the term “Bohemian” has a historic and geographic rather than an ethnographic or linguistic reference. Furthermore, Bohemia (*Čechy*) is only the larger, western part of the Czech Republic; the smaller, eastern part is Moravia (*Morava*). In the north, Moravia includes a part of Silesia (*Slezsko*), a historical region that lies for the most part in southwestern Poland.

LOCATION AND LINGUISTIC AFFILIATION

The Czech Republic, located in central Europe, is bounded by Poland on the north, Germany on the west, Austria on the south, and Slovakia (the Slovak Republic) on the east. The area of the Republic is 78,866 km² (about the size of South Carolina).

The language spoken in Bohemia and Moravia is Czech. It is spoken in several regional dialects, but outside their homes most Czechs speak Common Czech, a supraregional variety of the spoken language. Czech, a Slavic language, belongs to the West Slavic subbranch of the Indo-European language family; it is mutually intelligible with the Slovak language.

OVERVIEW OF THE CULTURE

Population

The population of the Czech Republic as of December 31, 2000, was 10,266,546, with females exceeding males

by 273,084. The ethnic composition of the republic is 94.9% Czech, with the remainder consisting of Slovak (3.1%), Polish (0.6%), German (0.5%), Ukrainian (0.4%), and Romany (Gypsy) minorities. Officially the Romany population amounts to 0.3%, but it may be as much as five to ten times larger. Because both the majority populations of Bohemia and Moravia speak Czech, they will be considered as belonging to the Czech ethnic group. When their practices differ, it will be indicated.

History

The ancestors of contemporary Czechs made the territory of what is now the Czech Republic their home in about the 6th century, replacing a Germanic people who migrated out of the area during the 5th century. In the early part of the 11th century what had become Bohemia and Moravia was brought under one control, becoming the kernel of the Czech state. The first Bohemian king was crowned in 1085, and the royal title became hereditary in 1198.

The peak of the kingdom's influence was reached under Charles IV, who reigned from 1346 until 1378, and in 1355 was also made emperor of the Holy Roman Empire. Prague became the seat of the archbishop and the site of the first university in central Europe (1348).

Czech national culture continued its development until 1620 when the Czech estates were defeated by the Hapsburg army in the Battle of White Mountain. Not only was the kingdom's independence lost, but its provinces were declared to be the hereditary property of the Hapsburgs. This loss led to a period referred to as “the darkness” (*temno*), which lasted until the end of the 18th century when, after the onset of national revival, a modern

Czech national consciousness began to form. Independence was regained at the end of World War I in 1918. From that year until the end of 1992 the Czechs and Slovaks shared a common state, Czechoslovakia, with the exception of the six years of World War II (1939–45). As of January 1, 1993, the Czechs and Slovaks peacefully separated to become two independent countries.

Economy and Occupations

The Czech Republic is and has long been a highly industrialized country. In 2000, the structure of employment in the civil sector broke down into services (54.9%), industry (40%), and agriculture (5.1%). The unemployment rate in 1999 stood at 8.7%, with the capital Prague experiencing the lowest unemployment, northwestern Bohemia and northeastern Moravia the highest.

Both imports and exports steadily rose over the final decade of the 20th century, with imports invariably exceeding exports, although not by a wide margin. In terms of monies expended, the main imports included (in descending order) machinery and equipment, chemicals and synthetic fibers, motor vehicles and trailers, communications equipment (including radio and television), basic metals, electrical machinery, crude petroleum and natural gas, rubber and plastic products, and fabricated metal products other than machinery.

The main exports included motor vehicles and trailers, machinery and equipment, electrical machinery, fabricated metal products other than machinery, chemicals and synthetic fibers, basic metals, communications equipment, certain nonmetallic mineral products, and rubber and plastic products.

The countries from which most goods are imported (in descending order) are Germany, the Russian Federation, Slovakia, Italy, France, Austria, the United States, the United Kingdom, and Poland; exports go to Germany, Slovakia, Austria, Poland, the United Kingdom, France, Italy, the United States, and the Netherlands.

The middle class is the largest socioeconomic class of the Czech Republic. Under the communist regime after World War II, the status of manual workers rose and that of the former upper middle class steeply declined. Since the velvet revolution of 1989, when democracy was re-established, some businesspeople have acquired luxury cars and expensive housing. By contrast, retired people must stretch their pensions to keep pace with the steadily, if slowly, rising cost of living.

Government

The Czech Republic is a parliamentary democracy with a Chamber of Deputies and a Senate. The President appoints certain high officials (for example, the prime minister) and can veto other than constitutional bills. During the post-communist times (from 1990 on), several dozen political parties have emerged, and the country has been governed by a coalition of some of those parties receiving the most votes. The results have not always led to an efficient government.

Family and Kinship

The effective kin group of urban Czechs is limited to the closest relatives. Those less close than grandparents, aunts, uncles, and first cousins usually meet only on such occasions as weddings and funerals, Christmas, or other holiday gatherings. Most villagers, however, especially in Moravia, maintain close contact with more distant relatives.

Religion

The first half of the 15th century was marked by a breach with the Roman Church as a consequence of the reform movement led by the Czech Jan Hus (John Huss). His death in 1415, when he was burned at the stake in Constance (Konstanz in southern Germany), initiated the ambivalent attitude of the Czechs toward Roman Catholicism; this ambivalence was later reinforced by the attempt at forcible re-Catholicization begun during the 17th century by the Hapsburg rulers. More recently, the 41 years of communist rule (1948–89) undermined the observance of religious practices even further.

At present, about 40% of the population are Roman Catholic, about 4% Protestant, and the remaining 56% uncommitted, atheist, or agnostic. Compared with the people of Moravia, the Czechs of Bohemia tend to be lukewarm in their religious beliefs and practices.

THE CONTEXT OF HEALTH: ENVIRONMENTAL, ECONOMIC, SOCIAL, AND POLITICAL FACTORS

Demographic Data

At present, the population of the Czech Republic is becoming smaller due to natural decrease. The year 2000

was the seventh consecutive year in which the number of deaths exceeded the number of births. Because of the low number of births, the average age of the population has been slowly increasing. In 2000, 53% of the population was below the age of 40 and 47% above.

Life expectancy at birth in 1999 was 71.4 years for men and 78.1 for women. On reaching the age of 65, an additional 13.7 years is added for men and 17 for women. Among 24 European countries, life expectancy in the republic ranked seventh from the bottom.

The number of live births per 1,000 inhabitants stood at 19.1 in 1975. The number has been decreasing in recent years, from 135,881 in 1985 to 90,910 in 2000. During 1999, when there were only 8.7 live births per 1,000 inhabitants, the number was the third lowest among 24 European countries.

There were 49.24 abortions per 100 births in 2000; of these 12.03 were spontaneous, 35.68 legally induced, and 1.53 for other reasons (primarily the result of ectopic pregnancies). The number of abortions in 2000 was lower by 9.1% than in 1999 and less than half of what it was in 1990.

The rate of death for infants younger than one year per 1,000 live births was 4.1 in 2000. In a comparison with 24 other European countries, only four had a rate lower, nine had the same rate, and 11 a higher rate than in the Czech Republic.

The marriage rate in the Czech Republic dropped to a historical minimum during the late 1990s, and by 2000 only 5.4 marriages took place per 1,000 inhabitants. This low number of marriages has resulted in part from the steadily increasing age at first marriage, which at the beginning of the new millennium was approaching that recorded for Western Europe. And just as in many parts of the world today, a man and woman frequently live together for several years before deciding to legalize their cohabitation.

Since the early part of the 20th century, the choice of a spouse has been the decision of the young couple, but educational attainments and the likely socioeconomic status of a potential husband or wife are of some importance. Whenever possible, the young married couple establish a neolocal residence, that is, a residence independent of the family of either one. However, the help of the husband's or wife's mother is sought and appreciated at the arrival of a child, particularly if the mother expects to return to a job.

Environmental Pollution

Before 1990, protection of the environment was subordinated to the fulfillment of economic five-year plans. Lack of

proper control over the sources of pollution caused increasingly serious problems for the population. Over 50% of forests were damaged, particularly spruce forests in the mountains along the Bohemian border. Of some 7,000 km (about 4,350 miles) of monitored streams, 60% were judged to be strongly or very strongly contaminated. Especially critical conditions existed in northwestern Bohemia around the towns of Most and Sokolov, both of which had large deposits of lignite and a variety of industrial enterprises. Altogether, about 2.5 million people were living in a substantially endangered environment.

Matters have greatly improved since 1990: for example, solid emissions decreased from 401,500 metric tons in 1990 to 16,100 in 1999; from 1,596,000 tons of sulfur dioxide in 1990 to 193,100 in 1999; from 493,900 tons of oxides of nitrogen in 1990 to 135,000 in 1999; and from 23,800 tons of hydrocarbons in 1990 to 17,700 in 1999. Only the amount of carbon monoxide has increased during that period, by about 50%; this increase parallels the increase in passenger and commercial automobiles.

Similar improvement is being achieved in the case of pollutants discharged into watercourses: for example, from 190,500 tons of undissolved substances in 1990 to 29,758 tons in 2000, and from 989,057 tons of dissolved inorganic salts in 1990 to 691,613 tons in 2000. The one remaining problem is the prevention of pollution from the disposal of the ever-growing amounts of toxic waste.

Diet

By American standards, traditional Czech food would be considered heavy and fat. Portions of meat served are not large, but potatoes or dumplings and substantial amounts of animal fats (lard, butter, and cream) are used both in gravies and in general cooking. Eaten as often as bread and butter is bread covered with lard rendered from pork fat (with cracklings) or with goose grease (and goose liver). Only since the 1990s have salad vegetables been available on a year-round basis; when out of season locally, fresh vegetables are now imported.

During 1999, consumption of the main types of food was as follows (amounts given are per person): pork 44.7 kg, poultry 20.5 kg, beef 13.8 kg, fish 5.2 kg, fats and oils 23.1 kg, lard and bacon 5 kg, butter 4 kg, fresh vegetables 85.3 kg, fresh fruit 75.6 kg, and potatoes 75.9 kg (1 kg = 2.2046 lb). However, during the final two decades of the last century vegetable shortenings, oils, and margarine began to replace animal fats. Despite some of the desirable changes in the basic diet, obesity is quite

common because the current wide ownership and use of personal automobiles tends to offset some of the trends toward consumption of a more healthful diet.

Beer is the favorite beverage of Czech men (and many women) and its consumption in 1999 amounted to 160 l per person (1 l = 1.057 quarts). Wine and spirits are also drunk, but beer is the drink of choice. Breweries are plentiful and beer is relatively inexpensive.

Health Infrastructure

The physical resources required for health care stabilized during the last three years of the 20th century. The network of establishments for inpatient care included 211 hospitals with 67,457 beds (including 2,304 cots for newborns), 160 specialized therapeutic centers with 22,667 beds, and 63 health-spa centers with 22,179 beds. The total number of inpatient beds per 10,000 inhabitants was 109.4 and has been slowly decreasing despite the fact that the number of hospitalized patients in 2000 showed a 0.5% increase over 1999.

The number of pharmaceutical service establishments has been growing rapidly since 1990, replacing most of the earlier dispensaries (for example, an additional 80 pharmacies were established during 2000). While in 1990 all of the 917 pharmacies and 1,216 dispensaries were state-owned, in 2000 only slightly more than 4% of the 1,706 pharmacies and none of the 183 dispensaries was owned by the state.

Health Insurance and Medical Expenses

According to currently valid laws, all persons who permanently reside in the Czech Republic, as well as persons who are not permanent residents but whose employer is located in the republic, have health insurance. The insurance is paid either by the insured (one third) and the employer (two thirds) or by the state. Self-employed persons (and others who qualify as such) pay their own premiums. The state pays for all those who for one reason or another do not belong to either of the above two categories—for example, women on maternity leave, physically or mentally disadvantaged people, soldiers, and others.

Health insurance pays for all legitimate care extended to patients to maintain or improve their health. These services include ambulance transportation, emergency service, preventive care, hospital stay, balneological

care, prescribed medicines, standard immunizations, and autopsy. Limitations and exclusions concerning the services provided by the health insurance plan are relatively few and reasonable.

Health care is financed partly from public resources and partly by individuals. Public expenditures for health in 2000 through the Ministry of Health amounted to 129.6 billion Czech crowns (Kč)—5% more than in 1999. The contribution from the state budget was 11%, while 89% was contributed by health insurance corporations, of which in 2000 there were nine. Amounts spent by individuals on health care have been steadily growing—from 5.282 billion Kč in 1994 to 12.245 billion Kč in 2000 (that is, from 511 Kč per person in 1994 to 1,192 Kč in 2000).

Significant among expenses for health care are medicines; such expenses almost tripled between 1993 and 2000. The most commonly dispensed medicines can be characterized as follows (the parenthetical percentages indicate the relative share of funds spent on them): for problems of the cardiovascular system (19.9%), of the digestive tract (13.2%), of the nervous system (11.8%), of the respiratory system (8.8%), to inhibit or prevent the growth and spread of neoplasms or malignant cells (8.6%), for antibiotics and chemotherapeutics (8.4%), for problems of the blood and blood-forming organs (7.3%), of the genitourinary system (6.1%), and of the musculoskeletal system (6%).

Compared with 18 other European countries the Czech Republic ranked sixth lowest in the percentage of gross national product spent on health services.

Domestic Abuse

According to the report of one among several agencies offering assistance to victims of domestic violence, out of 624 telephone calls received between September 4 and November 11, 2001, the victim was a woman in 538 calls, a child in 56 calls, and a man in 30 calls. Children were present when the violence took place in 239 cases. Both physical and psychological abuse occurred in 319 cases, psychological abuse in 127, physical abuse in 83, and sexual abuse in 16. According to a foundation concerned with children, during 2001 the most frequent forms of child abuse were infliction of pain, sexual abuse (both commonly under the influence of alcohol), forcing the child out of the family, and neglect.

Numbers of cases concerning child abuse and domestic abuse in general are never accurate because

many instances of abuse are not reported. The data that follow must therefore be viewed only as illustrative. According to one particular public survey, 13% of those questioned stated that they had been victims of a partner's violence, while 3% of those surveyed admitted to taking the role of aggressor, yielding a total of 16% of instances of domestic abuse. According to specialists, however, the figure of 13–16% represents only the lower limit of incidents of abuse. The actual rate of domestic violence is thought to be much higher.

Another organization offering help to abused individuals provided the following data (which must also be considered tentative): female victims of abuse fall primarily in the age ranges (in descending order) of 40–44, 45–49, 30–34, 35–39, and 25–29; most of the males who commit abuse are in the age ranges of 45–49 and 35–39. As to educational background, most female victims and men who abuse them had completed secondary schooling; the least violence was reported for those with only basic education.

MEDICAL PRACTITIONERS

Training of Medical Personnel

The training and education of future members of occupations related to the practice of medicine, pharmacy, and certain types of health services have been proceeding without problems. During the 2000–01 academic year, students of medicine numbered 8,251 (of whom 4,637 were women), of pharmacy 1,655 (1,280 women), and of types of health services requiring university training 3,383 (3,039 women). The numbers of graduates at the end of the 1999–2000 academic year were, respectively, 912, 254, and 665. At present, seven medical schools of three universities train physicians, two pharmaceutical schools at two universities train pharmacists, and two schools of social health at two universities train personnel for work in health and social care positions.

Paramedical schools in the academic year 2000–01 enrolled 26,301 students, of whom 3,405 attended evening courses.

Types of Medical Personnel

As of December 31, 2000, there were 39,342 (38,331 full-time equivalent) physicians serving the population of the Czech Republic. Of these, 22,212 were women.

The number of physicians per 1,000 inhabitants was 3.8. All specializations are represented; most numerous were physicians in the following branches of medicine (listed here in descending order): dentistry and dental surgery, general medicine, internal medicine, pediatrics, surgery, gynecology and obstetrics, anesthesiology, neurology, X-ray diagnostics, psychiatry, and ophthalmology. As of the same date, pharmacists numbered 5,191 (4,726 full-time equivalent), of whom 4,256 were women.

According to the latest survey conducted by the Center for the Study of Public Opinion, physicians enjoy the highest prestige among the 27 occupations listed. Their average income, however, rates only twelfth.

The full-time equivalent of paramedical personnel (that is, nurses, children's nurses, midwives, dieticians, rehabilitation workers, assistants in hygienic services, medical and pharmaceutical laboratory assistants, radiological technicians, and dental technicians numbered 107,321 in 2000; of this total, 64,450 were nurses (about 60%). Of the paramedical personnel, 54.3% worked in hospitals (including hospital outpatient care) and 28.2% in independent establishments giving outpatient care.

The number of full-time equivalent lowest-tier health personnel (auxiliary nurses, disinfectors, dental assistants, and others) came to 6,537.

Alternative Medicine

Although the biomedical approach has been accepted and employed throughout the 20th century in the region, until World War II some individuals in villages and small towns preferred to consult herbalists (folk healers) and use the recommended infusions, decoctions, or ointments made from various herbs. Consulting herbalists was not approved of during the communist era (1948–89). During the last 10 years (since the early 1990s) folk medicine has again become popular. It is practiced nonprofessionally and usually involves the use of plant-derived remedies on an empirical basis. To prevent some illnesses or to cure them, herbalists as well as many physicians recommend carefully watching one's diet, exercising, and using herbs and other natural remedies, both domestic and imported. Many patients of physicians also consult herbalists.

Balneology

Balneological institutions—that is, health spas making use of thermal mineral waters and mud or peat baths—are

numerous and popular. Some of these have been known for centuries and have become internationally renowned. Members of the European aristocracy and famous individuals (for example, Johann Wolfgang von Goethe) visited them on a regular basis. Among the best known are Karlovy Vary (Karlsbad) for gastroenterological and metabolic problems; Mariánské Lázně (Marienbad) for urological and orthopedic problems and for allergies; Františkovy Lázně for gynecological, circulatory, and orthopedic problems; and Luhačovice for gastrointestinal, metabolic, and endocrinological problems. These and other health spas are visited not only by Czech citizens but by thousands of foreigners.

CLASSIFICATION OF ILLNESS, THEORIES OF ILLNESS, AND TREATMENT OF ILLNESS

Medicinal Drugs

The biomedical approach to the diagnosis and treatment of illness has been accepted in the Czech Republic as long as it has been in other industrial countries of Europe. Furthermore, Czech medicine has always made every effort to keep up with modern advances in the treatment of illness.

During the first half of the 20th century extensive use of medicinal plants listed in Czech pharmacopeias was progressively replaced by the use of synthetic drugs. The pharmaceutical industry of the country has always been strong, but medications manufactured elsewhere are also prescribed and available in pharmacies.

The importation of medicinal drugs in 1999 and 2000 exceeded export by about 7,000 metric tons. The countries from which most of these drugs were imported are (in descending order) Germany, Slovakia, United Kingdom, Italy, Austria, and Slovenia; exports went primarily to Slovakia, Germany, Russian Federation, Poland, Austria, and Ukraine.

Diseases

Infectious diseases must be made known to the authorities. The most important infectious diseases reported during 2000 are listed in Table 1. Compared with 1990, increases in incidence occurred only for salmonellosis other than typhoid fever and paratyphoid fever B, whooping cough, viral encephalitis, syphilis, and AIDS.

Table 1. Infectious Diseases Reported to Authorities in 2000

Disease	Number of cases
Salmonellosis (other than typhoid fever and paratyphoid fever B)	40,233
Chicken pox	38,665
Scarlet fever	2,965
Viral hepatitis	1,979
Tuberculosis of the respiratory system	1,244
Syphilis	967
Gonorrhoea	888
Rubella (German measles)	743
Viral encephalitis	719
Bacillary dysentery (shigellosis)	548
Whooping cough	395
Bacterial meningitis	227
Other types of tuberculosis	198
AIDS (of which 14 were newly reported cases)	148
Mumps	120
Measles	9
Paratyphoid fever B	1

Of the noninfectious diseases, diabetes is quite widespread and gaining. In 2000 about 650,000 diabetics were under treatment, with females exceeding males by about 60,000. To put it differently, there were well over 12,000 diabetics under treatment for every 100,000 inhabitants of the Czech Republic—more than one in every ten persons.

The incidence of malignant neoplasms (tumors) rose steadily over the last 40 years of the 20th century while the rate of mortality from this cause over the past thirty years has remained virtually the same in men and has risen only slightly in women. During 1999, the most common malignancies in men were (in descending order) those of the skin, bronchi and lungs, prostate, colon, bladder, kidney, rectum, and stomach; in women those of the skin, breast, colon, uterus, bronchi and lungs, ovaries, and cervix. Compared with 30 other European countries, the standardized mortality rate for malignant tumors in the Czech Republic was the fourth highest for men and the third highest for women.

During 2000, the most common causes of death for both males and females were (in descending order) diseases of the circulatory system, neoplasms, external causes (injuries and poisoning), diseases of the respiratory system, and diseases of the digestive system.

Mental Illness

Over two million (2,057,952) psychiatric examinations took place during 2000; they concerned 361,931 patients

(or a total of 3,523 first examinations, that is, new patients, per 100,000 inhabitants)—not a small number. Neurotic disorders were most common; they were followed (in descending order) by affective (emotional) disorders, schizophrenia, organic mental disorders, personality disorders due to use of alcohol, developmental disorders during childhood and adolescence, and mental retardation.

Preventive Measures

The General Health Insurance Company of the Czech Republic pays for preventive examinations as follows: for men and women by a general practitioner once every two years; for women 15 and older by a gynecologist once a year; for pregnant women once a month by an obstetrician; for individuals under 18 by a dentist twice a year; for pregnant women by a dentist twice during pregnancy; and for persons older than 18 by a dentist once a year.

Required protection of children from transmissible diseases includes immunizations against tetanus, diphtheria, whooping cough, mumps, rubella, measles, polio, and tuberculosis; some of these immunizations are combined. Recommended immunizations are those against hepatitis B, hemophilia, tick-borne encephalitis, and other conditions.

SEXUALITY AND REPRODUCTION

Most young people feel relatively free to engage in sexual activity. While the fertility rate (the number of live-born children per 1,000 females of a given age) for women 15–19 was 44.7 in 1990, it fell to 13.2 in 2000. Because the number of induced abortions during the same period fell to only 31.1% of the induced abortions in 1990, it can be assumed that methods of contraception are being used more, and more effectively. Still, out of 90,910 live births in 2000, 19,792 (that is, 21.8%) were to single mothers.

The population of the republic has shown natural decrease over the last eight years. The size of a nuclear family averages between three and four members, but some couples have no children, and devoutly religious parents usually have three or four.

HEALTH THROUGH THE LIFE CYCLE

Pregnancy and Birth

Pregnancy is a condition that can be ended by legal abortion. It must therefore be assumed that pregnant women

have chosen to bear a child. Whenever possible—in an overwhelming number of cases—children are born in hospitals. Under normal circumstances, mother and baby remain under hospital care for three days. Healthy infants are seen by a pediatrician once a month during the first six months, and then every other month until the end of the first year.

Infancy

Most babies are bottle-fed, but some mothers nurse their babies. Breast-feeding of children up to 3 months of age decreased between 1996 and 2000 from 32.85% to 24.15%. Over the same period of time, the rate of breast-feeding of children older than 3 months increased from 24.3% to 31.07%. Some mothers swaddle infants, continuing a practice very common two generations ago. They believe that swaddling will calm their children.

Much attention is given to children for the first two years. For example, it is customary to take small children outdoors every day in prams or strollers. At about age 2 or 3, some children are sent to day nurseries (*crèches*), and a year or two later to kindergarten. The number of kindergartens fell from 7,335 in 1990–91 to 5,776 in 2000–01 as did the number of children attending them, from 352,139 to 279,838.

Infants and children with birth defects or other problems receive appropriate care and, if necessary, are referred to special residential institutions or to day clinics and centers, all of which are serviced by physicians. Some of these institutions are state-run, others are private.

Czech parents, as a rule, expect their children to obey, and if they do not, spanking (for the most part symbolic) is likely to be administered. But children are loved and no expense is spared to supply them not only with all their needs but also such extras as attractive clothing and the popular toys.

Childhood

Special schools are available for children who are mentally handicapped, have impaired hearing, speech, or vision, are physically handicapped, or have a combination of such problems. Four types of schools serve these children. The numbers of students in each type are given parenthetically for the academic year 2000–01: nursery schools (boys 6,309; the number for girls is not available); basic schools (grades 1–10; 14,159); special education and reform schools (49,494); and secondary, vocational,

and home economics schools (28,112). In the last two groups, the large majority of pupils are mentally handicapped, with the ratio of male to female 100 to 40.

The Aged

People in the republic seem to age faster and look older sooner than those of the same age in the United States. Because many have had a stressful life, they usually retire as soon as they become eligible. Widows and widowers sometimes live with one of their married children, but if their health and finances permit, are more likely to live an independent life in their own house or apartment, or in a retirement home. During 2000, 148 nursing homes with 12,129 beds were available for those pensioners who needed nursing services.

As for mortality age, in 2000 a full 7,118 men out of a total of 54,845 males died at 85 years of age or older; 16,734 out of a total of 54,119 females died at that age or older. The most common causes of death in 2000 were diseases of the circulatory system (53.39%), neoplasms (26.33%), external causes (injuries, poisoning, etc.; 6.49%), diseases of the respiratory system (4.55%), and diseases of the digestive system (3.89%).

Dying and Death

Death is accepted as the inevitable end of a person's life and is particularly mourned if the person has died prematurely.

More than half of the republic's population consider death as final; those who are religious believe in some sort of an existence beyond earthly life. Most people hope for a sudden, painless death, but in actuality many die in hospitals while being treated for a serious illness, usually associated with advanced age.

Prior to World War II, burial in the ground was as common as, or more common than, cremation. As of 2002, three fourths of the deceased are cremated—four fifths of those dying in Prague and about two thirds in Moravia. No special treatment of the body is performed except for preparing the face if the body is to be viewed before the funeral. In very exceptional cases, at the request of the family, the body may be embalmed. An autopsy is usually required in cases of death by accident or under unusual circumstances.

Datoga

Astrid Blystad and Ole Bjørn Rekdal

ALTERNATIVE NAMES

Datoga, Tatog, Tatoga, Datoog, and Mangati.

LOCATION AND LINGUISTIC AFFILIATION

The core Datoga area has for several centuries been the Hanang and Mbulu Districts of Arusha Region in northern Tanzania, but Datoga groups are spread over much of Tanzania in small localized enclaves.

Datoga is a Southern Nilotic language. The various subsections have different dialects which are internally comprehended among all Datoga.

OVERVIEW OF THE CULTURE

The Size of the Population

The size of the Datoga population is rather uncertain owing to the lack of ethnic variables in recent censa and to the

considerable dispersion of Datoga throughout Tanzania. The Datoga population of Hanang District has been estimated at 30,000 (Lane, 1996), but the total number of Datoga in Tanzania is probably several times that number.

Economy and Occupations

Datoga are pastoral in the sense that there is an immense cultural emphasis on cattle. The cultural elaboration of cattle does not mean, however, that Datoga have large herds. Except for a smaller number of rich cattle owners, the majority of Datoga today have merely a few head of cattle and increasing numbers have no cattle at all. With decimated herds, farming has become increasingly important for Datoga, and nearly every Datoga household in Hanang cultivates a smaller or larger plot of maize, beans, and/or sorghum. A large repertoire of myths with degrading descriptions of cultivation and cultivators nonetheless flourish.

Social and Political Conditions

Many Datoga have started to wear modern Tanzanian cotton dress, but the traditional and still commonly used dress is the bead-decorated leather cape and the leather skirt (*hanang'weanda*), a skirt which is vested with immense social and religious significance. Women carry heavy brass and bead decorations, while both sexes often have large facial scarification around the eyes and large extended earlobes with wooden or brass ornaments.

A husband and his wife or wives and their children and his old mother make up the prototypical inhabitants of a Datoga homestead. The traditional compound is characterized by a low flat-roofed men's house, several women's houses, and various animal dwellings placed in a half circle within a high thorn fence.

Datoga communities are linked together through rules and regulations that are enforced by an elaborate system of ad hoc meetings. The most common meeting is the "open meeting" (*geetabwaraku* or *girgweageeda emeeda*) which in practice is a male forum. The "clan meeting" (*girgweageeda doshta*), the "neighborhood meeting" (*girgweageeda gischeuuda*), the "youth meeting" (*girgweageeda gharemanga*), and the "married women's meeting" (*girgweageeda gademga*) are other examples.

Family and Kinship

Datoga have, like other East African pastoralists, commonly been described as polygynous, patrilineal with a

strong "warrior" tradition and male domination of social and political life. With renewed focus on pastoral communities in recent writings a more nuanced picture has appeared. In writings on Datoga it has been pointed out that clan affiliation is retained throughout life for both men and women, socio-political responsibility include matri- as well as patrikin, a "dowry" institution facilitates that women as well as men receive gifts of livestock at the time of marriage, and that women are central actors in Datoga political and religious life (Blystad, 2000).

Religion

Aseeta, the Datoga deity, appears as an androgynous, powerful, and inherently good deity, invested with immense creative potential. Communication between human beings and the deity takes place with female and male spirits (*meang'ga*) as mediators. The spirits are more closely involved in people's lives than Aseeta. Aseeta and the spirits are particularly powerfully addressed by married Datoga women or "women who wear the leather skirt" during the frequently arranged *ghadoweeda* ritual ("people seeking blessing"), a ritual located at the heart of Datoga "tradition."

THE CONTEXT OF HEALTH: ENVIRONMENTAL, ECONOMIC, SOCIAL, AND POLITICAL FACTORS

During colonial times as well as in the post-independent Tanzania period, Datoga pastoralists were subject to attempts to do away with their way of life. Colonial discourse associated Datoga pastoralists with primitivism, barbarism, and savageness. The discourse was reflected in public executions, arbitrary imprisonment, forced conscription into the army, collective cattle fines, and discriminatory resource allocation. The colonial portrayal of Datoga influenced the attitudes and actions of neighboring populations, politicians, bureaucrats, journalists, and scientists in post-independent Tanzania.

The new state of Tanzania pursued these policies more rigorously with their swahilization, villagization, and education policies. The so-called "Operation Barabaig" in the 1970s developed into a dramatic encounter between Datoga and state employees, who forcefully removed the people from their homes and relocated them in villages.

The official discourse after independence in 1963 facilitated a new wave of agriculturalists moving into what was formerly Datoga grazing land, leading to serious conflicts and to ethnic clashes with large numbers of casualties. Mechanized farming was in particular encouraged by the new state. In 1970 the Tanzania Canada Wheat Project (TCWP) initiated the clearing of woodland above the Rift wall in what is now Hanang District. With the total allocation of some 100,000 acres of land for large-scale wheat farming during the 1970s and 1980s the problem of land shortage in the area was magnified. Adding to the impediment of land loss, the appropriation of Datoga land took place in a manner that caused reaction from both the national and the international community owing to its violations of human rights.

MEDICAL PRACTITIONERS

The landscape of indigenous Datoga medical practitioners consists of primarily three categories: Daremgajeega, Bajuta, and Gijoodiga. Most male Datoga healers are Daremgajeega. Daremgajeega is the name of a particular clan of healers as well as of a group of healing clans. The other major group of male healers is called Bajuta (Bajuta being both a healing clan and a Datoga subsection).

The practices of the Daremgajeega and the Bajuta are often quite similar. A common healing session implies that the healer spits on his client's body for extended periods of time, usually on the back, breast, and belly. Spitting, in the characteristic way of sending showers of spit through the teeth, is always perceived to be a blessing among Datoga, but gains in significance when carried out by a healer. The spitting is usually combined with the use of mixtures of herbs and animal fat which are rubbed over the patient's body with slow massaging movements to soothing accompaniment of chanted prayers for blessing. Patients say their healers make them "calm down."

Daremgajeega and Bajuta healers use a large number of techniques in addition to the somewhat standardized sessions of spitting, application of medicine, and prayers in their attempts to cure their patients. Creative use of product from domestic animals, particularly from cows and bulls, goats, and sheep is essential for Datoga healers. This particularly includes a practice linked to the consumption of fatty soups served with or without meat, the consumption or the smearing of milk, gee, butter, or

blood onto the body, and the application of hides, manure, urine, or blood on parts or over the entire body. Incisions with or without the extraction of blood with a cup and the burning of parts of the body are other practices that commonly leave Datoga bodies with numerous little black scars. Quarantine or moving of particular homesteads or neighborhoods for shorter or longer periods of time are also common strategies used to prevent the spread of contagious conditions.

Although female healers are fewer in number than male healers, they make up a significant part of the landscape of Datoga healers. The most important category of female healers is *gijoodiga* (singular: *gijochienda*), women whose mothers are of the Bajuta clan. *Gijochienda* is a medium through which suffering individuals can communicate with the spirits, plead for help, and receive response and advice from the spirits. This communication takes place during night-time séances when the spirits "crawl onto the back" of the *gijochienda*.

The abilities of the *gijoodiga* will commonly be revealed when they are still young due to peculiar conduct. Rigorous training is nonetheless required before a *gijochienda* acquires proficiency in calling forth the voices of the living spirits. Some women of the Ghawooga, Hilbaghambowaida, or Bajuta clans may also in rare instances have special healing or spiritual abilities, but they are not as numerous as the *gijoodiga*.

Indeed, a prominent feature of the complex cultural environment of Mbulu and Hanang is that healing is often sought from individuals with foreign ethnic affiliation. Such cross-cultural therapeutic relationships are often established in spite of the fact that the ethnic groups involved have a long history of mutual hostility (Rekdal, 1999). Commonly consulted non-Datoga healers come from the Iraqw, Nyaturu, Rangi, Sukuma, and Tanga ethnic groups, as are health personnel at official or mission dispensaries, health stations, and hospitals.

CLASSIFICATION OF ILLNESS, THEORIES OF ILLNESS, AND TREATMENT OF ILLNESS

"Illness of God"/"Illness of Man"

There is a distinction made between "illness of God" (*Geyooda Aseeta*), and "illness of human beings" (*geating siida*). But Datoga illness classifications are ambiguous

and internally inconsistent; most illnesses can be classified into both categories depending on the circumstances.

Witchcraft, Evil Eye, and Curse

The prototypical illnesses located in the category “illness caused by humans” are conditions caused by witchcraft, evil eyes, curses, and the use of poison or other dangerous remedies. Datoga consider themselves to have few witches, but witchcraft is nonetheless said to cause increasing harm to the health and prosperity of people, animals, and plant life due to the escalating proximity in relations between Datoga and their Iraqw, Iramba, and other neighbors. A related and not less frightening skill among some Datoga is “the evil eye.” The evil eye can, with a mere glimpse, but more commonly with lengthy staring at its target, cause illness, death, and dying.

Curses commonly hit Datoga individuals who fail to adhere to fundamental Datoga norms of respect, and are commonly carried out by male or female meetings after the individual is given ample opportunities for redress. Curses cause social isolation of an individual as they are extended to persons who co-operate with the cursed individual.

Fever

Malaria and tuberculosis (TB) are conditions typically categorized as “illnesses of God.” Living in a harsh and disease-ridden environment, malaria and TB are common conditions among Datoga of Hanang and Mbulu, and with relatively little variation, the theoretization and treatment linked to these conditions are similar to those of a whole range of common illnesses in the area. Normal fever conditions are distinguished from intermittent fever and fever in combination with bloody cough and weight loss as in TB.

These conditions receive similar treatment consisting of a combination of drinking of melted butter/gee, eating fatty soups cooked on beef meat, and drinking of herbal mixtures. The herbs utilized vary somewhat from one illness condition to the next. The aim of this treatment is to cause diarrhea and vomiting in order to expel the harmful substances from the body. For the pure fever conditions the drinking cow’s, bull’s, or goat’s urine is added to make the expulsion more efficient. With worsening conditions patients suffering from any of these conditions may eventually be sent to hospital, but many Datoga choose hospitals as a last option, and their health may have severely declined by the time they arrive.

Physical Handicaps

Conditions that are particularly feared among Datoga are illnesses linked to burning, severe bleeding, acute diarrhea, and conditions affecting the bones, all conditions which may be attributed to either the will of God or to human agency. The last condition warrants a few remarks owing to its particular elaboration among Datoga.

The birth of malformed babies, that is, babies lacking fingers or toes or entire limbs, or accidents causing such losses, are particularly feared among Datoga. Such handicaps have caused expulsion and fear of infants as well as of adults throughout the known history of Datoga.

The fear of a person without a finger, “without feet,” or without other “bony” parts of the body, must be understood with reference to the connection made between such conditions and a clan’s poor semen. In Datoga semen is thought to be the substance that builds the bony structures of a body, and hence malformed bones imply poor contribution by the genitor and in extension by his clan. What is important in this context is that such an “incomplete” condition can be transmitted to others, particularly through the sharing of meals.

The fear of incomplete bones make Datoga shun amputations, which at times cause flights from hospitals. Severe and lengthy ritual activity carried out by Datoga healers is the only remedy that, to some extent, can cleanse individuals with such handicaps. Other categories of handicap, such as deafness, dumbness, or blindness are not feared. Individuals with such handicaps are rather often located at the heart of Datoga ritual life.

Illness of the Bones

Another and somewhat related condition to the one we just described is called “bones” (*geaka*) which strikes an individual who either purposely or accidentally kills a fellow Datoga. Such an act is said to be so grave that it enters into a man’s bones—and in extension the semen which is to produce new “bony structures.” The condition follows him for three generations, and in practice expels him from life in Datoga communities.

SEXUALITY AND REPRODUCTION

Datoga men and women intensely desire children. Both men and women need children to achieve adult status, and they gain prestige and influence with the birth of

every additional child. A man or woman who dies without a son and a daughter, may never be given the honor of an “official” Datoga funeral (*bunged*), an ultimate goal among Datoga of this part of Tanzania. For fear of envy, great secrecy surrounds the fecundity of a compound, and the total number of children and cattle can only be traced with great difficulty. Any kind of population control in the married population is a highly foreign concept among Datoga who follow traditional religious concepts and ideals.

A woman’s future is closely linked with her own ability to conceive and successfully give birth. Pressure to successfully conceive and give birth may follow a woman throughout her entire reproductive life if she fails to fulfill the goal of having at least one son and one daughter. A newly married woman will often have several sexual partners, classified as “brothers” of her husband, in order to ensure her first pregnancy. The younger “brothers” of her husband are usually particularly welcome in the young woman’s house, as the “blood is often warm between them” and “the seeds of young men are good.”

There is a strong belief that all women can conceive, although some may have problems carrying through a pregnancy or giving birth, due to the “will of *Aseeta*” or influences of “bad humans.” If time goes by and there is no sign of a forthcoming offspring, a woman will set about seeking answers and cures. A husband is usually eager to cooperate in their wives’ attempts to seek a cure against barrenness which often implies the spending of large amounts of wealth for treatment.

The status of a childless woman will remain ambiguous throughout her life, and her husband may demand a divorce. It is more common, however, that a woman who has difficulties conceiving will divorce her husband and remarry, in the hope that a new husband and his “brothers” may bring her better fortune. A childless couple will commonly receive a child or two from kin who are “rich in children.”

HEALTH THROUGH THE LIFE CYCLE

Pregnancy and Birth

The Physical Growth of a Fetus. Semen and a woman’s blood are considered to gradually thicken into a mass which forms the fetus. The blood produces the soft

parts such as the flesh and blood, while the semen produces the white bony parts, namely the spine, bones, and skull.

For its growth, the child is said to be dependent upon a continuous supply of blood, as the fetus “nurses its mothers blood.” The fetus is also said to benefit from the periodic addition of sperm for the growth of the bones and simultaneously to the development of hard, male qualities such as a tall and erect body posture, and a woman will therefore usually welcome sexual contact during a pregnancy.

Though fundamental in procreation, blood and sperm are both potentially destructive fluids that can harm the unborn child if contaminated by bad substances. A woman must watch her diet as “her blood becomes what she eats” and sperm may in some instances be too “strong” for a child in the womb and may cause the fetus to sicken and die. During the last couple of months of a pregnancy, the addition of sperm should cease completely since the sperm at this point unproductively merges with the milk in the mother’s body and breasts.

Diet during Pregnancy. A pregnant woman strives to get the foods she craves for since these “go well together with the child inside.” Raw blood products are desired by the pregnant woman as “they increase her blood”; whenever a slaughter has taken place, raw blood is served to the visibly pregnant. Generally speaking, the common diet of maize porridge, maize soup, and milk, with the periodic adding of millet and beans, is usually not altered dramatically during a pregnancy. In fact, far more attention appears to be given to the persons a pregnant woman eats with than with the actual food she consumes.

Precautions taken by the Pregnant. A pregnant Datoga woman considers herself to be surrounded by human beings, substances, and states that may harm her unborn child. There are certain sights that should be avoided by a pregnant woman at any cost; this applies to people, animals, or items that look peculiar or damaged, such as, for example, crawling snakes, broken pots or calabashes, and persons who are crippled. This fear of looking at people who do not have complete bodies—or, more seriously, of eating together with them—is not limited to pregnant women, but this fear takes on new proportions during pregnancy since the shape and character of the “soft” or “watery” child in the womb can easily be influenced by such abnormality. Foul smells, frightening

sounds, or odd sensations are also shunned during pregnancy. When severe illness occurs during pregnancy, a sheep or a goat is commonly slaughtered in order to cook nourishing soup for the woman, and in due course the assistance of healers is sought.

Itself so vulnerable and dependant, the child in the womb may also be demanding and a source of potential peril. Indeed, a pregnant women's body is considered to be inhabited by a tiny strong-willed human being who has the ability to make her ill or even cause her death. Thus, a pregnant woman may experience herself as being vulnerable to both external and internal forces. Her leather skirt is tied tightly around her womb in a manner that pushes her growing belly downwards. "We close the womb with the leather skirt" informants would say, indicating the way they seek to prevent the unruly fetus from engaging in unproductive wild play. In addition, this technique prevents her condition from becoming visible until the final stages of pregnancy, thereby reducing the danger of evil eyes.

Stuck Pregnancy (*Muldeaneeda*). In Datoga experience, a fetus may suddenly cease to develop, in which case the child becomes stuck in the maternal womb (*muldeaneeda*). In such instances the woman experiences symptoms of pregnancy, but the fetus ceases to develop due to bleeding which leads to insufficient nourishment for the child. For years the child may "hide" in the back of a woman's womb "feeding on her body," leaving her thin and weak. Some women are bothered throughout their entire lives by recurring *muldeaneeda*, some of which are said to simply die off, while others are eventually born. Children that are born after years of *muldeaneeda*, are often given the names Gidamulda (male) or Udamulda (female), and these children are particularly adored, since their births relieve their mothers of years with pain and anxiety. The immense admiration of these children is moreover related to their alleged potency.

Miscarriage and Infant Death. Other dreaded outcomes of a pregnancy include miscarriages and the death of nursing infants. Such deaths are considered to be frightful, and constitute severe breaches in what is perceived to be the correct development: from conception through pregnancy and birth to convalescence and nursing. Such events produce "dirt" and those who are going to "eat the dirty condition"—usually the woman, her children, and sometimes her husband—are isolated in separate enclosures

(*ghawiida*), in principle until a new pregnancy is ensured. Isolation is necessary because such events are considered to be contagious and can harm the potential fertility of others.

Ghawiida is part of the elaborate Datoga seclusion practices (*metiida*). *Metiida* involve the isolation of people and compounds for varying periods of time in order to prevent "dirt" from entering fertile processes. The most common conditions requiring a quarantine are deaths, abnormal births, conception outside of marriage, and conditions that require the purification or healing of people, places, or activities.

The most serious type of *metiida* is the *ghawiida jeapta* related to the death of a nursing infant, a stillbirth, or a miscarriage. It is particularly the milk dripping from the woman's breast that is feared. In contrast to the milk received by nursing infants, the unproductive mother's milk that drips from a woman's breasts after the death of a nursing infant is perceived as being entirely bad and infertile.

In principle, only a new pregnancy has the power to fully remove *ghawiida jeapta*, and a woman who does not become pregnant may remain in an ambiguous position, being neither completely clean nor completely dirty. A woman who experiences recurrent miscarriages or infant deaths will "have dirt" and substantial restrictions will be placed on her social conduct to the extent that years of her life may be spent isolated behind high thorn fences.

Giving Birth. There are commonly a number of older women ready to assist a woman in labor, and news about a woman who is about to give birth causes immediate moves by neighborhood women who move in to take part at this precarious time.

The woman in labor is placed in a half sitting, half hanging position, holding onto a rope which is hanging from the low ceiling. The rope the woman holds onto is fastened close to the fire "so that her blood can be heated and the delivery speeded up." Her feet are firmly planted on the large hide on her bed, with her leather skirt placed on top of it. With small modifications, a woman commonly remains in this position throughout the delivery. The midwife will fasten and unfasten a leather thong around the woman's abdomen—following the rhythms of labor—in order to increase the downward movement. She will also massage the woman's back and repeatedly change the position of her legs.

After the birth of the child, the leather strap is again carefully fastened around the womb to speed up the expulsion of the placenta. When the placenta appears it is

closely inspected. The umbilical cord is then cut with a knife before the wound is covered with cow dung to heal. Later the placenta is placed in the cattle enclosure, while the remnants of the umbilical cord are tied to the foot of a heifer.

Both breech births and twin births are feared among Datoga. After such abnormal births there will be no *ghawiida* since no death has occurred, but the compound is isolated for 6–8 days. Despite their relatively light isolation, a breech birth is regarded as a most serious matter, and several of the practices that follow such a birth imply associations with death. The later consequences for the child are, moreover, serious, since the person may have difficulties finding a marital partner. Children born in breech births will also appear unpopular on the marital market. Twin births are commonly followed by the brewing of honey mead and diverse ritual activity which aims at “separating” the two children.

Increasing number of Datoga women will give birth at a health center or at a hospital.

Infancy

The sensation of having calmed down after birth is soon followed by another unsafe phase, post-natal convalescence (*ghereega*)—the months during which the woman is to regain her strength, and the infant is to face its initial harsh encounter with the world. *Ghereega* is a new liminal phase which is associated with almost total seclusion of the mother and infant in the low, dark, private room of the mother for a period of 2 months after the birth of a boy, and 3 months after the birth of a girl.

During the months the woman remains inside, she focuses on ensuring her own and her child’s health. The midwife commonly stays on with the mother until the first peril is passed, and until a male goat has been selected, strangled, and butchered, and the “song of the child” initiated. A girl is then commonly selected to stay with her and assist her. Some women will move outside with care after the remnants of the umbilical cord have fallen off, but they usually remain close to the compound. In such cases she places her baby deep in a leather sling, and if the child is a boy she carries an arrow and a ritual stick for protection. If she meets a stranger she will commonly look at the ground or bend down to signal that she does not want contact.

A woman will generally let her infant suckle whenever it cries. However, breastfeeding does not begin

immediately after the birth of a child. Water is substituted for mother’s milk the first 2–5 days of an infant’s life, or until every sign of the meconium, the first black feces of the child, has passed. Our informants would explain that water cleanses the infant’s stomach. This practice cannot be understood without a fundamental recognition of water as a sacred life-giving source; rain water is referred to as “the spit of Aseeta” (*ng’usheanda Aseeta*). The feeding of the unboiled water causes diarrhea in many new-born Datoga babies.

Cow’s milk, when available, is usually given a couple of days later in combination with mother’s milk. When a mother starts to nurse her child, therefore, she also makes an effort to get some cow’s milk. Mother’s milk and cow’s milk ideally provide the sole nourishment for the child the first year.

Milk has tremendous cultural significance among Datoga. Feeding the child cow’s milk is crucial in order to gain the experience of sharing bodily substance with livestock, and is perceived as initiating a life-long pastoral education, implying the instilling of embodied, pastoral knowledge in the child. Later on ghee, butter, meat, and blood will be added to the diet. Despite the ideals of feeding Datoga infants cow’s milk, Datoga mothers of Hanang and Mbulu are often forced to feed even tiny children maize-soup, soft maize-porridge, or bean stew since the shortage of cow’s milk often becomes acute in the dry season.

Mother’s milk and the flows that exist between the mother and her child during the period of nursing are considered to be inherently good, intimate, and nourishing. However, this milk is thought to be liable to be contaminated by other substances that enter the mother’s body. Bad food, bad sperm, or other bad substances have the potential to negatively affect the quality of a woman’s breast milk.

A Datoga woman commonly nurses her child for at least a year, and often up to two years. While the woman is nursing the child, the two are perceived to be “one,” just as they were while the child was still in the womb. The intimate links between the two bodies during pregnancy are thus extended throughout the period of breastfeeding. The separation of the two bodies is said to start first after weaning. As we saw above, the death of a still-nursing infant requires that precautions parallel to those associated with a miscarriage be taken; and these events differ fundamentally from the way the death of a weaned child is handled. The notions that a mother and child “are one body” as long as the child is breastfeeding, and that death

of a suckling child is like a delayed miscarriage have also been noted among neighboring peoples such as Iraqw and Maasai (Rekdal, 1996, p. 376; Spencer, 1988, p. 41).

The new mother will also spend a substantial amount of time studying every inch of the baby's body. She makes sure the painful but necessary burning of the infant's skull is carried out to "hasten the closing of the fontanel," and should the infant suffer from pains in the chest or stomach, she may allow the same treatment of burning to take place again, often leaving the little child with numerous small burn marks. She selects charms to hang on the baby's body to protect it from the first dangers of life. A weak baby girl may at this early point in her life be circumcized "in order to prevent further illness." While in seclusion a new mother spends cherished time on the composition of the "song of the child," which was initiated by the midwife. The mother holds her baby close while rocking her upper body slowly back and forth, thus providing it with soothing sounds and soft movements.

Childhood

The custom of mutating the physical body for beauty, socialization, or preventive health purposes takes place throughout childhood. The most common practices include the initiation of a process of extending the earlobes, the removal of the two lower incisors, and circumcision of both girls and boys.

The mandatory removal of the clitoris and labia minora is commonly carried out when a girl is between 2 and 5 years of age. This painful operation is carried out by a local elderly woman with only a handful of women present in the homestead. The incident is not talked about much and receives no cultural elaboration. This appears in stark contrast to male circumcision, which is a grand ritual occasion characterized by the brewing of large quantities of honey mead, sung prayer, and dancing. The operation takes place when boys are between 5 and 12 years old. Large numbers of boys, sometimes several hundred, are circumcized at the same occasion. The operation itself is commonly carried out with a knife or razor blade, and is followed by the feeding of milk and blood for the boys to regain their strength.

Adolescence

Youth is a time when Datoga pay substantial attention to their maturing bodies, and spend time on modifying it for

beautifying purposes. For example, earlobes are extended with large wooden earrings and large facial scarifications are commonly inscribed around the eyes.

Particularly intricate and poetic youth talk takes place between potential boy/girlfriends. A man who fails to encourage the continuation of the relationship through dialogue may attempt to win a girl's heart through a spearing in the *lilicht* tradition, a traditional hunt for dangerous animals (usually a lion) linked up with youthful fertility.

Although sexual play is an integral part of youth activity, norms prohibit a couple from carrying out sexual penetration while the girl is unmarried. The norm is related to the absolute condemnation of children born without clan affiliation on the father's side. Indications of breaches of the sexual norm, and rumors that a particular girl "has become a woman," may lead to her being required to undergo a physical checkup by a group of older women, and they may conclude that "the girl has now become like us," and should be married off immediately. Such incidences severely reduces a girl's chances of influencing the choice of her marital partner.

This is not to say that premarital sexual intercourse does not occur. Preventive measures such as *coitus interruptus* are common and remedies that cause abortion are known. But girls were generally said to be reluctant to agree to sexual intercourse. Medical personnel confirmed that virginity among unmarried Datoga girls is the rule rather than the exception.

Adulthood

Alcohol Consumption. Datoga elders have customarily consumed the sacred honey mead primarily on ritual occasions and on grand occasions of festivity. Women and youth have according to Datoga custom not consumed alcohol. With the tremendous transformations taking place in Datoga communities, not the least with the increase in contact with outside peoples who brew a large variety of brews on which there is no customary restrictions, the consumption of alcohol has increased substantially. Youth and sometimes women may today be seen consuming non-indigenous brew, particularly on market days. The increase in alcohol consumption, the transformations of the people involved in the consumption, and of the timing and settings where the consumption takes place is readily addressed by the Datoga informant.

Domestic Abuse. Datoga have strong ideals of peaceful co-operation and complementarity between a husband and his wife, or wives, in order to ensure sound reproduction of a compound. Despite these ideals, however, conflicts between spouses and violent outbursts are common in many Datoga compounds. A generally accepted norm states that a man has the right to punish his wife or wives when they do not fulfill their obligations, and women will commonly defend their husband's abuse by referring to particular instances of lack of compliance or misconduct on their part.

There are however restrictions put on a husband's right to physically reprimand his wives, and men may be penalized by the female community when breaches occur where women experience their "procreative bodies," in the broad sense of the term, are infringed upon by male misbehavior. Such infringement must be instantly addressed lest all Datoga life suffer. The consequences of action taken by the married women's council (*girg-weageeda gademga*) against a man who has seriously infringed upon women's fertile domain may be quite severe. The offender will not only be fined a rare and cherished black bull, but will be humiliated by the women in front of the entire community.

Any male interference at critical moments of procreation—such as mistreating or quarreling with a pregnant or convalescent woman, or watching the birth of a child, if not specifically summoned to assist as a member of a healing clan—are regarded as particularly serious offences. Serious argument arising over funds for the treatment of barrenness, miscarriage, or illness related to pregnancy, birth, or nursing may require action, as may male violence inside a Datoga woman's private room. Men's behavior also comes under the scrutiny of women following incidences of misconduct in relation to what are perceived as sacred female activities in connection with ritual gatherings. Female animals, not only livestock, but also domestic animals such as cats and dogs, are protected in ways parallel to women when they have kittens or puppies.

Dying and Death

The treatment of dying persons who leave families and offspring behind them is colored by the notion that the person is soon to become a living guardian spirit; a condition requiring utmost respect and care.

Datoga fear corpses to the extent that individuals closely associated with the dead will be isolated for up to

a year. The severe restrictions linked to miscarriages or deaths of still suckling infants were reviewed above. Deaths of spouses will experience a similar set of restrictions which imply that either the widow or widower experience months of isolation where they do not eat, work, or socialize with other than the potential person who might "eat the dirt" with them. Simultaneously they modify their dress, shave their hair, and remove all decoration except for a black bead necklace so their appearance becomes filthy.

The corpse is handled by female members of the household only. Dead bodies should ideally be placed in a horizontal position on a litter and carried to the east of the compound where it will be left to be "eaten" by the bush. The Government of Tanzania has prohibited the placing of corpses in the bush, and many Datoga will today bury the dead inside the compound even if a communal funeral is not held. Each year, however, a handful of deceased Datoga elders, both men and women, will be buried in grand communal funerals. In such instances the corpse is placed in a sitting, fetus-like position with the head bent toward the chest and the hands closed around the knees. The tomb that is to mark the grave for years to come is created in the image of a large pregnant female womb, which after 9 months "gives birth" to the new spirit. The funerary ritual is a ritual unique in scale and elaboration in Datoga culture.

The deceased who is to receive this honorary departure must have had many children, of whom at least one daughter and one son must be married and have children. The deceased must not have died "a bad death," which includes deaths caused by accidents, sudden diseases, severe bleeding, diarrhea, fire, or the breaking of bones. All limbs, including the fingers and toes, must be intact, without fractures or abnormalities such as the lack of a joint or even a fingernail. The most important criteria, however, are that the deceased is ritually clean, that is, is not suffering from "bones," which is related to homicide involving a fellow Datoga; and that the deceased comes from a wealthy family and clan. It is the male and female spirits born in such grand burials that are sought by "people seeking blessing" (*ghadoweeda*)—and whom Datoga informants consider themselves to be wholly dependent upon for health, wealth, and prosperity.

Fore

David J. Boyd

ALTERNATIVE NAMES

None. The name “Fore” (pronounced FO-rey) was created by an Australian patrol officer during a patrol into the region in the early 1950s. Standing on the northern border of this different linguistic group, he asked local people for the name of those who lived further to the south. The answer was “*porekina*” (*kina* = people), meaning “people living downhill.” “Pore” was transcribed as “Fore” (Lindenbaum, 1979, p. 39).

LOCATION AND LINGUISTIC AFFILIATION

The Fore are located in the southeastern region of the Central Highlands of the island of New Guinea. Their territory, centered on 6°35′ south latitude and 145°35′ east longitude, is a wedge of approximately 950 km², bounded on the north by the Kratke Mountains and on the west and the southeast by the Yani and the Lamari Rivers, respectively. In this mountainous montane zone, altitude varies from 400 to 2,500 m, although most people live within the altitudinal range of 1,000–2,200 m. Fore territory is divided into a northern and a southern region by the Wanevinti Mountains and the corresponding populations are referred to as North Fore and South Fore. Currently, the entire Fore region falls within the political boundaries of Okapa District, Eastern Highlands Province, Papua New Guinea.

The Fore language is the southernmost member of the East Central Family, East New Guinea Highlands Stock, Trans-New Guinea Phylum of Papuan languages.

Three distinct dialects that reflect the geographical division are recognized: Ibusa dialect is spoken by the North Fore, and Atigina and Pamusa dialects are spoken by the South Fore. This is a region of considerable linguistic diversity and the Fore share common territorial boundaries with speakers of seven other mutually unintelligible languages.

OVERVIEW OF THE CULTURE¹

Until the mid-20th century, the Fore, who currently number approximately 20,000 people, existed in relative isolation and had scant knowledge of the larger world beyond their territorial boundaries. They lived as subsistence horticulturalists practicing an extensive form of shifting swidden cultivation to produce their staple crop, sweet potato (*Ipomoea batatas*), and a variety of subsidiary foods. New gardens regularly were cleared in the surrounding forest and settlements were quite mobile as people moved their living sites to stay close to their gardens. They also tended domestic pigs, which were the most important form of local wealth and also essential objects of transaction in acquiring wives, settling disputes, rewarding allies, and compensating enemies. Although the Fore did share a common language, they did not consider themselves one people. They had no encompassing name for all speakers of Fore, no unifying political organization, and no collective ceremonies. In fact, social relations between local groups were generally antagonistic and intergroup warfare was common (Berndt, 1962). Groups would form impermanent

alliances for intermarriage, small-scale ceremonial exchange, mutual defense, and trade, but these relationships were altered frequently as patterns of amity and enmity shifted.

Social and Political Organization

The primary Fore residential unit is the hamlet consisting of 70–120 people living in 12–20 houses. One or several adjacent hamlets combine to form a parish whose members share a corporate interest in the territory they occupy, including a sacred grove where spirits reside. Typically, parishes are subdivided into parish sections composed of several allied hamlets and these sections in the past were the effective political and military units. All sections and parishes were headed by a “big-man” leader. Since there were no permanent political positions or ranked statuses among the Fore, big-men won the respect and loyalty of fellow group members by showing superior skill in organizing activities that enhanced the well-being of the group. They directed most group activities, including warfare, managed exchange transactions, and recruited new members to enlarge and strengthen the group. Men competed with each other to achieve big-man status and those who succeeded were strong, dominant individuals, feared warriors, eloquent orators, and skilled negotiators. However, when a big-man faltered, the support of followers could be quickly transferred to a competitor who aspired to become a big-man.

Then, as now, the dominant organizing principles of Fore society were kinship and co-residence. All social groups are assumed to be founded on kin relatedness between members and patrilineal connections are stressed. But, genealogical memory is shallow, rarely extending beyond the grandparental generation. Also, in this very mobile society, local group membership changed often. In practice, then, unrelated newcomers were easily incorporated as new members of a group by adoption, affiliation, or mutual consent if they behaved as kin. People who lived together and demonstrated loyalty, cooperation, and mutual support could become kin, “one blood.”

These putatively kin-based groups are still hierarchically organized. The smallest unit, called a *lounei*, consists mainly of co-residents of a single hamlet and is an exogamous group. Several *lounei* together form a subclan that may or may not be exogamous. And, several subclans form a non-exogamous clan and share a common territory.

Gender Relations

The relations between Fore men and women are relatively egalitarian, but important differences do exist in the social spaces men and women occupy. In the political arena, men dominate the public domain and vie with each other through oratory and subtle persuasion to influence the course of group activities. Also, in earlier times, men as warriors were responsible for defending their groups and for prosecuting offenses against them. In the domestic sphere, the gender division of labor still assigns relatively few tasks to only men or women. Men fell the trees for new food gardens and women assist in cutting the undergrowth and burning the debris. Men then build the garden fences and women prepare the soil and plant most of the crops. However, the bulk of labor required to cultivate, weed, harvest, and transport garden produce continues to be provided by women, although men do assist as they wish. The burden of pig rearing also falls largely to women who transport food and fodder from the gardens and feed the pigs each day. Most food for household members is prepared and cooked by women and men help with the gathering of firewood. Childcare again is largely the responsibility of women who enlist the willing aid of older siblings. Women, who once made all articles of clothing and net bags from pliable tree barks and other forest products, now purchase most clothing items or sew them on hand-crank sewing machines. Men, who used to craft weapons (bows, arrows and spears), no longer do so. In sum, although the division of labor assigns complementary tasks to men and women, women continue to provide a much larger portion of the labor required for essential household activities.

Female Pollution

The separation of male and female spheres is underpinned by an ideology of female pollution. Fore men, as do men in many other societies in New Guinea and elsewhere, fear contamination by wives and other actual or potential sexual partners. Especially debilitating would be any contact with vaginal blood associated with menstruation or childbirth. Should such contamination occur, either accidentally or as a deliberate act of assault, the male victim is expected to suffer severe respiratory symptoms and a gradual wasting away. Living arrangements in the past reduced the contact that men had with their wives. All adult men and older initiated boys lived

together in large men's houses that were surrounded by the smaller houses of women and their children. Also, to safeguard the health of men, especially husbands, and to control the threat of contamination of public spaces and gardens, women were confined during menstruation and childbirth to small seclusion huts on the edge of residential settlements. Today, seclusion huts have largely disappeared, although a few families maintain them for birthing purposes. During their menstruation periods, women refrain from preparing food and have no contact with their husbands.

Male Initiation

This theme of male–female separation also is an important aspect of the Fore male initiation ritual. At the onset of male initiation, pre-pubescent boys about 10 years of age are taken from their mothers and sent to live with men in the men's houses. During the various stages of the ritual, which earlier lasted for several years, boys were initiated into manhood. In addition to being instructed in the proper behavior and responsibilities of men, they also were taught the techniques of nose bleeding, cane swallowing, and vomiting that were thought to promote their physical growth and maturation and to protect them from the polluting powers of women. Armed with these personal defenses, they eventually were deemed marriageable adult men capable of protecting themselves from the inherent dangers of marital relations. Male initiation ceremonies were halted in the late 1970s, but were resumed in the late 1980s in a truncated form. Fore boys now become men in a single week-long ritual.

Cannibalism

At some point in the early 1900s, the Fore adopted cannibalism, or anthropophagia. The consumption of human flesh was common among various neighboring groups to the north and gradually passed first to the North Fore and later to the South Fore. Among the South Fore, a selective form of endocannibalism was practiced: only the bodies of deceased group members were considered appropriate for consumption while those who had died of dysentery or leprosy, or had contracted yaws were avoided. Of the corpses selected for consumption, all body parts except the bitter gall bladder were eaten. As in the distribution of a cooked pig, specific body parts were given to designated relatives. But, not all Fore participated.

Most adult men and initiated boys living in the communal men's houses eschewed human flesh in favor of wild animals and domestic pigs. Women, children, and elderly men, then, were the principal consumers of human flesh.

Sorcery

Sorcery is an abiding concern in Fore society. All contacts between members of different parish sections, and even some contacts within one's own local group, are edged with the fear of sorcery. This appears to be a longstanding concern among the Fore. Genealogical evidence from c. 1900–62 for one South Fore parish attributes more than half of all deaths to sorcery (Lindenbaum, 1979, p. 65). In general, sorcery is thought to emanate from the intentional, malicious activities of political enemies and social inferiors who seek to harm rivals and those of higher social status or members of their families. Sorcery is judged to be a political act, a silent aggression, and big-man leaders are thought to be common targets. Although sorcery techniques are quite varied, most require some contact between the sorcerer and the victim or with items that have been in close contact with the victim. To protect against such contact, Fore go to extraordinary lengths to guard their hamlets and living spaces from unknown and suspected sorcerers. Typically, the sorcerer acquires bodily exuvia (hair, fingernail clippings, spittle, feces, etc.), personal items (clothing, tobacco, etc.), or food leavings of the intended victim. These are then treated by physical manipulation and verbal spells that transmit the sorcerer's evil intent to the victim. Alternatively, a sorcerer may cast an evil spell on some common item (food, tobacco) and place it in a location where the intended victim likely will come into contact with it. Angered wives, too, are thought to employ the latter technique against their husbands by contaminating their food, water, or tobacco with debilitating menstrual discharge. If the sorcery assault is successful, the victim will sicken and, in some instances, die. (See Lindenbaum, 1979, pp. 60–64, for a list of Fore sorcery practices and likely disease diagnoses.) As might be expected, Fore people carefully dispose of all excreta and food leavings and closely monitor personal possessions.

With the arrival in Fore territory of Australian colonial authorities in the late 1940s and as the increasing influence of various outsiders spread during the 1950s and 1960s, many of the above aspects of Fore life began to change. At the insistence of the colonial administration, warfare was quickly curtailed and cannibalism had

ceased throughout Fore groups by 1960. The delineation of group boundaries by colonial agents reduced the mobility of settlements. The planting of coffee trees as a cash crop also restricted residential movement as people needed to remain near their coffee groves. The extensive trade networks that before had integrated large regions disintegrated as retail outlets sprung up in government outposts to offer alternative manufactured goods. Men gradually abandoned the communal men's houses and took up residence with their wives and families. Big-men remained important leaders at the local level, but their political influence was subordinated to new regional and national political authority. The introduction and adoption of many new vegetable crops expanded the array of garden foods. Many people also now benefit from the provision of modern health care offered by foreign Christian missions and government aid posts. The threat of sorcery remains a concern although many Fore now have converted to Christianity and deny the efficacy of sorcery. Indeed, the Fore proved to be quite receptive to adopting many new ways of living and sociocultural change was rapid. At present, local loyalties remain, but all Fore now recognize themselves as members of a common ethnic group within the nation of Papua New Guinea.

THE CONTEXT OF HEALTH: ENVIRONMENTAL, ECONOMIC, SOCIAL, AND POLITICAL FACTORS

Prior to the late 1950s, the Fore had no access to modern medical treatment. In that context, they suffered from a number of infectious ailments common to other peoples living in the montane environment who shared similar living conditions. Important among these were tropical ulcers and yaws followed by upper-respiratory infections, bronchitis, and pneumonia. These latter diseases likely are attributable to, or at least exacerbated by, the hearth fires in the houses. Houses often are filled with choking smoke and people routinely enter houses in a crouch position and quickly sit down to reduce exposure to the smoke. Also, most adult men and a few women smoked a harsh home-grown tobacco in bamboo pipes. Gastrointestinal and diarrheal diseases also were common, a likely consequence of poor village sanitation and casual approaches to food handling and personal hygiene.

People shared their living space with their domestic pigs, and Fore notions of personal hygiene did not include frequent bathing or washing of hands. Other diseases observed were meningitis, tetanus, scabies, and leprosy. Most of Fore territory is above the altitudinal limit for malaria (about 1,500 m), but it did occur in a few deep valleys at the lowest elevations. Today, malaria is a common affliction that has been brought home by labor migrants returning from coastal work sites.

The Fore experienced several epidemics of introduced diseases that swept through the area prior to the arrival of the Europeans who brought them. In the late 1930s and 1940s, mumps, measles, whooping cough, and dysentery ravaged the population. In the 1950s, visiting indigenous police officers introduced gonorrhea. In 1959 and 1963, influenza resulted in many deaths, hitting children under five years of age especially hard. Although Europeans and their associates did introduce new diseases, early government patrols also eliminated yaws and gonorrhea among the Fore with penicillin injections.

Pigbel

Another illness that afflicted the Fore people is *enteritis necroticans*, called "pigbel."² It was associated with ceremonial feasts during which pigs were butchered and cooked in earthovens, and large quantities of pig meat typically were exchanged and consumed. During the preparation of the carcasses for cooking, meat often was contaminated with a strain of the *Clostridia* bacteria present in the bowels and feces of the animals. This was transmitted by various means to people during and after the feast. Importantly, children were given raw entrails to play with and small pieces of raw meat to chew on. Also, undercooked meat was not consumed for several days as it passed from hand to hand in extensive exchange networks. Symptoms of severe abdominal pain, bloody diarrhea, and vomiting appeared within a day or two of consuming the contaminated meat. Most cases were mild, but if severe cases were left untreated, gangrene would progressively affect the small intestine and could cause death. Pigbel was endemic throughout the highlands region, but was largely unknown in the lowland areas of New Guinea. It appears that this restricted distribution of pigbel to the highlands was related to a diet that relied heavily on one staple, sweet potato, which commonly provided some 75% of calories. This low-protein daily diet resulted in low levels of protein-digesting enzymes.

Also, sweet potato contains an enzyme inhibitor that is not destroyed at the temperatures usually reached in earthen cooking. This combination of factors meant that the toxic protein secreted by the *Clostridia* survived in the intestinal tract of infected humans. Pigbel most commonly affected children between the ages of 2–5. The blood of most adults contains an antibody to the toxin, which suggests that mild exposure as children provided some immunity for adults. Today, pigbel infection is extremely rare. Researchers attribute this decline to a public health immunization campaign and to somewhat increased protein intake in the diets of children in the highlands (M. Alpers, personal communication, 2002).

Kuru³

The Fore are most well-known in the medical and medical anthropology literature as the unfortunate subjects of the neurological disease, called *kuru*, which is a Fore word meaning to shiver, shake, or tremble. *Kuru* is a disease of the central nervous system that is progressive and always fatal. Major symptoms progress from a slight unsteadiness when standing and walking to severe tremors and the inability to walk without total support. Eventually, as the tremors become increasingly severe, the patient is unable to sit up or swallow and loses control of all motor functions, including speech. Death typically occurs about one year after the onset of symptoms.

Since *kuru* was initially noticed by outsiders in the early 1950s, it has become one of the great medical mysteries of the 20th century. Early epidemiological evidence showed that the epidemic was confined to the Fore and their close relatives in neighboring groups. Also, certain families and hamlets were more affected than others, and women and children of both sexes comprised the vast majority of cases. It initially was proposed that *kuru* might be an inherited genetic disorder, but the high incidence and lethal nature of the disease made this seem unlikely. Ethnographic investigations in the early 1960s by Robert Glasse and Shirley Glasse Lindenbaum (Glasse, 1967) found that *kuru* had first appeared during the lifetimes of older informants. Also, the first cases had occurred among the North Fore with subsequent outbreaks spreading south, the same spatial pattern reconstructed for the adoption of endocannibalism. This indicated a potential infectious agent. Also, it was known that in the distribution of body parts, the brain was consumed only by women and children. This conformed to

the fact that the overwhelming majority of *kuru* victims were women and children. Transmission experiments finally proved that an infectious agent was involved as D. Carleton Gajdusek and co-workers at the U.S. National Institutes of Health succeeded in transmitting the disease to chimpanzees with symptoms appearing after a 20-month incubation period (Gajdusek, Gibbs, & Alpers, 1966). An unusual “slow” viral agent with an extremely long incubation period was suspected. Transmission, however, still occurred after all nucleic acids were destroyed, a result that seemingly would eliminate normal viruses from consideration. Finally, in 1982, S. B. Prusiner determined that the likely infectious agent for *kuru* and other related diseases is a small proteinaceous particle he termed a “prion” (Prusiner, 1989). If correct, *kuru*, along with Creutzfeldt–Jakob disease, Gerstmann–Straussler–Scheinker syndrome, and fatal familial insomnia in humans, scrapie in sheep and goats, bovine spongiform encephalopathy in cattle, transmissible mink encephalopathy in mink, and chronic wasting disease in mule deer and elk, comprise a new category of prion diseases.

Kuru is anthropologically significant for several reasons. First, the high mortality among women devastated the household economy, which is based on gender complementarity. This skewed mortality pattern created an overall male:female sex ratio of 2:1 in the total affected population, and was as high as 3:1 in some hamlets. Men of marriageable age were unable to find wives and many married men were made widowers. Without wives, men had to perform all domestic tasks themselves as well as provide childcare. Also, many infants lost their mothers. Second, much social disruption ensued as suspected sorcerers were hunted and pleas were made for them to cease their destructive activities. Suspicions and open accusations tore at the very core of communal cooperation as the Fore increasingly feared each other. Third, the Fore attributed the disease to a powerful new kind of sorcery. They were not certain of how this came about or who was responsible, but the fact that local curers were unable to counter its lethal effects proved that it was a previously unknown evil force. *Kuru* was a crisis that threatened the very survival of Fore society.

As news of the epidemic spread, the Fore became infamous throughout the region for possession of a powerful and deadly kind of sorcery. Neighbors lived in fear that this force might be turned against them and took special precautions whenever it was necessary to visit Fore territory. At the same time, some assumed Fore sorcerers

were hired by members of other groups to attack their enemies. To this day, people from neighboring groups enter Fore territory with caution.

The *kuru* epidemic peaked in the early 1960s when the number of cases annually was about 200. With the cessation of cannibalism, the number of victims began to decline. The Fore, however, attribute this decline not to the end of cannibalism, but to the fact that elders stopped teaching the younger generation how to perform this powerful type of sorcery. By the early 1990s, about eight cases a year were recorded. Today, annual victims number two or less, all people in their 50s who likely were infected as children and survived an incubation period of more than 40 years. While confirmed cases now are few and occur only among the South Fore, people still fear *kuru* and often incorrectly assume that the feverish shaking associated with malaria is an initial indication of *kuru*.

MEDICAL PRACTITIONERS

In the past, the Fore relied on local curers to treat their various maladies. Curers were individuals, both men and women, who possessed the knowledge, techniques, and spiritual power to cure the afflicted. The Fore recognize two categories of curers: Bark Men and Bark Women, and Dream Men. Bark Men and Bark Women usually reside in the same parish as their patients and use forest medicines to treat minor ailments. They also are capable of intervening with ghosts and forest spirits on behalf of the sick. In the 1950s, new, more powerful curers emerged who were thought to be able to counter illnesses caused by sorcery, including *kuru*. These Dream Men, or Smoke Men, always lived in distant parishes and in many cases were not Fore. Relying on dreams and trance states induced by the rapid inhalation of tobacco smoke and the ingestion of psychotropic plants, they were able to see beyond the realm of ordinary reality. They also were capable of identifying the offending sorcerers by using various divination techniques. To counter the sorcerers' evil acts, they prepared curative meals of pork laced with masticated ginger and special tree barks. They also would attempt to relieve the suffering of their patients by shooting small arrows into the skin at locations where the pain was most acute. In the context of the *kuru* epidemic, Dream Men enjoyed much influence and acclaim and many acquired substantial wealth. Today, the Fore still

visit local curers, but also seek, when available, modern medical treatment for their ailments.

CLASSIFICATION OF ILLNESS, THEORIES OF ILLNESS, AND TREATMENT OF ILLNESS

The Fore recognize two major categories of illness based on assumed causation. First, there are illnesses caused by the malicious actions of other people. Such diseases, including *kuru*, serious respiratory infections, and liver disease, are the result of sorcery and are life-threatening. These can only be treated by the intervention of powerful curers. Second, there are several kinds of less serious illnesses that are attributed to less dangerous forces. Forest spirits, called *masalai*, may become angered when people intrude on forested areas that are set aside by all hamlets as spirit abodes. Diagnosed retrospectively, their anger may result in minor illnesses or injuries for the violator or some close relative, or slight physical impairments of a child of the violator. The spirit can be assuaged with ritual offerings of pig fat and the victim consumes a medicinal meal of pork and appropriate herbs. Ghosts of the recently deceased also may punish individuals who remove produce from the deceased's gardens. Guilty parties can expect to suffer nausea, weakness, and fainting spells. The offended ghost can be placated only by an offering of pork and pig blood poured into the ground at the head of the deceased's grave. Infringement of social rules governing appropriate behavior among the living may cause minor ailments to the offender or a close relative. Relief can be gained by giving compensation to the aggrieved party, who in turn will provide a meal of pork and bush medicines to restore the health of the stricken person. The victims of all of these illnesses that are not caused by sorcery can be restored to good health by an indemnity payment to the aggrieved party, be they angered *masalai*, spirits of the recently dead, or neighbors.

SEXUALITY AND REPRODUCTION

Sexual relations among the Fore remain guarded encounters. Given the ideology of female pollution, partners rendezvous outside the residential living space and away from food gardens to avoid subjecting others to potential

contamination. Young people are expected to refrain from engaging in sexual intercourse until marriage, and mature, unmarried women are carefully supervised by family members. Transgressions, however, are known to occur. Adultery also is considered a serious offense and, when discovered, causes intense social disruption and occasional violence. Marriage typically occurs when women are in their late teens or early twenties and men are in their mid- to late twenties. Marriage involves a public ceremony that lasts for several days that includes feasting and payment of bridewealth from the family of the groom to the parents and siblings of the bride. This effectively transfers her reproductive potential to the groom's social group and compensates the bride's family for the loss of her labor. Newly married couples usually take up residence in the same hamlet as the husband's close relatives. Children are highly valued, both for the vibrancy and the potential longevity they add to their natal group. Barrenness is thought to be extremely unfortunate. Fosterage and adoption commonly are used to provide childless couples with children and occasionally to make certain that sibling sets include both males and females. This is thought to ensure the viability of households and assistance for parents as they age.

HEALTH THROUGH THE LIFE CYCLE

Pregnancy and Birth

The beginning of life for the Fore is a time fraught with uncertainty and pregnancy is a time of considerable anxiety for the expectant mother. In the past, there were no means of surgical intervention, so complications during delivery occasionally resulted in the death of both mother and infant. Also, infant mortality was high. Pregnant women continue normal activities until the birth is imminent. When contractions begin, a woman goes to stay in a birthing hut at the edge of the hamlet. Some women prefer to give birth alone, but most are attended by close female relatives, who eat the placenta following the delivery. The birth of more than one infant was thought to be an aberration and in the past only one child survived the birthing hut. After a period of confinement in the birthing hut, during which the umbilical cord dries up and detaches from the infant, women return to their houses and gradually resume most normal activities. Post-partum sexual taboos, however, ideally remain in effect until the child is named during a celebratory feast

approximately one year after birth. Today, most women go to local clinics to deliver and if serious complications occur, they are transported to urban hospitals by ambulance or helicopter. This has resulted in a decline of infant and post-partum mortality. Some women now seek contraception to limit the size of their families.

Infancy⁴

Infants are highly valued and the subjects of constant attention. They are nurtured most closely by their mothers and are rarely away from physical contact with their mothers for more than a short period of time. Other women and older siblings willingly assist when asked to do so. Breastfeeding is on demand at all times, with infants sleeping next to their mothers, and continues for a minimum of two years. Supplementary feeding of masticated sweet potato begins at about 6 months of age. Weaning is a gradual process. Mothers may ignore nursing requests, divert their toddlers' attention toward other activities, or rub bitter leaves on their nipples. If a subsequent pregnancy occurs during this period, weaning will be more abrupt. Toddlers are never scolded or disciplined by anyone and their requests for attention and physical contact with adults and older children invariably are met.

Childhood

Childhood is a time of relatively carefree play, but gradually children are given more responsibility. Girls are integrated into female work roles as soon as they are physically able to imitate their mothers. Boys, on the other hand, are allowed to roam hamlet territory with play groups, often away from adult supervision, and rarely are asked to help with household chores. However, this life of little responsibility comes to an abrupt end when they are taken to live in the men's house and begin the initiation process. Children gradually are expected to act responsibly and follow the requests of adults. They will be admonished for unacceptable behavior, but physical punishment is rare.

Adolescence

Fore adolescents experience increasing expectations of adopting adult work and social roles. Girls are instructed in proper adult behavior and provide important assistance to their mothers in gardening and household activities. A young woman's first menstruation is cause for a

celebratory feast sponsored by her family to which the families of potential husbands are invited. Such women are then instructed by senior women of their group in the proper comportment of mature, but unmarried, women. If they prove themselves to be well behaved and strong and diligent workers, they reflect well on their families and gain reputations as desirable future wives. Boys, by the same token, are under increased supervision by adult men during the male initiation process. They are taught the important lore thought to be known only by men, are expected to learn the techniques required to protect themselves from female pollution, and are instructed in the proper demeanor and fighting skills necessary for defending group interests.

Adulthood

In the past, adult men frequently succumbed to injuries sustained in warfare. Adult women were most likely to die during childbirth or from contracting kuru. More recently, local health has been influenced by the movement of Fore people as labor migrants to coastal work sites. Beginning in the early 1960s, Fore men entered the labor flow and were joined by wives and other family members in the late 1970s. While this reallocation of labor to external cash-earning activities brought money into the local Fore economy, it also brought malaria and sexually transmitted illnesses. Gonorrhea, syphilis, and trichomoniasis are now common, and chlamydia and herpes also are present. HIV/AIDS has just been recognized among the Fore, but the details of incidence remain sketchy. Fore migrant workers did return home with money, but also with new diseases.

The Aged

As Fore people age and infirmities accumulate, they gradually and reluctantly withdraw from normal adult activities. They are respected by younger adults, but also acknowledged as a necessary burden. Close family relatives provide them with the necessities of life, but the influence of elderly men in the political arena and elderly women in the domestic sphere eventually is assumed by the next generation.

Death and Dying

Deaths of the very young and very old and of the physically or mentally disabled usually are mourned only by family members. Such deaths are not unexpected and are not politically significant, so only small groups of the

living are directly affected. However, the deaths of older children and of all able-bodied adults are cause for serious concern and in most cases are attributed to sorcery. Mortuary payments for the death of an adult man are made by his brothers to his maternal relatives and to relatives of his wife; on the death of an adult woman, payments flow from her husband and his kin to her maternal relatives. If the deceased was especially prominent, such mortuary payments can involve large amounts of food and money. Burial usually occurs within three days of death, but mourners stay as guests for two weeks and eventually are sent home after a large feast and the distribution of expected payments.

Following death, the ghost of the deceased is thought to reside in the sacred spirit grove of his or her hamlet.

NOTES

1. This description of Fore culture relies on Lindenbaum (1979, and personal communication, 2002), and M. Alpers (personal communication, 2002).
2. Information on pigbel is taken from Lawrence (1992) with additions from M. Alpers (personal communication, 2002).
3. This account of *kuru* relies on Lindenbaum (1979) and Alpers (1992).
4. The sections on Infancy and Childhood draw on information in Sorenson (1976).

ALTERNATIVE NAMES

France, French Republic, République Française.

LOCATION AND LINGUISTIC AFFILIATION

At slightly less than twice the size of the state of Colorado, France is the largest Western European nation. The French boundaries cover approximately 547,000 km² in Europe and its overseas administrative divisions add approximately another 600 km². With about 3,400 km of coastline on its western border, France is a boundary of Western Europe, from the Bay of Biscay in the Southwest to the English Channel in the Northwest. France is located between the present-day countries of Belgium and Spain, it is Southeast of the United Kingdom, and borders the Mediterranean Sea on the Southeast, situated between the borders of Italy and Spain.

French is the national language, with a rapid decline in numerous local dialects and languages (e.g., Provençal, Breton, Languedoc, Alsatian, Corsican, Catalan, Basque, Flemish).

OVERVIEW OF THE CULTURE

With a population estimated at 59,765,983 in July 2002 (ratio of 0.95 males/females), the demographic structure is comprised of 18% aged 0–14 years (1.05 male:female ratio), 65% 15–64 years (1.00 male:female ratio), and 16% 65 years and over (0.69 male:female ratio). The population growth rate is 0.35%, with a birth rate of 11.9 births/1,000 population, death rate of 9.0/1,000 population, and a net migration rate of 0.64 migrants per 1,000. Immigration has increased since unification of the European Union in 1992, creating increasing social tensions in a country already faced with significant unemployment at that time. The life expectancy at birth is 79 years, with females averaging 83 years and males 75 years. The fertility rate is 1.7 children born per woman.

The HIV prevalence rate was 0.44% in 1999 and estimated at 130,000 individuals living with AIDS.

Literacy, defined as reading and writing over 15 years of age, is said to be 99%.

Having suffered extensive losses in terms of manpower and economic well-being during World Wars I and II, France is one of the most modern countries in the world and a leader among the European Union. Since 1958, it has had a presidential democracy which has provided greater stability than its previous parliamentary democracy. It is a republic, divided into 22 regions, including the territorial collectivity of Corsica and is subdivided into 96 departments. France includes four overseas departments (French Guyana, Guadeloupe, Martinique, and Reunion) and three overseas territorial collectivities (Mayotte, Saint Pierre, and Miquelon). In addition, there are approximately 12 dependent areas over which France has transnational disputes of sovereignty. There are numerous political parties in France of opposing values, with a president elected by popular vote for a five-year term.

France is an ethnically heterogeneous population, representing peoples from North Africa, Indo-China, the Basque region, Celtic, Latin, and Teutonic populations, and nomadic Gypsies. France is presently predominantly Roman Catholic (85%), with Muslims comprising about 5–10% of the population and Protestant, Jewish, and unaffiliated sects equally apportioned.

France's economy is composed of historically extensive government ownership, much of which is presently undergoing privatization. Unemployment has been high over the past decade. Steps to improve this include mandatory retirement with an extensive and expensive pension system. France's economy suffers from a 35-hour work week, lengthy paid vacations, and national medical care. These expectations incur high taxes. The labor force is comprised of 70% in services, 25% industry, and 4% agriculture. Approximately 23% of the population are white-collar workers and 30% of the working population are manual workers.

France was the world's fourth largest economic power in the mid-1990s and the world's number one

destination for tourists. Its industries include automobiles, machinery, metallurgy, textiles, food processing, and tourism. Seventy-seven percent of its electricity is nuclear generated. Its agricultural products include wheat, cereal, sugar-beet, potatoes, wine grapes, beef and dairy products, and fish. It exports 61% of its products to the European Union and 9% to the United States. France is a trans-shipment point for, and consumer of, South American cocaine, Southwest Asian heroin, and European synthetics.

THE CONTEXT OF HEALTH: ENVIRONMENTAL, ECONOMIC, SOCIAL, AND POLITICAL FACTORS

In its geographic position in the midst of industrial Europe, France faces major environmental issues with health consequences at the present time, including forest damage from acid rain, air pollution from industrial and vehicle emissions, water pollution from urban wastes, and agricultural runoff. Its beaches receive garbage from dumping grounds off the coast by numerous neighbors and it was within reach of air-borne radioactive waste from Chernobyl.

France has a state-subsidized medical system in which people are free to choose their own providers and are reimbursed up to 85% of most costs. Doctors are concentrated in the cities, leaving many rural areas underserved with facilities that are inadequate. The health profile in France follows its economic and social position in the industrial world in which the principal causes of death are cardiovascular disease and cancers.

The modern-day country of France consists of numerous small communities, each with long histories of self-identity. Historical geopolitical disputes notwithstanding, these are expressed in regional specialties in terms of consumable products from bread and chocolates to wines and cognacs. Salts from a particular coastal area, prunes from Agen, cheeses whose flavors reflect what sheep, goats, or cows find to eat in a particular region—all reflect the unique features of local natural environments. In 1986, a French doctor turned archeologist recorded his medical observations from 20 years of medical work in the Berry countryside (Allain, 1986). In these memoirs, he outlined the influence that social and geographic location had on patterns of health. He emphasized what an intimate relationship between man and animals,

both wild and domestic, had on people's understandings of their own illness and health. Speaking from the viewpoint of a physician in need of understanding his patients, he wrote about his experiences learning to simply read his patients' anatomy, so that he could provide medical care. When they said they had a pain in the "name of the father," and two nerves, jumping one under the other, they meant that they had a pain in the forehead and a musculo-skeletal joint problem. Some of them had "nerves stronger than the blood," referring to a disequilibrium between two antagonistic forces that referred to a polymorphic assortment of maladies ranging from psychologically based digestive troubles to menopause. Local diagnoses were based on the color and fluidity of the blood, and bread and wine were thought to generate the force of the blood—but not if the bread was toasted.

Local remedies included those for bloody noses and menstrual bleeding, a premier occupation in their health world. Some of the remedies were considered to be magic formulas. Oral ulcerations in infants prompted treatment by sympathetic magic, employing a herb with white spots on its leaves, visually similar to those evident in the mucosa, cooked and tied to the head of the infant's bed. While secret remedies have a long history, they were banned by decree in 1926 (Warolin, 2002). However, while no doubt this created a point of conflict between urban and rural settings as regulations were enforced in towns, the ancient remedies did not disappear by decree. While pharmacists took over the role of dispensing remedies in urban environments, rural peoples did not change their treatment plans to follow (Lafont, 2002). In the absence of alternative medical care—the alternative being biomedicine—traditional remedies shared a place with pharmacists for many years. Today, local pharmacists are themselves facing an increasing share of their work being taken over by international pharmaceuticals, in an increasing international arena since 1992.

MEDICAL PRACTITIONERS

French medical practice focuses primarily on physicians who undergo traditional biomedical training. In contrast to the United States, where four years of medical school follow four years of undergraduate work, in France, medical training is initiated immediately after secondary school education is completed. Competition is intense for positions in this field. Physicians may become either

generalists or specialists, with foci on individual body functions (e.g., neurology, cardiac and renal specialties, rheumatology), age-related care (e.g., pediatrics), and surgical versus non-surgical approaches (e.g., internal medicine) in accord with international biomedical practice. Medical licensure examinations are given and extensive clinical training is the norm.

Chiropractic medicine is not regularly practiced in France, where historically homeopathic approaches became more acceptable in the early part of the 20th century. Some individuals choose to specialize in homeopathic treatment approaches and undergo further training. These physicians are not seen as practicing or offering alternative medicine: homeopathy is a moderately mainstream medical approach.

Individuals specializing in musculo-skeletal problems, known as kinesotherapy, are popular and are often sought by individuals with back problems, in particular. Somewhat the equivalent of physical therapists, they share with other non-medically trained practitioners a more narrow focus on functional aspects of the body. Pharmacists have historically had a wide range of abilities to prescribe treatments, and a number of medications that require prescriptions in the United States are available over the counter in France.

CLASSIFICATION OF ILLNESS, THEORIES OF ILLNESS, AND TREATMENT OF ILLNESS

Biomedicine provides the primary construct of illness and health in France. In the midst of the increasing internationalization of scientific knowledge and medical care, there remain differences in concepts of what constitutes a disease and its treatment. There are diseases whose symptom complex is uniquely culturally constructed, and there are symptoms and signs that are not yet culturally constructed in the medical domain. In the first category is the uniquely French disease, spasmophilia; in the second, osteoporosis among elderly French.

Spasmophilia has been called a polymorphic disease with numerous symptoms. But the overwhelming one is fatigue: there is never enough sleep and individuals awake in the morning exhausted. Difficulties in temperature regulation, ranging from feeling too cold or too hot; difficulties in eating from anorexia to overeating; sensations from

nervousness to great anxiety; and being barely able to breathe are all typical complaints of spasmophilics. Muscle cramps from the throat to the extremities, headache, lightheadedness, and Reynaud's sensations are often reported, in addition to heart palpitations, digestive problems, hypoglycemia, and allergy. People who have spasmophilia take care to watch for the signs. The scientific question is: What could be biologically responsible for all of these signs and symptoms? Are they of psychogenic origin or do they reflect a metabolic disturbance? Some researchers suggested that it was a problem at the level of mineral salt exchange at the cell membrane and treatment included calcium supplements. More recently, it has been suggested that the symptom complex is a synonym for hyperventilation syndrome (Delvaux, Fontaine, Bartsch, & Fontaine, 1998) or, alternatively, similar to chronic fatigue syndrome or fibromyalgia (Maquet, Croisier, & Crielaard, 2000) and may reflect magnesium imbalance (Durlach, Bac, Durlach, Bara, & Guiet-Bara, 1997).

Alternatively, there are signs and symptoms that people exhibit that are not necessarily considered a disease or treatable entity in France, in contrast with the United States. An example is osteoporosis, which has been viewed merely as the normal process of aging—and untreatable. When do the processes of aging become treatable clinical categories and how is cross-cultural scientific information filtered? The high incidence of osteoporosis is evident from walking down any French street: numerous elderly women and men exhibit the so-called “dowager’s hump,” characteristic of vertebral compression resulting from bone loss. The statistical incidence in France is presently unreported. It is not a disease. It is not a condition in need of identification or treatment. In fact, one study identified that few general practitioners investigate the presence of osteoporosis (less than 6% in one study), and correct treatment was carried out by less than half (Laroche & Masieres, 1998). This is notable in a population where several studies have reported rather high prevalence of vitamin D deficiency in both the general adult population (Chapuy et al., 1997) and elderly women in particular (Cals et al., 1996). Aging of the skeletal system is to be expected and is not medicalized at this time.

Health is not something that comes merely as the result of a doctor’s visit on the occasion that one does not feel well. It is not something to reflect upon because of a lab report indicating a high cholesterol level. Bodily well-being is a part of daily lifestyle. Taking care of oneself

is not necessarily goal-oriented toward “health,” but “well-being” is often a goal that has the side-effect of serving health. Teas, wines, and cognacs bolster and ameliorate; month-long vacations and rests at thermal baths rejuvenate. Social class has an important influence on daily life in France, and influences who has access to information, facilities, and cultural capital—but there are many aspects of lifestyle that cross these boundaries in modern-day France. National health insurance covers the greater part of payment for most culturally acceptable treatments.

Personal theories of health and well-being focus on all manner of daily practices. The importance of consumables set the background for a strong presence in France of a reliance on remedies in lieu of antibiotics. Too much to eat and struck by a “liver crisis” (*crise de foie*)? Try some champagne, it is also very good for a hangover. “Water? I have heard that some people drink it.” Oysters are good for children weakened by disease, and are part of the sea cures. Indeed, oysters are filled with mineral salts—calcium, sodium, magnesium, iron, zinc, and copper—proteins, lipids, and vitamins A and B.

The body is constructed in a distinctly French manner, or *habitus* as Bourdieu put it (Bourdieu, 1990a, 1990b, 1999). Unlike the mechanically based approach of American medicine, where fixing the objectified body machine is the goal, whether through antibiotics, surgery, or therapy in the midst of a distinctive Cartesian dilemma, the French tend to their bodies outside of the biomedical domain on a daily basis as a lived experience. To be sure, the French access doctors and hospitals when called for, in a superb medical milieu where some of the great breakthroughs have occurred—from radiology and vaccines to HIV. But there is also a level of everyday bodily experience that involves responding to sensations in terms of culturally appropriate alternatives through which the French take care of their sense of well-being, their bodies, and in some cases, their “health.”

There is an underlying sensibility that it is only natural for the body to become susceptible to discomfort as normal experience displaces the body’s balance. From overeating and drinking, from stress to aging, people experience discomfort and require care. In an ancient society, food can poison people, weakness of the body is to be expected, and it is important that one knows what to do for these life experiences oneself.

Some people share in the sense of control over “health” as medically conceived and attend to physical

exercise—there are parks filled with weekend runners and fitness centers that welcome people for work-outs. There is a strong influence of American lifestyle in these activities, and, thus, they are not shared by all people. It is entirely acceptable to claim that you are “allergic to exercise” and continue to enjoy a fine foie gras when it is available, regardless of one’s last LDL blood level. *C’est la vie.*

What is called psychoneuroimmunology in the United States stands in stark contrast to a value system that involves life at a slower pace. One suspects that the reputed health benefits referred to by the “French paradox” (Perdue, 1992) and included in the “mediterranean diet” are more than merely drinking red wine and eating foods with olive oil. There are small reference texts that document the appropriate choice of wines—not to match the food, something every good wine purveyor can assist with—but to match bodily needs and contribute to health (Saint-Clair, 1993). Researchers have identified the potential chemical benefits of wine and epidemiological studies verify a correlation between daily wine consumption and decreased cardiovascular disease risk among middle-age and elderly men in France (Renaud, Gueguen, Schenker, & d’Houtaud, 1998). But, it is difficult to disentangle the direct effects of the wine from the lifestyle in which it is consumed. It is unlikely that these effects would be mimicked by extracting chemicals and taking them as a pill, transforming the French wine effects to an American lifestyle. Attention to details that keep people in touch with their senses and the natural world around them cross economic boundaries. Differences in social class notwithstanding, at the present time it is almost a cliché to say that for the French food consumption is more than eating. Much of health is grounded in gastronomy.

Depending on one’s bodily state, a meal can be prepared to match sensations from head discomfort to stomach uneasiness based on the appropriate collection and sequence of herbs in the dish or liquid consumed. Infusions can be brewed to alleviate urinary troubles, joint pains, or lift the spirits, calm the nerves, and encourage sleep. Daily personal experience of the body can dictate subtle choices following the evening meal. There are a number of fermented fruit and herb-based drinks, each a specialty of a particular region, with a long history of local production and common consumption. Today, some are said to be best consumed before a meal, as they aid in relaxing the individual and assisting in the transition to a calm after work, and an enticement of the appetite. Others

are known to aid in digestion. Some of these eau de vie (literally, water of life), or digestifs, may be so named not merely by chance. While the grand cognacs are enjoyed on special occasions, more modest eau de vie are consumed regularly. Some are reserved for specific needs—for example, when the meal may have contained a questionable food item. Numerous brandies and eau de vie are part of family heritage as being the *specific* amelioration for individual circumstances. To make an aperitif at home: macerate medicinal plants, add spices and aromatics, ferment. During the harvest season, substitute fruit—each has a focal effect on the body's well-being. These practices are part of people's lived experiences.

At more than 100 natural hot springs, there are sites that serve as therapeutic centers, available to accommodate individuals with symptoms ranging from respiratory difficulties, skin diseases, gynecological disorders, arterial problems, and psychosomatic ailments. The water therapy may involve bathing, inhaling the vapors, drinking the waters, or application of the waters to the ailing body site. The daily consumption of mineral water from various locales, such as "Perrier," "Vichy," "Vittel," "Badoit"—each slightly different in terms of the minerals that it contains—speaks to the common acceptance of this approach. Each of the water sources is as distinctive as the result of its geological context. Containing different concentrations of local minerals, each of the spas is seen as benefiting distinctly different bodily conditions. For arthritis one might choose the conditions of the baths at Ax-les-Thermes, whereas problems of infant development might be better treated by the salts in the water found in Jura. These practices tie people to the earth and the correspondence of bodily sensations to regional distinctiveness in mineral baths conforms to a mind-set oriented toward choosing regional wines for the character each uniquely possesses due to the soil and climate conditions in the locale of origin.

French scientists have asked, "Do these water therapies really work?" One conclusion is that it is difficult to say. In their review of a number of research studies, Schilliger and Bardelay (1990) noted that very few have been prospective case-control studies with objective outcome criteria. This includes a large-scale prospective study conducted by a branch of the national medical service of more than 3,000 patients. The demographic profile of the people in this study is useful, providing insight into who seeks these treatments. Three groups were included in the study. The first had a mean age of 36 years (a group

of children 5–15 years with their parents, 30–65 years), nearly evenly divided by sex, presented for treatment of chronic sinusitis and bronchitis, asthma, and recurrent ear infections. A second group of men, average age of 62 years, were treated for arterial problems, and a third group of women, mean age of 51 years, were treated primarily for urinary problems. The results of the study stated that more than 80% of these people reported being helped by the end of their first cure. However, no control groups were used and no quantifiable criteria of improvement were employed.

One of the few studies meeting objective research criteria was conducted at the Royat Spa, which receives 25,000 people annually. A prospective study of 140 people with a mean age of 57 years focused on a clinical versus control sample with vascular problems of the leg. They reported that more than half of the clinical sample experienced amelioration during the treatment by objective criteria (Fabry, Pochon, Trolese, & Duchêne-Marullaz, 1985).

Schilliger and Bardelay (1990) note that a number of negative effects have been reported from spa visits, ranging from exacerbation of symptoms to contagious respiratory outbreaks. Critics question their utility (Brockliss, 1987; Weisz, 2001). Nonetheless, national health insurance continues to support these options, and surveys report that many people say they feel better. Those who do not are not necessarily respondents.

In summary, the lived well-being of the body occurs largely outside of the medical domain for many French. Taking a cure and healing a discomfort is not merely an outcome, it is an ongoing process, a lifestyle of bodily experience. In a world filled with media regarding the health effects of smoking, drinking, and fat consumption, a study of more than 13,000 hypertensive French men in 1999 and 2000 found that fewer than one in four followed the recommended lifestyle changes of weight loss, decreased salt and alcohol consumption, and increased physical activity in order to lower their blood pressure (Tilly, Guillhot, Salanave, Fender, & Allemand, 2002). Physicians prescribed medications appropriately only two thirds of the time, and more than one fourth of these included a potentially contra-indicated drug. The study concluded that it was necessary to increase communication between healthcare administrators and clinicians to better educate patients to take responsibility for their health. It will be interesting to see if the French lifestyle will change for health, when so much of well-being is based on lifestyle. Will cultural values and ideas about the nature of

human life alter, or are the outcomes of the well-lived life, well, simply, la vie?

Homeopathy

Homeopathic physicians are trained in the same way as all other physicians in France and then undergo further specialization. They learn the unique diagnostic and treatment approaches of homeopathy, first developed by Hahnemann in 1810 (Hahnemann, 1991). It is necessary for the homeopathic physician to get to know the patient, for even the same symptoms of disease may require different treatment depending on the personality of the patient. The diagnosis is fundamentally the treatment in homeopathic medicine. By identifying an individual's temperament, much can be ascertained about immune function and, with time, the appropriate chemicals will restore balance to an individual and, thus, one's sense of well-being. Each individual is treated in accord with his or her internal milieu. It is critical during the initial interview to identify the nature of this temperament. This requires a long conversation with the patient, directed toward the identification of his/her individual responses to temperature, stress, foods, and daily life. The homeopathic physician develops a profile of the patient based on a typological classification. While the reason for an individual seeking medical attention matters, it is not the core of the homeopathic interview. This is at first glance a singularly culture-bound diagnostic approach, and contrasts with the checklist approach posed by many doctors, where diagnosis follows a rote pattern, and treatment is focused on scientific prescription and crisis management. Homeopathic approaches follow a style that works quite well in France for a number of people.

The central tenet of homeopathic treatment is similarity, or like treats like: remedies are chosen to match the distinctive features of plants or minerals with the characteristics of the individual patient and his/her disease/discomfort. For example, herpes simplex virus of the lips (HSV II), results in chronic cold sores that are notoriously recalcitrant to treatments in biomedicine. This is treated homeopathically with success by small doses of *rhus toxicodendrum*—a derivative of poison ivy—a treatment chosen because the effects of the plant mimic the disease that is being treated. Additionally, several chemicals may also be prescribed to an individual apart from anything directed toward the presenting complaint. The goal of this further treatment is to improve the patient's mental and

physical well-being and help him/her to avoid disorders for which he/she may be constitutionally and temperamentally predisposed (Vannier, 1992).

Homeopathic treatment involves small balls, approximately 3 mm in diameter, that are packaged in blue plastic vials (about 50 mm long by 15 mm in diameter). The vials have carefully constructed openings that permit only a single round pill to escape at one time. The pills must be deposited under the tongue, directly from the vial with no contact from the hands for maximum efficacy—and not taken in proximity to eating mints, drinking coffee, or brushing the teeth.

The principle of homeopathic treatment is microdoses, and traditionally is based on molecular-level ingredients. The packaging permits people to carry them in their pocket or purse and use them when they feel the need. The contents are chemicals, ranging from plant extracts to most of the elements of the chemical chart. Many people have a *Family Guide to Homeopathy* (such as Horvilleur, 1981) which they can consult for information on appropriate treatments for minor aches and pains of daily life. The blue homeopathic vials are available without prescription at homeopathic pharmacies. In consultation with a homeopathic physician, an individual can learn about his/her own temperamental type and self-medicate as life occurs.

There has been significant scientific debate regarding whether or not homeopathic remedies really *work* (reviewed in Poitevin, 1987), with numerous critiques matched by reports of efficacy in clinical trials (Kleijnen et al., 1991) with patients who suffer from symptoms as diverse as allergy (Reilly, Taylor, McSharry, & Aitchison, 1986) flu (Ferley, Zmirou, D'Adhemar, & Balducci, 1989), and anxiety (Benzecri, Maiti, Belon, & Questel, 1991). Like water therapy, there are people who simply feel better taking homeopathic treatments. Does this make homeopathy an example of the placebo effect? The people who take it say, "No, and anyway, does it matter?" Since often physicians do not know the underlying cause of people's symptoms and, therefore, how to treat them, why worry?

Homeopathic treatment often helps where allopathy fails. One woman reported that she had had recurrent sore throats prior to taking homeopathic remedies. After two years of seeking help from traditional physicians, she saw a homeopathist. She feels better: her discomfort "*was* in her throat, not in her head." This is a case where general practitioners did not know precisely what was wrong with the patient because a causative pathway has yet to be established to explain her experience.

There is an underlying sensibility that it is only natural for the body to be pushed off balance from overeating and drinking, from stress to aging; people expect to experience discomfort. In this sense, homeopathy is not an alternative medical system, a non-mainstream approach to cure. It is not likely that it can be exported and fill the gap where biomedicine leaves people's needs unmet more generally. It is tied into an essentially culturally distinctive lifestyle of individual and social experience. A culturally based experience of everyday life based in feelings and bodily senses inform our perceptions of health and ill-feeling, and our attempts at sensory alleviation or intensification. Small doses make sense in a society where local historical traditions design reactions to subtle sensibilities. It would be less likely to be effective in a society where "bigger is better" and "if a little is good, a lot must be better," which drives many people to take mega-doses of vitamins, for example, in the United States.

Homeopathic diagnosis gives voice to people's personal concerns and their theories about what is bothering them. They do not have to fit a biomedical conceptual category to be validated and receive treatment. The sensations experienced by the body are not reconstructed into a medical paradigm. Homeopathic treatments permit the individual—who knows himself or herself best—to maintain a sense of privacy regarding one's well-being and sensations. The over-the-counter availability of the blue vials further permits a person to respond to body fluctuations on a daily basis with an acceptance of individual strengths and weaknesses. The self remains private.

Perhaps, also, homeopathy finds agency because it continues a long tradition of home-based treatments, from foods to waters. It upholds the values of individual privacy in intimate matters, and the belief that health and well-being change with the natural order of life. The homeopathic interview fits into the social mores of polite interaction.

In terms of health-seeking, it has been reported that homeopathy is mainly used in mental, infectious, and rheumatological disorders where it is a useful alternative and avoids the abuse and adverse effects of sedatives, antibiotics, and anti-inflammatories (Colin, 2000). Some studies have shown that women use homeopathic treatments more than men (Bancarel et al., 1988), but the reasons are not clear. Perhaps this may be related to women seeking more healthcare than men in general.

In the year 2000, an investigative overview (Chafferrin, 2000) identified that the price of homeopathic

products was only a quarter of the average cost of all health expenditures from insurance for reimbursable medicines. The total reimbursement for allopathic products, by contrast, was three times more than homeopathic. These figures were not explained by patient profile or diseases treated. Overall, homeopaths' annual financial outlays were one-half of general practitioners'. In terms of patient satisfaction, 87% of the patients whose physicians prescribed a homeopathic treatment did not seek a second opinion or further treatment. It is notable that since the patient is the decision-maker regarding treatment, issues of compliance are not significant in homeopathy.

SEXUALITY AND REPRODUCTION

Sexuality is a normal part of the life cycle and both advertising and social norms accept the body as a source of enjoyment. On average, sexual activity begins in adolescence and while a responsible and healthy emotional state of individuals is a stated concern, there is no requirement that love and marriage either precede or accompany sexual activity. While marriage is the expected social domain for child-bearing, a number of young French couples live together and have children prior to marriage. While many French would question women who never marry, but take occupations in lieu of child-bearing, this status is quite acceptable and the role of women in powerful positions depends greatly on the work domain and socioeconomic class.

The French have a strong sense of privacy in matters of their personal life. They are also quite tolerant of the right of individuals to choose a lifestyle that is best suited for themselves. Extra-marital affairs are not uncommon, although they are expected to be discretely managed.

The fundamental right to contraception was first affirmed in a public campaign in 1981–82. In 1992, a second national campaign was launched as the result of AIDS and focused on public education regarding condoms. In recognition of the 25th anniversary of the law establishing the fundamental right to contraception, a third national campaign was launched in 2000. With the slogan, "It is up to you to choose your contraception" appearing in advertisements on TV, radio, and in the press, the combined efforts of the Department of Health and the minister of education aimed to educate adolescents on sexuality. The goal was designed to inform teenage girls and women of the availability of state-funded contraception options,

including the morning-after pill. The goal was to reduce the abortion rate among adolescents in France and in women in the French protectorates. For example, in the mid-1990s, in Guyana, 10% of births were to minors and 1% those were girls less than 15 years of age. The number of voluntary interruptions of pregnancy ranged from 73% in Guadeloupe to 30% in Guyana.

While great controversy from parents surrounded the reforms of 2000, 66% of the population supported them. A pocket guide to contraception was distributed to high school students and France lifted requirements for females under 18 to have parental consent for abortions or a morning-after pill. The timing of legal abortions was extended from 10 to 12 weeks to bring France in line with other countries in the European Union, and pills became available without prescription in pharmacies across France.

Presently, between the ages of 20 and 44, more than two out of three women use contraception. This is one of the highest rates in Europe. However, the Demographic Institute at the University of Bordeaux has identified that there is great regional and social inequality in access to contraception. For example, only 17% of public facilities propose RU 486 to women, compared with 60% of private facilities.

The effectiveness of these campaigns has been followed: while only 8% of women chose to use condoms in 1987, as a result of numerous advertising campaigns, 87% of young women and those not in permanent relationships chose this method in 1998. This is replaced by the pill in a stable relationship. However, about 15% of young women have no protection during their first sexual encounter. In fact, of women aged 20–24, 56% stated they used nothing if their first experience was at ages 14–15; and 23% if the ages were 18–19. The average age of first sexual experience is about 17 and it is estimated that about 10,000 young women each year have an unwanted pregnancy.

In 1994, two out of three women between the ages of 20 and 44 used contraception. The pill was the most common choice, and 58% of younger women (aged 20–24) were the primary users. Sterilization was the second choice overall (16%), chosen primarily by women between the ages of 35 and 44. The third choice was condom use (5%) and 31% used nothing (source: Demographic Institute of the University of Bordeaux).

According to a popular survey published in the magazine *Marie Claire* in 1999, while 8 out of 10 women believe that contraception is a liberty, one in three does not want to take the pill because she believes that the pill

makes women fat. Only 4 in 10 young girls and 2 in 10 women were aware that the pill was available without prescription. Four out of 10 women responded that they believed withdrawal to be an effective mode of contraception, and 2 out of 10 thought that temperature taking was effective in preventing conception.

HEALTH THROUGH THE LIFE CYCLE

Pregnancy and Birth

In the mid-1990s, there were 220,000 voluntary interruptions of pregnancy per year for 730,000 pregnancies. On average, each woman has had an accidental pregnancy in her life and one in two was interrupted (Demographic Institute, University of Bordeaux, 1994). These statistics prompted the increased efforts at public information regarding contraception, as noted.

For couples who want to have children but are having difficulties with infertility, France is one of the most advanced scientific communities and in vitro procedures are available. These, however, are confined to urban areas on central medical research teams.

Pregnancy is a normal event in a woman's life and is respected, supported, and culturally valued. Women do not hide their bodies and clothing that aims to follow fashion is available. Women follow the advice of their female relatives and friends regarding their health and well-being, and like other biomedically oriented countries, seek prenatal care for the best interests of their infants. With national health insurance, this care does not discriminate on economic grounds and is more readily available in urban areas than rural areas. Public health campaigns identify the risk to the fetus of AIDS, but fewer campaigns identify smoking or alcohol as potential risks.

Hospital births are the norm at the present time, with women speaking out against the medicalization of birth in recent years. Citing that medical interventions in France were the highest in Europe in 1998, with 85% of pregnancies employing the medical arsenal, feminists are now demanding greater consideration of midwifery and personal choice in birthing (perinatalite.chez.tiscali.fr).

Infancy

The birth rate in 1995 was about 12/1,000 individuals in France. As a modern European country, most births occur

in hospital with medical attention and women are discharged approximately three days later, returning with their infants to their homes. For the predominantly Catholic population, this is an opportunity for family and friends to celebrate the arrival of a new family member and a christening follows. Godparents are chosen for the child from amongst family friends and relatives, and depending on the economic circumstances of the family, a party with various levels of decorum occurs. A popular mark is the distribution of candy-coated almonds—pink for girls and blue to announce a boy. Small shops exist that specialize in this confection for births, weddings, and other formal celebrations.

Infants are valued as small, dependent, and temporarily incompetent members of society who need to be cared for and who deserve patience while gaining the ability to learn how to become contributing members of society. They receive care from both parents, as well as doting grandparents, who often contribute significantly to care-taking. Infant feeding follows contemporary industrial countries' notions of what is best, with breastfeeding supplemented by infant foods within the first 6 months the most common pattern at the present time. Weaning normally occurs by one year of age and toilet training follows as soon as the child can manage. Social class differences, based on ethnic background and economic levels, affect the early patterns of care-taking and expectations, but appropriate behavior is valued in the larger society and children receive strong negative reinforcement for public displays of emotion beginning at early ages.

The primary health problems of infants follow other industrial countries, with ear infections and upper respiratory complaints at the top of the reasons for seeking medical care. Asthma and allergies have recently been noted to be on the rise.

Childhood

French children are expected to adopt appropriate behavior and customs from an early age. Moderate physical and negative verbal discipline are the norm as demands for children to conform to behavioral rules are clarified. A narrow range of individual liberties are tolerated as cultural values are inculcated.

Health problems of French children parallel industrial countries at the present time, with infectious diseases leading the common cause for pediatric consult. Childhood cancers of both tissue and blood are significant

chronic diseases. French children seem to have poor eyesight diagnosed at an earlier age than their counterparts elsewhere, but it is unclear if this is due to diagnostic concerns or biological predisposition.

A cultural preference for males is sometimes reported, but is not universal. At times of economic/food shortage, meat, when available, was preserved for the boys and men who need it for strength, said one woman of her childhood. Girls received broths and vegetables while the heartier foods were saved for the males. No overt sex biases are evident in child-rearing practices and child abuse has not received any large measure of public health attention.

Adolescence

By the age of 12, French adolescents are mature young adults, with expectations of taking on fully adult roles in a short time. They are in training for their future jobs with a choice already being made in terms of the schools that they attend. Adolescents take responsibility in the home and family and are learning about the larger socio-political sphere in which they live. They are becoming sexually active and part of the school curriculum is designed to provide public health information about safe sex practices. Adolescents are expected to behave like adults, although parents are not surprised to find them having difficulties at times in this role.

The Aged

Aging is culturally reinforced by mandatory retirement at the age of 60. Seen as a socially responsible action to provide jobs for the younger generation, this practice moves an active individual into a category of retiree and forces them to adjust their lifestyle to new economic and social circumstances. For some people, this is a "new" time of life, a socially approved change of job and focus and an opportunity to explore new experiences. For others, this can be a serious economic hardship and the severing of ties with work-related social contacts can be isolating. While no formal epidemiological studies have been undertaken nationally to investigate the health consequences of taking retirement, it would be interesting to follow patterns of alcohol consumption and depression amongst the aging population.

There are a number of retirement homes that accept individuals as they become infirm. Many families, however, take care of their aging relatives themselves, with

primary responsibility falling on eldest daughters as caretakers. Respect and consideration of aging family member's wishes is a priority in many families.

Dying and Death

Death is a natural part of the life process and the importance of religious faith in many people's lives helps them through the grieving process. A predominantly Catholic society, the church organizes death rituals and modern mortuary practices are followed. Each small community has its local cemetery, where people return to be buried with their families, and where their graves are visited by surviving family members. While appropriate grieving periods are socially expected, a surviving spouse is not expected to forfeit his or her remaining life in memory of the deceased. Re-marriage occurs frequently and is encouraged. With a history of a century of significant losses in war, each small village has a memorial to the dead from each battle in the center of town. These are carefully tended by local residents.

Fulani

Kate R. Hampshire

ALTERNATIVE NAMES

Fulani is a Hausa term, which is also commonly used in English to describe this ethnic category. With the exception of Nigeria, most Fulani live in Francophone West Africa, where they are widely known by the French (and Wolof) terms *Peul* or *Peulh*. Fulani living in the westernmost parts of the Sahel (Senegal, Gambia, Sierra Leone, and Guinea) are usually referred to by the Manding word, *Fula*. The Fulfulde term *FulBe* (sing. *Pullo*) is often equated with Fulani, although it actually refers only to high status, pastoral Fulani.

LOCATION AND LINGUISTIC AFFILIATION

The Fulani are distributed over a very large geographical area, essentially spanning the West African Sahel, from Senegal and the Gambia, as far east as Chad and the Sudan. There are Fulani in every West African state, but in each country they constitute a minority of the population (Dupire, 1970; Riesman, 1992). Because of this wide geographical dispersion, it should be borne in mind that some beliefs and practice vary from place to place, and generalization is thus problematic.

Estimates of Fulani population size are problematic for several reasons. First, national censuses are often inadequate data sources because they frequently under-enumerate nomadic and semi-nomadic groups, and not all censuses include questions on ethnic identity. Second, and very importantly, the Fulani ethnic category is fluid and its boundaries are fuzzy (e.g., Burnham, 1996). That said, estimates range from 6 million in the early 1960s (Dupire, 1963) to 9 or 10 million today (Riesman, 1992). The largest national group of Fulani is in Nigeria (some 4.8 million) (Riesman, 1992).

The main Fulani language is *Fulfulde* (known in some parts of Senegal and surrounding areas as *Pular* or *Fula*). Because of the wide geographical dispersion of Fulani, the Fulfulde of different regions varies, often incorporating words of other local languages. However,

Fulfulde is still more or less mutually comprehensible by speakers from nearly all areas, implying that geographical expansion was relatively recent. It should be noted that some non-Fulani groups have adopted the Fulfulde language (Burnham, 1996), and that some Fulani speak other languages, such as Hausa in Nigeria (Riesman, 1992).

OVERVIEW OF THE CULTURE

Pastoralism and the Importance of Cattle

The Fulani are the major cattle-herding group in West Africa. Much of the Fulani tradition is tied up with nomadic pastoralism, and the importance of cattle features prominently in most portrayals of Fulani society (Bonfiglioli, 1988; Hopen, 1958; Stenning, 1959). Cattle are seen not only as economically important, but as a social necessity, upon which much social organization is based (Hopen, 1958; Riesman, 1977; Stenning, 1958). Cattle are also considered to be inextricably bound up with FulBe identity, such that their loss represents something far more serious than economic or social insecurity.

However, by no means are all Fulani today are pastoralists. Particularly since the serious droughts of the 1970s and 1980s, many Fulani now combine pastoralism with other economic activities, and some have forsaken pastoralism altogether and live in cities (De Bruijn & Van Dijk, 1995; Maliki, White, Loutan, & Swift, 1984). Neither is this necessarily a new phenomenon: historically many Fulani may have moved in and out of pastoralism (Raynault, 1997).

Social Organization

Fulani society is hierarchically organized into “castes” associated with social status and occupation. The main categories are *FulBe*: free-born, pastoralist Fulani, and their

erstwhile slaves or serfs: *RiimaaiBe* or *MaccuBe*. In most areas the system of slavery has been formally abolished, but the hierarchical relationships remain. In addition, there are other castes associated with particular trades, such as blacksmiths, merchants, bards, etc.

Fulani operate an essentially patrilineal descent system, with patrilocal residence. On marriage, a woman moves to her husband's family, and their children become part of his lineage. However, this is interpreted flexibly, and women typically retain important rights in their natal homes, and in their own patrilineages (*suudu baaba*) and matrilineages (*suudu yaaya*). Divorce is common (e.g., Hampshire & Randall, 2000; Stenning, 1959), and divorced women return to, and are generally accepted by, their *suudu baaba*.

Religion

Most Fulani are Muslim, and a strong identification between being Fulani and being Muslim has been noted in many areas (Burnham, 1996). Islam has been used as a vehicle of conquest, and Fulani became the rulers of large stretches of the Sahel in the 18th and 19th centuries through Holy War (*jihad*). However, the versions of Islam practiced by Fulani incorporate many aspects of pre-Islam cosmology. This is apparent in the way illnesses are conceptualized and treated. A minority of Fulani (e.g., the *WoDaaBe* groups in Niger) are not Muslim, but practice traditional religions.

Fulani Identity: Pulaaku

The sense of identity—what it means to be Fulani (specifically *FulBe*)—is strongly and explicitly expressed in the concept *Pulaaku*. *Pulaaku* is principally about control and restraint, linked with a strong sense of shame (*sem-teende*). This includes being in complete control of one's emotional and physical needs, and is often defined in opposition to assumed *RiimaaiBe* traits of lack of self-control. Another important aspect of *pulaaku* is cattle-ownership.

Despite the essentialist nature of this Fulani discourse on their culture, it would be wrong to see *pulaaku* as being uniform, unchanging, and representing all Fulani behavior. Individual Fulani construct and interpret *pulaaku* variously at different times and under different circumstances (Burnham, 1996; De Bruijn & Van Dijk, 1995). This is important in understanding people's responses to illness.

THE CONTEXT OF HEALTH: ENVIRONMENTAL, ECONOMIC, SOCIAL, AND POLITICAL FACTORS

Good quality demographic and epidemiological data for the Fulani are scarce, owing to the inadequacy of many national censuses and surveys. However, various indicators suggest that Fulani populations suffer as a whole from relatively poor health status and poor access to health services. The Fulani live in many of the world's poorest states, where health status is generally poor and health services under-developed (Table 1).

However, even *within* those countries, Fulani in rural areas may be particularly disadvantaged because of their nomadic or semi-nomadic status. Various pieces of research have pointed to barriers of access to health services experienced by mobile pastoralists (Foggin, Farhas, Shiirev-Adiya, & Chinabat, 1997; Loutan, 1989; Meir, 1987; Sandford, 1978; Swift, Toulmin, & Chatting, 1990; Zinsstag, Bidjeh, & Idriss, 1998). Pastoralists tend to live in sparsely populated, geographically marginal areas, while health services are typically concentrated in more densely populated areas of permanent settlement. Mobility in itself may restrict access, particularly where extended courses of treatment are indicated. Other barriers include political marginalization, cultural, ethnic, and linguistic differences with service providers, and very low levels of literacy.

Data collected among a sample of 9,000 Fulani in northern Burkina Faso suggest a high infant mortality rate, even compared with the rest of the country: 140 infant deaths per 1,000 live births (Hampshire & Randall, 1995). Maternal mortality is also extremely high among the Burkinabè Fulani, with a lifetime risk for women of

Table 1. Health Indicators and Services in Selected Countries Inhabited by Fulani

Country	Infant mortality rate (per 1,000 live births)	Life expectancy at birth (years)	Doctors per 100,000 people
Burkina Faso	106	46	3
Chad	92	47	3
Mali	134	47	5
Niger	191	48	2
Sources	UNICEF 1998	UNDP 1997	UNDP 1997

dying of maternal causes estimated to be around 1 in 17 (Hampshire, 2001, 2002b).

On the positive side, pastoralist Fulani may have better nutritional status than non-pastoralists, because of the availability of milk and meat. Again, while not shown specifically for the Fulani, this has been demonstrated for other nomadic pastoralists, such as the Turkana (Barkey, Campbell, & Leslie, 2001; Shell-Duncan & Obiero, 2000).

MEDICAL PRACTITIONERS

For many common ailments, and for prevention of illness, everyone becomes a medical practitioner. For example, Riesman (1992) describes how all Fulani mothers in northern Burkina Faso prepare *basi*, an infusion of herbs and tree barks, which they give young babies to protect them from various ailments. Women learn the secrets of *basi* preparation from their mothers and grandmothers; these include both the ingredients and the method of preparation. In Chad, many common ailments are self-treated by Fulani using remedies made from ingredients found around the home, such as milk, butter, spices, and animals' urine (Hampshire, 2002a, in press).

For more serious conditions, the range of medical practitioners used by the Fulani reflects the variation in perceived cause of illnesses. Most illnesses are perceived to have their origins in malevolent external powers: spirits or djinns, witches, or non-human animals (De Bruijn & Van Dijk, 1995). Such illnesses can only be treated by confronting and defeating those forces, and are thus amenable only to intervention by those with power in the supernatural realm. *MooDiBaaBe* (sing. *mooDiBo*), Islamic learned men, are frequently called upon in these cases. *MooDiBaaBe* may use herbal medicine or Koranic texts in their practice, or a combination of both (De Bruijn & Van Dijk, 1995; Hampshire, 2002a; Riesman, 1992). An example of the use of Koranic texts is given by Riesman (1992, p. 92). As a cure for madness, a *mooDiBo* wrote Koranic verses on a wooden tablet in ink. The ink was then washed off, and the solution drunk by the afflicted person.

Today, the healing of *mooDiBaaBe* often goes hand in hand with the use of "modern" medicine. Because of the remoteness and poverty of many areas inhabited by Fulani, many of the modern health facilities to which they have access are fairly limited and basic health posts.

In addition to formal provision of modern medicines, in several areas, informal dealers of non-registered drugs provide another means of access to medicines in some areas (De Bruijn & Van Dijk, 1995; Hampshire, 2002a).

CLASSIFICATION OF ILLNESS, THEORIES OF ILLNESS, AND TREATMENT OF ILLNESS

Most illness is thought by the Fulani to originate from external malevolent forces. It may be caused by non-human animals, particularly birds (*pooli*), spirits or djinns (*jinnaaji*), or by "witches" (*sukunyaaBe*) (De Bruijn & Van Dijk, 1995).

Jinnaaji may be anywhere in the bush, and the risk of encountering one makes many people fearful of going out at night. An encounter with malevolent spirits, *seedaani*, will almost certainly result in illness. The illnesses associated with *seedaani* are *henndu* (wind) and *haandi* (madness) (De Bruijn & Van Dijk, 1995). One who has come into contact with *henndu* is called *jom-henndu* (possessor of the wind). *Henndu* can attack the body, causing fever and wasting, or the mind, causing a person to lose their wits (*hakkile dillii*) (De Bruijn & Van Dijk, 1995). *Haandi*, or madness, is described by Riesman (1977) as being caused by the extreme fear a person experiences upon seeing a spirit. A crazy person (*kaanaDo*) is, by definition, someone who has encountered a djinn. The fear-induced craziness then drives the person to behave in ways opposite to that expected from normal people: tearing off his clothes, screaming, fleeing into the bush, etc.

SukunyaaBe ("witches") are another cause of illness. They are transformations of human beings that seek to suck the life-force/soul out of their victims. De Bruijn and Van Dijk (1995), from their work in Mali, describe them as being visible at night, appearing as white spots. Among some Fulani groups in northern Burkina Faso, *sukunyaaBe* are believed to be humans that transform themselves into birds of various kinds, who eat the souls of their victims by pecking at their chests. Unless a *mooDiBo* can effect a cure, the soulless victim is destined to die shortly afterwards (Hampshire, unpublished field-notes). *SukunyaaBe* are found mostly among outsiders and non-Fulani who live close to Fulani settlements.

A very different kin of witchcraft, which is also a common cause of illness, concerns the use of *dabare*.

Sukunyaabe, while evil, are generally believed to have no choice: as *sukunyaabe*, they have to feed off human souls in order to survive. *Dabare*, by contrast, is the conscious practice of black magic against a particular person, and is usually related to jealousy (*haasidare*) (De Bruijn & Van Dijk, 1995). It is often used between co-wives, among whom jealousy might easily arise. Only *mooDiBaaBe* or non-Islamic practitioners of black magic (*bonngoBi*) can make *dabare*, which they do when commissioned and paid to do so by an aggrieved person. *Dabare* may be used to cause illness, or other evil (i.e., death), causing a person to act against his/her will, driving someone away, etc. (De Bruijn & Van Dijk, 1995; Hampshire, unpublished fieldnotes).

A third common set of causes of illness are non-human animals, particularly birds (*pooli*) (De Bruijn & Van Dijk, 1995; Hampshire, unpublished fieldnotes). *Pooli* are a particular danger for young children left unattended. Particularly feared is the owl, whose spirit may invade and attack a young child. Children taken by the *pooli* often have clenched fists, and they may have a fever and be restless (De Bruijn & Van Dijk, 1995). Mothers suspecting that their children are in danger may try to frighten the *pooli* away by making lots of noise (Hampshire, unpublished fieldnotes).

Finally, there are many illnesses that may be described as inconveniences rather than dangers, and which people expect to experience on and off, for much of the time. These include minor aches and pains, particularly headaches (*naoora hoore*), fever (*jonte*), stomach pains (*nyao reedu*), and diarrhea (*doggu reedu*) (De Bruijn & Van Dijk, 1995; Hampshire, unpublished fieldnotes). The causes of these generally are believed to be to do with relatively simple, physical causes: tiredness, lack of food, lack of tea. The remedies for such conditions are self-evident and straightforward, unlike the more serious conditions described above, where effective treatment can only come from a *mooDiBo*, skilled in interacting with external malevolent forces.

SEXUALITY AND REPRODUCTION

Having children is essential for Fulani men and women. Children are seen as conferring status in their own right, and are an important source of economic wealth and security (Hampshire & Randall, 1999, 2000). To have no children is seen as being a social disaster since, without children, it is very difficult for a Fulani to become a full

social being and to set up his or her own household (Riesman, 1977; Stenning, 1959).

Child-bearing for the Fulani should ideally happen within marriage. Indeed, child-bearing is such an integral part of marriage that a marriage is often not seen as being formally completed until a child is born. Among the *WoDaaBe* of Niger, newly married couples do not initially have their own domestic space or hut in which to sleep. On becoming pregnant, the young wife returns to her own family. There she stays until the birth and often for an extended period afterwards (up to a year or more). Only when the woman returns to her husband's family with her year-old child is the marriage considered formally complete, and are the couple permitted to occupy their own domestic space (Dupire, 1970; Stenning, 1958, 1959).

Because of the central place of child-bearing as part of marriage, pre-marital fertility is generally regarded as extremely bad, and carries strong sanctions. In one case described by Hampshire (2001), the family of an unmarried young woman was driven out of their village when she became pregnant. Extra-marital fertility (for example, during the absence of a husband) and inter-marital fertility (following divorce or widowhood, and before re-marriage), though frowned upon, are more often tolerated, and are frequently the subject of joking. Hampshire (2001) describes how one young Fulani woman in Burkina Faso whose husband was working away said: "While the men are away, they go with other women. Why should we keep our legs closed?"

The wide geographical dispersion of the Fulani makes it impossible to generalize fully about factors influencing fertility and fecundity. A study carried out among Burkinabè Fulani in 1994–96 suggests a strong desire for very large families, for reasons of status, wealth, and security (Hampshire, 2001; Hampshire & Randall, 2000). For many Fulani informants, family size did not enter into the realm of conscious choice. It is, therefore, no surprise that contraceptive use in this population was virtually zero. Similarly, induced abortion was almost unheard of, although some old women claimed to know of very powerful herbs that could be used for this purpose. Demographic and Health Survey data of other countries with significant Fulani populations also indicate contraceptive prevalence rates among the lowest in the world, so it is likely that conscious birth control is not an important determinant of fertility in many Fulani societies.

Among the Burkinabè Fulani, the major proximate determinant of fertility is post-partum infecundity due to

extended periods of breast-feeding—typically for around two years (Hampshire & Randall, 2000). Extended breast-feeding has been documented among other Fulani populations by Riesman (1992) and Dupire (1963). Other factors constraining fertility to a lesser extent among the Burkinabè Fulani were spousal separation following births and during migration and, more importantly, secondary sterility, probably acquired through sexually-transmitted diseases (Hampshire & Randall, 2000). Secondary sterility acquired through sexually-transmitted diseases was found by David and Voas (1981) to have a major impact on the fertility of Fulani living in Cameroon. Over half the women in their study were apparently sterile, due in particular to the high prevalence of gonorrhoea and syphilis.

HEALTH THROUGH THE LIFE CYCLE

Pregnancy and Childbirth

Pregnancy and childbirth among the Fulani occupy ambiguous positions. On the one hand, the birth of a child is greeted with joy and celebration. In particular, the birth of a first child is essential in cementing a marriage and giving the parents their new status in life (Dupire, 1963). On the other hand, pregnancy and childbirth are times of danger, and are surrounded by feelings of secrecy and shame, associated with *pulaaku*.

A pregnant woman can be the focus of much jealousy, particularly from any co-wives she may have, and other young wives in her husband's extended family. As such, she is at particular risk from *dabare* (black magic), which might be used to cause any number of serious misfortunes: miscarriage, death in childbirth, deformity of the child, etc. Pregnancy is, therefore, concealed for as long as possible. When it is no longer possible to continue concealment, a pregnant woman often returns to her natal home (*suudu baaba*), where fewer people will wish her harm.

Childbirth, therefore, particularly for younger women, usually takes place in the *suudu baaba* rather than the marital home. For first births, it is usual practice for the woman's mother to assist. For subsequent births, the ideal is for childbirth to be alone and unassisted (Hampshire, in press; Riesman, 1992). Adherence to the *pulaaku* ideal means that a woman should be able to face childbirth, and all its dangers, alone and without fear. It is important not to cry out, or to show any sign of

succumbing to physical pain. Of course, it would be a mistake to assume that all women interpret *pulaaku* in the same way, and accounts of practice show considerable variation in childbirth experience (Hampshire, in preparation). That said, unassisted childbirth remains an important ideal.

Childbirth, therefore, represents a time of danger for women on many levels. Not least is the physical danger of death or serious incapacity. As stated above, lifetime risks of maternal death among the Burkinabè Fulani are in the order of 1 in 17 (Hampshire, 2001), and Demographic and Health Survey data from other regions inhabited by Fulani suggest that this risk may be similar elsewhere. Second, there is a risk of *dabare* (black magic) associated with jealousy, which may cause serious, long-term harm to mother and baby. Third, there is the fear of shame, through not being able to live up to the *pulaaku* ideal of stoicism in the face of pain and danger. It is little wonder, therefore, that a first pregnancy can be greeted with very mixed emotions by young Fulani women.

Among the DjelgoBe Fulani of Burkina Faso, Riesman (1992) describes how, when a Fulani baby is born, it is important that it comes out on the ground. This contact with the earth helps establish a connection between the child and the place of birth. The placenta, which is widely believed to have great power, is usually buried in the earth at the spot where the baby first touched it. In the following days and weeks, hot water is poured on the spot where the placenta is buried in order to prevent it from rotting (Riesman, 1992).

Infancy

Post-Partum Practices. From the day of the birth until the naming ceremony 8 days later, the mother is confined to her hut or tent (Riesman, 1992). She leaves only to urinate or defecate in the bush and, even for this, she is always accompanied by someone. A fire is lit when the baby is born, and this fire burns continuously for the first week of the child's life, until the naming ceremony. The fire is used to heat water for bathing and preparing infusions.

On the eighth day after birth, the naming ceremony (*indeeri*) takes place (Riesman, 1977, 1992). The infant is washed and its head is shaved. It is carried back and forth between the hut and the outside three times for a boy, four times for a girl. A goat is sacrificed and the name of the

child pronounced. This represents the first stage of becoming a social being.

Protection of Newborn Infants. Newborn infants are thought to be vulnerable to many forms of harm and, as such, are protected in multiple ways. Every day for the first few days of life the infant is washed with hot water containing a medicinal herbal infusion. *Basi*, another medicinal infusion of herbs and tree barks, prepared by the mother, is given to the infant to drink. Various talismen or charms, often provided by *mooDiBaaBe*, are worn by the child from a very young age to offer protection against malevolent external powers (Riesman, 1992).

Because children are very highly valued, people are fearful that others may become jealous and wish harm on the child. To this end, it is regarded as being very dangerous to praise a young child by saying (s)he is good-looking, healthy, or fat (De Bruijn & Van Dijk, 1995; Hampshire, unpublished fieldnotes; Riesman, 1992). To make such a remark is interpreted as an intention to cause harm. Instead, visitors often make derogatory comments, remarking on the ugliness of the child. Another strategy used by some parents is to cover the child in dirt or dung, or to give it nicknames such as “cow dung” to make it appear unattractive.

Infant Feeding Practices. Fulani women typically breastfeed for extended periods of time. In northern Burkina Faso, this typically extends to the two years proscribed by the Koran (Hampshire & Randall, 2000). In cases where the child is weak or sickly, this may be extended further, and it is not unknown for mothers to nurse until 30 months or more (Hampshire & Randall, 2000). Early weaning occurs if the mother becomes pregnant again, because the milk in the breasts of a pregnant woman is believed to “belong” to the new baby and is thought to be harmful to the breast-feeding child (Hampshire, 1998; Riesman, 1992). Accounts of other Fulani groups also point to extended periods of breast-feeding (Dupire, 1963; Riesman, 1992).

During the period of nursing, the breast is offered on demand, and is seen as a panacea to be offered whenever the child appears distressed. Co-sleeping of mothers and infants allows infants to feed on demand through the night too. Other women may also offer a breast to an infant, particularly grandmothers (Hampshire, 1998; Riesman, 1992) although, among the *WoBaaBe*, this may be extended to all nursing mothers in the camp (Dupire, 1963).

In addition to breast milk, Fulani infants are typically given supplementary foods from quite a young age. Butter and cow’s or goat’s milk may be given as early as the first week of life, and thin millet gruel may be tried after a few months (Dupire, 1963; Riesman, 1992). This is in addition to the medicinal *basi*, given from birth (Riesman, 1992).

Cessation of breast-feeding typically happens abruptly (Hampshire, 1998), although mothers may vary in how strictly this is enforced (Riesman, 1992). Because, until this point, feeding has been on demand, weaning is a difficult period for young children. To aid the process, the child may be physically removed from its mother by, for example, being taken by its grandmother until it has “forgotten” the breast (Hampshire, 1998).

Caretakers. While a mother is primarily responsible for the care of her infant, in practice this is often shared with many other women, since childcare happens as a part of women’s ongoing life, while they cook, fetch water, wash, weave mats, and do each other’s hair (Riesman, 1992). Consequently, all first-time mothers will have had years of experience watching and helping other mothers take care of their children. In turn, they will also be watched, criticized, and helped. Help may include anything from offering advice or carrying the baby to offering a breast. For the first few years of life, fathers are relatively uninvolved with the care of their children and in decisions relating to their health, welfare, and feeding.

Childhood

Between the ages of 5 and 7, children are thought to begin to develop *haYYillo* (a social sense) and are given their first responsibilities (De Bruijn & Van Dijk, 1995; Riesman, 1992). These responsibilities may include helping mothers with food preparation, or beginning to look after small animals. Until that time, children are not expected to know how to behave socially, or indeed to comply with the demands of their caretakers. From ages 5–7 onwards, children are thought to be more responsible for their actions, and are thus more likely to be reprimanded and corrected for behaving in inappropriate ways.

A particular danger to the health of children is *pooli* (described above), and mothers take precautions, such as making a loud noise, to try to prevent this (De Bruijn & Van Dijk, 1995). Other health risks to childhood include the belief that it is dangerous for a child to have contact with its mother, and particularly with her milk, for the

last months of her pregnancy with her next child, and continuing after the birth of that child. To protect against this, an older child may be given an egg to eat, cooked directly in the coals, from a chicken that has not had any offspring (Riesman, 1992).

For very young children, the main responsibility for healthcare lies with the mother (De Bruijn & Van Dijk, 1995). It is she who decides when treatment for illness should be sought, and she who must find the means to pay for it, which are typically very limited. If very young children die, grief tends to be borne privately by mothers, rather than being a public matter. For older children (over age 5 or so), the responsibilities shift, with fathers beginning to take a more active role in the well-being of their offspring, and contributing financially to their healthcare (De Bruijn & Van Dijk, 1995).

Adolescence

Childhood ends quite early, for Fulani girls in particular. Marriage takes place typically at an early age—mean age at first marriage for Fulani women in Burkina Faso was found to be around 16 years, with a high proportion of marriages happening considerably earlier (Hampshire & Randall, 2000). For some time prior to marriage, girls are expected to take on roles appropriate to adult women, and much of the freedom associated with early childhood is lost. In Burkina Faso, some Fulani girls from the age of about 12 are sent to live with their future mothers-in-law, as part of preparation for married life (Hampshire, 1998).

Fulani men marry later than women: among the Burkinabè Fulani, mean age at first marriage for men was 24–25 years (Hampshire & Randall, 2000). Fulani men, therefore, enjoy a more extended period of adolescence during which they are free from many of the responsibilities of having their own family and herd. Among some Burkinabè Fulani men, it is common to begin to travel during this period, in particular to cities for temporary work (Hampshire, 2002b; Hampshire & Randall, 1999).

Adulthood

Until old age, Fulani are married for most of their adult lives. Marriage is effectively universal and re-marriage is typically rapid following divorce or widowhood (Hampshire & Randall, 2000). Polygamous marriage is practiced, although most marriages are monogamous: among the Burkinabè Fulani, for example, 7.6% of

married men and 13.5% of married women were in polygamous unions (Hampshire & Randall, 2000).

For adult Fulani women, the most pressing health issues are pregnancy and reproductive health, and unequal access to health services. The health risks associated with pregnancy and childbirth have been discussed above. Maternal mortality ratios are typically high (e.g., 850 deaths per 100,000 live births among the Burkinabè Fulani, which corresponds to a 1 in 17 lifetime risk (Hampshire, 2001).

The reasons for such high risks of maternal death or injury relate in part to the lack of facilities for dealing with obstetric emergencies in particular (also ante-natal and post-natal care) in many of the areas inhabited by rural Fulani. They may also relate to a mismatch of services currently provided with the felt needs of Fulani women. Many of the beliefs and practices associated with pregnancy among the Fulani make use of standard maternity services problematic for many. Ante-natal care is difficult where women conceal pregnancy, and delivery in hospital or maternity units runs counter to the ideal of unassisted childbirth. Issues such as the disposal of the placenta in hospital are also areas of concern for many Fulani women (Hampshire, in preparation).

Gender inequalities in access to health services also exist in many Fulani populations, such as those in central Chad (Hampshire, 2002a). Because of both resource constraints and various cultural and institutional factors, Fulani women often have to rely on male affines and kin to gain access to particular health services and practitioners. Hampshire (2002a) found considerable variation in the ability of married women to mobilize their husbands' support in times of illness. Particularly vulnerable were childless wives, those least well established in the marital households, and those in polygamous marriages and/or in large, extended marital households. A woman's own kin network is important in terms of her access to health resources, particularly for unmarried women, or where husbands and other affines are unprepared to help (De Bruijn & Van Dijk, 1995; Hampshire, 2002a).

The Aged

Old people are generally treated with deference and respect in Fulani society (De Bruijn & Van Dijk, 1995; Riesman, 1992). According to De Bruijn and Van Dijk (1995), there are established ideas about help for old people in cases of illness or hardship. An old, widowed woman may receive

help from her brothers, her own children, members of her *suudu yaaya* (mother's lineage), and neighbors. However, such support is not always forthcoming, and depends on the willingness and ability of such relatives to help out (De Bruijn & Van Dijk, 1995; Hampshire, 2002a).

The respect accorded to the elderly is not without ambiguity (Riesman, 1992). Important aspects of being a Fulani adult include being useful/able (*waawude*), and being in control of physical needs or wants—qualities that diminish in old age. Riesman (1992) discusses the sense of irony surrounding old age, in which the elderly are, on the one hand, respected, and yet, on the other hand, the objects of ridicule or joking, since they may no longer be capable of exercising that power in any meaningful way. Riesman even quotes elderly informants who describe themselves as being “dead,” since they are no longer able to fulfil their social or productive roles.

Death and Dying

Reactions to death and dying in Fulani society are characterized by the restraint shown in other aspects of life. De Bruijn and Van Dijk (1995) describe how, for very young children (under about 5 years), death and mourning are private affairs, with no public expression of grief. For older children and adults, public mourning is typically very short. Burial happens very shortly after death, without an elaborate ceremony (De Bruijn & Van Dijk, 1995). Condolences are offered to the bereaved family but, thereafter, the grief becomes private, with no collective ceremony or remembrance at a later stage. Riesman (1977) points out that one should not mistake a lack of public mourning with lack of emotion or sensitivity. Fulani are expected to have strong emotional feelings surrounding death and other sadnesses. However, they are also expected to master those feelings, to control them, and not to display them publicly. This is particularly true for men; it is expected that women may shed tears over a death, particularly of a close family member, while men should be able to control and master their emotions.

CHANGING HEALTH PATTERNS

It is important to remember that the information presented here refers to particular groups of Fulani, documented by particular ethnographers at particular moments in time. It is now widely accepted within the field of anthropology that “culture” is neither static, nor rigid, nor is it interpreted

by everyone in the same way. Within a Fulani camp or village, individuals will think about and interpret situations differently, with substantial variation in practice and action. This applies to beliefs and practice associated with health as much as any other element of life.

The variation is increased by the fact that the Fulani are a vast and fluid ethnic category, spanning the breadth of Sahelian Africa. In addition to the variation in health-related beliefs and practices within villages, there are also substantial variations between Fulani groups living in different areas. I have tried, throughout this entry, to draw the reader's attention to such differences and similarities. However, existing ethnographies of Fulani groups do not cover the whole range of Fulani life in every area. It is probable, therefore, that there is more regional variation in Fulani health patterns, beliefs, and practices than is documented here.

It must also be remembered that the various ethnographies of the Fulani drawn on in this entry are situated in particular moments in time. Health patterns, beliefs, and practices, like all other aspects of life, are not static, nor can they be properly understood ahistorically. Many Fulani societies have undergone substantial social and economic change over the period covered by the ethnographies, with important implications for health patterns, beliefs, and practices. Most of the states in which Fulani live achieved independence from colonial rule in the years around 1960, which precipitated, among other things, changing social and economic relations between the FulBe and slave groups. This, in combination with climatic and ecological changes, has meant that many Fulani have left behind agropastoral subsistence to pursue economic strategies that draw them increasingly into a national and global economic framework (Hampshire & Randall, 1999).

Modernity has brought about different changes for different groups of Fulani. Some of these changes can be illustrated by considering the case of Fulani groups in northern Burkina Faso. On the one hand, increased contact with health services has resulted in improving infant and child health for many, as indicated by falling infant and child mortality rates over recent decades (Hampshire & Randall, 1995). On the other hand, modernity brings with it new health challenges. Young Fulani men migrating temporarily to cities to find work are increasingly exposed to sexually-transmitted diseases, including HIV and conditions that result in sterility, such as gonorrhea and chlamydia (Hampshire & Randall, 2000). It is likely that these are being transferred back to Fulani villages, with possibly devastating future consequences.

Garhwali

Satish Kedia

ALTERNATIVE NAMES

The current name of Garhwal is of relatively recent origin. Etymologically, *Garhwal* means a region formed by

the integration of *Garhs* (fortresses) and their territories, an act that took place in the 16th century when King Ajaypal consolidated 52 small princely states and their forts to expand his empire over the whole Garhwal

(Rawat, 1989, p. 20). The original inhabitants of the Garhwal hills are known as *Garhwali*. They are also called *Pahari*, meaning “people of the mountain,” by the neighboring communities in the plains.

LOCATION AND LINGUISTIC AFFILIATION

Garhwali live in the North Indian Himalayas in the western part of the State of Uttaranchal. Uttaranchal comprises 13 districts and was part of the State of Uttar Pradesh until 2000, when it was given autonomous status. The Garhwal region is in the middle zone of the Himalayas, which have a varying width of about 60–90 km and an elevation ranging between 1,000 m and 3,000 m above sea level. The region is full of peaks and valleys and is marked by rivers flowing through the deep gorges.

Most Garhwali people speak Garhwali and some Hindi, both in the Indo-Aryan linguistic group. Prior to the 19th century, Persian with Arabic script was used for administrative purposes, but Garhwali with Devanagari script remained the language of the commoners. Many inscriptions and state orders were written in Garhwali. In some regions of Garhwal, such as Rawain, Jaunpur, and Juansar-Bawar, dialects of Garhwali called Rawalti, Jaunpuri, and Jaunsari respectively are spoken.

It would not be prudent to generalize this commentary to all regions of Garhwal. This narrative is primarily based on the author’s fieldwork among a peasant community near Tehri in the western part of Uttaranchal during the mid-1990s. However, a concerted effort was made to incorporate pertinent information from the writings of other researchers who have worked in various parts of Garhwal.

OVERVIEW OF THE CULTURE

Garhwali are predominantly peasants and have approximately 8.5 million people living in Uttaranchal. The initial archeological evidence in Garhwal includes inscriptions and artifacts from the time of King Ashoka (269–232 BC) and suggests that the region was inhabited long before this period. The mythical Hindu texts, *Puranas*, *Mahabharata*, and *Ramayana*, contain numerous indications that a society existed in this region. At that time, the people were variously known as *Kedarkhand*, *Uttarkuru*, *Kurujangal*, and *Uttarakhand*. However, it remains a matter of debate among historians as to who were the original inhabitants.

The economy in the Garhwal region is primarily agrarian with approximately 85% of the adult population

practicing intensive agriculture. The other economic activities include horticulture, animal husbandry, forestry, and some cottage industries. The crop cycle and harvest determine the work and festivities in these villages. In addition, a sizable portion of adult males have either permanently or temporarily migrated to nearby cities to pursue wage-labor in factories, hotels, restaurants, and offices or to serve in the military.

While there are four major caste groups in India, Garhwali society is stratified in a tripartite caste system comprising priests (*brahmin*), warriors and landlords (*kshatriya/rajput*), and low occupation groups (*sudra*) (Berreman, 1997). Caste is a system of social hierarchy among Hindus where individuals are ascribed to a particular group by virtue of being born into it. The merchant caste is absent among Garhwali society because of the lack of trade at any significant level in the mountains. Social mobility has been largely upward among Garhwali. The non-caste local groups (*khas*) emulated the caste-like features to get into the fold of the caste system. Once in the caste system, attempts were made to move up to even higher categories of actual caste groups (*asal*) through marriage or by changing religious practices. Garhwali society is patrilineal with an emphasis on joint family structures consisting of parents, married sons and their families, and unmarried children.

The Garhwal region has a long tradition of Hinduism and is a hub of some of the most sacred pilgrimage sites. The Garhwali practice a syncretic form of orthodox Hinduism and animistic religion. The ritual practices differ among castes based on their past affiliation with primitive religion. Garhwali worship various forms of the Hindu trinity (*Brahma*, *Vishnu*, and *Shiva*) as well as different local deities such as *Narsing*, *Nagraj*, and *Bhairon*. Garhwali have ardent beliefs in the power of spirits and regularly worship them. Most villagers worship their village deity and each family has family deities (*kula devata*). The rituals and other religious practices involve magic, animistic beliefs, spirits, dancing of spirits and gods, and nature worship.

THE CONTEXT OF HEALTH: ENVIRONMENTAL, ECONOMIC, SOCIAL, AND POLITICAL FACTORS

Approximately 78% of the people in Uttaranchal live in the rural areas with fewer resources to maintain a balanced diet and healthy lifestyle. Fifty-three percent of the

households have electricity, 44% have access to piped drinking water, and 39% have toilets in their houses (International Institute for Population Sciences & ORC Macro, 2000, p. 2). The environmental conditions limit the productivity of the land; even though the majority of the population work on the farm, there is always a food deficit. Local agricultural production fails to sustain the population, and the demand for additional food is met by importing food grains from the plains. The healthcare resources are abysmal in the region. Few biomedical doctors are available in urban areas, and those who use these doctors frequently complain about the poor quality of service. Government officials have found it difficult to provide healthcare services in the isolated villages of Garhwal. Many of these villages require hours of walking on steep, narrow, and winding mountain paths from the nearest road (Kumar, 1991). The state officials of the newly formed Uttaranchal are now paying closer attention to enhancing the healthcare services in this region.

MEDICAL PRACTITIONERS

Garhwali use an eclectic mix of medical healers; biomedical practitioners are just one of the available options. Biomedical practitioners with a medical degree are rare in the Garhwal hills; most have only an associate's degree with a couple of years of medical training or apprenticeship and are in private practice. The district headquarters or towns have a local hospital with doctors that have a medical degree and, in some cases, other specialists. The fees and traveling distance to the biomedical healers make them unavailable to much of the population. There are health centers with a health worker and a nurse for every five or six villages.

Herbalists (*deshi vaidhya*) are available and found throughout the Garhwal region. They use herbs and medicinal plants indigenous to the Himalayas and are consulted for prolonged and serious illnesses. Along with the herbalists are the Ayurvedic doctors (*Ayurvedic vaidhya*) who have formal training in practicing medicine. An Ayurvedic doctor uses many natural substances and food in addition to herbs and medicinal plants to cure illnesses. In Garhwal villages, it is difficult to make distinctions between a herbalist and an Ayurvedic doctor; they are both synonymously called *vaidhya*.

A variety of religio-magical healers in this region specialize in warding off the malign effects of supernatural

agencies. These healers are mostly part-time specialists and inherit or learn their skills from experienced healers. Garhwali have tremendous faith in these specialists. Priests (*pandit*) conduct worship, give sermons, perform rites of passage, and neutralize the effect of evil eye or evil spirits. They advise people to perform rituals, to worship deities, and to offer homage to their ancestors. They also perform *hawan* for clients and, on a larger scale, *yagya* can be arranged for the whole community. A trained priest chants sacred verses (*mantra*) and blows consecrated ash on their clients to get rid of some illnesses, particularly those believed to be caused by supernatural agencies.

Exorcists, another religio-magical specialist, chant *mantra* to cure illnesses. They make charms or talismans (*tabeez*) to prevent illnesses. They can give the patient consecrated water or sugar to consume or give a consecrated piece of stone for the patient to wear. In addition, special rituals are performed under the supervision of an experienced exorcist, such as placing consecrated vermilion, hair, salt, chili, and lemon on the road intersection (*chauraha*) for specific desired outcomes. Shamans (*baki*) are believed to have supernatural powers and mystical contacts with spirits. They invoke tutelary spirits to diagnose illness and prescribe treatment. The shaman's knowledge and power are mostly inherited or learned from someone who has had extraordinary life experiences. The traditional healers serve all segments of the Garhwali population, but people with less education, women, and the elderly appear to consult these healers more frequently.

CLASSIFICATION OF ILLNESS, THEORIES OF ILLNESS, AND TREATMENT OF ILLNESS

The Garhwali explanatory scheme divides causes of illnesses into two sources: natural (*bhautik*) and supernatural (*daivik*). Natural sources include the weather, hygiene, food, pathogens, and physical and emotional imbalances. Supernatural sources incorporate spirit and ghost intrusion, ancestral neglect, wrath of deities, evil eye, witchcraft, sorcery, breach of a taboo, totem violations, community sin, fate, ominous sensations, and contagion. An illness can be caused either by one factor or a combination of factors. Among Garhwali, the confines of

health beliefs are stretched to accommodate the demands of their emotional and psychosocial state. Generally, the more serious and chronic the illness, the more likely the perceived causes will include supernatural agents.

Natural Causes

Garhwali perceive factors in the surrounding environment as potential causes of illness, such as poor drinking water, air quality, and changes in the weather. Poor hygiene is an issue in some places of Garhwal, particularly due to overcrowding and poor sanitation. Hygiene problems cause and exacerbate the spread of diseases, especially those carried by mosquitoes and parasitic worms (Rizvi, 1991). While the lay Garhwali person has little knowledge of specific pathogens, there is an awareness that mosquitoes can spread malaria and that worms (*pillu*) cause stomach upsets and diarrhea. The balance of the body humors can be disturbed by rain, cold, wind, heat, and changes in weather conditions, such as from hot or cold. Garhwali believe that hot weather can cause fever, malaria, headache, joint pain, stomach ache, backache, and diarrhea, while cold weather can cause cold, cough, fever, pneumonia, and body and joint pain. The rainy season is said to cause fever and skin diseases, among other illnesses, while the cold east wind, called *purvia*, is believed to cause fever and other minor illnesses.

Garhwali consider food to be a major factor in the maintenance of good health. Most food has been classified according to its hot and cold properties. In the local humoral classification, most spicy and oily foods are considered hot and can imbalance the body fluids, resulting in indigestion and diarrhea. Heat-producing foods lead to headache, joint pain, backache, stomach ache, indigestion, diarrhea, and high blood pressure. Smoking *hukka* (a form of pipe tobacco) and cigarettes leads to coughing and other respiratory illnesses.

Supernatural Causes

Garhwali divide supernatural causes into three categories: animistic, magical, and mystic. Spirit intrusion (*opra*, *chhaya lagna*, *bhuta-pret lagna*) is the hostile or punitive act of a malevolent supernatural spirit possessing a person and causing dramatic symptoms of illness in the process. Garhwali believe that spirits and ghosts are invisible, intangible, and free-floating divine forces. However, they do make a distinction between spirits and

ghosts: spirits belong to local deities, whereas ghosts belong to ancestors or other deceased human beings. The common feature of spirit or ghost intrusion is a general illness of the person. The illness caused by ghost intrusion has a number of symptoms, including the widening of the eyes and discoloration of the face, meaningless babbling, unconsciousness, dementia, excessive weeping or laughing, and convulsive movements or locking of the jaw (Rizvi, 1991). If someone suddenly gets sick with fever, headache, or backache and feels dizzy, then people diagnose the person with spirit intrusion, especially if the ill person is a young child, newlywed woman, or expectant mother. The symptoms tend to vary with the age of the afflicted person (Rizvi, 1991). Illnesses caused by the spirit influence are considered debilitating and are mostly chronic, prolonged, and recurrent.

Similar to spirit intrusion are illnesses believed to be caused by the wrath of deities (*devi-devata ka kop hona*). Deities are angered if they are not revered and cause illnesses and destruction. The most frequently mentioned disease believed to be caused by the wrath of a deity in this region is measles (*khasara*) among children. Leprosy is another disease that is supposed to be caused by the wrath of a particular deity, if she is propitiated improperly. The illnesses that are commonly attributed to the wrath of deities are insanity, babbling, extreme weakness, and any illness that is incurable by any other therapy.

Garhwali believe that all people have some supernatural power that can affect the well-being of others through the evil eye, witchcraft, and sorcery. They believe that compliments of any sort, especially those that have a sense of envy or jealousy, can trigger the evil eye (*najar lagna*). Extraneous objects such as fancy dress, jewelry, or food that evoke jealousy can make the person possessing them afflicted with illness. This means that anyone with anything admirable is susceptible to the evil eye. Young children and pregnant women are particularly vulnerable. Common symptoms of the evil eye include fever, loss of control, weeping, irritation, closed eye, sleeplessness, weakness, children's loss of appetite for milk, and loss of appetite in general (Kedia, 1997).

In addition to potentially casting an evil eye, Garhwali believe that certain individuals possess evil power or may control certain spirits and use their malevolent power to harm a person. Witchcraft can be defined as the intentional or unintentional act of a person possessing supernatural power that causes illness in a targeted person. The victims

of witchcraft suffer losses and misfortune. Many different kinds of individuals are identified in the community as having these powers. Sometimes people in the community think a young widow cursed her husband and has the potential to harm other people. There is also a belief that if someone is born on the darkest midnight of *Bhando*, a specific month during the rainy season in the Hindi calendar, then he or she would possess this power naturally. Some people believe that the power is hereditary. For example, a woman may acquire evil power from her mother. Again, people believe that a female with malevolent power may be more dangerous than a male with similar power.

Sorcery differs from witchcraft in that it is a learned magical skill that is used primarily to harm others. A sorcerer employs an aggressive magical procedure to cast a spell that potentially can cause an illness. The practice of sorcery takes various forms such as spells, curses, magic performed over hairs, nails, excreta, or clothing, object intrusion, administration of presumptive poisons, or dispatch of an alien spirit to possess the victim's body. Many times Garhwali attribute sudden serious illness to sorcery, especially if they have a dispute with a family who believes in sorcery or has contact with a sorcerer.

Garhwali believe that illnesses can be caused by a violation of some taboo or moral injunction. These taboos consist of prohibitions on the consumption of certain foods, contact with people in certain ritual states, breach of appropriate behavior toward kinsmen, trespass or theft, use of forbidden words, urination on a religious site, incest, or pre- or extra-marital sex, and so forth. When a taboo is violated, the person may or may not be aware of it. For example, if someone urinates unknowingly over a site where a person was buried, it is an unintentional violation of a taboo. The consequences of unintentional taboo violations are milder than violations that are committed willfully, but illnesses still may occur. Intentional violations of a taboo result in guilt, which in turn can consume a person until he or she physically falls sick. Garhwali believe that violation of a taboo results in chronic and incurable illnesses such as skin infections or cancer. Illnesses are seen as a warning from punishing supernatural agents against breaking taboos.

One of the taboos prohibits killing certain animals, such as cows, peacocks, snakes, and monkeys, which are considered totemic. In the Hindu tradition, these animals are supposed to have mystic ties with the deities, and their death and consumption would incite supernatural anger and endanger entire communities with epidemics and

other communicable diseases. In the event of a totem's death, it should be ceremonially cremated or buried to protect the person and the community from the wrath of a deity.

In the Hindu scheme of life, every human being has the responsibility to follow right conduct. Any act or even the mere thought of something that is detrimental to other living beings, including humans or divinities, is considered sinful (*pap karma*). Most sins accumulate until the death of the person and result in a divine justice in the "other world" or in the next life, which might include being born as an animal or other non-human life. Some sins, especially those committed against the deities, ancestors, or human beings, may receive a punishment in the current life in the form of illness. Most Garhwali believe that if one commits sins, he or she has to pay the price in this life only. Those who get dreaded diseases such as leprosy do so because of some sin they committed against mankind. Some of the commonly cited illnesses that result from committing sins are mental illness, barrenness, congenital malformation, and blindness. Garhwali attribute a number of illnesses to what can best be termed as fate (*bhagya*) and ascribe a number of illnesses to astrological influences or bad luck.

Treatment

Garhwali practice a pluralistic system of medicine with an emphasis on herbal and religio-magical healing with increasing use of biomedicine. In response to the onset of an illness that does not appear to be serious or life-threatening, Garhwali frequently opt for self-treatment (*gharelu ilaz*) at home. A number of therapeutic subcultures exist in the realm of self-treatment, such as herbal and food therapy, massage, and over-the-counter Ayurvedic and biomedicine. The strategies used in self-treatment are passed down within a family and are sometimes shared by the whole community. Self-treatment is less expensive and does not require consulting a biomedical practitioner or folk healer, saving time, money, and energy. Self-treatment also means either self-care or care provided by the family, who ensures that the patient gets appropriate food and proper rest. Restrictions may be imposed on the patient to avoid exposure to the wind or consumption of certain kinds of food. Another form of self-treatment involves doing simple rituals to ward off the effects of the evil eye or worshipping deities or ancestors for their blessings to cure an illness.

On many occasions, people buy over-the-counter medicines based on the recommendations of friends, relatives, and even strangers as most medicines can be bought from a pharmacy without a prescription from a doctor. People remember the name of the medicine recommended by a doctor for use in future illness. This practice saves them both the consultation time and the hassle of going to a doctor. Another mode of procuring medical advice is through a pharmacist. If a villager has an illness, then the person simply goes to the pharmacist and describes his/her condition, and the pharmacist prescribes and sells the medicine without any consultation fee.

Many Garhwali prefer to consult an indigenous herbalist or Ayurvedic doctor before going to a biomedical practitioner. However, for any illness presumed to be caused by a supernatural agent, they go to religio-magical healers. When Garhwali perceive an illness to be caused by a supernatural agent, but are uncertain as to the specific cause, they often try to find out the exact nature of the problem by consulting a shaman (*baki*). The shaman may identify the family with whom the patient might have had an altercation in connection with land, houses, cattle, or even chickens and hold their ancestral spirits or family deities responsible for the current situation. An exorcism is performed if evil eye, sorcery, or witchcraft is deemed the cause. If someone suddenly becomes very sick in the family, then people prefer to call a specialist who goes into a trance, a practice called *ghadiyala* (deities' dance ritual), to get rid of the invasive spirit. Family members and the people in the community gather and perform the ritual, and in the process these specialists or family members go into a trance. Once they achieve a trance, they challenge the spirit to leave the person. Depending on who the believed spirit is, the specialists sometimes severely beat the sick person in order to rid him or her of the spirit, frequently to the point of unconsciousness. The specialist also suggests remedies to cure mental ailments. However, not all Garhwali believe in these remedies. Those with more education say, "take the sick person to the hospital rather than wasting the time in making these deities dance."

SEXUALITY AND REPRODUCTION

Garhwali avoid any overt expression of sexuality. Adolescent girls and women are encouraged to cover their bodies with *duppatta* or *sari*. Chastity is highly valued in this society and one rarely indulges in premarital sexual

relations. If a premarital relation results in pregnancy, the fetus is aborted in the most secretive way. Among Garhwali, premarital relations or pregnancy bring dishonor to the family and make it very difficult for a woman to find a husband. Sexual and gynecological issues are matters of shame and embarrassment; women rarely discuss gynecological or pregnancy concerns with the family or a doctor. This results in poor reproductive health and outcomes for many of these women. The median age of marriage for women in Uttaranchal is 18 years, four years younger than men (International Institute for Population Sciences & ORC Macro, 2000, p. 3). Homosexuality is not acknowledged as an option. Such practices are considered abnormal and immoral; people indulging in homosexuality are reprimanded by the family members.

The idea of maternity is stronger than the idea of sexuality. Fertility is important evidence of a woman's femininity. Infertile women are stigmatized and are not invited by the community on auspicious occasions. Women usually conceive within two years of marriage and continue to conceive until they reach a desired family size that, on average, in this society is three children. However, due to the joint family structure, most households have 9 to 11 members in the family. Families desire to have at least one son. Garhwali are patrilineal, not having a son endangers the continuity of the family and family heritage. Families with only daughters continue trying for a son, even if it means insufficient nutritional resources for the mother and children already born. Many women with one or two sons begin using some form of contraceptive. Men rarely participate in birth control measures; the use of condoms is resisted by men with the notion that it results in the reduction of pleasure. Some women use intra-uterine devices (IUDs), but it is discouraged because of a fear of tampering with the uterus and obstructing vaginal and menstrual fluid. According to a survey of 320 housewives in Garhwal, about 40% used some form of contraceptive. Those using contraceptives practiced the following: 59% tubectomy, 7% vasectomy (by their husbands), 7% IUDs, 10% pills, 10% condoms, and 7% other methods (Srivastava, 1997).

HEALTH THROUGH THE LIFE CYCLE

Pregnancy and Birth

Getting pregnant is a major transition for a married woman that dramatically enhances her status in the family. Now

she is the bearer of potential sons who will continue the family lineage and provide economic security to their parents and grandparents. Pregnancy is a complex event that is influenced by cultural rules, supernatural beliefs, economic situations, and healthcare resources. Women work extremely hard (up to 16 hours a day) until very late in the pregnancy, causing health complications, poor pregnancy outcomes, and even miscarriage. Pregnancy does not alleviate the burden of the day-to-day household chores until the final weeks (Rao, 1995).

A pregnant woman is supposed to avoid any polluting agents and places, such as lonely, dark, haunted places, and cremation grounds. Women avoid heat- and wind-producing foods. Milk and milk products are avoided, especially in the second trimester, because they are believed to spoil the fallopian tubes and might increase the size of the fetus. A pregnant woman is not supposed to attend any rites of passage ceremonies, including birth, marriage, and death in the community. A pregnant woman is vulnerable to all kinds of evil forces. A pregnant woman avoids throwing clippings of her hair and nails because of the fear that a jealous person can perform sympathetic magic using these items.

The fetuses are rarely aborted. However, those who decide to abort use certain mechanical practices or local herbs to induce abortions for unwanted pregnancies. Garhwali believe that a pregnant woman can be invaded by the spirit of an unmarried woman, preventing a baby from settling in the womb. If a woman has multiple miscarriages, they perform a ritual called *aunja puja*. This ritual is conducted on the darkest night of the month when the mother, two or three males, and a healer visit a water source in the natal village of the mother. The ceremony takes about an hour. The ritual paraphernalia include an animal for sacrifice (lamb, goat, or chicken), seven kinds of grains (*satmaju*), black glass bangles, a black quilt, and black thread. The animal is sacrificed and eaten raw with a pinch of salt and pepper by the members of the ritual team. The healer wraps black thread around the woman's wrist. She takes off all her clothes and discards them at the ritual site, covers herself with the black quilt brought by the group, and proceeds to her in-law's village. In her in-law's home, she remains confined in a completely dark room for two or three days.

Babies are usually delivered lying flat on the back, which can adversely affect the mother's blood pressure and pulmonary ventilation, decrease the normal intensity of contractions, inhibit efforts to push the baby with

contractions, increasing the need for forceps, and inhibit the spontaneous expulsion of the placenta. Access to healthcare services is fairly restricted. According to one survey of 320 housewives, 88.9% of deliveries took place at home assisted by family members or midwives. The majority of deliveries were performed by midwives (Srivastava, 1997). The usual practice of applying force on the abdomen has led to traumatic rupture of the uterus in some cases. Sometimes more than one person applies force, even using their feet. A razor, household knife, or sickle is used to cut the umbilical cord. None of the instruments are sterilized, and boiled water is not used in all cases. The outer tip of the umbilical cord is burned, turmeric and castor oil are applied, and the placenta is buried in an isolated place. Roughly one or two women out of every 100 die from birth-related complications. A majority of these maternal deaths are due to anemia, hemorrhage, toxemia, sepsis, induced abortion, and miscarriage.

Infancy

The birth of a baby in the family brings mixed emotions among people. While it is a time of celebration, the process of the birth itself is considered unclean. Special care is taken to ensure that all ancestral worship is performed, especially on the patrilineal side. Spirits and other people can be a threat to both mother and baby, who are vulnerable to spirit intrusion and evil eye. Visitors are regulated and need to wait outside before they can get in. Any kind of visible birth defect is considered an act of a deity or spirit or an outcome of sins previously committed by one of the parents. After the baby's birth, the mother is not brought into the sun for five days and is not exposed to even an oil lamp lit in the same room. On the fifth day, the village priest mixes cow urine with cow milk, puts a copper coin in it, and chants verses. This liquid is then given to the mother and all family members to consume as ambrosia, which is supposed to have purifying effects for the whole family.

Midwives or a sister-in-law usually takes over the responsibility of maintaining the physical well-being of the new mother. Sometimes women return to their natal home for deliveries to be taken care of and to avoid daily chores in their homes. Women are given a semi-solid diet for 21 days after delivery. These 21 days, called *sujan*, are considered polluting for the entire family; the family limits their participation in community celebrations and exchange of food with others. On the twenty-first day, the family performs rituals, prepares special food, and thereafter returns

to mainstream life in the community. According to the NFHS-2 survey, only 44% of the mothers with children born in the preceding three years received an antenatal check-up (International Institute for Population Sciences & ORC Macro, 2000, p. 7).

In Garhwal, children are gently rubbed with warm oil twice a day until they are two years old. Most mothers squeeze their first milk before feeding the baby and may not breast-feed the new baby until the second or third day after delivery. On average, children are breast-fed for two years, which also helps prevent conception for these women. Since many infants are taken care of by grandmothers during the day, some infants suckle on their grandmothers' breasts as well, even though there is no milk. Children co-sleep with their mothers until 8 to 10 years of age. Sometimes sons get preferential treatment in terms of food and healthcare because they are considered essential for continuation of family life and potential support for parents and grandparents.

Childhood

Childhood is considered to last until 12 years of age. Since mothers are busy with household chores, children are taken care of by grandparents or older siblings. Only about 69% of children get immunizations. The children in Garhwal suffer from a variety of communicable diseases. Common diseases among children are pneumonia, upper respiratory infections, diarrhea, and fever. Approximately 4% of the children experience disability, with hearing loss being the most common. Child mortality in Uttaranchal is 56 per 1,000 (International Institute for Population Sciences & ORC Macro, 2000, p. 6). Malnutrition is commonplace due to inadequate and imbalanced nutrition because of a higher dependence on the carbohydrate-based diet as opposed to the traditionally diverse diet. According to NFHS-2, more than half of the children under the age of three are underweight and, between 6 and 35 months, 77% are anemic.

Adolescence

When girls reach the age of puberty, they are expected to take the role of adult women—increasing participation in the household chores, restricting lifestyle, and avoiding mixing with boys. Menstruation for a teenage girl is a traumatic event and is considered unclean and a matter of shame. Menstruating girls are not allowed in the kitchen

or in any religious place. Family members will not even drink water brought by her. She is considered untouchable and is not supposed to touch green and fruiting trees. After the fifth day, she can be reintegrated with the family and community after a purifying bath. The boys also reach adolescence at the age of 12 and begin to notice changes in their physical appearance. They are expected to help their fathers in the field with the agricultural work and take care of the animals. Neither girls nor boys go through any specific rites of passage during this transition, and there is no cultural practice of genital operation either for the girls or boys. Many of the health issues of childhood continue through adolescence.

Adulthood

Women in Garhwal have to work extraordinarily hard compared with men. Many men work in the cities or are in the military. Even those who are home do not assist the women with the household work. Women complain of general weakness, body aches, and anemia and are prone to accidents in the fields and forests. Women report respiratory infections, chronic bronchitis, gall bladder and urinary stones, and gynecological problems. Many married women have limited access to healthcare and suffer from reproductive health problems. According to one survey, 67.7% women reported abnormal vaginal discharge but 87.6% had not received treatment for it. Many others suffer from urinary tract infections, pain, and bleeding. Sometimes men bring sexually transmitted diseases. Adult men suffer the health consequences of drinking country liquor, which many Garhwali men do. As described in the disease causation section, mental illnesses, presumably caused by the animistic, magical, and mystical agents, are common among Garhwali adults.

The Aged

The life stage of the elderly starts at roughly 60 years of age. The elderly continue to live in joint family households and contribute significantly by watching fields and taking care of children. Women sometimes help prepare meals, and both men and women help feed the animals. The elderly hold considerable power within the family and community and play important roles in village and regional politics.

With age and inadequate and imbalanced nutrition, the majority of the elderly suffer from chronic diseases, including body aches, stomach ailments, respiratory

illnesses (due to prolonged use of cigarettes or pipe tobacco), diabetes, cardiovascular diseases, blood pressure, and hearing and vision loss. Women also suffer from back problems stemming from lifting heavy loads and gynecological problems. Owing to poor dental hygiene, both older men and women have very poor oral health. As much as half of the elderly are chronically ill. The elderly are taken care of by family members. Their generation relies primarily on religio-medical healing and herbal treatment.

Dying and Death

Death is distressing for most Garhwali. The entire lineage, and sometimes the whole village, is in a state of mourning. High levels of emotion are expressed in private and in public. The body is taken to the cremation site in a procession. Family members take the clothes off the body and apply purified butter and sandalwood paste to the body. The body is then cremated in the presence of male members of the family, relatives, and community. The bone remains and the ashes are thrown into the river. After the cremation, an elaborate ritual ceremony lasts for more than 11 days. During these days, the family and the lineage of the dead are considered polluted and do not attend any celebrations. On the last day, relatives and members of the community are invited for a feast. Because Garhwali believe in ancestral worship, the dead are treated with special reverence. They also believe that the dead could be reincarnated in human or animal form.

CHANGING HEALTH PATTERNS

Like anywhere else in the world, changes are taking place in the Garhwal region. While there is an increased use of

biomedicine, there is a gradual loss of traditional healing practices and resources. Owing to exposure to the outside world, the Garhwali beliefs about disease causation are consistently changing from supernatural to natural causes. Women are becoming more aware of their health problems and seeking more healthcare services. With increasing contact with outsiders, Garhwali are also contracting new infectious diseases including sexually transmitted diseases. At this time, there is not much knowledge and awareness among Garhwali about the threats of HIV/AIDS.

Garifuna

Nancie L. González and Gloria Castillo

ALTERNATIVE NAMES

Garifuna, which is actually an adjective, is the term now preferred by the people themselves, and most widely

used, but until the 1970s they were more often known in anthropological and travel literature as *Black Caribs*, and as *Morenos (Dark Ones)* to their compatriots of other ethnicities. When speaking their own language, however, the

correct usage is “(we) the *Garinagu*,” which derives from Arawakan *Kalinago*.

LOCATION AND LINGUISTIC AFFILIATION

The Caribbean coastline of Central America, extending from Belize to Nicaragua, has been home to the Garifuna since 1797 when the British forcibly transported them there from the island of St Vincent in the Lesser Antilles (González, 1988). Their phenotype reveals their African heritage, but their language, culture, and genotype demonstrate that they are a hybrid people, with both African and (South) Amerindian roots (Crawford & González, 1981; Taylor, 1955). The people encountered by the first Europeans in the Caribbean became known as Caribs, and the language family widely spoken there and in the tropical forests of South America, as *Carib*. The term is probably a corruption of *Galibi*. By the middle of the 18th century, after numbers of enslaved Africans had arrived—by capture or through flight—on St Vincent, the term Black Carib was coined to refer to the population darkened by intermixture.

Ironically, the language, still spoken today by perhaps 75% of all Garifuna, is not of the Cariban, but of the Arawakan family—also originating in South America. Despite some allegations to the contrary, it does not contain more than a few possible words of African origin (Taylor, 1952; Taylor & Hoff, 1980). It seems that it was important for this new group to hide and deny their African roots, at least at first, in order to escape recapture by Europeans. In time, the Amerindian culture that had received and nurtured them became theirs. However, both the people and their culture were further “Africanized” through continued contacts with other African people, especially after 1763, when the British seized the island and began major sugar cultivation, importing large numbers of African slaves as laborers.

OVERVIEW OF THE CULTURE

Subsistence fishing and the cultivation of cassava, yams, rice, plantains, and various other crops have been the basis of the economy and the diet for centuries. However, even on St Vincent there is evidence that the Garifuna learned to desire some European foods and goods, and were willing to do migrant wage labor in order to obtain

them. In Central America this practice escalated into what became a full-time endeavor for many men, and a part-time experience for most. Increasingly the men remained away for longer periods during their mature years, and although their sense of belonging to their home villages remained strong, their women, by default, took over the roles of parent/provider/protector/disciplinarian/guardian of ritual/ and more (Kerns, 1983).

Since the 1960s, however, more and more women have also chosen to emigrate—primarily to the United States, where they either join their men, or make their way independently. As more Garifuna are born in the U.S. and benefit from the educational opportunities there, the diaspora has enlarged, become more dispersed, and changed its character. Many Garifuna are now well educated, reasonably affluent, and are truly transnational in their outlooks. Some, having achieved a comfortable seniority, have chosen to retire to their original villages, where they live in such relative affluence, that it sometimes makes them targets of unkind gossip, and a certain alienation. Others, having experienced such, give up and return to the United States.

Among these expatriates are some who rue the loss of what they still define as “their” culture, and they have organized several mechanisms for retaining, rehabilitating, and reeducating themselves and the world at large as to their origins and their ethnicity. Belizean Garifuna, both at home and abroad, have been especially active in this, and one of their successes has been the May 2001 United Nations proclamation of the Garifuna culture as “Masterpiece of the Oral and Intangible Heritage of Humanity.”

The growth of international tourism has directly affected the Garifuna, whose culture is seen as deliciously exotic by nearly everyone. This has, no doubt, helped to slow out-migration as individuals and villages struggle to organize themselves to receive and entertain visitors from abroad. This has had both beneficial and negative impacts on health. Although providing some cash income, it has also brought new diseases, drugs, and prostitution.

The Sources of Garifuna Ethnic and Political Identity

The symbols of ethnicity for the Garifuna, wherever they happen to live, are language, indigenous spiritual beliefs and practices, and increasingly, what they believe to have

been a forgotten and buried African past. Although they see themselves as different from other African-derived peoples whom they encounter in the United States, there are good reasons for them to identify their culture as a variant of African, rather than North Amerindian, culture. It is difficult to have it both ways, so today's Garifuna increasingly cling to the African component of their heritage. They are witness to the success of the civil rights movement in the United States, as well as to the developing awareness on the part of Latin American "Blacks" of the discrimination against people of their color.

Spiritual Life

Traditional Garifuna religion focused attention of the living on the deceased—both ancestors and the spirits of the many children who died young. The former were believed to be either benevolent or malevolent, depending upon the relations one had with them in life, and on how well they are attended to ritually after death. Spiritual guides or shamans, called *buwiyes*, are capable of communicating with these spirits, often using as helpers the spirits of dead children, many of whom seek to be born again to their mothers. Although conversion to Roman Catholicism occurred for many on St Vincent, and for most others during the early years in Central America, it is rare to find a Garifuna today who does not harbor beliefs in the reality and the power of the spirits of their own relatives (Foster, 1982; Howland, 1984). Rituals to honor and placate the dead occur apart from, but in conjunction with Catholic masses, and enlightened Catholic priests close their eyes to what some might think of as blasphemy.

THE CONTEXT OF HEALTH: ENVIRONMENTAL, ECONOMIC, SOCIAL, AND POLITICAL FACTORS

Overview

There exist no precise figures on how many Garifuna there are, either in the world as a whole, or in Central America. Davidson (1979) estimated that there were about 60,000–70,000 in Central America in the 1970s; estimates given by the senior author for Honduras alone suggested a figure of 100,000 in 2000. Guatemala has less than 10,000 today, Belize perhaps 20,000, and

Nicaragua less than 5,000. Due to permanent out-migration and developing transnationalism, the population is difficult to estimate, and is probably diminishing in Central America, while it grows in the United States. No one doubts that there are more Garifunas living full or part-time in the United States than in all of Central America today. Because of this wide dispersion, with people living in any one of five different countries, it is impossible to do more than make guesses about this and about mortality and morbidity rates.

Probably the most significant health problem today is AIDS, but other venereal diseases, cardiovascular problems, viral respiratory illnesses, and diabetes have plagued those in Central America for generations. Because of the relatively high frequency of the sickle cell gene, homozygotes suffer sickle cell anemia and its consequences, while heterozygotes enjoy resistance to malaria. (Crawford, 1984; González et al., 1965).

Environment

The Caribbean coastline of Central America is hot, humid, and has long been considered unhealthy by Europeans, primarily because of their susceptibility to the fevers that were endemic in the area until the middle of the 20th century. The Garifuna flourished there, both because of their resistance to malaria, and because they were pre-adapted to the tropics. They knew how to build their houses so as to catch the sea breeze, and to stay out of the sun during the height of the day, and they knew how to harvest the natural resources. Most importantly, they were excellent seafarers (McKusick, 1960; Nicholson, 1976).

Wild palms and other fibrous plants provided raw materials for their traditional baskets, fish traps, mats, hammocks, cassava presses and sifters, and roof thatching. An abundance of hardwoods was available for manufacturing canoes and other wooden implements, such as cassava-graters. Houses were made of reeds, wattle and daub, or palm boards, although cement blocks and lumber are increasingly used today.

Citrus, avocado, mango, and other tropical fruit trees adorn every village and most home sites. The oil-bearing "milk" extracted from the fruit of the coconut palm is a major ingredient in their cuisine, a primary source of cholesterol. Fish and shellfish such as shrimps, lobsters, and crabs, were easily caught using nets and traps. At one time the men also did some hunting in the interior, but this was never so important as the harvests of seafood. Chickens

and pigs were introduced while still on St Vincent, and their meat continues to be appreciated, although fish is still preferred. Cows and goats are rare. Upland (dry) rice, beans, and plantains became important after they reached Central America. Unlike the indigenous people of the interior, they prefer bread and tortillas made of refined wheat flour rather than of maize.

In recent decades their healthy traditional diet has deteriorated, due to several interactive factors, including the out-migration of both women and men during their most productive years, the loss of lands suitable for horticulture, the rise of commercial fishing enterprises that seriously affect the availability of fish and shellfish in local waters, the influence of television and other advertising for processed, often “junk” foods, and the scarcity of cash to buy foods that were once locally produced.

Economic Factors

The coastal location was also important for the opportunities it afforded the men to seek employment among the increasing numbers of foreign explorers, casual travelers, missionaries, and would-be settlers arriving in the area after the 1821 independence. Even before that time they earned a reputation for being skilled, valiant mercenary soldiers, serving both government and rebel leaders. Concomitantly, the women, who were the chief agricultural producers, found markets among the same people.

At first the men traveled only on occasion, providing transport for both people and goods in their large seaworthy canoes, and as stevedores loading and unloading ships in the several ports. In Belize and Honduras they cut mahogany and dyewood, and in Guatemala they helped with the construction of buildings in the ill-fated colony of Santo Tomás (Blondeel Van Cuelebrouk, 1846). The migration gradually became more intense, some men traveling daily or weekly to and from their villages, others working seasonally, and still others virtually disappearing for months or years at a time. In the early 20th century they began working on ships carrying fruit—especially bananas—to the United States, and many elected to stay on there, working first on the docks in ports such as New Orleans, Mobile, and New York. Later, many signed on as seamen, cooks, or waiters on ocean liners (Sherar, 1973).

Women began to emigrate in large numbers in the 1960s. Small children were left with their grandmothers, and the households, which formerly contained three

generations of related women and their children, were increasingly composed primarily of only two—the middle generation living abroad (González, 1984). Emigrants originally sent money to care for both the children and the elderly, but too often the amounts were insufficient to provide what is needed for optimum health and well-being. Many Garifuna leaders have long recognized this problem, but there is no simple solution. The United States has not always offered the easy and inexpensive life that many expected, and as many emigrants are undocumented visitors, they must accept the lowest paying jobs and cannot take advantage of government sponsored assistance programs. Thus, they often do not have sufficient resources to share with those at home.

Social Factors

Garifuna society has long been characterized as “matrifocal,” meaning that women are prevalent and influential, especially in household and village affairs, and in maintaining ritual and other traditions (Kerns, 1983). Households are consanguineally based, centered on a group of related women and their children (González, 1970). This stems from two circumstances. First, there were only 496 men, 547 women, and 422 children upon arrival in Trujillo, Honduras in 1797 (González, 1988). None of the children were under three years of age, which meant that virtually every woman of childbearing age was at risk of pregnancy. High fertility would have been expected and desired under these demographic circumstances. Second, as described above, the out-migration of men became more frequent, and because their return and length of stay were always uncertain, mother–daughter households became the norm. Polygyny had been customary on St Vincent (Helms, 1981), and in Central America this developed into a system of serial monogamy for the women as various men came and went in their lives, while the men had temporary or lasting common-law wives in more than one village. The resulting pattern, which condoned multiple partners for the men, brittle unions, and the right of the woman to seek new partners as old ones disappeared, was beneficial in increasing fertility and in maximizing a woman’s ability to seek men who would be economically successful and supportive of her household (Brown, 1975; McCommon, 1982). It also contributed to widespread venereal diseases, and to difficulties in gender or psychological differentiation for the men (González, 1979; Mertz, 1977).

Political Factors

The Garifuna have until recently lived virtually outside the framework of national politics in Central America, although the circumstances have varied from country to country. In part, this was because they lived in relatively isolated villages on a sparsely settled coastline that others eschewed. They are readily identifiable by their color, their accents when speaking the dominant language, and by other cultural characteristics. Despite the fact that the general populations of both Honduras and Belize include a strong component of genes from Africa, the Garifuna are looked down upon, even by others with similar racial characteristics. In Guatemala, which has a much smaller “Black” population, they are feared and despised by the indigenous people, and either ignored by the others or appreciated only for their singing, dancing, and sexual prowess. Ladinos have nearly always held the important local offices, and as a class, hold a higher social position than Garifuna of comparable economic and educational status.

The Garifuna did not participate actively in Guatemala’s civil violence (1964–98), but the peace agreement of 1998, in promising to better the human and civil rights of minority peoples, specifically mentions the Garifuna as one of the beneficiary groups. This has helped politicize those still living in the country, and many have left the coast to attend university level courses in the capital city. Formerly this had been a career path open to and chosen by only a handful of others. Although basic literacy and fluency in a second language are nearly universal today, many cannot do advanced academic work owing to poor preparation—itsself the result of poor schools, inattention to studying at lower levels, lack of discipline, and expectations of emigration.

Politicization of Garifuna in Belize and Honduras began earlier, and although they do not vote as a minority block in either country, they are taking various actions to make their concerns known and addressed by the national governments. In this, they have been assisted by the United Nations and other organizations that bring together indigenous peoples of the world to share their concerns, ideas, and agendas.

Above the level of the extended family women wield considerable influence, but little political power. Only in Belize have women achieved public office at the national level, and that occurred more often a generation ago than now. New organizations aimed at strengthening ethnic

solidarity and pride are dominated by men, and women are now more often relegated to serving as secretaries and as spokespersons for the leaders.

MEDICAL PRACTITIONERS

In the villages now and previously, formal biomedical assistance is rare. The elders, as always, are a source of information on home cures, some of them based upon purchased remedies such as paregoric, aspirin, cough medicine, and even antibiotics, the latter, like most medicines, being available without medical prescriptions. In choosing these they may be advised by pharmacists, if there are such. Some villages have government-run clinics, which are consulted as a last resort. Traditional curers, who may be either men or women, include herbalists and diviners, as well as buwiyes. The latter are thought to have innate abilities and to be “called” to their profession, after which they undergo lengthy training with a practicing buwiye. As discussed below, they are usually consulted after home remedies are exhausted, or if the illness is suspected of having a supernatural cause (Cohen, 1984; Staiano, 1981).

A few Garifuna, including the second author, have taken university degrees in medicine, but they rarely practice in their home villages. Some have studied pharmacy, medicine or nursing at different levels in the United States, but they also have, in effect, left their traditional culture and people, and practice in cities. It is not known what percentage of their patients, if any, is Garifuna.

CLASSIFICATION OF ILLNESS, THEORIES OF ILLNESS, AND TREATMENT OF ILLNESS

Western (Hippocratic) medical ideas were first introduced by French missionaries in St Vincent in the 17th century, but these were of a pre-biomedical character, and became part of what is thought of today as traditional, or pre-scientific medicine. This lore included many or most of the medicinal plants still in use (Cosminsky, 1976), as well as concepts concerning “hot” and “cold” conditions of food and the body, “humors” and so on (Sanford, 1976).

Diseases and illnesses are classified according to whether they result from natural or supernatural causes. The former are often susceptible to treatment with home

remedies, including both herbal and chemical agents. Some of these are traditional, others recent introductions through biomedicine. If, however, the condition is not relieved, or if it returns frequently, a biomedical doctor may be consulted. If the symptoms persist, suspicion grows that either some living person has used obeah, or “black magic” against the patient, or that a deceased ancestor is feeling neglected and seeking to punish the sick one and to goad him or her into sponsoring one of several different rituals. All of these begin with a mass in the local Catholic church, and continue, either in the patient’s home, or in the case of the more elaborate ceremonies, in a special sanctuary reserved for such occasions.

But before a ceremony is prescribed, either a diviner or a buwiye may be consulted merely to advise as to the cause and the cure. As such, the buwiye is both priest and physician. In his latter role he or she may use a variety of techniques, some of ancient Arawakan origin, such as blowing tobacco smoke or aguardiente over the patient, or using ventriloquism to suggest the voices of spirits talking from the rafters (Glazier, 1980; Taylor, 1951). The buwiye’s knowledge and rituals have undergone modification over the past generation, largely through interactions with other Caribbean peoples in the United States, and probably stem from one or another African culture.

If a ceremony to placate an ancestor is prescribed and the patient does not comply, psychological consequences may ensue. The sick one may experience dreams in which the ancestor first beseeches, and later threatens to do even more harm if he or she is not bathed, or fed. The duration of a ceremony varies, but the activities always include drumming, singing, and dancing, and the offering of favorite foods to the deceased. It is expected that one or another participant will experience “possession,” a state of trance in which the spirit of an ancestor speaks to the congregation, offering advice, and information (González, 1995; Goodman et al., 1974; Howland, 1984).

In addition to seeking supernatural remedies for those illnesses caused by spirits, Garifuna may also seek help from their ancestors through the buwiye to address diseases such as cancer, for symptoms of mental distress, or for any other condition of unknown or misunderstood etiology. This compares with the use of prayers to various gods in other societies (González, 1966). Garifuna see no conflict between their primarily Catholic faith and the ritual honoring of their ancestors. Indeed, over the past generation more and more Christian elements have been included in the latter (González, 1963, 1966, 1988).

SEXUALITY AND REPRODUCTION

Garifuna have a reputation in Central America for what is perceived by others as promiscuous, guiltless, sexual freedom for both sexes. This has led, over the years, to the higher fertility mentioned above—a necessary element for survival of the group. Their reputation for sexual prowess has brought many European and American women tourists to the area seeking new experiences with the younger men. Some of these have taken their lovers home with them—a possibility that has made such encounters attractive for many men. Male tourists also seek partners—among both men and women, and sometimes these have led to lengthy liaisons.

Among themselves, heterosexual unions, whether permanent or fleeting, have long been the norm, but modernity and gay tourism have brought out what may have long been an unconscious homosexuality in some men. Psychologists may attribute this in part to matrifocality, which has penetrated the culture, as well as the household structure, in many ways (González, 1979; McCommon, 1982; Mertz, 1977; Munroe & Munroe, 1971; Sanford, 1976).

Children are desired by both women and men, the latter because they offer proof of their virility, even when they are otherwise disconnected from both the mother and the child. Women desire children to validate their femininity and maturity, and in an effort to tie the father(s) to them and their household, even though this is not always the result. Having children by more than one man increases the number of possible sources of income and other assistance, not only from the various fathers, but from the grandparents as well (González, 1969, 1988; McCommon, 1982). Beliefs about the afterlife also give impetus to reproduction, for to die without issue means that there will be no one to remember and care for one in the spirit world.

HEALTH THROUGH THE LIFE CYCLE

Pregnancy and Birth

Birthing in the villages usually occurs at home, assisted by a midwife, but in cities hospital or clinic births are preferred. Latin American food taboos related to hot and cold apply during pregnancy and the postpartum period, during which the mother is urged to rest, preferably in bed, for 40 days. The placenta is buried, in earlier times

in the floor of the house, but the amniotic sac, after careful examination for what it may reveal of the child's character, is dried, then wrapped in a red or black cloth to protect it and the child from evil spirits or living enemies (Idiáquez, 1982). The stump of the cord is also dried, preserved, and may be used for medicinal purposes during the child's lifetime.

The *couvade* appears to be an ancient, probably Arawakan, custom (Riviere, 1974), of which there are only traces today (Coehlo, 1949; Kerns, 1976; Munroe & Munroe, 1971; Munroe et al., 1973; Taylor, 1950). Fathers are still said to suffer some of the symptoms of pregnancy, such as nausea and labor pains, and they are advised to refrain from certain activities and foods, as well as sexual relations with other women, so as not to endanger the fetus.

Abortions are usually termed miscarriages, and both occur with some frequency. Many of them are never reported to authorities, so there is little information concerning them, but recent observations by the second author suggest they are now increasing, especially among younger women. Most women will admit to having lost children, either before or after birth. Stillbirths also occur with some frequency, for unknown reasons.

Infancy

Children are breast-fed, supplemented almost from birth with a pap made of manioc starch. Unfortunately, although this is thought to be especially nourishing, it provides only calories and tends to suppress the amount of breast-milk, leading to early weaning—often after only a few months, although many continue up to 2 years. The broths from boiling either meat or black beans, with bread, are offered after about 6 months, and the mother will pre-masticate other foods before offering them to a child without many teeth (González, 1963; Jenkins, 1984).

Respiratory and intestinal illnesses, exacerbated by undernutrition, are two of the most common ailments of childhood. Vaccinations against the common childhood diseases are available through government clinics, and most children are so protected. Still, infant mortality is relatively high in the villages, where biomedical assistance is not always available. Sickle-cell disease may also contribute to many early infant deaths. Protection against the evil eye and other malevolent dangers includes painting blue crosses upon the forehead, and the wearing of amulets containing various charms.

Childhood

Children are cared for primarily by women—the mother, grandmother, older sisters, and aunts—but men who may be resident in the household (e.g., mother's brothers) will be called upon to help discipline little boys when the others fail to control their behavior.

From the time children are able to walk without assistance and to understand directions, they will be given chores, such as carrying small pails of water and other burdens, running errands in the neighborhood, or selling homemade candy in the streets.

Adolescence

In early adolescence, when they can be really useful in household and productive activities, girls and boys may be passed around within the larger kin group whenever help is needed. A child learns to feel comfortable sleeping and eating in several different households (Sanford, 1971).

Adulthood

Despite the relatively high status of women, many of them suffer physical abuse by the men with whom they consort, but since sexual dimorphism tends to be slight, the women are not adverse to striking back—but usually not enough to risk losing the man. Due to the migrant labor customs, men are in short supply between late teenage and retirement. Women often vie with one another for a man's favor, sometimes coming to blows, although shouting matches, including name-calling, insults and denunciations, are more common.

Most people have several different mates during their lifetimes, but as late middle age approaches, many of them settle down into a monogamous relationship, that may or may not include co-residence. It is not uncommon for such couples to go through a legal marriage ceremony, often just days or even hours before the death of one of them.

The Aged

The elders are respected, but often neglected or ignored by their adult offspring or grandchildren. In return, or in order to secure a favor, an individual may threaten to haunt their children after death.

Dying and Death

With advancing age, references to “taking a trip”—a euphemism for death—will be heard. Roman Catholic beliefs concerning what happens later, are blended with those from other traditions, some very old and probably of Amerindian origins, and others clearly showing the influence of more recent associations with other Caribbean peoples of African descent (González, 1995).

Deaths of infants and of the elderly are considered “normal,” but persons in the prime of life are not expected to die, and when they do some evil is suspected—either from living enemies, a variety of evil spirits, or from jealous or angry dead ancestors. Even when the death is recognized as the result of an incurable illness or an accident, it is thought that these misfortunes may have been brought about by one or another of the above agents.

Immediately after death the women begin to keen; in the villages the news may be further announced by drumming, and relatives and neighbors begin to arrive for help. If there is a resident Catholic priest, he may be called to administer the last rites, but this is not always done. The body is washed and dressed, placed in a wooden coffin, and set upon a table for viewing. An allnight wake is held, during which paid mourners join the closest family members, offering prayers at intervals (Cayetano, 1977). Coffee or tea and sweet bread is offered at midnight to visitors. Burial occurs early the next morning in the community cemetery. In Belize in the 19th century, missionaries reported that there were rituals on the beach that first night, suggesting that the deceased would be leaving by sea, but this is no longer done.

On the ninth night after death, which today is usually held on a Saturday night, another wake is held. This is considered to be so important that it is attended by nearly the whole community, as well as by friends and relatives from other villages, and even from overseas. It is believed that the soul wanders the earth, and may present a danger to the living, until this final ceremony. The atmosphere is not one of grief, but of celebration, including drinking and feasting, traditional drumming and dancing, gambling, and formal story telling (McCauley, 1981). The custom has been reported from societies throughout the Caribbean area, as well as in Ireland, and its origin among the Garifuna is not well understood. In this way, the community shows the deceased that she/he is remembered, but that it is now time to leave the living in peace (González, 1995; Howland, 1984).

CHANGING HEALTH PATTERNS

The Garifuna have been in contact with Western civilization for some 300 years. Although some traditional beliefs and practices remain, most people today are aware of and respect biomedicine. Most communities have running water, electricity, government schools, television, telephones, fax machines, and computers. Thus, everyone knows something about bacterial and viral infections, diabetes, intestinal parasites, cancer, high blood pressure, and the like. They do not, however, always connect these or their own symptoms with poor hygiene or nutrition, or with potentially damaging behavior patterns involving substance abuse or irresponsible sexual activity.

Many young Garifuna believe themselves to be immune to AIDS, even when they prove to be positive for HIV. Ironically, despite this belief, there is considerable stigma attached to having the disease, so it is probably under-reported. Once diagnosed, many believe it to have been a punishment from God or from the ancestors. Castillo (2002) believes it to be the major cause of death among adult Garifuna in Livingston today. It is also ravaging the communities in Belize and Honduras. It is also no doubt responsible for a good bit of morbidity among adults, including probable psychological problems that go undiagnosed.

Genetically related diseases such as diabetes, arthritis, and sickle cell anemia are similarly less well understood, and are sometimes not recognized for what they are. Recent studies in both Honduras and in Guatemala indicate that drug use and alcoholism are increasing, as is obesity. All are undoubtedly related to aspects of the modern lifestyle, including relative sedentariness, transnationalism, migration, poverty, tourism, and a general decline in the quality of life.

Those Garifuna who do make these connections in general and in their own lives, live in the cities of both Central America and the United States, and at the most visit the villages only occasionally and for short periods. In their effort to learn more of their own roots and traditions, in what anthropologists call a “nativistic” or “revivalistic” movement (Sanford, 1974), they concentrate on the more romantic symbols of their past, and fail to recognize the sometimes-serious problems that beset the people left behind. Local leaders have become more sophisticated in political matters, and in Honduras and Belize there are efforts underway to improve economic

opportunities so as to reduce emigration. However, the remaining Central American communities need all the help they can get if the people and culture are to survive.

LOCATION AND LINGUISTIC AFFILIATION

Greece is located in the southeastern corner of Europe and occupies the southernmost tip of the Balkan peninsula. Its territory of 131,990 km² also includes some two thousand islands, only a few hundred of which are inhabited. Greek, the official language, is a member of the Indo-European family.

OVERVIEW OF THE CULTURE

Greece has a population of approximately 10.6 million. With over four million of its inhabitants residing in Athens, the nation's cultural and political center, and another million in Thessaloniki, Greece is a highly urbanized country. The rural population has been steadily declining since at least World War II and comprises less than 20% of the total population. Today, only about a quarter of Greeks are employed in agriculture. Another quarter work in industry and construction, and nearly half of the population works in the service sector. Tourism, both internal and international, is one of the most dynamic areas of the economy. In 2000, per capita GNP had reached \$15,400. Unemployment, which officially hovers

at about 10% of the work force, is a serious and persistent problem (United Nations Development Program, 2001).

Greece was established as a nation-state in 1832, following a protracted war of independence against the Ottoman Empire. The new kingdom of Greece embraced only a fraction of the Greek-speaking population under Ottoman rule however, and irredentism was a recurrent theme in the century that followed. By the early 20th century, expansion of national territory through war, as well as an exceptionally high rate of natural increase, resulted in tremendous population growth. This growth was not easily absorbed by Greece's relatively underdeveloped economy, which consisted of large plantations producing export crops such as currants and small, fragmented peasant holdings growing wheat, olives, and grapes largely for subsistence.

Throughout its history, Greek society has been characterized by sizable communities of Greek-speakers scattered far beyond the lands of its circum-Aegean core. In the 19th century, diaspora Greeks, many of whom were wealthy and well educated, played an important role in the struggle for Greek independence. Beginning around 1890, a massive wave of emigration sent 500,000 Greeks, 90% of them men, abroad, principally to the United States. A second significant wave of emigration began around 1950, when the economic hardship of World War II and the Civil War that followed prompted many to seek work in Canada, Australia, and Western Europe. By the 1990s, however, economic growth had transformed

Greece into an attractive destination for thousands of migrants from Albania and the former Eastern bloc countries.

Political instability characterized much of the 19th and 20th centuries. The Greek population suffered terribly from the occupations of German, Italian, and Bulgarian troops during World War II. In 1941–42, close to 200,000 people died of famine. The hardship of the war was followed closely by a devastating Civil War that finally ended in 1950. Hopes of political stability were shattered when a military junta seized power in 1967. Its demise in 1974 signaled a new era in Greek society and politics, as peaceful democratic elections became routine, and new social movements, such as feminism, flourished. Greece's full membership in the European Union in 1981 has been a major impetus for further social and political changes (Clogg, 1979; Gallant, 2001).

The family is the central institution of Greek culture. Individuals derive their primary identity from their family, and ideally, family members provide lifelong support, love, and care to one another. Marriage is regarded as the destiny of men and women, and children are highly desired as sources of happiness in themselves and because they perpetuate the family. Most families are nuclear, but residence patterns vary by region. On the mainland, and especially among shepherds, couples live virilocally, sometimes in the same house as the husband's parents. On the islands of the Aegean, the practice of providing a dowry house to daughters commonly results in uxorilocality and close-knit networks of related women. In urban areas, residence tends to be neolocal (Loizos & Papataxiarchis, 1991).

Nearly all Greeks belong to the Greek Orthodox Church. Although everyday practices do not necessarily correspond to the teachings of the Church, the sensibility of Orthodoxy permeates most aspects of Greek life. Under Ottoman rule, religion was an important means of identifying and governing subject populations. With the founding of the Greek nation, Orthodoxy was appropriated by the state to help forge a sense of national identity (Just, 1989).

Greek cultural identity is premised on the often competing pillars of Greek Orthodoxy, which traces its heritage through Ottoman rule to Byzantium, and the heritage of Classical Greece, as idealized by Western European thinkers (Herzfeld, 1982). The tension between these two legacies has led to what some observers have called a "perennial crisis of national identity." In recent

years, integration into the European Union has fostered an increasingly cosmopolitan orientation that favors modernization and development.

THE CONTEXT OF HEALTH: ENVIRONMENTAL, SOCIAL AND POLITICAL FACTORS

Greece's health indicators are among the best in the world. Life expectancy at birth in 2000 was 78 years, higher than in the United States and several Western European countries. In 1999, the infant mortality rate was 6 per 1000 live births, and the under-five mortality rate was 7 per 1000. The probability of a female born between 1995 and 2000 surviving to age 65 years was 91.4%; for a man, it was 81.6% (United Nations, 2001).

The economic development of the second half of the 20th century is closely related to the nation's positive health profile, but it cannot fully explain Greece's advantage over many far richer nations. Among the reasons for Greece's favorable indicators are: (1) The continued social significance of strong familial ties, which provide economic and psychological support across the life cycle. Family members commonly rally around pregnant women and new mothers, provide childcare for children when both parents work, and absorb and support the unemployed and the aged. (2) A diet that, despite considerable increase in meat consumption with the growing prosperity still includes abundant consumption of fresh fruits, vegetables, nuts, and legumes. In recent years, the positive publicity surrounding the health benefits of the so-called "Mediterranean Diet" has helped reverse a local trend away from some traditional foods, such as olive oil. (3) The low rate of divorce and the almost complete absence of births outside of marriage, which elsewhere have been associated with poor health outcomes for infants and children. Abortion is an integral part of Greek contraceptive culture, and pregnancies either lead to marriage or end with abortion. (4) Universal access to health care through the National Health System (ESY, established in 1983), as well as to subsidized prescription drugs.

Beginning in the early decades of the 20th century, and accelerating rapidly after World War II, Greece has witnessed a marked decline in the birth rate. At 1.3 births per woman, the total fertility rate is among the world's

lowest. In conjunction with the related “graying” of the population, the low birth rate, known in Greece as “the demographic problem,” has become the focus of much official concern and policy debate (Georges, 1996).

Greeks have high frequencies of the genes for the blood disorders beta thalassemia (8% of the population) and G6PD deficiency, both of which have been linked to the endemic malaria that plagued the region until fairly recently. G6PD deficiency is a red blood cell deficiency that can result in acute hemolytic crisis, often provoked by eating fava beans, a food commonly consumed in rural areas, especially during the Lenten period. To avoid the stigma attached to this inherited disorder, hemolytic episodes were popularly attributed to “fava bean poisoning” (Trakas, 1981). Children who inherit the thalassemia gene from both of their parents develop a serious disease characterized by severe anemia starting at a few months of age, distinctive deformities of the facial bones and enlarged spleens. They can only survive with the aid of frequent blood transfusions. Heterozygote individuals manifest only mild anemia and can live normal lives. In some regions of Greece, such as the Dodecanese Islands, up to one third of the local population are carriers of the genes for G6PD deficiency or thalassemia. The Greek government has mounted highly successful public health campaigns to screen for the trait and educate the public about thalassemia, known popularly as the “stigma” in Greek. As a consequence of aggressive prenatal screening, fewer than ten infants a year are born with thalassemia major.

MEDICAL PRACTITIONERS

Over 90% of the Greek population are covered by some form of health insurance to which both employers and employees contribute. Of the approximately 35,000 physicians working in Greece, two thirds are employed by the National Health System and one third work in full-time or part-time private practices. There is an ongoing oversupply of medical doctors in Greece, many of whom may wait years for a job opening in the public sector (Colombotos & Fakiolas, 1993).

Lay practitioners such as bonesetters, practical midwives and herbalists were important providers of health care in rural areas through the middle of the 20th century. Today, however, they are completely extinct. In recent years, complementary healing traditions such as

homeopathy have become available in the major cities as alternatives to biomedicine.

CLASSIFICATION OF ILLNESS, THEORIES OF ILLNESS, AND TREATMENT OF ILLNESS

The biomedical model of disease is unquestionably hegemonic in contemporary Greece. Many older beliefs about demonic forces and spirits as the causes of serious illness have almost completely disappeared. Nevertheless, classification, etiology, and treatment of illness are characterized by a situation of medical pluralism, as biomedicine coexists with longstanding and persistent humoral models, religious healing, and belief in the evil eye and witchcraft. Furthermore, aspects of the biomedical model display specifically Greek inflections.

Demonic Forces

Up until the middle of the 20th century, many Greeks living in rural areas maintained belief in a variety of demonic forces known collectively as the *xotika*, forces existing “outside” (*exo*) the bounds of Greek Orthodox Christianity. Haunting the woods, streams, and crossroads beyond the protected enclosure of the community, these forces were prone to attack people during liminal periods in the life cycle, particularly pregnancy, birth, and the postpartum, and at the time of one’s wedding. Unless protected by symbols and objects associated with the Greek Orthodox Church, such as crosses, icons, amulets, phylacteries, holy water, or olive oil, a person encountering these demonic forces could fall seriously ill or become paralyzed, lose their sanity, and eventually die. These beliefs today are chiefly found among the oldest Greeks, who only reluctantly divulge them to avoid the derision of the younger generations (Stewart, 1991).

Humoral Pathology

Humoral understanding of health and illness underpinned many of the everyday practices of Greeks until relatively recently and still guides aspects of popular health care. Humoral theory was premised on an essentially Galeno-Hippocratic approach to the body that understood health and illness prevention in terms of maintaining an

equilibrium between the opposed qualities of “hot” and “cold.” These qualities could be literally thermal, as in cold currents of air or water, or metaphorically so, as in the symbolically “cold” valence of particular foods, such as lemons. Illness was caused by a two-step process: first, a person became vulnerable when their body’s thermal balance was somehow disturbed; then, exposure to an assault of excessive “hot” or “cold” precipitated an episode of illness. Diagnosis was normally a retrospective process that reconstructs a person’s recent history of vulnerability and exposure to specific environmental insults. Deducing the etiology of an illness and deciding on a diagnostic label, in turn, pointed the way to appropriate therapy through the application of the “principle of opposites”: illness caused by “cold” is treated with “hot” therapies, and vice versa. This humoral logic persists today, and is implicit in many daily practices whose aim is to protect the body from exposure to cold assaults.

Evil Eye

Another common cause of illness is the evil eye, *to kako mati*. The evil eye is the conscious or unconscious product of human envy. Its vector is a psychic force that emanates from the eyes. Ultimately, the evil eye derives from the devil: it is the devil’s work if people are envious and covet the good fortune or possessions of others (Campbell, 1964; Herzfeld, 1986). Once struck by this malignant force, the person who is the object of envy may take ill, or if the coveted object is inanimate, a car, for instance, it may begin to malfunction (Stewart, 1991). The evil eye may also be inadvertently caused by more benign admiration, even on the part of those closest to a person and who otherwise sincerely wish them well. Whatever the origins and intentions, the harmful consequences are the same: headaches, body aches, depression, and severe illness (Blue, 1991). To forestall the undesirable effects of the evil eye, and to avoid being blamed for causing another’s misfortune, one should either avoid making compliments, especially of babies and children, who are thought to be especially vulnerable to the evil eye, or be thoughtful enough to bracket one’s admiration with an apotropaic gesture: formulaic spitting, or making the sound of spitting (“ftou”) three times, or uttering a ritual phrase.

Religious Healing

Religious healing in Greece encompasses a wide variety of practices, ranging from supplications and promises in the

form of vows made privately to a saint or to the Panayia, or All Holy One, as the Madonna is most commonly addressed in Greek, to dramatic public displays of self-sacrifice performed during pilgrimages to specialized shrines (Dubisch, 1995). Although women predominate, both genders participate in healing rituals for the gamut of illnesses, from mouth sores (Stewart, 1991) to cancer. Some holy personages specialize in particular ailments or body parts, while others, such as the Panayia, have more general capabilities and may be called upon for all sorts of ills. In addition, the Panayia has her local manifestations, and some of these may be specialists in particular illnesses.

Mental Health

Mental illness, popularly associated with violent behavior, is highly stigmatized and infused with strong sentiments of shame for both the patient and his or her family. Severe mental illness is believed to be inherited through the blood. Thus, the mental illness of one family member may affect the chances of marriage of others in the family. For this reason, efforts may be made to conceal mental illness or to isolate the afflicted family member in a mental asylum.

Mental illness is commonly expressed through somatic complaints, such as headaches and chest pains, and through culturally specific idioms of distress, such as “nerves” *nevra*, and lack of *kefi*, roughly glossed as a positive mood that is associated with high spirits and zest for life. To avoid the stigma associated with the profession of psychiatry, sufferers usually seek care from internists, who will often prescribe tranquilizers. They may also prefer to visit a neurologist who will treat their “nerves.” Mental illness may also be attributed to the evil eye, possession by the devil, or to black magic, in which case, religious and magical practitioners may be consulted in addition to internists and psychiatrists. Pilgrimages may be undertaken to holy sites to pray and make votive offerings to saints and to the Panayia for the patient’s recovery (Blue, 1991).

Greek psychiatrists, aware of the intense stigma attached to mental illness, often avoid precise diagnoses, such as schizophrenia, in favor of more vague, but less socially damaging labels (Blue, 1991).

SEXUALITY AND REPRODUCTION

Sexual norms and attitudes have changed dramatically over the last few decades. In the past, chastity was a

highly valued component of an unmarried woman's identity and reflected positively on the reputation and honor of her entire family. Men, in contrast, were believed to be physically incapable of enduring abstinence for any length of time, and their sexuality was not confined to marriage in the same way as was a woman's (Hirschon, 1989).

In contemporary Greece, the historical value placed on virginity is often described as a "taboo," a relic of the past that has been transcended. Sexual intercourse is now a routine element in courtship, and many brides are pregnant when they marry (Loizos & Papataxiarchis, 1991). However, Greeks have an almost negligible rate (approximately 1%) of births outside of marriage, as unwanted pregnancies are almost always aborted (Agrafiotis & Mandi, 1997).

The one to two child family is today the norm, if not precisely the ideal. Family size is limited primarily through the use of condoms, coitus interruptus and abortion. Abortion has been legal since 1986, but safe medical abortions were available and widely resorted to decades before legalization. Greek women and couples have a marked aversion to medical means of contraception: only 2% of Greek women use the pill and another 7% use the IUD. Abortion is used as a backup when the less reliable, but vastly more popular methods of birth control fail, or fail to be used. An estimated 200,000–300,000 abortions occur each year, in a country with roughly 100,000 live births. Across the political spectrum, the low birth rate and high abortion rate have caused alarm, and concerns for the continuity of the Greek nation and "race" are commonly voiced in the media and other public arenas (Georges, 1996).

Homosexuality, especially among men, and in particular for the passive partner, was highly stigmatized in the past. In recent years, the loan word "gay" has begun to replace the older, pejorative terms and new sexual identities are being articulated. The islands of Mykonos and Mytilene have emerged as popular destinations for both internal and international gay and lesbian tourism.

HEALTH THROUGH THE LIFE CYCLE

Pregnancy and Birth

In the prewar period, pregnancy was not regarded as a state that required the care, advice, and esoteric knowledge of specialists. Pregnancy was nonetheless a condition marked

by special behaviors that were carefully observed by the pregnant woman and those around her. Because children were regarded as sacred "gifts from God," the pregnant woman, as bearer of this gift, was herself imbued with a sort of sacred aura. As a consequence, not only her immediate family and wider circle of kin, but her co-villagers generally, treated her with special consideration, forbearance, and respect. Pregnant women, for example, could demand and expect special foods to satisfy their cravings. After their fifth month or so, they could sit comfortably with their legs apart, an immodest posture that would otherwise certainly have provoked criticism and gossip (Chryssanthopoulou, 1984).

If carrying a child conferred a sacred aura and a degree of behavioral latitude on a woman, it also increased her vulnerability to a panoply of dangerous forces. Pregnancy was among those desirable states and qualities, such as youth and beauty, which acted like magnets for demons eager to attack and destroy both the woman and the new life within her (Stewart, 1991). Thus, by virtue of her pregnancy, a woman entered into an endangered state from which she would emerge only at the completion of the 40-day postpartum period.

By far the most significant dietary rule during pregnancy concerned the aroma of cooking food. If a pregnant woman smelled a food as it was being prepared, she was obligated to taste at least a bite. Failure to do so could cause something to go badly awry with the pregnancy. In the worst case, a miscarriage could result; in the best of outcomes, the baby would be born with a birthmark in the shape of the food not eaten on the precise spot that its mother happened to scratch after catching the scent of the food.

In the past, each village had at least one practical midwife, known as the *mammi*. The midwife assisted and supported the woman throughout her labor and delivery, and visited her daily during the week following the birth to examine her and the infant, wash the infant's clothes, and help clean the house. When called to assist a birth, the midwife examined the woman internally to determine her dilation and to ascertain the baby's position. If the baby did not present head first, the midwife attempted to turn it internally by inserting her fingers and manipulating the baby's limbs. External version was also performed by having the woman lie on a blanket held by several people who then tossed her in the air. To prevent tearing and to help women achieve an optimal state of "openness" essential for a successful birth, midwives massaged the perineum

with olive oil or soap. The auspicious state of openness was also sympathetically invoked by always leaving the windows and doors of the house slightly open during the birth. In many parts of Greece, husbands removed their clothes, unbuttoned their shirts, and loosened their belts for the same purpose (Chryssanthopoulou, 1984).

Women usually gave birth in a sitting or semi-reclining position, often astride special birthing stools. To help the woman to push more effectively, in the Dodecanese Islands, a rope was tied to the iron window bars for women to pull down on. In Northern Greece, midwives put some of the exhausted woman's hair in her mouth, causing her to gag and automatically contract her abdominal muscles.

Postpartum. The postpartum period was the most richly elaborated dimension of a woman's procreative experience. The 40-day seclusion period represented a kind of symbolic death and entombment after the act of physiological birth. During this period, the woman who had just given birth, known as the *lehona*, was said to live with "one foot in the grave." Ideally, she should not leave her house for the full 40 days. Confinement protected both her and her newborn from the many dangers, both spiritual and physical, that literally threatened their lives. Safely tucked away within the house, whose every means of entry was guarded by layers of protective devices, woman and infant were buffered from the spiritual attack of the demons whose malevolent designs, activated by her pregnancy, were now driven into high gear with the arrival of new life. At the same time, the *lehona* herself was considered polluting and her isolation and confinement were necessary to prevent the endangerment of others as well. Only at the conclusion of the postpartum period, marked by the special Orthodox ritual of "churching," would both woman and child be safely incorporated into the social life of the community.

Today, pregnancy and birth have become fully medicalized. In distinct contrast to the prewar period, elaborate attention is now focused on the prenatal period as opposed to the postpartum. Women are intensively monitored throughout their pregnancies by a battery of procedures. Fetal ultrasound imaging is universal, and on average, Greek women are scanned four times per pregnancy. The rate of birth by cesarean section has risen rapidly in recent years, from 16% in 1988 to about 40% today. There is no "natural childbirth" movement in Greece, and all births now occur in the hospital (Georges, 1997).

Infancy

In the past, infants were not immediately nursed after birth. The colostrum, the clear, nutritious fluid that precedes the first flow of milk, was always expressed and discarded. In contrast to the colostrum, which, perhaps because of its transitional status, had an ambiguous valence that led to its avoidance, breast milk was regarded as a pure and even quasi-sacred substance. It was used to cure eye ailments of all sorts (Blum & Blum, 1965). Until its mother's milk came in, the infant was spoon-fed chamomile tea. Chamomile also helped the baby expel the meconium, its first, dark sticky stools, and clear the phlegm from its throat. Although the infant was a highly desirable, even quasi-sacred presence, these effluvia were considered "dirty," and had to be eliminated from its body before nursing could begin. Chamomile tea was also occasionally fed to the baby afterward as well, especially if it had a stomach problem. Mothers nursed their infants exclusively for the first 5 or 6 months. At that time, weaning foods, often made of toasted wheat flour, were introduced.

On the third, fifth or seventh day after birth, depending on the region of Greece, a "salting" ritual was performed. The infant's body was rubbed with salt and then bathed. Salt, which has positive connotations and protective powers in Greek culture, helped the baby develop physical toughness, good sense and a logical mind, and "cured" its skin, just as meats were cured for preservation, to prevent rashes.

Infants were wrapped in three layers of inner cloths and then swaddled from head to toe. Swaddling helped the baby's legs to grow straight (although more than one woman I interviewed during my research observed that her child had turned out bow-legged, nonetheless). Swaddling also effectively immobilized the infant and made it easier for women to mind as they went about their chores. When mothers removed the swaddling cloth to change or bathe their babies, they vigorously stretched the infants' limbs to help them develop properly. Stretching was done according to a standard formula, with each leg or arm first gently tugged and then crossed over to touch the opposite leg or arm.

From its ears to its feet, the infant's body was the focus of intense attention and concern, and mothers followed a number of practices to encourage its proper physical and esthetic development. In the weeks following the birth, the new mother was fed plenty of soup made from roosters so that the baby's neck would become strong. To

insure that the baby developed a well-shaped head and to prevent colds, a special head covering was worn continuously for at least the first 2 months. To prevent one side of the head from becoming flatter than the other, mothers took care to turn their swaddled infants at least twice a day and after each nighttime feeding.

Childhood and Adolescence

Today, as in the past, considerable vigilance is exercised to prevent children from catching a chill. As with infants, young children may be bundled in layers of clothing that from an American perspective would seem excessive (Sutton, 1998). In the past, girls in particular, were admonished not to stand in pools of cold water or walk barefoot or sit on a cold tile floor, lest the currents of cold air or water attack their womb and cause health problems or even infertility later on. In the past, young girls generally were not told about menstruation, and menarche was often a frightening experience.

Improvements in nutrition and sanitation have resulted in a secular increase in height among Greeks. Average height over the last 70 years has increased 9 cm for boys and 7 cm for girls. Mean age at menarche has decreased to 12.1 years. In recent years, childhood obesity has become increasingly common (Papademetriou, 1999).

In contemporary Greece, older children and adolescents are subjected to considerable stress from the demands of the highly competitive educational system. To pass the grueling exams that until very recently were required for entry into the prestigious national university system, students had to study long hours and attend private cram schools in the afternoons and evenings.

Adulthood

As in the past, marriage continues to mark the passage to full adulthood for Greek men and women. Even in contemporary Greece, marriage is usually the first time that individuals will establish an independent household.

Patterns of parenting have undergone massive changes in the postwar period. Older gendered idioms of maternal suffering and sacrifice have been largely replaced by the discourse of “stress” and “anxiety,” as likely to be heard from fathers as from mothers. Both motherhood and fatherhood have been profoundly rewritten, each in their own ways, by the child-centered, emotionally-intensified, financially taxing, consumerist

model of contemporary parenting. The Greek context stands out for the intensity with which children’s education is culturally valued as a means for confronting an increasingly uncertain future (Tsoukalas, 1977). The cultural expectation that parents will make every effort to assist children in obtaining formal schooling as well as the “shadow education” provided by private cram schools has generated considerable stress and anxiety for parents. To facilitate their children’s educational advancement, mothers may forego their daughters’ help with housework and fathers may work extra hours or take a second job to pay for their children’s private classes. In many parts of Greece, an added burden is the expectation that parents will provide their daughters with a dowry, often in the form of an apartment or house.

Menopause. Middle-aged Greek women regard menopause with some ambivalence. Because the regular flow of blood in the form of menses is an important mechanism for cleansing a woman’s body and renewing her health, the cessation of menses is seen by many older women as a harbinger of health problems. On the other hand, menopause puts an end to the constant worry about unwanted pregnancy and the need for abortions, especially acute among Greek women because of the lower reliability of the forms of the most popular birth control methods. Menopause remains largely unmedicalized in contemporary Greece (Beyene, 1989).

The Aged

Institutionalization of the infirm elderly is rare in Greece. The aged are usually cared for by their families, and increasingly, by immigrant home caretakers. Grandmothers in particular often provide valuable household labor and assistance with childcare and housework that enables their daughters to work full-time.

Dying and Death

In rural areas of Greece, a priest is summoned to pray over the dying person and offer communion. At the moment of death, the soul leaves the body through the mouth. The body of the deceased is washed, dressed in new clothes, and laid out in the house. The closest female relatives express their grief by donning black clothes, and kerchiefs, crying and singing heart-wrenching laments known as *miroloyia*. The deceased must be buried within

24 hours, in a loosely made wooden coffin that will facilitate decomposition. After a period of 3, 5 or 7 years, a rite of exhumation is performed, after which the bones of the deceased will usually be deposited in the community ossuary. The condition of the exhumed bones reflects the moral and spiritual status of the dead: clean white bones indicate that sins have been forgiven and that the soul of the deceased has entered paradise (Danforth, 1982; Panourgia, 1995).

CHANGING HEALTH PATTERNS

Into the early decades of the 20th century, the major killers were infectious diseases such as malaria, which affected an estimated two thirds of the Greek population, tuberculosis, and diarrhea. Today, the top causes of mortality in Greece are the well-known “diseases of civilization”: heart disease, cancer, and stroke. To date, Greece has among the lowest rates of HIV/AIDS infection in the European Union. Automobile accidents are a major cause of death. Smoking rates are also very high.

The Hadza

Frank Marlowe

ALTERNATIVE NAMES

Hadzabe, Hadzapi, Hatsa, Tindiga, Watindiga, Kangeju, Wakindiga.

LOCATION AND LINGUISTIC AFFILIATION

The Hadza are located at approximately 3° south, 35° east, around Lake Eyasi, North Tanzania, Africa. Their language, Hadzane, has clicks, and for that reason has often been classified with the San languages of southern Africa, but may be only very distantly related (Sands, 1995).

CULTURAL OVERVIEW

The Hadza are nomadic hunter-gatherers who live in a savanna-woodland habitat around Lake Eyasi in northern Tanzania (Woodburn, 1968). They number about 1,000 (Blurton-Jones, O'Connell, Hawkes, Kamuzora, & Smith, 1992), of whom many are still full-time foragers and almost none of whom practice any kind of agriculture. Men collect honey and use bows and arrows to hunt mammals and birds. Women dig wild tubers, gather baobab fruit, and berries. Camps usually have about 30 people and move about every month or so in response to the availability of water and berries and a variety of other reasons, such as a death.

The Hadza are very egalitarian and have no political structure, indeed they have no specialists of any sort (Woodburn, 1979). There is a slightly greater respect afforded to older people but not very marked compared to that in other East African societies. One manifestation of this respect is the fact that camps are usually referred to by the name of some senior man, usually in his 50s or 60s. The core of a camp, however, tends to be a group of sisters, one of whom the man has long been married to. There is no higher level of organization than the camp and people move into and out of camps with ease. Post-marital

residence is best described as multi-local. Of those marriages where one spouse had parents living in the same camp, in about 60% it was the wife, 40% the husband (Woodburn, 1968).

There are no clans, or unilineal kin groups of any kind. Descent is traced bilaterally with overlapping kin ties so that any Hadza can usually decipher some kin connection to any other. Generation and gender are distinguished. For example, gender is distinguished among grandparents but matrilineal and patrilineal grandparents are not distinguished (though a suffix can be added to distinguish them). Cousins are distinguished by gender but matrilineal and patrilineal are not distinguished, nor are parallel distinguished from cross-cousins. The term for a female cousin is the same as for sister and male cousin the same as brother, though in both cases, they can be distinguished from siblings with a prefix. A distinction is made between maternal and paternal aunts and uncles. Father's brother is called by the same term as father, which may be related to the fairly common practice of the levirate in which a man marries his dead brother's widow. Mother's brother is called by a different term than father. Maternal and paternal aunts on the other hand, are both called by the same term as mother. When personal names are used, there is only a given name. In recent times, when asked to give a surname by government officials, missionaries, or researchers, Hadza use the first name of the father as the child's second name.

There is no organized religion and no belief in an afterlife. There is a cosmology with the sun and moon in the role of mother and father of all the stars. There is a creation myth that explains how people came to be, and how there came to be different tribes. Religious symbolism is associated with epeme meat (the heart, kidney, back, and genitals) of larger game animals. There is a ritual epeme dance performed at night. Men perform one at a time, stomping and singing and whistling to the women who sit and return their calls. The man attempts to rouse the women into getting up and twirling around him. There must be no moonlight, nor firelight, but must be pitch dark. The women try to guess who the man is through the

call and shout interchange and his anonymity allows them to interact with him in a way they would not otherwise do, suggesting sexual overtones.

There are several different neighboring tribes of farmers and herders, the Nilotic-speaking Datoga and Maasai, the Cushitic-speaking Iraqw, the Bantu-speaking Isanzu, Iramba, and Sukuma. Since Hadzane is in a completely separate linguistic phylum, this means there are four different language phyla represented, which is a high degree of linguistic diversity for such a small area. Some of these neighboring tribes have been in the area for a long time, the longest being the Iraqw, who moved down from Ethiopia 2,000–3,000 years ago. Relations between the Hadza and their neighbors are somewhat hostile but do involve some trading. For example, the Hadza give the Datoga honey which is made into beer and the Hadza in return get some beer or meat. The Hadza also trade meat and snakebite medicine for iron, cloth, and food. The Hadza resent the encroachment of the pastoralists, especially during the dry season when their herds can drink up all the water and eat up the plants needed to support the wildlife the Hadza hunt. In days past, Hadza would occasionally hunt a cow belonging to the pastoralists but if caught, would be hunted down and killed by a posse of pastoralists. When the first European explorers traveled in Hadza country, the Hadza would hide, which was probably their response to many outsiders (Marlowe, 2002b). Obst, the first person to write about the Hadza who actually met them, was told that around the turn of the 19th century the Maasai would hunt and kill Hadza (Obst, 1912).

There is no written Hadza language and until very recently few Hadza had had any schooling. Today, about half of the Hadza have been to school for a year or two. Only some of those who have attended school know their ages so we have to guess at their ages. In the late 1950s, James Woodburn collected genealogies, in the 70s, Lars Smith began collecting demographic data and this was continued from 1982 on by Nicholas Blurton Jones (Blurton-Jones et al., 1992). Thus, for those who were born from the early 60s or 70s, we know their ages well. In the late 1960s a team of researchers did an anthropometric study including measurement of color blindness, blood pressure, cholesterol, levels of certain diseases, among other things (Barnicot, Bennett, & Woodburn, 1972; Barnicot & Woodburn, 1975). Only recently has any genetic research been conducted and results are yet to be published.

THE CONTEXT OF HEALTH: ENVIRONMENTAL, ECONOMIC, SOCIAL, AND POLITICAL FACTORS

The most important fact about Hadza health is that they are hunter-gatherers who live wholly outside during the half of the year when it is dry and only sleep in minimal grass huts during the rainy season. They occupy an area of about 2,500 km² at a population density of about 0.24/km² (Blurton-Jones et al., 1992). They live in camps that average 29 individuals and move about 10 times per year, though the number of moves is slightly decreasing these days (Marlowe, 2002b). Because they live in the open at low densities and move frequently, they are less vulnerable to many of the contagious diseases that spread among their farming and herding neighbors, who live indoors. In 1964, soon after independence, most Hadza were rounded up by the army and forced to settle at Yaeda Chini where a school and clinic were built in order to settle and modernize them. Within a few months however, many Hadza caught contagious diseases and many died with, “respiratory and diarrheal infections” (McDowell, 1981, p. 7). This caused the Hadza to return to the bush. Today, there are no Hadza children in that school and the clinic is used mostly by the other ethnic groups who were attracted to Yaeda Chini by the school and clinic.

The Hadza have a much less monotonous diet than their agricultural neighbors, who eat maize or rice almost every day with only the occasional bit of meat. The Hadza eat a variety of berries, tubers, honey, baobab fruit, and a wide variety of game from birds to mammals. Of course, there is more fluctuation in the quantity of food consumed by the Hadza than among their agricultural neighbors. However, while the Hadza are often hungry, they do not recall any Hadza ever starving to death. When some big game animal is killed, they gorge themselves for days. During the berry season however, they may sometimes eat almost nothing but one type of berry for 2 months. A variety of wild tubers, three species in particular, are the staple of the diet since they can be found all year round. Medium-sized to large game is shared pretty equally among all those in an average size camp and this sharing helps minimize the variance in daily consumption. There is probably less equitable sharing of other types of food but still some sharing occurs, which also minimizes variation in daily consumption and variation in the amount consumed by each household. This extensive

sharing of food that is taken back to a central place, which is typical of foraging populations, must have had a significant impact on human life history since it subsidizes young even after weaning. However, children begin foraging for themselves quite early and by age 10 acquire about half their own needs (Blurton-Jones, Hawkes, & O'Connell, 1989).

Even though the Hadza are sometimes spared epidemics that hit their neighbors, they have an appreciable infant and juvenile mortality rate. Infant mortality in the first year is 21%, and juvenile mortality by age 15 is 46% (Blurton-Jones et al., 1992), both of which are close to the mean for foraging populations (Marlowe, 2001). By the time women have completed their child-bearing years, they have given birth to an average of 6.2 children (also about the mean Total Fertility Rate for foragers). The total population of Hadza is slightly increasing, perhaps partly because it is rebounding from past declines caused for example by the Maasai expansion in the late 1800s, and the deaths during the 1960s settlement attempt (Blurton-Jones et al., 1992). The life expectancy at birth is about 31 years but this is greatly driven by the infant mortality rate, and does not mean there are few old Hadza around. A woman who survives to age 45 has a life expectancy of about 21 more years (Blurton-Jones, Hawkes, & O'Connell, 2002). The mean inter-birth interval regardless of whether children live or die is about 3.4 years.

The overall sex ratio is very close to equal, as is the operational sex ratio (OSR), the ratio of reproductive-aged men to reproductive-aged women. The sex ratio of those under 5 however, is quite skewed toward males, who die at a higher rate. This is despite the fact that male infants nurse at a higher frequency than females. Fathers spend more time holding and interacting with male infants and toddlers but this is almost balanced by mothers spending slightly more time with female children, so that overall care received by children is not significantly different for males or females (Marlowe, 2002a).

Adult male weight was 53.1 kg in the late 1960s and 46 kg for adult females (Barnicot et al., 1972). In 2000, I found male weight had not changed (53.6 kg), but female weight had increased slightly to 47.2 kg. Height was 1.625 m for adult males and 1.513 m for adult females, up from 148.6 cm in the late 60s. I found the percent of body fat was 20.4% for adult females and 11% for adult males. Body Mass Index (BMI) is 20.2 for adult males and 20.6 for adult females. These statistics show that the Hadza are not malnourished, and in fact are in quite good

shape for a subsistence population, with men having plenty of muscle and women plenty of fat.

Despite being in good health generally, the Hadza have a hard life and many have had broken bones or serious wounds. This is evident in their fluctuating asymmetry (FA). FA is a measure of the deviation from perfect symmetry in bilaterally symmetrical traits, which is assumed to reflect the degree of environmental stress experienced by organisms. Measuring 10 body traits, Hadza FA is significantly greater than FA in the U.S. (Gray & Marlowe, 2002). The Hadza sleep on the ground on an Impala skin, with little covering, sometimes a thin shawl to keep off the cold before dawn. Both men and women get lots of exercise since women go foraging about 4 hr a day and men about 6 hr. While foraging, women dig with sticks in hard ground to get under big boulders, which is very tough work. Men often use axes, they make, to chop into trees and get the honey in bee hives, which is jarring to the body.

The Hadza smoke as much tobacco as they can get their hands on (women chew it), but it seems their vigorous activity keeps them from suffering from emphysema because they are not short of breath compared to non-Hadza who try to keep up with them when walking. They have been making stone pipes for many centuries, suggesting that they have been able to get tobacco through some trading with others for a long time, and probably marijuana or another plant before that (Fosbrooke, 1956; Sutton, 1990). The Hadza also drink as much alcohol as they can get, which is very little. They do not make alcohol themselves but trade honey to their agro-pastoralist neighbors who use it to make beer and give them some in return.

Normally, the Hadza receive little or no standard medical treatment. When injuries occur or someone is seriously ill, unless someone like a researcher is around to dispense medicine or take them to the nearest clinic or hospital, they simply endure (though they do have certain medical practices as described below). There is one hospital, which is quite good by Tanzanian standards, only a day's walk from part of Hadza country but since it is still a long walk up steep hills, few Hadza are treated there. There are three small clinics with very limited facilities and medicines a bit closer but unless someone pays for them, Hadza are rarely treated. For the most part, the Hadza continue to exhibit natural mortality and morbidity, only slightly influenced by medical attention. Due to their foraging lifestyle however, they have extremely good eyesight, hearing, teeth, no obesity, and apparently little cancer.

MEDICAL PRACTITIONERS

With the exception of the few older women who know how to perform a clitoridectomy, there are no medical specialists or specialists of any kind among the Hadza. Every adult knows about the various medicinal plants and practices that the Hadza use. Any adult present may treat someone with an ailment. Women often sit and groom children, removing lice, washing them, and blowing their noses. When anyone is injured and cannot forage for a while, their close kin usually attend to them and bring food back for them until they recover.

CLASSIFICATION OF ILLNESS, THEORIES OF ILLNESS, AND TREATMENT OF ILLNESS

Illnesses and causes of death tend to be explained in four ways. (1) If someone falls to their death, the Hadza say the cause of death is simply an accident. (2) If someone is killed by a lion or a snakebite, this is just part of the dangers of the natural world. Likewise, malaria is understood to be caused by mosquito bites and sleeping sickness (African trypanosomiasis) the bite of the tsetse fly. (3) When the cause is less obvious however, and especially when death is sudden, a heart attack or poisoning, and the person had been healthy before, then the witchcraft of their non-Hadza neighbors is often said to be the cause of death. The Hadza do not themselves practice witchcraft but fear that of their neighbors. Even when a death is clearly caused by some disease, the Hadza may say this was due to witchcraft if that person had had some quarrel with someone earlier. The percentage of deaths attributed to such witchcraft is on the rise, and these days even a few Hadza are suspected of having learned witchcraft from their neighbors. (4) Finally, there is the supernatural cause not involving witchcraft. There are few rules or taboos in Hadza society, but one such taboo relates to the eating of the epeme meat. Only the adult epeme men can eat these parts of larger game (heart, kidneys, genitals, and back). Sub-adult males and all females cannot eat this meat nor can they even see the men eat it. If they do, it is said they can get ill or die.

There are several types of medical treatment (Woodburn, 1959). For example, there is a certain type of plant that is boiled and then drunk to relieve the symptoms of malaria. Several plants are used to cause one to

vomit after being bitten by a poisonous snake. With the most poisonous snakes, there is little hope since they can kill a person in a minute or seconds, but these plants can apparently work with less poisonous but still deadly snakes, as many people say they have been saved this way. Bark from a certain tree is boiled and consumed like tea to treat syphilis and gonorrhea. A certain plant is given to someone who falls down with a seizure, presumably epilepsy, which must be rare, given that there are only 1,000 Hadza. Some say there are plants that can induce miscarriage in the early stages of pregnancy, though it seems they are rarely used, or that they are ineffective, since women sometimes complain that they just keep having babies and cannot stop. There is also a plant that is supposed to help men overcome impotence.

When one has general pain in the body, a horn is used to create suction to suck "the poison" out. A knife is also used to make cuts and let blood run for general pain. Some Hadza have several scars on their arms and backs as a result. When one is badly cut, a tourniquet is applied after boiled animal fat or honey is applied to the wound. The Hadza do not like to wear bandages and believe it is better to let wounds have fresh air, which is probably true most of the time, but they also have a problem keeping wounds clean and free of infection since hygiene is unavoidably poor.

SEXUALITY AND REPRODUCTION

Boys and girls begin playing house around the age of 6 or 7 and probably begin having sex for real in their mid teens. First marriages follow courtship that is carried on clandestinely and if the couple like each other enough, they begin living together, hopefully with parents' approval though it is not required. Because a man might kill his wife if he catches her having an affair, female marital infidelity is probably fairly rare, though many marriages end when the husband is away for so long (usually pursuing another woman) that his wife begins an open relationship with another man, saying that her husband has left her. Most extramarital sex occurs between a married man and a single woman. Polygyny is rare and polyandry, at least of an overt kind, does not exist. Serial monogamy is the rule. Apparently syphilis and gonorrhea have been present for some time since the Hadza have a treatment which they say cures it. So far there have been few cases of AIDS, even though the frequency is high throughout Tanzania.

Men sometimes experience impotence, and try to treat it with a plant. Infertile women feel sad about not having any children and others feel sorry for her. On the occasions when men admit to having left their wife (they usually say they were left by her) they most often say the reason is that she bore no children. There appears to be no ideal family size. Women sometimes say they wish they could stop having babies. Men seem to think more is better but both men and women think having no children is not good.

HEALTH THROUGH THE LIFE CYCLE

Pregnancy and Birth

The Hadza understand much about conception. A Hadza woman will wash on the last day of her period and then the couple has sex. They think that if she gets pregnant, it is on that first day after her period, though whether she does they would not know until she misses her period a month later. Young women, up until their early 30s perhaps, often carry around a thin, 2–3 foot long stick with designs carved by their husbands, which they say is a fertility stick that will make them get pregnant.

Women give birth at home, squatting. They are attended by their mothers, sisters, and/or friends, or their husband if there is no other woman to help. The attendant cleans the baby and cuts and ties the umbilical chord. Women apparently die at fairly high rates from giving birth, given that I was able to elicit the names of several women who had died in childbirth from many different men and women. Men say women are clitoridectomized because if they were not, the baby would have trouble coming out, since the opening would be obstructed by the protruding clitoris.

There is no evidence of infanticide and the Hadza say only in the case of severe deformity, might a baby be killed. Even when twins are born, they do not kill or neglect one, though the risk is higher that one will die since it is difficult to rear two at the same time. Even though some women say they know of ways to induce miscarriage, those same women complain of not being able to stop having babies, so these methods are either ineffective, or they do not really want to use them.

Infancy

Infants are carried at almost all times during the first 6 months of life and nurse on demand. Women carry infants

on their back wrapped in a skin, or in these days a shawl. When the baby cries, they swing it around to the front or side so that the infant can nurse while the mother continues her work. Infants are carried on their mother's back when she goes foraging and can sleep right through the vigorous movements of digging for tubers. Children are usually completely weaned by 3 and nurse at low frequency by age 2 years (Marlowe, n.d.). Mothers chew some weaning foods before giving them to the infant. Most mortality occurs in the first year of life. These deaths are apparently due to various respiratory and diarrheal infections, malaria, and at a later age measles, over which parents have little influence.

Childhood

By age 3, children have small slits made on their cheeks by their mother, uncle, or grandparent, which leaves them with small scars to identify them as Hadza. Toddlers are not easy to take foraging because they are too young to walk very far and too old and heavy to carry. They are therefore, usually left in camp and that means someone must be in camp to watch them. This can be almost anyone, but is often a grandmother, and during the dry season when men hunt at night, it is often the father who is dozing in camp all day. Men interact most with their young children when they are 1–3 or 4 years of age (Marlowe, 2002a).

There is very little disciplining among the Hadza. When children are in their “terrible two’s” and throw violent tantrums, they pick up sticks and beat adults, who merely fend off the blows, rather than take the stick away. Children tend to learn how to behave from older children because when a 2-year-old hits a 4-year-old, the 4-year-old does take revenge. The most disciplining adults do is to simply make a noise of displeasure. Their leniency extends to letting young children play with whatever they want. A baby can often be seen with a sharp knife or other dangerous object in its mouth with adults not bothering to take it away. Nor do they try to keep little ones out of the fire. Children get burned or get cut and learn on their own. By the standards of modern America therefore, Hadza adults would appear to be guilty of child neglect, if not abuse. Actually Hadza parents are very loving and very rarely hit or abuse their children, and children never feel unloved. They grow up to be extremely well-behaved by the age of 4, without parental disciplining. They do not disobey their parents, nor argue with them, and by 4 or 5 will wait on adults or run errands often without even being asked.

Boys usually get their first bow when they are about 4 and spend hours each day in target practice. By the time they are 7 or 8 they are already very good and kill small birds and rodents. Girls begin accompanying their mothers on foraging forays by around 8–10 and also look after their younger siblings.

Adolescence

By age 10–12, boys and girls may begin having some sex but only begin courting when girls are about 15 or 16 and boys 17 or 18. There is no disapproval of premarital sex but it is kept secret anyway. There is no public display of affection even between married couples. Age at menarche is about 16 or 17. At this time, or close to it, there is a puberty ritual for girls attended only by females, called *Mai-to-ko*, during which the tip of the clitoris is cut off with a knife by one of the few older women who know how to perform this. The Hadza may have acquired this practice from their neighbors, the *Iraqw*, *Datoga*, or *Maasai*, since all clitoridectomize women, though several Hadza claim it is not a borrowed custom. Males are not circumcised and there is no puberty ritual for boys. There is a ritual eating of the *epeme* meat when a teenager has killed his first big animal.

By the age of 10, girls are not only supplying about half their own food needs but bringing food back to share with others. They also tend younger siblings and other children much of the time. Boys by the age of 10 or 12 go hunting in groups of 2 or 3 and kill birds and small mammals. There is also no generation gap. Teenagers look up to adults and get along well with the elders. This is at least partly due to the fact that adults do not try to control them and rarely express a strong opinion about whom they should marry. The fact that there is little polygyny means the young males are not in such intense competition for females as they are in many cultures. In addition, since there is no wealth, men do not have the same kind of leverage over their sons as they do in societies where inheritance is important (Marlowe, 2003).

Adulthood

Age at first marriage for females is about 17–18 and median age at first reproduction is 19 (Nicholas Blurton-Jones, personal communication). Age at first marriage for men is around 20. Marriage is not arranged and there is no ceremony, it consists of a couple that has been secretly

courting for a while, beginning to live together. Men are expected to kill a large animal to become *epeme* men and eat *epeme* meat with the other men. This often happens when a male reaches about 18 or 19. Even men who have not killed such an animal, however, would be considered *epeme* men after reaching the age of 25 or 30. Men feel the need to bring in enough meat to keep their mother-in-law from counseling her daughter to look for someone better.

There is a fairly high rate of divorce, especially in the early years of a marriage (Blurton-Jones, Marlowe, Hawkes, & O'Connell, 2000). Divorce consists of a couple simply ceasing to live together. Because women usually have their kin around them, there is not a heavy price to pay for being divorced. While a child has increased risk of mortality if its mother dies, there is no evidence of increased child mortality resulting from a child not having its father present (Blurton-Jones et al., 2000). There is also little or no stigma associated with out-of-wedlock births. Normally, there is little domestic abuse, though a man may sometimes hit his wife and be forgiven by others if there is considered to be good cause (infidelity or laziness). However, wife beating is now on the rise (see changing patterns below).

Being a natural fertility population with frequent nursing, strenuous exercise, and mere subsistence level intake of calories, women do not cycle frequently. They probably have less than $\frac{1}{4}$ of the number of menses of American women, perhaps 80 in a lifetime. When they finally reach menopause, they are usually nursing a child and are not sure whether they will resume cycling or not. This may mean they experience fewer side-effects, such as hot flashes, upon reaching menopause, since none of these symptoms has been reported. No cancer has been observed among the Hadza but with such a small population it would be difficult to know whether it exists. A similar absence among other foragers as well has led some to speculate that reproductive cancers may be absent in natural fertility forager populations (Boyd Eaton et al., 1994).

The Aged

Even though the life expectancy at birth is only 31.5 years, there are plenty of very old Hadza. A person who makes it to age 18 is likely to live to be 60 and one who makes it to 45 is likely to live to be 66. Most women over 60 are single, either because their husband has died or left them for a younger woman. These women usually

live with one or more of their daughters and tend their grandchildren. They certainly do not feel alienated, no Hadza does, and they are an integral part of the camp and family life, but they express bitterness over the fact that men leave them once they get too old. Old men are shown extra respect until they reach the age of perhaps 70 or 75, when their status drops a bit. Old men are the most likely to fall out of tall baobab trees and to their deaths since they continue to try to collect honey into old age. They are somewhat grudgingly fed and are expected to watch children in camp when they are not out foraging.

Dying and Death

The Hadza leave corpses out for hyenas to eat, or if the deceased is an older person, they may push his or her hut down on top of them and set it ablaze, then move away (Woodburn, 1982). Increasingly, they are under some pressure from the government to bury dead. There is no belief in an afterlife. While most Hadza say they have never heard of anyone committing suicide, there are two recent cases of people attempting to hang themselves. One was a man whose wife left him for another man, another a woman who thought her husband was pursuing other women. In both cases the rope broke and they fell from the tree.

Common illnesses and injuries include: scabies, backache, malaria, eye infections from hearth smoke, broken bones, and wounds from accidents. Causes of death include tuberculosis, malaria when young, sleeping sickness, viral diarrhea, falling from baobab trees when collecting honey, murder by another Hadza, snakebite, and being charged by a buffalo after hitting them with an arrow. Hadza often scavenge meat from the kills made by lions, leopards, and hyenas and this sometimes gets them killed by one of these predators. Finally, childbirth apparently results in the death of the child and the mother at a fairly high rate.

CHANGING HEALTH PATTERNS

The Hadza habitat is being damaged by their pastoralist neighbors' overgrazing and their horticultural neighbors' felling of trees for firewood and planting of crops. They have almost lost the best spot with a large underground spring to the burgeoning number of villagers. More Hadza are attending school where a steady, if monotonous

diet, means they grow faster and larger and more are becoming literate. However, future development and a more sedentary existence will probably prove deleterious. While the consumption of tobacco might pose the greater direct threat to health, the ramifications of drinking are much more severe. Promiscuous sex near the village is bound to result in sexually transmitted diseases and death from AIDS. In the village, begging and money from tourists (for whom they perform a song and dance) leads to drunkenness and quasi-prostitution, injuries from fights, and murder. Murder is becoming more common, mainly as a result of increasing alcohol consumption. Other Hadza do not approve of a man beating his wife and will reluctantly intervene to stop it, but when drunk, men may seriously injure or kill their wives with little or no provocation before anyone can prevent it.

Haitians

Robert Lawless

ALTERNATIVE NAMES

The ethnonyms for Haitian include the Creole word *ayisyen* and the French word *haïtien*. In English language sources the word is also sometimes spelled *Haytian*. Haiti in Creole is *Ayiti*; and in French, *Haïti*.

LOCATION AND LINGUISTIC AFFILIATION

Occupying the western third of the Caribbean island of Hispaniola, which it shares with the Dominican Republic, Haiti covers 27,750 km² and is located 90 km southeast of Cuba, 187 km northeast of Jamaica, and about 1,000 km from Florida. Although Haiti has some flat, semiarid valleys, much of the country consists of rugged and sharply dissected mountains with about two thirds of the almost 28,000 km² divided into three mountain ranges. La Selle Peak, the highest elevation, tops off at about 2,680 m. The average temperature falls within a typical Caribbean range with the capital city of Port-au-Prince having a mean annual temperature of 26.3° Celsius.

Although difficult and chronically misunderstood, the language situation is not complex. All Haitians speak Creole, sometimes referred to as Haitian Creole. For most

of modern history, however, the official language of government, business, and education has been French, though only about 3% of the population speaks French with any recognizable fluency. Traditionally the educated elites have used the requirement of French to exclude the masses from competing for positions in government and business. Creole has, nevertheless, come into its own in recent years and is gaining prestige as the natural tongue of Haitians and of Haiti. The current constitution states, “All Haitians are united through one common language: Creole. Creole and French are the official language of the Republic.” Due to the recent flood of Haitian migrants to Florida, the international decline of the French language, and various economic and cultural trends in the Caribbean, there has been a considerable expansion in the use of English.

OVERVIEW OF THE CULTURE

Demography

Although demographic information is highly undependable, an estimation of the total population would be 8,500,000 million, and the capital of Port-au-Prince would

be estimated at 1,500,000 million people. In addition, Haiti has a tradition of emigration, and many Haitians live in the neighboring Dominican Republic, on other Caribbean islands, in the countries of Central America, northern South America, and in North America, especially New York City, which hosts the second largest Haitian community after Port-au-Prince.

History

The Republic of Haiti is the second oldest independent nation in the Western Hemisphere, and it is the only one with an overwhelmingly African culture. The people who occupied the island of Hispaniola at the beginning of the 16th century when Europeans first arrived in significant numbers rapidly succumbed to imported diseases, died in battle, or were killed off by slavery in the first 50 years of Spanish occupation. The Europeans then brought slaves from Africa.

These slaves primarily worked the sugar cane plantations that made the French colony of Saint Domingue an economic success. This success, however, was based on unimaginable brutality and cruelty, and in 1789 the slaves began their 5-year struggle for freedom. On January 1, 1804, the ex-slaves of Saint Domingue renamed their country Haiti and proclaimed its independence.

From 1915 until 1934 the United States occupied Haiti and suppressed peasant movements, revamped the army, and concentrated sociopolitical power in Port-au-Prince. Until 1946 the Haitian administrations were pale reflections of U.S. political interests in the Caribbean. Then from 1946 to 1950 President Dumarsais Estimé ushered in a progressive era that saw an interest in African heritage, cooperation with other Caribbean nations, the development of peasant economic cooperation, the introduction of progressive income tax, expanded education and economic opportunities for the poor, and the rise of a middle class.

In 1957 President François Duvalier emerged as the proclaimed heir to Estimé. The Duvalier regime was marked by brutal oppression against opponents and isolation from the international community. Many professionals fled into exile, and the economy descended into a serious slump. With the 1971 transition from Duvalier to his 19-year-old son Jean-Claude, the United States guided Haiti to a new economic program that featured private investments from the United States featuring no custom taxes, a very low minimum wage, the suppression of labor

unions, and the right of U.S. companies to repatriate their profits. For most of the population living conditions continued to decline.

With little to show after 14 years of rule by a second Duvalier, Haitians began protest demonstrations in 1984. In February 1986 Jean-Claude Duvalier fled to France, and an era ended. After several provisional governments the popular priest Jean-Bertrand Aristide was elected president and installed in office in February 1991—5 years to the day after the end of the Duvalier dynasty.

Despite the widespread popularity of Aristide and the heightened expectations of the masses, the military ousted Aristide after only 7 months. No government or state except the Vatican recognized the de facto military regime. This brutal and illegal 3-year occupation of Haiti by its own army saw a rapid downward spiral in the economic and health conditions of Haitians.

Under U.S. sponsorship Aristide was returned to power in October 1994. Since Aristide could not succeed himself, his protege René Préval was elected and took office in February 1996. Four years later Aristide was again elected president and took office in February 2001.

Economy and Occupations

After defeating the colonial government of the French slave owners the newly independent nation faced the threat of a French army returning to re-enslave them. To counter this perceived threat, the new government at first confiscated private land and imposed forced labor in an attempt to develop an export agriculture leading to the importation of war material. Such a plan proved impractical, and eventually the confiscated plantations were distributed to the ex-slaves and the Haitian elite retreated to the provincial cities. The result was the fragmentation of land holdings, peasantization, and the alienation of the masses from the government and the ruling elites. Currently an estimated 80% of the rural population owns its own land, though the plots are fragmented and small, and about 65% of the labor force is in agriculture. Despite the importance of agriculture and the peasantization of Haiti, the government traditionally expends little effort or money on agricultural research or on integrating the rural population into the politics of the country.

Haiti's primary export products have traditionally been coffee, sugar, rice, and cocoa, though the political uncertainties of recent decades have meant a low rate of export. Haiti has some light manufacturing along with a

few cotton mills. Before the so-called de facto regime, when offshore industries were in operation, Haiti was a major source of garments, toys, baseballs, and electronic goods for the United States. Many people engage in the manufacture of tools and small items.

Market women from the rural areas bargain their produce in open-air markets, and most of this produce moves by foot as these women often carry heavy loads. All sorts of merchandise may be found in the city markets, including black-market items. Much of the trading is done in kind. The annual per capita monetary income is estimated at only US\$480.

Social and Political Conditions

The early distribution of land to the rural population created a large class of peasants who generally regard the government as a nuisance. Haiti does, nevertheless, have a political structure. The nation is traditionally divided into several *départements*, each of which is further divided in several *arrondissements*, and each *arrondissement* consists of several *communes* that usually coincide with church parishes. Finally, each *commune* is divided into several *sections rurales*, each of which is headed by an appointed *chef de section*, who reports to the *commandant* of the *commune*, who reports to the *préfet* of the *arrondissement*. The government official that rural Haitians deal with is generally the *chef de section*. In urban areas the most important government official is usually the *préfet*. For the most part, however, the rural population polices itself under the watchful eyes of village elders. A rather subfunctional police force and a largely corrupt court system exist in the urban areas.

International Relations

Internationally Haiti is closely tied to the United States with a sizeable majority of its exports coming to North America and a goodly portion of its economy dependent on government and nongovernment aid from the United States. Although twice-elected Aristide remains popular among Haitians, his socialistic and anti-American rhetoric means that influential sectors in the U.S. government will continue to oppose his administration.

Since May 2000 when the party of President Aristide won approximately 80% of the seats in a parliamentary election and the U.S.-backed opposition front Democratic Convergence alleged that the election was

rigged, Haiti has been in a political and economic crisis. Largely under pressure from the United States, more than US\$500 million in international aid has been frozen until the government and the opposition reach an agreement to hold new elections.

Family and Kinship

The family and kinship pattern most prevalent in rural Haiti is the somewhat patrilineal extended family and patrilocality resulting in a cluster of consanguineously and affinely linked joint households headed by the oldest male member. Traditionally the rural population has tended to avoid involvement both with the Roman Catholic church and with the government, which means that this population also avoids legal and church marriages. The result is a wide variety of mating and parenting patterns, including completely informal unions, non-conjugal couples, fathers who do not participate in rearing their children, and non-nuclear family households, as well as conventional church weddings, long-term monogamous unions, and neolocal nuclear family households. Also, both men and women may simultaneously, or in succession, enter several different kinds of union with the same or with different partners. Since all children from all the varieties of conjugal unions have equal rights of inheritance, the complexities of the domestic unit often lead to significant inheritance problems. In addition, the specification of the adult responsible for the care and health of a child can be easily disputed.

Religion

All religions have a close connection with health and illness, and an understanding of the religions of Haitians is essential for developing an appreciation of their health care system. Although some of the population is nominally Christian, the major religion of Haiti is Voodoo. Between 50 and 75% of the population of rural Haiti actively practice Voodoo, and 90% believe in it to some degree. Voodoo is also very popular among the urban working class, and to some degree among people in all classes, including the educated elite. Many important ceremonies revolve around celebrations of milestones in the life cycle, such as birth, maturity, marriage, and death. Other important ceremonies focus on agriculture, planting, harvesting, and insuring a sufficient crop yield. An ancient, affirmative, and legitimate religion that focuses

on contacting and appeasing ancestral spirits, Voodoo provides a folk medical system that attributes illnesses to angry ancestors. The performance of ceremonies that appropriately appease these ancestors is, then, extremely important in curing illness. Such ceremonies include divination rites, used to find the cause of illnesses; healing rites, used to interact directly with sick people; propitiatory rites, used for offerings to specific spirits; and preventive rites, used to offer sacrifices to prevent trouble.

THE CONTEXT OF HEALTH: ENVIRONMENTAL, ECONOMIC, SOCIAL, AND POLITICAL FACTORS

Demography

According to various studies, the birth rate is probably around 35.5 per 100,000, and the annual growth rate somewhere just less than 2% per annum; the mortality per 1,000 is approximately 13; the infant mortality per 1,000 is estimated to be about 140; and life expectancy at birth is about 54 years.

Colonial Era

No reliable information exists on the conditions for slaves during the colonial era. The treatment of the slaves was most certainly deplorable, and their diet was no doubt substandard. Various estimates suggest that the life expectancy of slaves after their arrival in Saint Domingue was 7 years. As inhuman as it sounds, the economies of slavery dictated that it was cheaper to export labor and quite literally work the slaves to death rather than waste time and energy on reproducing and maintaining a domestic work force.

Postcolonial Era

Currently tuberculosis is Haiti's most serious disease. The country is also infected with malaria, influenza, dysentery, tetanus, whooping cough, and measles. Eye problems are endemic, and blindness is not uncommon and is usually caused by cataracts, scarring of the cornea, and glaucoma.

Many Haitians, especially the poorer masses, suffer many health problems associated with malnutrition. The daily per capita food consumption is estimated at 1600

calories, and measles, diarrhea, and tetanus claim the lives of many children before they reach 10 years of age.

A 92-page study released in 1992 by the Permanent Commission on Emergency Aid, which represents more than 60 non-governmental development and democracy organizations in Haiti, reported that the death rate has been rising and the health of the population dropping since the 1991 military takeover. Pointing out that there has been a deterioration in state services amounting to a descent into chaos, the report stated, "The situation is extremely critical and just waiting for cholera to strike" (Staff, 1992). Other problems that were reported included an increase in garbage in the streets, a rise in the number of preventable illnesses, and a deterioration in mental health. This report is the most recent one covering a general overview of health in Haiti. There is every reason to believe that the situation has deteriorated further as Haiti enters the 21st century. The most recent estimate, for example, is that only 40% of the population has easy access to potable water (Farmer, 2002).

Current Era

An obvious current difficulty is the U.S.-sponsored embargo. In an electronic message sent in March 2002 to the Haitian Discussion Group the anthropologist and physician Paul Farmer spells out the health problems resulting from this embargo (Farmer, 2002). Farmer's 80-bed charity hospital has delivered health services in the central plateau for the last 18 years, and he writes that the situation there has gravely deteriorated because of a serious lack of resources, medical personnel, and an increase in diseases. He draws a direct connection between this suffering and the aid embargo.

Farmer points out that while the brutality of the 1991–1994 de facto military regime is well known with thousands killed outright and hundreds of thousands made homeless, the current catastrophic decline in overall health is much less publicized. There have been measles epidemics, outbreaks of dengue fever and polio, as well as the appearance of other vaccine-preventable diseases. Most of these diseases are related to the increasing prevalence of malnutrition. According to Farmer, "The nationwide network of public clinics and hospitals was left to fend for itself, and many health professionals left Haiti as this network foundered" (2002).

Although democratic rule was restored in 1994, and a coalition of international donors promised more than

\$500 million of aid, no monies have yet been disbursed. During 2001 the United States declared a formal aid embargo that blocks all loans and grants from the Inter-American Development Bank, the World Bank, and the International Monetary Fund. As a result 40,000 or so inhabitants of the commune where Farmer's hospital is located (Thomonde in the Departement du Centre) are without a single doctor or nurse, except for Farmer's hospital, which is now overwhelmed with patients. In the nation at large there is only one physician for every 11,000 patients.

Health Infrastructure

Although Western medicine has been available to the urban elite for several decades and is, indeed, available from a few rural clinics, Voodoo healers are a major part of the medical system of Haiti. Interestingly Haitians place an enormous emphasis on physical cleanliness. It is very important to be clean-looking and clean-smelling in your body, your clothing, and your home. This value may be important in helping Haitians to accept modern medical practices. Bathing is explicitly health-oriented. According to Haitian folk model, regular morning baths are necessary to maintain the balance of the body. Irregular bathing causes heating up of the body and may result in stomach boils. Incidentally bathing, which is often done in a nearby river, is usually done with the clothes on, and it is thought that keeping the clothes on helps cool the body and prevents loose bowels. For the most part, however, health and healing for most Haitians are handled by herbal medicine, bonesetters, injectionists, Voodoo rituals, and by a rich body of folk knowledge.

MEDICAL PRACTITIONERS

Voodoo is a particularly egalitarian religion with both men and women serving as intermediaries, and this rule follows for most of the indigenous therapists. There are at least four types of indigenous therapists who can treat illnesses caused by natural phenomena and two who treat illnesses caused by unnatural phenomena: (1) herbalists, (2) bonesetters, (3) injectionists, (4) midwives, (5) Voodoo priests and priestesses, and (6) sorcerers.

- (1) Among the most common therapists are herbalists (leaf doctors, or in Creole *dòktè fèy* or *medsin fèy*). As with the other indigenous therapists, herbalists have no manuals or organized

schools for training. They can be either men or women, and they treat natural illnesses through administering teas and with the use of various baths and compresses, which are usually accompanied by incantations and rituals. They seem to come in families, and every village has several people who specialize in herbal treatments, most of whom work only part-time as herbalists. Many herbalists are also Voodoo priests and priestesses. The herbalists may also use injections and pharmaceutical preparations.

- (2) Bonesetters (*dòktè zo* or *medsin zo*) are not very numerous, and frequently those in rural areas with broken bones may have to hike for several hours to the home of a bonesetter. The bonesetters are generally recruited through spiritual revelation and serve a fairly long apprenticeship. They realign broken bones and fix obstructed blood vessels. Most use a flour-based plaster cast that is applied and left on for several weeks.
- (3) Injectionists (*pikirist*) usually learn their trade through affiliation with a medical center and are usually found in urban areas. They often are patronized by tuberculosis patients, and they administer the daily streptomycin in the patient's home. Although some injectionists use pharmaceutical preparations, they may also be found in the streets pushing carts holding jars of medicine that often contain only cough syrup. The injectionists diagnose the patient's illness on the spot and select a syrup to inject, which they may do with a previously used syringe. Due to the obvious implications for the spread of disease, especially AIDS, some of the several recent administrations have cracked down on these itinerant injectionists, and nowadays few are found roaming the streets.
- (4) Midwives (*fanmsay*) are always women, and it is estimated that they deliver at least 85% of all babies born in Haiti. Some learn their trade from an apprenticeship and others from their mothers, though some have in the past been trained and paid by the state. They all use herbal treatments for all neonatal complaints, and they sometimes consult with herbalists.

The most typically Haitian medical practitioners are the Voodoo priests (*ougan*), priestesses (*manbo*), and sorcerers (*boko*). Their role will be treated in more detail at the end of the next section.

CLASSIFICATION OF ILLNESS, THEORIES OF ILLNESS, AND TREATMENT OF ILLNESS

The traditional healing system of Haiti is complex, but it can profitably be discussed in terms of (1) humoral systems, (2) the concept of personhood, (3) the anatomy of the body, (4) the etiology of disease, and (5) mechanisms of diagnosis.

- (1) Haitian concepts of health incorporate the familiar hot-cold dichotomies imported from ancient Europe and used throughout Latin America. Haitian concepts may also incorporate

humoral-related ideas from West Africa, but little information exists on related African indigenous health systems, which themselves may have been influenced by Islamic sources. In its simplest form humoral systems depend on controlling health through the monitoring of intakes of hot and cold items, primarily food.

Good health requires people to maintain their individual balance of the four humors. Sickness results from a humoral imbalance and from extremes of hot and cold, dry and wet. One's humoral equilibrium can be influenced by age, climate, style of living, and the seasons, and especially by one's diet.

Over the generations in Latin America the humoral system of the Spaniards was altered and simplified with the wet and dry categories disappearing. Although not well studied, the humoral system is widespread in Haiti, and "is a guiding principle in rural Haitian behavior" (Wiese, 1976, p. 198). Interestingly H.J.C. Wiese lists Haitian foods' hot and cold ratings and gives the vitamin and mineral content of Haitian food (Wiese, 1976, pp. 196–197).

P. Minn supplies a recent account of an illness rooted in humoral pathology that is called simply heat (*chalè*) (Minn, 2001). When Haitians say, "*M gen chalè*" (I have heat), they mean that they have been exposed to excessive amounts of heat and are therefore ill, with the most common symptoms being dizziness and headaches, though almost every part of the body, especially the skin, can be affected in various ways.

- (2) Religious beliefs in general and religious practices in particular involve some degree of loss of control over the natural world, and all, therefore, leave the individual vulnerable. The defense against being damaged when in a vulnerable state is the establishment of good relations with the supra-natural world. Such good relations come primarily through being possessed by entities from the supra-natural world. Such possession is easier when the person is composed of various tenuously related parts. Such a characteristic is, indeed, found in the Haitian concept of personhood. The head is, for example, seen as the seat of the good big angel and the good little angel (*gwo bon anj e ti bon anj*). The little angel is the one who goes to heaven and is the guardian of the person. The big angel feels emotion and can be displaced through possession. The usual struggle before a person is possessed, which is sometime quite violent, is the attempt of the little angel to prevent the possession. At the death of the natural person the big angel goes back to Africa (*Ginen*).
- (3) The head is also the seat of the spirits. It must be washed, fed, and, at death, the master of the head (*mèt tèt*), who controls thinking, must be removed. When people are worried, their head is "loaded." In excitement the head heats up. The medium of heating and cooling is the blood. As might be expected in a system largely based on the humoral system, a major part of both causing and curing illnesses involves manipulating heat and cold, and influencing the state of the blood, and the condition of the head. The tools of manipulation usually focus on the intake of food; food as a sacrifice to the ancestors, food as charity, food as poison, and also oral and injected medicines.
- (4) In terms of etiology illnesses have various causes, but the basic distinction is between natural and supra-natural phenomena. Natural illnesses include everything from infectious to chronic degenerative diseases and may be treated by priests

and priestesses or physicians or other types of indigenous therapists, according to varying criteria such as severity of illness, customary local practices, availability of competent practitioners, and ability to pay. Supra-natural illnesses are attributed either to sorcery or to the supra-natural spirits and can be treated only by priests and priestesses.

- (5) The first step in diagnosis is to determine the complexion of the disease and the natural humoral balance of the patient. Following the principle of opposites, a disease thought to be hot will be treated with cold herbal remedies and the patient will be advised to eat mainly cold foods. A person complaining, for example, of *chalè* in the head will usually be treated with cold water and with medicinal leaves on the head. In general, treatment consists of attempts to restore the normal humoral balance. Actual methods of diagnosis and treatment vary from one priest and priestess to the next, but the pattern is generally something like this: After receiving the initial complaint, which is often very general—a headache or a stomachache—the priests and priestess call for the aid of their spirit helper. They most likely sit before a domestic altar, recite the rosary, light candles, and purify the floor with holy water, often chanting in a language that is supposed to be African. They then become possessed by their spirit helper, who gives them advice about how to proceed. Usually they then collect a detailed medical history from the patient and the patient's relatives. They may also try to get more specific details through the use of various divination techniques.

If the problem is caused by black magic, the priests and priestesses may have to employ counter-magic techniques, often calling again on their spirit helper. Mischievous or neglected spirits can cause illnesses. Sometimes spirits are purchased and told to make trouble for others. Indeed, much of the Haitian population firmly believes in the existence of sorcery and the effectiveness of sorcerers, though they are rare and difficult to find. A sorcerer may also use bad spirits to cause various diseases, such as tuberculosis and epilepsy.

SEXUALITY AND REPRODUCTION

The health focus in terms of sexuality is clearly on AIDS. One of the poorest countries in the world, Haiti also has the highest seroprevalence rate in the Caribbean and the highest rate outside sub-Saharan Africa. In May 2002 representatives of the Haitian health community met with international AIDS experts to discuss the AIDS pandemic in Haiti. Again the focus was on the harm being perpetuated by the U.S.-sponsored embargo. The problem was no longer labeled simply a health crisis but a national development crisis.

Throughout the meeting the specialists, both American and Haitian, recited the overwhelming statistics

of poverty and the high rate of HIV/AIDS in Haiti. It is estimated that Haiti accounts for more than 90% of HIV/AIDS cases in the Caribbean, and the number of children orphaned by the epidemic is estimated as approaching 200,000.

HEALTH THROUGH THE LIFE CYCLE

A bibliographic account of works on Haiti in English and Creole lists only 228 items (Lawless, 1992, pp. 194–170). This rather meager literature does not allow for any detailed accounts of the health beliefs, attitudes, and practices as they might change through the life cycle.

Han

Xingwu Liu

ALTERNATIVE NAMES

Chinese, *Zhongguo-ren*, *Han-ren*, *Hua-ren*, *Tang-ren*. Because of their predominant numbers in China, the Han are commonly referred to as Chinese in the English language, though in China (including Taiwan) they have always called themselves “*Han-ren*” (Han people). Outside China they tend to call themselves “Chinese” (*Zhongguo-ren*) and many overseas Han Chinese also use their provincial names or other local origins in China (such as Guangdong, Fujian, Hakha, Taishan, etc.) to refer to themselves since their Han identity is virtually unknown outside China.

The name “Han” was derived from the Han River, an upper tributary of the Yangtze River. It was further strengthened by the famous Han Empire (206 BC–220 AD) which lasted for several hundred years when the people began active interactions with the outside world. It is understood the Han are the result of amalgamation of numerous ancient ethnic groups.

While the term “*Han-ren*” is used in China to differentiate the Han from other ethnic groups, “*Hua-ren*” now mostly refers to Overseas Chinese, such as *Mei-ji Hua-ren* (American Chinese), *Yindunxiya Huaren* (Indonesian Chinese), etc. “*Hua*” is an ancient name for China, and it is still used when referring to China in combination with the word “*Zhong*” (middle), such as *Zhong Hua Ren Min Gong He Guo* (People’s Republic of China) and *Zhong Hua Min Guo* (Republic of China). Chinatowns in other countries are referred to as *Tang-ren-jie*, meaning “Town of the Tang People.” *Tang* refers to the ancient Tang dynasty (618–907) in China.

LOCATION AND LINGUISTIC AFFILIATION

The Han are the majority ethnic group in China in East Asia, accounting for 91.59% of the whole Chinese population. The Han language (*Han Yu*), outside China known as “Chinese,” belongs to the Tibetan-Han Language Family. It consists of seven major dialects, namely the Northern dialect, the Wu dialect, the Xiang dialect, the Gan dialect,

the Hahka dialect, the Min dialect, and the Yue dialect. The modern common speech (*pu-tong-hua*) is based upon the Northern dialect with Beijing pronunciation.

These dialects are mutually intelligible in most cases, especially between the Northern dialect and others. However, since 221 BC, there has been an unified idiographic (actually it is an idiographic script with phonetic elements) script which has survived the long history of China and which has been one of the most important factors in holding the people and the country together.

OVERVIEW OF CULTURE

The population of Han in China mainland was 1,167 million, and about 22 million in Taiwan in 2000. As of 1999, the Han Overseas Chinese population was about 35 million (about 27 million in other Asian countries; 6 million in the Americas; and about 1 million in Europe).

Confucianism, which made its appearance between the 6th and 5th century BC began its glorious era during the Han Dynasty not too long after the First Emperor’s ruthless persecution of Confucian scholars. While Daoism shaped the accepting and yielding, joyful, and carefree side of the Han character, Confucianism molded the Han people with a moral and duty-conscious, austere, and purposeful group mentality. As a set of social ethics governing interpersonal relations, Confucianism is largely responsible for the secular nature of Han social thought. Its social philosophy advocates filial piety in the family and benevolence in the administration of the government. Confucianism virtually played the role of a state religion together with ancestor worship, and has been a strong binding force that has kept Chinese society a super stable agrarian one in spite of more than two thousand years of dynastic changes.

In Confucianism an ideal society is a peaceful and harmonious one in which everyone plays by the rules and everyone loves the other. It is the enlargement of the family model in which responsibilities and obligations to the group reign supreme and personal freedom and individual rights are unheard of.

The Han family is patriarchal, patrilineal, and patrilineal in nature. The key link that binds everyone together in the family is *xiao*, filial piety. It means obligations of descendants to their progenitors, especially one's father and mother. The family is an unending chronic continuum linking the dead, the living, and the unborn. The principles underlying the kinship system are lineage, generation, sex, and seniority, and the most important relationship in the family is between the father and the son (Hsu, 1948). In this closely-knit network everyone is taken care of and nobody is left alone. The family clan may exert enormous influence over individual families and their members.

Extensive use of kinship terms outside the family and family clan, and even with strangers is a strong indication that among the Han the ideal society is one constructed on the family model.

While Confucianism provides the guidelines for interpersonal relations in this world, ancestor worship provides the solution for the next. As a religion Daoism plays an auxiliary role. Mahayana Buddhism which originated in India also has considerable influence. Christianity, both Roman Catholic and Protestant, is present and the followers are a small minority.

THE CONTEXT OF HEALTH: ENVIRONMENTAL, ECONOMIC, SOCIAL, AND POLITICAL FACTORS

Environment and Population Distribution

The Han people live mainly in the most developed agricultural regions and large metropolitan areas in the Song-Liao plain, drainage areas of the Yellow River, Huai River, Yangtze River and the Pearl River, and in Taiwan. Most of the areas where the Han live belong to temperate and subtropical zones with four distinct seasons. The north has a long winter when things are covered with ice and snow. The south is warmer and has more rain. 36.09% of the population live in urban areas and 63.91% in rural areas. Illiteracy and semi-illiteracy rate was 6.72% (2000).

Sedentary Agriculture in History and Recent Industrial Development

The Han people have practiced sedentary agriculture for thousands of years and developed sophisticated irrigation

systems that played an important role in the economy. While in the north one crop is raised, in the south two crops are planted. As majority of the population live in the countryside and practice agriculture, most of the activities have evolved according to a lunar calendar, that is agricultural routine. But recent changes have accelerated the country's industrial development. Now China ranks seventh in the world in GDP following the United States, Japan, Germany, France, Great Britain, and Italy. The way of life is changing fast.

Diet and Nutrition

Han diets vary with geographic location. The main staple foods in the north are wheat, corn, and millet and in the south rice and sweet potatoes. Vegetables form an important part of the Han diet. In the south, fresh vegetables are available all year round, while in the north, preserved cabbage, potatoes, and radishes are mostly relied on. With economic development, northern areas have more fresh vegetables in the winter. Red meats, poultry and fish are also important, but in the past they were consumed by the common people only during major festivals or on the occasions of entertaining guests. A Han meal is divided into two parts: *fan* and *cai*. *Fan* includes food grains and potatoes, and *cai* may consist of vegetables, meats, poultry, fish, and pickles. Dofu (soybean curd) made of soy is a popular food item which provides good nutrition and is a major protein source.

According to a 1990s survey, an average of 66.8% of dietary energy originated from cereals, 57.4% for urban residents and 71.7% for rural people. The proportion of protein coming from cereals was 50–60%, beans 5–6%, and from animals 20–30%; dietary fat provides 22% of energy intake (Ge, 1996).

As there is no clear demarcation between food and herbal medicine, Han people often mixed food with herbs and call them "Yaoshan" (medicinal foods). Herbs used are either tonic or are effective cures for some health problems.

Han people generally do not drink milk and dairy products were not very common, though milk and milk products are on the increase. Many of them do not have the tolerance for milk. Protein is obtained mainly from soy products like tofu and soy milk.

With the new economic policy and affluence, McDonalds, Hamburgers, Coca-Cola, Pepsi, etc., have made their way into the Chinese cities and are quickly becoming favorites of the children. Some nutritionists are critical of the new changes and predict serious health consequences.

Nutrition has improved substantially since the turn of the century. According to *The Dietary and Nutritional Status of Chinese Population, 1992 National Nutrition Survey*, average energy intake per person per day was 2,328 kcal, accounting for 97.1% (99.8% for urban residents and 95.7% for rural) of the Recommended Dietary Allowance (RDA). This shows adequate food has been consumed and hunger is no longer a problem. However, there are still serious problems with regard to nutrition.

Average protein intake was 68 g, accounting for 90.3% of the RDA. The intake of nicotinic acid (15.7 mg) and ascorbic acid (100.2 mg) was adequate, the intake of thiamine (1.2 mg) was fair, and that of retinal equivalent (Vitamin A, 156.5 mg) and riboflavin (vitamin B₂, 0.8 mg) was low.

Deficiency of calcium is rather common, and the intake (405.4 mg) accounted for only 50% of the RDA. As a result rickets is relatively common among children. The high incidence of osteoporosis among elderly women is also related to calcium inadequacy.

The apparent iron intake (23.4 mg) is adequate. However, iron deficiency and iron deficiency anemia are the most common nutritional deficiency problems, particularly among women and children. This is due to poor absorption of iron from plant food and specialists suggest enriching food with iron (Ge, 1992). In 1998, more than 50,000 people were found to suffer from Keshan disease due to lack of selenium, more than 1 million had Keshin Beck disease, while more than 9 million had diseases related to lack of iodine (China Yearbook of Health, 2000).

According to another report, inadequacy of zinc among children and early youth, and of iron among women is worrisome. Fifteen thousand people die every day (70% of total deaths) due to chronic diseases caused by malnutrition and nutrition imbalance, 21.6 million children are below their normal body weight, and 42 million children suffer retarded growth (China News Service, 2002).

Major Diseases

The ten leading causes of death in rural areas in order of incidence are; (1) respiratory disease, (2) malignant tumors, (3) cerebral vascular disease, (4) heart disease, (5) traumatic injuries and toxicosis, (6) digestive diseases, (7) urinary and reproductive diseases, (8) new born baby diseases, (9) TB, and (10) endocrine, nutritional, metabolic and immune diseases. In metropolitan areas they are

(1) malignant tumors, (2) cerebral vascular disease, (3) heart disease, (4) respiratory disease, (5) traumatic injuries and toxicosis, (6) digestive diseases, (7) endocrine, nutritional, metabolic and immune diseases, (8) urinary and reproductive diseases, (9) mental disease, and (10) neuropathy. Malignant tumors have risen 69% for the last 20 years. Specialists attribute this to more intake of red meats and heavy use of tobacco. China now has 3 million smokers. Environmental pollution is the third major factor contributing to increased rate of cancer (New China News Service, 2001).

Leading infectious diseases are viral hepatitis (incidence rate per 100,000 is 68.93), dysentery (45.91), gonorrhea (20.63), and newborn baby tetanus (16.55).

Since the Han people use nightsoil for crops, fecal-borne diseases are very common. Typhoid fever, dysentery and cholera were once causing the highest mortality in rural areas (Simoons, 1991). Parasitic infections and other major health hazard diseases that used to be prevalent have been put under control after the 1950s. In 1999, out of 1919 rural counties, 409 found snail fever (schistosomiasis) infecting 366,784 people (China Yearbook of Health, 2000).

Venereal diseases that were once rampant in the country were almost eliminated after the 1950s. But following the opening up and reforms that began in 1970s and the issuing economic development, they have come back at an alarming rate.

AIDS has become an urgent issue in recent years. According to UNAID, an agency of the United Nations, estimated persons infected with HIV might be as high as 1.5 million at the end of 2001. Chinese official reports estimated the figure of HIV carriers at one million during the first half of 2002, a 16.7% increase over 2001 (China Daily, October 16, 2002). Predictions are, that if no effective measures are taken, AIDS cases may reach 10 million before the year 2010. Drug use, illegal blood transfusion practices, and unsafe sex are the main problems. In a culture where the talk of sex is almost a taboo, dissemination of the right information concerning AIDS is very difficult.

According to an official report, in 1999 0.054% of the total population were drug addicts, which means that about 681,000 people were drug users. Of the drug addicts, those taking heroin made up 71.5%, and those under the age of 35 were 79.2% (CPIRC). The suicide rate is rising, especially among rural women. According to an official report 250,000 people commit suicide every year and the rate is 22 per ten thousand. Women are three times more likely to commit suicide when faced with unsolved problems, and suicide has become the leading

cause of death among people between 15–34 years of age (People's Daily Online, 2002).

Alcohol and Tobacco Use

Drinking strong liquor brewed from rice and other food grains is viewed as entertainment. There is no legal age for drinking; some may begin to drink from childhood. However, alcoholism is not a serious threat. People begin to smoke very early in life. No legal age limit is set and almost everyone smokes in the countryside. To offer a cigarette is considered a very friendly gesture few can decline. This is one of the reasons why respiratory diseases are so common.

Infrastructure

Among the Han people there are two medical systems, namely biomedicine that they call “Western medicine,” and traditional medicine which they call “Chinese medicine” (*Zhong Yao*). In both Japan and Korea, Chinese medicine is called the “Han medicine.” For clarity this article will use the terms “Western medicine” and “Chinese medicine.” Though Western medicine came to China during the early 20th century, it has never been able to replace Chinese medicine which has long become part of daily life.

Today Chinese medicine and Western medicine enjoy equal status. All medical doctors must be trained in both Chinese medicine and Western medicine although they may have either as their major area of training. All hospitals provide both services and when a patient comes to see a doctor, he or she may have a choice with the help of the doctor.

Health care in China was notorious before the 1950s. Steady progress has been made in public health since then. At the end of 2000, there were 325,000 health institutions (including clinics) throughout the country, with a total of 3.18 million beds, 2.21 million of which were in hospitals and public health centers. There were 4.49 million health workers, including 2.08 million doctors and 1.27 million senior and junior nurses (China Yearbook of Health, 2000).

By mid-1960s, an effective healthcare network was established and the whole population was provided with basic preventive and curative health care. Strict control by the government on drug production and sales ensured low

prices for quality drugs. Since early 1980s however, things have changed drastically. Market oriented reforms brought about an economic boom in the country, but at the same time, medical costs have risen sharply as public health sector is put to the mercy of profit-making markets. Corruption is rampant in the country; some reports reveal that many doctors are on commissions from drug suppliers. Major operations cost dearly. In addition, families of patients who need surgery give to the surgeons and other personnel they consider important good amounts of money and expensive gifts called “red envelopes” (*hongbao*).

While higher medical costs do not affect urban residents too much because they are mostly covered by medical insurance and special aid, higher costs have caused enormous difficulties for rural populations. The three-tier (county, town, village) health network that covered most of China's rural area with active participation from what were called “barefoot doctors” is no longer effective because of lack of public funding, privatization of village clinics, and profiteering of medical institutions. A 1998 survey conducted by the Ministry of Health revealed that due to financial difficulties, about 36% of sick farmers did not seek medical treatment and 61% of inpatients had to leave the hospital halfway through getting proper care. The fact that only one fifth of government total public health spending in the late 1990s went to rural areas, where more than 70% of the total population live, has caused controversy among government circles (Zhu, 2002.)

Some pilot programs with village-level public clinics which pool funds from villages, local government, and businesses are underway and collective medical insurance or social medical insurance systems are being tried, but the results are yet to be seen.

Status of Chinese medicine is very different among Overseas Chinese (Han). In some countries, they are still using it in their health care. In the United States and Western Europe, stringent policies against traditional practices favor biomedicine. The Dietary Supplement Health and Education Act of 1994 (DSHEA) and the issuing policy by the U.S. Food and Drug Administration created another category that is neither regular food nor drug: dietary supplements. Since Chinese medicine is not recognized as medicine, many Chinese medicinal patent formulas came to the U.S. under this category.

Some methods of treatment in Chinese medicine may be considered abusive by Westerners outside the culture. Skin-scraping, a procedure of scraping the surface

of the body until it is purple (near bleeding), and even acupuncture and moxibustion occasionally cause legal problems.

MEDICAL PRACTITIONERS

Four Thousand Years of Unbroken Tradition

The beginning of Chinese medicine was lost in antiquity. Legend of the Han attributed it to Shennong, “The Divine Peasant,” one of the earliest emperors who was said to have tasted hundreds of herbs. Later *Shennong Ben Cao Jing* (Shennong’s Herbal) was compiled in his name. It is perhaps the world’s first pharmacopoeia. Thereafter the investigation of herbal medicine has never been interrupted. A great amount of information has been recorded. Methods of preparing herbal formulas have been successfully refined, and the number and variety of clinical applications of herbal medicine have grown in proportion (Hsu, 1986).

In the 3rd century BC, *Huangdi Nei Jing* (*The Yellow Emperor’s Classics of Internal Medicine*) was compiled showing how advanced practical medical knowledge was at that time. Many of the formulas described in it are still being used today. Hua Tuo, a historically famous medical specialist in the beginning of the 3rd century, was able to perform major surgery including opening the stomach cavity and repairing the intestines, under anesthesia.

As a tradition, Chinese medicine is shaped by the influence of Confucianism in many ways. Its secular nature came from the Confucian attitude “to respect gods and ghosts but hold them at a distance.” In history, many Confucian scholars were also famous doctors, and their strong sense of history and responsibility to society made them instrumental in making the medical system a strong and unbroken tradition (Li, 1990). Landmark medical writings including materia medica and treatment experiences are countless including such works as Zhang Zhongjing’s *Shang Han Lun* (*Discussion of Cold Diseases*, about 200 BC), Sun Shimiao’s *Invaluable Prescriptions for Ready Reference* (652 AD), Li Shizhen’s *A Compendium of Materia Medica* of the Ming Dynasty (1368–1644), *A Grand Dictionary of Chinese Medicine* (1979), *Encyclopedia Sinica, Volume of Traditional Chinese Medicine* (*Zhongguo Dabaiké Quanshu Zhongyi* 2000) and the *China Pharmacopoeia* (2001).

Shamanism

Shamanism may have been practiced since the beginning of the Han civilization. The famous bone-shell script that evolved into the present Han writing (Chinese script) and was used to predict the future may also have been used to diagnose diseases. Since people also believed in supernatural causes of diseases, including gods, spirits of both dead people (ancestor or dead relatives) and some mysterious animals such as the fox and weasels, shamans were much needed to solve the problems acting as a go-between or a messenger between these supernatural beings and the human world. These shamans played an important relieving role in the countryside. Even during the time after 1949 when the Chinese government waged extensive campaigns against superstition and religion, shamanism has never disappeared entirely. With softening of the policy toward traditional beliefs, shamanism seems to have come back to the countryside especially in economically poor areas and remote regions.

Religious Personnel

In cosmology, disease and destiny (in the Chinese language destiny and life share the same word) are closely connected. Therefore it is understandable that religious personnel played a part in Chinese medicine. Most of the Daoist (Taoist) priests and Buddhist monks had very good knowledge of traditional medicine and used them in their congregations. People also looked to these religious premises for ultimate cures, especially in case of tenacious diseases or in case of barrenness.

Traditional Herbal Practitioners

Chinese medicine as a strong empirical tradition has always kept its secular nature, and to diagnose, treat, and cure diseases has always been an important profession. Some of these professionals people call “doctors” were full time herbalists while others, depending upon the circumstances in the community, might be part time practitioners and part time peasants.

Doctors of Chinese medicine were trained mainly in master–apprentice relationships. More often than not this master–apprentice relationship was just between the father and son. The founding of the People’s Republic of China brought about many changes in medical practice. Chinese medicine is officially recognized and enjoys the

same status as Western medicine. Training of doctors of Chinese medicine became formalized and institutionalized and research institutions have been set up with the China Academy of Traditional Chinese Medicine as the nation's highest authority. Universities and colleges have been set up to train traditional doctors and other specialists. They major in Chinese medicine, but at the same time they must have basic training in Western medicine as well. After graduation they would work in metropolitan hospitals or rural clinics. While they mainly use herbs to treat and cure, they also can legally use Western medicine, integrating the two systems as they see fit. Patients would also have a choice to elect for either Western drugs or herb formulas.

View of Western Medicine

Doctors in Chinese medicine tend to be more personable than their counterparts in Western medicine due to their training. They inquire into many aspects of the patients' way of life and tend to form closer interpersonal relationships with the patients and their families.

Many Han people feel that Western medicine is particularistic and analytic, and focuses on the ailing part of the body, "seeing only trees, but not the forest." On the other hand, Chinese medicine, though slow in efficacy, tackles the root cause of the diseases. So people would tend to go to a western medical doctor when the illness is acute, and go to a doctor of Chinese medicine when it is not.

Since the 50s, a process of integration took place in China and combination of the two systems has shown promising results. A popular statement in this connection is that $1 + 1 > 2$, and the experience has enriched both Western medicine and Chinese medicine.

CLASSIFICATION OF ILLNESS, THEORIES OF ILLNESS, AND TREATMENT OF ILLNESS

Theories of the Universe and of the Human Body

The Universe and Nature. The "Universe" or "Cosmos", as expressed in Han language, is *Yu Zhou*, designating space and time. "*Yu*" is the collocation of three-dimensional spaces and time. What they call

"*Zhou*" is constituted by the one-dimensional series of changes in succession—the past continuing itself into the present and the present, into the future. *Yu* and *Zhou* taken together represent the primordial unity of the system of space with the system of time. Han Chinese consider the world, man, and history in terms of comprehensive harmony that permeates anything and everything (Fang, 1986). Everything in the Universe including the Universe itself, is changing all the time, and each has two opposite aspects: *Yin* and *Yang*, which are in conflict and at the same time interdependent; any change is the result of the *Yin-Yang* change within it. Everything is related to everything else in the Universe in the way they should be: the *Dao* or *Tao*.

The Human Body and Five Elements. Humans are part of the Universe, or nature, and the ideal relationship between humans and nature is harmony. Adaptation to nature and to be one with it is the way (*Dao*). The human body, like the larger Universe, is an organic whole. The various organs and tissues are all connected to one another. The connected system includes meridians (or channels) and collateral which are the lines along which blood, vital energy, and the impetus to functional processes move. While meridians are the cardinal lines, the collaterals are the branches at various levels, which form a structural network (Xie, 1995).

Due to Confucian norms of filial piety which forbid hurting the human body, anatomy is not very developed in Chinese medicine (Li, 1990). That is why it is quite different from Western medicine with regard to the structure and functions of the human body. What are called the visceral organs are referred to rather as comprehensive systems of physiological functions than as anatomical entities. Among the most important ones are the heart, liver, spleen, lung, and kidney. But they are not the exact organs as understood in the English language. They should be read when used in the Chinese medical context, as the heart and/or higher nervous system (heart); the system that controls emotional activities, muscle action, bile secretion, and blood storage (liver); the system responsible for digestion, absorption, assimilation, and energy metabolism (spleen); respiratory system (lung); and the system which works to secrete urine and provide vital essence for heredity, reproduction, development as well as replenishing the brain, nourishing the bone, and producing marrow (kidney) (Xie, 1995).

The relationship among the five systems is represented with the relationship among the five elements: fire,

Figure 1. Relationship among the five elements. (Translated from Li, 1989.)

earth, metal, water, and wood in a complete circle as shown in Figure 1.

Here one can see the attempt of the ancient Han people trying to illustrate the most important human organs or systems with things they considered basic in nature. Properties and nature of the five elements are being used to explain the relationships of the five visceral organs. In the scheme, things go clockwise in a circle with one promoting the one next to it, but constraining the one next but one to it as is shown in the five point star. This must be considered in case of diagnosis and treatment as everything must be taken into consideration in both processes.

In order to carry out their normal functions, these visceral organs and other organs and tissues need *Qi*, blood, vital essence, body fluid, and nutrients. Here *Qi* are the basic particles which constitute the cosmos and produce everything in the world through their movement and changes. In Chinese medicine it refers to the force or energy required for various functional processes. It consists of two sources, the inborn and the acquired.

Concept of Illness

In Chinese medicine disease is defined in terms of breaking up of the relative balance in the human body. According to this theory, there is an endless process of adaptation among all parts of the human body and

between the human body and the environment. This process maintains a relative dynamic balance that in turn supports normal biological activities. When the human body is in harmony with the environment, pathogens will not harm it.

Diseases happen under two circumstances, one is when functional disorders occur in the human body and the “right *Qi*” is relatively weak, and the other is when strong “evil *Qi*” has affected the body. Right *Qi* means normal functional activities and the body’s ability to resist diseases, and the evil *Qi* means pathogenic factors. Onset and changes of the disease reflect the course of the struggle between the right *Qi* and the evil *Qi*.

The Han people attach primary importance to maintaining the right *Qi* which largely means “immunity” in terms of Western medicine. Diseases strike only when the right *Qi* is relatively weak. Outcome of the struggle between the right *Qi* and the evil *Qi* depends on the constitution, mental state, environment, habits, nutrition and exercise.

Pathogenic factors include atmospheric factors, epidemic pestilence, personal emotions, improper foods and physical fatigue, traumatic injuries, parasites, phlegm-rheum, and blood stagnancy.

There are six excessive atmospheric factors (*liu Yin*) that are wind, cold, heat, damp, dryness, and fire. Normally these natural changes will not cause diseases. They do only when the body’s resistance is low and adapts poorly to natural changes, or abnormal natural changes become too much for the body. Sometimes in-coordination among different organs may also produce the same symptoms. These are called “internal wind,” “internal cold,” “internal heat,” “internal damp,” “internal dryness,” and “internal fire.”

There are seven emotions that are the normal reactions to the outside world, but when subjected to repeated long term stimuli, especially drastic ones, each may cause imbalance between the *Yin* and *Yang*, between the *Qi* and blood, and malfunction of the internal organs, thus leading to diseases.

Classification of Illness

Chinese medicine classifies diseases according to their major patterns in terms of *Yin* and *Yang*, internal and external, heat and cold, vacuity and excess. In connection to the state of *Qi*, blood, body fluids, and different body functions, it identifies the nature of the major problems as

external cold, external heat, internal cold, internal heat, excess, vacuity, *Yin* problems, *Yang* problems, *Qi* inadequacy, blood inadequacy, etc.

Methods of Diagnosis

Doctors of Chinese medicine diagnose in four major ways including inquiry (asking questions concerning body temperature and how the patient feels, perspiration, general body feeling, urination and stool, diet, feelings of the lung and stomach, monthly discharges in case of woman, etc.), visual observation (patient's mood, face color, shape of body, and color, shape of the tongue, etc.), smelling and listening (patient's body odor and voice), and pulsation. Generally the information collected and the observed symptoms are enough to help the doctor determine the nature of the disease. Today doctors of Chinese medicine are also using modern equipment and methods such as stereoscope, X-ray, CT, etc., to verify conclusions.

Treatment Principles

Prevention as Priority. The overall guiding rule in treating diseases in Chinese medicine is determining the root cause. It includes two aspects: one is taking precautions before disease strikes; the other is prevention after a disease strikes. There are many formulas and methods to help enhance the immune system. As early as the 16th century, the Han people invented inoculation for smallpox. After a disease strikes, medical practice tries to intercept possible pathological changes. For instance, when the liver is out of order, it is important to protect and strengthen the spleen.

Balance as the Ideal State of Health. Because everything is connected to everything else in a relationship of cooperation and coordination it is the mission of Chinese medicine to redress any imbalance. What is more, in reestablishing this balance, efforts must be taken to avoid creating any new imbalance. That is why treatment with Chinese medicine is expected to be slow and noninvasive (Liu, 2002).

Holistic Considerations and Individualized Treatment. In prevention, diagnosis and treatment, everything, including the season and local conditions, physical and psychological environment, the patient's

age, gender and general physical conditions, family history, etc., all have to be considered. A patient from a Western culture may feel uncomfortable with a doctor of Chinese medicine when the doctor asks questions that are too personal.

Chinese medicine is an art of healing, and a good doctor of Chinese medicine treats the patient rather than the disease. Since everyone is a complete organism himself subject to different physical and psychological environments and every organism is changing all the time, every patient is necessarily different in Chinese medical concept, and therefore everyone must necessarily be treated differently. Every patient needs to be examined individually and individualized diagnosis must be made, and the treatment is unique. In high plateaus that are cold and dry, exterior pathological factors are mainly related to cold and dryness and treatment should use herbs that have the property of dissipating aridity, enriching, and moistening; and in an environment of heat and damp such as lowland area, herbs that can dispel heat and transform damp should be given the priority. Even in the same location, patients are different. For an instance, two persons are both diagnosed by Western medical doctors as having essential hypertension. But patient one is robust with a red face, red eyes, constipation, irritability, a thick yellow coated red tongue, and a wiry full pulse. A doctor of Chinese medicine would provide a treatment to calm down his or her liver fire (to cleanse the liver). Since patient two has pale and frail appearance, loose stools, low energy, pale flabby tongue, and a weak pulse, the same doctor would formulate a treatment plan to invigorate the patient's kidney *Yang* (to tonify the kidney).

Strengthen the Immune System and Eliminate Pathogenic Factors. In case of weak defenses, the emphasis has to be on enhancing the immune system in order to eliminate pathogens. On the other hand, when pathogenic factors are too strong, the focus has to be the elimination of pathogenic factors in order to strengthen the body's defenses. Sometimes, it is also necessary to do both at the same time.

Differentiation of Root Cause from Symptoms and Determination of Acuteness of the Disease. To treat the root cause instead of the symptoms is always the principal aim of Chinese medicine, but in treatment considerations are given to the actual circumstances. For instance

when it is a mild disease and not acute, it is right to treat the root cause. In case of acute diseases however, it may be necessary to treat the symptoms first. When the patient is running a high fever, bleeding, or suffering from severe pain, the symptoms themselves may lead to death if no drastic measure is taken to treat the symptoms. Eliminating the high fever, stopping bleeding and pain are imperative before going for the root cause. In some cases it may be better to treat both the root cause and the symptoms.

Straight Treatment and Paradoxical Treatment.

Straight treatment is to meet cold with heat and heat with cold, supplement in case of inadequacy (vacuity), and discharge in case of excess. These are the normal ways of treatment. However, when symptoms do not reflect the root cause, the opposite is called for. For instance cold symptoms may be the result of extreme heat, and in such case the right way is to use cold method. This paradoxical treatment is a hallmark of a good doctor.

Methods of Treatment

Since Chinese medicine is nutrition oriented, it treats various health problems in terms of excess syndromes, deficiency syndromes, and deficiency with excess syndromes. Deficiency includes deficiency in *Qi*, in blood, in *Yin* and *Yang*; excess includes excess in wind, cold, heat, damp, dryness, fire, phlegm, and *Qi*.

There are numerous methods of treatment in Chinese medicine, but basically there are eight approaches that are used singularly or in combination as the situation calls for: (1) The diaphoretic approach induces sweat to expel pathogenic factors. It is used for external problems such as unripe pox, sores, and boils. It may be due to external cold or external heat, and therefore there are two basic ways which are resolution of exterior with coolness and acidity, or resolution of exterior with warmth and acidity; (2) the emetic approach induces vomiting to expel pathogenic factors or toxins. It is used in case of thick phlegm in the throat or stagnant or poisonous food in the stomach; (3) the purgation approach is used in case of serious constipation, bloating, stagnant phlegm and blood, or in case of parasites. It is comprised of cold purgation, warm purgation, expelling of water, dissolution of stagnation, or expelling parasites; (4) the harmonization approach is used to resolve poor co-ordination between internal organs in their functions. Malaria and irregular menses are also treated this way; (5) the warming approach is taken

mainly to dispel cold pathogens, etc., as in case of internal cold pattern of diseases; (6) the febrifugal approach is to remove internal heat to protect body fluids; (7) the tonification approach is employed in case of deficiency or vacuity including tonification of the *Yin*, tonification of the *Yang*, tonification of blood and tonification of the *Qi*, etc.; and (8) the dispersion approach is used for stasis and accumulation in blood, *Qi*, phlegm, rheum and foods, etc.

It is obvious that the objective of all these is to achieve balance and harmony of the various organs and their functions while dynamic biological changes and processes are maintained.

Classification of Medicine

Sources of Chinese Medicine. Chinese medicine is characterized by natural, low cost, and nutrition oriented sources. So far there are 12,807 medicinal materials out of which 11,146 are herbs, 1,581 are from animal sources, and 80 minerals (*Encyclopedia Sinica*, Volume of Chinese Medicine, 2000 Edition). Because of the predominance of herbal sources, people refer to Chinese materia medica as herbal medicine. Based upon principles of Chinese medicine in formulation, there are more than one million patent formulas that can be adjusted with addition or reduction of some ingredients to suit particular needs of the patient. They represent a great rich treasure house for health care and fitness.

Properties of Herbs. Herbs are said to have four properties: cold, cool, warm, and hot, and five flavors: sour, bitter, sweet, pungent, and salty. The four properties have nothing to do with the temperature of the herbs. They are the resulting effects produced by the herbs. Coptis, phellodendron bark, gardenia fruit are classified as cold medicine because they eliminate heat, dryness, remove toxins, and they are normally used to tackle heat patterns of diseases, while aconite and dry ginger are classified as hot medicine because they are normally employed to warm the center and dispel cold.

From the beginning, Chinese medical practitioners found that herbs of certain taste possessed certain medical properties. With long historical development, the five flavors actually come to represent the properties rather than the actual flavor or taste. Herbs with sour flavor possess the ability of astriction and are used to treat seminal emission, night sweating, enuresis, enduring diarrhea, anal desertion, etc. Those with bitter flavor including

such herbs as coptis, phellodendron bark, gardenia fruit, etc., have the properties of dispelling heat, dryness, and toxins. Sweet herbs generally tonify and supplement, relax tension (acuteness), and harmonize the functions of different herbs. For instance, codynopsis, astragalus, and cooked rehmannia tonify and supplement in case of vacuity. Licorice and sugar relax tension, and harmonize different herbs. Pungent herbs disperse external pathogens, move the *Qi* and promote blood circulation. Mahuang treats wind cold and external problems, Cnidium (Chuangxiong) activates the blood, and carthamus disperses accumulation. Salty herbs soften hardness and drain precipitation and are used to treat scrofula, phlegm nodes, lump glomus, and dry and hard stool. Oyster shell, for instance, may help disperse hard lumps, and mirabilium can ease constipation.

Flavor and properties of an herb must be considered together. Herbs of same properties may be different in their flavor, and vice versa.

Herbs are also classified according to their tendency to reach certain parts of the body or channels. This selectivity of the herbs in their functions is called *gui jing* (channel entry). For instance, both phragmite and gentian root belong to cold herbs used to clear away heat. However, the former is particularly effective in clearing lung heat and the latter heat of the liver.

According to their functions herbs are classified into more than 20 categories, including diaphoretics or exterior resolution herbs, either for dispelling wind-cold or wind-heat; Antipyretic or Ferifuges; Antitussive, Expectorants and Anti-asthmatics; Digestives; Tonics including *Qi* replenishing herbs, blood replenishing herbs, *Yin* replenishing herbs and *Yang* replenishing herbs; Carminatives or *Qi* flow herbs; Blood circulators to remove blood stagnation; Hemostatics; Laxatives; Diuretics; Fragrant herbs for resolving damp; Anti-rheumatics including herbs for arthritic pain, for muscles and collaterals and for strengthening the bone and tendons; Warming herbs; Anticonvulsants; Sedatives; Aromatic stimulants; Astringents; Anti-malarial herbs; Anthelmintics; Analgesics, and Topical agents. These herbs are used as soldiers for specific missions whether singly or in groups to achieve prevention or curative effects.

Herb Preparation. Doctors of Chinese medicine are very sensitive to authenticity of the herbs depending upon the areas where they are produced. Through longtime

observation and composition they know that some herbs produced in certain areas are best in quality and therefore in curative effects. Ginseng, deer antler, and schisandra fruit in northeast China, rehmannia root, Chinese Yam of Henan, coptis root and fritillary bulb in Sichuan, wolfberry in Ningxia, and notoginseng in Yunnan are the most famous. They are more sought after than others.

Herbs must be carefully prepared and processed before they are used. Preparations include stir baking with or without auxiliary fluids (such as vinegar, wine, honey, salt water or ginger juice), calcination, roasting, steaming, boiling, water purification, fermentation, germination, and frosting. Different preparations may enhance the curative effects, reduce toxicity, remove undesired ingredients and taste, and make them easy to use and store.

Prescription Formulation Principles. After diagnosis and determination of the treatment principles, the doctor of Chinese medicine decides the principal herb and the auxiliary herbs in the formulation to achieve the curative effects wanted. Sometimes a single herb is used, but most often it is a compound preparation that may consist of anything from four to twenty herbs.

A compound prescription normally includes four different component parts. They are called Monarch (principal), Minister (adjuvant), Assistant (auxiliary), and Guide (conductor) respectively.

The principal ingredient provides the main curative action. The adjuvant helps strengthen the principal action; the auxiliary is a corrector ingredient to relieve secondary symptoms or to temper the action of the principal when it is too potent, and the conductor is to direct the actions of the principal and adjuvant herbs to the affected area or site or acts as a minor ingredient.

In a compound prescription, drug interactions must be considered. According to Chinese medicine, herbs may be either mutually reinforcing, mutually restraining (to weaken or neutralize each other's actions), mutually counteracting (one ingredient reduces the potency or toxicity of another), mutually neutralizing (one counteracts the toxic reaction of another), or mutually incompatible. Modern research has found that some of these relationships are valid and some are not. However a good herbal doctor is one who knows really well the properties of the herbs and uses them correctly and innovatively to treat his patients.

“Food Therapy”

A very important medical tradition is what is called *shi liao*, that is, food therapy. The origin of this can be traced back in history to several thousand years. *The Shennong's Herbal (shen nong ben cao jing)* carries 365 herbs classified into three categories including superior, medium, and lower grades. Most of those listed as superior are food grains, vegetables, fruits, meats, and herbs with a friendly nature. As herbal drugs are strong and taste awful, and long-term use may hurt the stomach, the best way is to use food to do the work. This is considered an ideal since foods may not only cure in the long run, but may also be made into something enjoyable. Food therapy follows the same principle as herbal treatment, that is, to warm up when cold is present, cool off when heat is the problem, to supplement in case of deficiency (vacuity) and discharge in case of excess. For this, food items are classified into different categories according to their properties and diet is planned in such a way as to achieve therapeutic result in different situations. Food therapy is often employed to supplement medical treatments, especially for chronic diseases.

Health through Proper Diet

Another tradition based on Chinese medicine is called *shi yang*, health through proper diet. It is to select certain diet to regulate various biological functions of the related organs of the body, to nurture the *Qi*, the blood, body fluids, to build up the body's resistance to diseases according to different needs in terms of constitution, age, gender, the season or local conditions. For this, people are classified into several types with different constitutions. For instance, those who tend to suffer *Qi* deficiency should include yam, lotus seeds, pork, and eel in their diet, and those who have blood deficiency problem should include longan, wolfberry, mulberry leaf, chicken, carrots, etc. Those who have *Yin* deficiency should eat white fungus, honey, sesame, black bean, etc. And those who are identified to have *Yang* deficiency should add mutton, shrimp, chives, etc. Foods are different in different seasons, and local conditions differ. People in different regions have different needs in foods.

“Yangsheng” (Life Preservation)

Shi liao and *Shi Yang* are included in another wider approach called “*Yangsheng*,” that is, life preservation. This includes a variety of ways to prolong life.

A very important part of *Yangsheng* is *Qigong*. It is to achieve good health through breathing exercises, meditation, mental channeling, etc. As a component part of Chinese medicine it has a history of over 4,000 years originating from a kind of dance to maintain good health and to prevent diseases. Along the way it absorbed many elements from Daoism, Confucianism, and Buddhism and in a way it also acquired some religious characteristics to certain extent (He, 1998). The key concept is energy cultivation. It is said to be very effective in eliminating fatigue and achieving relaxation, enhancing the immune system for prevention of diseases, and treating and curing diseases connected with certain systems such as the nervous system, the circulatory system, the respiratory system, the digestive system, the endocrine system, and the immune system.

Many schools have developed over the years. Most of the Chinese medical writings cover *Qigong* exercises. The best known is the *Taiji* exercise, a set of slow movements which have spread far and wide outside of China. During the so-called “Great Proletarian Cultural Revolution” from mid 1960s to mid 1970s, *Qigong* was suppressed until the chaos was over. In 1986, the Degree Committee under the State Council made a decision to adopt *Qigong* in Chinese medicine as a new science discipline, and special funds were set up for further research and it became part of clinical treatment. Doing *Qigong* became part of daily life, especially in the morning in parks.

Currently the enthusiasm for *Qigong* seems to have had a setback with the government suppressing the *Falun Gong*, a quasi-religious group officially named an evil cult. It started as a *Qigong* organization and attracted many people. The government was taken by surprise when suddenly it organized a mammoth sit-in demonstration surrounding the government seat in Beijing.

Another area of *Yangsheng* is to control desire and avoid indulgence, especially sexual indulgence. Self-emotional control is also a very important part of these exercises. All these are aimed at achieving balance between *Yin* and *Yang*, promoting normal flow of the *Qi* and blood, increasing the essence and preserving the semen.

Tuina

Another treatment method in Chinese medicine is *tuina*, a special type of therapeutic massage. The origin can be traced back to pre-historic times. Its basic therapeutic orientation is the Chinese medical theory of the flow of *Qi*

through the meridians. *Tuina* has many unique techniques including one finger pushing, rolling, *neigong* (internal *Qigong*), pointing, bone setting, etc. It can be done alone or in combination with *Qigong*.

Acupuncture and Moxibustion

Originally a component part of Chinese medicine, acupuncture and moxibustion have developed into a medical system in themselves. Two things are involved, one is to stimulate locals on the human body to achieve therapeutic effects, and the other is to use heat to achieve therapeutic results. They are used either separately or in combination. The origin can be traced to Neolithic times, 8,000 to 4,000 years ago. Needles were made of stones, wood, bamboo and finally metal, especially silver or stainless steel. Moxibustion uses leaves of mugwort (*artemesia vulgaris*) made into a cone and burned on oilment or ginger slice. The basis of both acupuncture and moxibustion is the concept of channels (meridians and collaterals) in the human body through which *Qi* travels. Channels (meridians and collaterals) are distributed all over the body and coordination or various functional processes are realized through the *Qi*. Acupuncture and moxibustion rely on the relationship between the *Qi* and the meridians for successful therapy (Xie, 1995).

Now electricity, magnets, laser, infra-red, and microwave are added to needle stimulation. Clinically it is comprised of four aspects: treatment with acupuncture and moxibustion, maintenance of good health with acupuncture and moxibustion (mainly to enhance the immune system), anesthesia with acupuncture and diagnosis through channel-local manipulation. Acupuncture has been accepted as legal and valid method of treatment in many countries in the world.

SEXUALITY AND REPRODUCTION

Sexual Attitudes

As noted above, Chinese medicine holds that congenital essence is responsible for reproduction. It is stored in the kidney and serves as the origin of life. Congenital essence can be transformed into acquired essence and vice versa. Sexual over-indulgence is regarded as one of the major causes of disease. Exhaustion of the reproductive essence stored in the kidney impairs other organs and has serious

health consequences. For this serious efforts were made, especially among the leisure class, to preserve semen. Many writings, mostly Daoist in nature, discussed ways of sex without ejaculation. Occasionally some “masters” would advocate sex with young girls as it was thought to be tonifying for the man. In a way, women are considered dangerous for a man since she could deplete him of semen.

People generally avoid talking of sex. The purpose of marriage is understood to be to produce children to continue the family line. Sex, except for producing children, is generally considered immoral. So there has been great secrecy surrounding sex.

Seclusion of Women

Historically, seclusion of women was practiced and premarital sex was strictly forbidden. Marriages were arranged by parents and often the nuptial night was the first time the couple met. It was a great scandal if the bride was found to not be a virgin. Even now it is still common to have a relative or a friend to “introduce” a girl or a boy since it may be considered improper to approach the opposite sex directly for purpose of marriage.

Traditionally, only men could initiate divorce and a divorced woman carried stigma and little hope of a happy remarriage.

Fertility

The average lifetime fertility rate of Chinese women was reported to be 1.81 (1.98 in rural and 1.22 in urban areas) in 2001 (National Family Planning & Reproductive Health Survey, 2001). As the Han are a huge majority, this may well represent the fertility of Han women.

Barren women are considered unlucky and for a long time it was blamed on the woman if a couple failed to produce children or failed to produce a boy. It was generally hoped that a married couple should have as many children as possible and begin to have children as early as possible. It was common to find a woman having eight or even ten children. After 1949, there was a time when having more children was encouraged by the Chinese government until there was a population explosion. Since then there has been a policy encouraging late marriage and fewer children. During the seventies and eighties, the policy was to allow only one child per couple among the Han people while minorities may have more. The policy was quite successful in urban areas while in the countryside it was

not so successful. As only the male child would be able to continue the family line, people generally prefer a boy, and the government One Child Policy met with great resistance. Forced abortion took place frequently, but rural people could evade it in several ways. Abandoning of unwanted children and infanticide due to poverty were quite common before 1949. After 1949, they were virtually eliminated. But the One Child Policy led to frequent female infanticide and abortion of female fetuses. The Fifth National Census (2000) reported the sex ratio at 116.9:100, alarmingly different from the international ratio of 105:100. Specialists attribute this to social factors and biological factors, but to what extent infanticide of female children, selective abortion or other factors each contributed to this ratio remains unexplained.

Ideal Household

Large families comprising three or four generations are generally considered ideal. Historical records often highlight large families, sometimes with a few hundred people living under the same roof. But these are exceptions rather than the rule. Statistics show that the average family size through different times in history was 4.84 persons (Qiao, 1990), though the clan, mostly under the same surname and therefore having the same ancestry, could be quite strong organizationally. The 2000 census indicated that the current average family size is 3.44 per family. There are many joint families and extended families in the countryside, but most of the families in the urban areas are nuclear families.

HEALTH THROUGH THE LIFE CYCLE

Pregnancy and Birth

Since the purpose of marriage is to have children, especially male children, the news of pregnancy is always a good one to the family and it is also the beginning of good expectations, particularly for a boy. People begin to be protective of the pregnant woman and she may be excused from heavy labor. Habits and practices around pregnancy and birth differ from place to place. The husband's mother may even go to a temple to pray for a healthy grandson. Generally the expectant mother should not go to unlikely places such as the burial ground or participate in a funeral. There are taboos as to what she may or may not eat. For

instance, in some places she is not to eat rabbit for fear of giving birth to a child with cleft palate.

Han people had the practice of what is called "fetus education" in order to have a child healthy both physically and mentally. The mother should avoid sex, noise, bad thoughts, and bad images, and adhere to correct and nice language and demeanors.

A birth of a boy was called "great happiness" which was an occasion of elaborate celebrations and the mother's position in the family could be said as established, while a birth of a girl was called "small happiness." Normally there was not a problem if the first child was a girl as she may help take care of her younger siblings. It would become worrisome if the couple continued to have girls. The One Child Policy puts great pressure on women to have a boy.

Traditionally babies were born at home with help from a midwife and other experienced women. No man or child should be present, though the husband was normally kept close by for emergencies. His urine was sometimes given to the wife to drink in case of difficult labor. Children are generally kept from any knowledge about sex and birth. The answer to the question of where the baby is from is answered evasively. Often it is said to have been picked up from a dung-heap outside by accident.

As of 1999, 70% of deliveries were in hospitals. Hospital births are much higher in urban areas (83.3%) than in the countryside (61.5%). Births with new delivery methods (both in and out of hospitals) account for 96.8% of all births (China Yearbook of Health, 2000). Formerly the greatest risk for the new born baby was tetanus due to use of dirty scissors and un-sterilized cloth ropes to tie the umbilical cord, and for the mother it was puerperal or childbed fevers. Infant mortality in China was rated the highest in the world, 275 per 1,000 live births in 1927, and maternal death was estimated to be about 200 or more per 10,000 live births, at least three times that of western countries (Simoons, 1992). Since then things have changed and infant mortality in 1990 was 33 per 1,000 and maternal death was 95 per 100,000 (China Yearbook of Health, 2000).

For the first month after birth, both mother and child are kept indoors for fear of severe environmental conditions such as drastic temperature changes and evil spirits. For the mother, this is called "doing the month" (*zuo-yue-zi*) when she is given nutritious food to recuperate and to generate enough milk for the baby. This was perhaps the only occasion for her to enjoy extra treatment since in daily life women were expected to eat last and poorest.

Traditionally, a new mother had to avoid any exercise and washing of her body and hair for fear of future chronic diseases such as arthritis and headache. For government employees these mothers are given a paid leave. If no one in the family can take care of the baby, she would put the child in a nursery during the day when she returns to work.

Infancy

A newborn baby is taken care of by everybody in the family. A preferred caretaker both of the new mother and the baby is the husband's mother. In some regions the baby is tied with three cloth-made ropes, one just under the shoulders, the second around its waist with both hands on the sides, and the third just above the ankles. From time to time the grandmother would turn the baby to a different direction and a well-cared baby would have a round head and long limbs. Breast-feeding is generally the rule and may continue for up to 3 or even 5 years; 90–95% of infants were reported nursed by their mothers (Simoons, 1992). Newborn babies are kept from people considered unlucky, such as widows and those who have serious diseases. When traveling with young children, it was important to come back the same way so that their souls may not get lost. When the child was thought to have lost its soul the mother or grandmother would knock the door upper lintel with a ladle to call it back. In some places children are shaved with a pigtail behind called "*gui-jian-chou*," meaning "devil's fear" to ward evils away. It is quite common to have a boy with a name of a girl to appear cheap so he may be left alone by evil spirits. Children whom the family considered vulnerable and had fear of losing may even be given a name meaning, a dog, or a monk to ensure their safety. A boy may be called "*ya-tou*" (girl) for the same reason. To ensure safety of the child, the family might also make clothes for it from oddments of cloth, or a meal of rice collected from a hundred families.

Childhood

Children were taken care of by the elders, preferably the grandmother on the father's side, (though it is quite common, and even more preferably by the grandmother on the mother's side in urban areas), and older siblings. Corporal punishment is common and people believe it is good for the child. Traditionally Han Chinese thought children belonged to and were at disposal of their parents, grandparents, etc., and theoretically these elders could do

anything with them. It was not even a crime to kill them if they so wished. Generally there was no concept of child abuse as such. How to treat children was a moral issue rather than a legal one until recently.

With older siblings as caretakers and playmates, it helped to build up the pecking order according to age and form close sibling relations called *Ti* (fraternal duty) among them. But the One Child Policy of the government in which a couple is allowed to have only one child has changed this enormously. Social scientists are worried that a future generation without siblings will lead to social problems. A popular name for these children is "small emperors" characterized as spoiled, selfish, overweight, etc.

Adolescence

Children participate in adult activities early and learn life skills by direct observation or by assisting adults in chores. Anthropologists say that traditional Chinese (Han) children did not have adolescence. Girls were taught skills they would need after marriage. There was virtually no sex education especially in the countryside where young people had to pick up scraps of sexual knowledge from older friends. Now children begin to go to school at 6 or 7, mostly in their own neighborhoods in urban areas and villages in the countryside. They are encouraged to help their parents in their work, especially during vacations.

Adulthood

Traditional Han society considered men and women adults at marriage. The basic objective in life was to take care of the man's parents and other elders in the family and to have children to continue the family line. Marriage was arranged by parents and other elders in the family with help from go-betweens. Ideal age of marriage was 16 for the bride and 18 for the bridegroom, but often a girl child was taken to her husband's house to be raised by her parents-in-law first. After 1950s, free choice has been encouraged though in most cases people still use friends or relatives as go-betweens to introduce the couple to avoid embarrassment. Menopause starts between 45 and 49.

The Aged

Age carried great respect and authority in traditional Han society. The eldest male was generally the family head

with decision-making powers. Normally they had light work and would be given better food and tonics to eat. They were the center of everybody's attention and it was the obligation for everyone to take good care of them. On important occasions they were worshiped by everybody in the family. Even today, elderly people continue to live with family until they die, and only those who do not have sons or daughters are living in what is called "jing-lao-yuan" (home to respect the elderly), the Chinese version of a nursing home paid by the community.

China is an aging society. In 2000, one in every 10 people was 60 years of age or older. Those beyond 65 made up more than 7% of the population. The sharp decrease in birth rate since the mid 1970s has resulted in a huge number of one-child families. By around 2010, parents of these single children will be getting frail or senile. In the future, an adult couple will have to support four parents and one child. With rising cost for child rearing, including education and medical care, the financial burden on the couple will be formidable. Besides, senile dementia, common for senior citizens, will rank the third highest health problem in incidence by the middle of the 21st century, next only to cardiovascular and cerebrovascular diseases. Caring for these people will become a big problem for families psychologically and economically. There is an urgent need to build a social security system (Zhang, 2002).

Dying and Death

Traditional Han people believed in a next life after death and it was imperative for the living to send money and necessities for their comforts. This is the reason why one should not die sonless. Only those who had a grandson (son's son only) could avoid becoming hungry ghosts. The dead would be washed and dressed in their best, normally black suits or coats. Mourning would continue for days depending upon family means and what the astrologer would say. The occasion was important for the large clan members and relatives to revisit the notion how closely related they were with each other either through the dead or other connections.

Han people used to bury their dead and every clan or family would have their own burial ground where people went to burn paper money and other things, and cremation was limited to abnormal death such as death in traumatic accidents and painful diseases. Since the late 1960s, the

Chinese government began to encourage cremation and forbid burial in order to save land for agriculture. Now urban residents have accepted cremation, but many rural people still bury their dead.

A rich family may invite Buddhist or Daoist monks or both to recite sutras to add to the merits of the dead so that they would be treated well in their next life by being sent to heaven.

Hausa

Murray Last

ALTERNATIVE NAMES

“Hausa” is the most common term for these people. Earlier terms include “Habasha” (from which “Hausa” probably derives) and “Afnu” (used by Kanuri-speakers of Borno), but political scientists are apt to use “Hausa-Fulani” to indicate the fact that the old ruling elite is often labeled “Fulani” for historical reasons (they no longer speak the language of the Fulani, *fulfulde*) (Paden, 1975).

LOCATION AND LINGUISTIC AFFILIATION

Hausa-speaking people number at least some forty million and live mainly in the most northerly states of Nigeria and in the Republic of Niger. Hausa-speakers are also found in the Republic of the Sudan as well as in Eritrea, Chad, Cameroon, and Ghana. And there is a diaspora to North Africa and the Middle East (Tunis, Tripoli, Cairo, the Saudi cities), to Europe (especially France, Britain, with immigrants to Spain and Germany coming from the Hausa communities in Ghana), and to the USA. In the past Hausa traders traveled widely, and could be found living in India and southern Russia for example; there were also Hausa-speaking communities in 18th and 19th century Brazil due to the slave trade. Hausa was a written language using Arabic script (*a'jami*) for poetry and personal correspondence; prose works were later, dating from the late 19th century, and in the 20th century Hausa has been printed using a slightly modified roman script for textbooks (e.g., on subjects like health), religious works, and novels. The Hausa language is one of the “Chadic” languages, within the Afro-Asiatic language group (Newman, 2000). It became the language of cities and long-distance trade, and has spread as a *lingua franca*. It was used as the language of government by the British colonial administration in northern Nigeria. There is also an elaborate traditional sign-language used by the Hausa deaf and their neighbors (Schmaling, 2000).

OVERVIEW OF THE CULTURE

In the 19th century, Hausaland constituted the political and economic core of the Sokoto Caliphate, then the largest autonomous state in pre-colonial Africa (Last, 1967). The caliphate, governed from Sokoto and from Gwandu, consisted of a large number of emirates, in Hausaland the most important of which were Kano, Katsina, and Zaria. Under colonial rule (1903–60), the emirates formed the core of separate Provinces, and these became states during the Nigerian civil war (1967–69). The original states have since been sub-divided to create more states; each state is in turn divided into Local Government Areas.

The economic base of Hausaland was its farming (Hill, 1972; Mortimore, 1989). Cotton growing and weaving was a major activity, and still is today. Under colonial rule, groundnuts became an important export crop. Otherwise, trading and transporting was the staple of the urban economy, along with a variety of craft production using metals, wood, leather as well as cotton; the production and trading of books in classical Arabic was also significant, requiring a large learned class (cf. Koki, 1977). Since the 1980s, oil has supplied over 95% of Nigeria’s national income. The rural economy is focused on food production, while the urban economy is heavily dependent on revenue funneled to the states and to the local governments from the Federal Government and its oil account.

Hausa society is Muslim (Sunni, using the Maliki school of Islamic law). In the countryside, there exist small non-Muslim communities (*Maguzawa*; *Arna* or *Anna*), and there are converts to Christianity, many of whom speak Hausa as the language of the church (Crampton, 1979; Last, 1993b; Nicolas, 1975). Inheritance is patrilineal, and polygyny is permitted; though the limit is four wives (and, in the past, any number of concubines), two wives are not uncommon for a man in his 30s or 40s. Divorce is common and easy; a woman might get through four husbands in a lifetime, even taking her very young children with her. Slavery was made illegal by the British administration in the 20th century.

The relatively brief period of British administration (1903–60) transformed Hausaland, not only by making it part of the new confederation, Nigeria, and eliminating local warfare, but also by slowly introducing new schools, a new medical system (including public health), new methods of transport (railways, roads, later airlines), and an economy of export crops (groundnuts, cotton); a market in hired labor replaced the previous use of slave labor, while dry-season migrant labor traveled far south, beyond Hausaland, for work. Existing Quranic schools and the tradition of Islamic learning were maintained, as were the courts administering the sharia law (with modifications). Hausa medical and surgical practices continued, as did the methods for controlling and curing mental illness; healers were neither illegal (as elsewhere under colonial regimes) nor persecuted. Christian missionaries were not allowed until the 1930s, and then restricted to non-Muslim areas; apart from leprosaria (and an eye hospital in Kano since the 1940s) their medical work was minimal (Schram, 1971).

The sixth largest oil-producer in the world, and with a population of some 120 million people, Nigeria has several major medical schools (among its 36 universities). There are some 3000 Nigeria-trained doctors working abroad, so that there is a shortage of high-caliber medical staff in Nigeria itself. Currently the shortcomings of most biomedical facilities have meant that Hausa people are still using traditional medicines, self-medicate, or opt to take no medicines at all.

THE CONTEXT OF HEALTH: ENVIRONMENTAL, ECONOMIC, SOCIAL, AND POLITICAL FACTORS

Oil-derived wealth has transformed young people's awareness of health and medicine. Traders in village markets opened booths selling a variety of biomedicines, with some having needles to offer injections of antibiotics as well as capsules. Medicines have become a profitable business; little expertise is needed, as diagnoses and prescriptions can be had from hospital staff even when the hospital pharmacy has no drugs on its shelves. Cut-price but fake drugs are commonplace and undermine confidence. By contrast, leprosy clinics handing out a weekly supply of dapsone (thought useful for a range of disorders) have all but disappeared. And cigarette smoking has plummeted as

women, once the greatest purchasers of cigarettes, have turned against it, persuaded by Muslim preachers in the marketplaces.

The elimination of smallpox and the control of sleeping sickness have made a significant difference in rural areas. A more common yet major hazard for country-dwellers used to be guinea-worm (often acquired when washing after a day's work). New hazards include the widespread use of amphetamines (and now a cheaper local tonic known as *gadagi*), to make one work faster or for longer hours, and some take overdoses and have to be taken to a mental hospital. Another new hazard is road accidents; emergency services are poor, with neither phones nor ambulances and stocks of blood rarely ready for transfusion. Most recently (in the late 1990s) HIV has been diagnosed in country villages, with occasional deaths noted as being from AIDS. In the big cities of Hausaland it has been more commonly reported, but the stigma (and the lack of diagnostic facilities) has kept figures down. Less than 5% are infected (according to the government), with much higher levels among the sex workers surveyed; the military are also concerned about higher-than-average infection rates in army barracks. Epidemics of measles and cerebro-spinal meningitis cause higher numbers of deaths, as does cholera. Malaria, too, is a seasonal cause of death.

In rural areas meat is rarely eaten (dogs are vegetarian too), except at the annual festivals. Milk products have become rare as reduced grazing areas have reduced cattle herds; soured milk and butter were once regularly available (raw milk, being indigestible by adults, was not drunk). Only in far northern areas of Hausaland might camel's milk be available for making cheese. Hens' eggs are not eaten (except in cities), while those of guinea fowl are sent for sale to southern Nigeria as they have stronger shells and last three weeks unrefrigerated. No game remains; even birds are rare as children shoot them with catapults to eat roasted. Some insects (*gara*) are also roasted seasonally by rural children. In recent years bread has been widely marketed, with sugar but not salt added; biscuits, boiled sweets and mints are widely available, as is Coca-Cola and similar drinks in village market shops. Sugar consumption has therefore increased, even though the once-common supplies of semi-refined brown sugar blocks (*mazarkwaila*) have all but disappeared. Honey (*zuma*) from wild bees is comparatively rare now too. In general, foods that are sweet (and "sweet" includes salt) are thought to be bad for you, producing a mucus-like

substance (*majina*) in the body; many snack foods are indeed sweet but are taken in small quantities. Late-onset diabetes is quite commonly diagnosed among the well-to-do (who have access to the routine tests of clinical medicine), and may be a response to an unusually high consumption of imported sugars taken with tea and breakfast cereals, foods that are not commonly found in the village diet.

Hausaland thus offers two distinct dietary regimes: the rural areas which would normally be self-sufficient in foodstuffs and export surplus grains to the big towns; and urban economies which import their food supplies not only from surrounding areas but also from abroad. Imported rice and maize as well as processed “fast” foods such as semolina and pasta, along with a variety of ready-made sauces and spices, have altered the “traditional” diets of many wage earners whose staples in the past were sorghum and millet, with gravies including products of the baobab or locust bean tree, or with local groundnut- or palm-oil. Cowpeas added variety, as did spinach leaves mixed with processed groundnut; so too did cassava, grown on special plots and sold, cooked as snacks; in the cities especially, fried fish of various kinds are available on the street, cheaper now that dams have been built for irrigation and rivers are no longer the main site for fishing. Goats, sheep, hens, and ducks are reared within houses, especially by women, but their role is not as food for the household but as items for sale: they serve as a woman’s “savings bank,” especially in cities.

Water from wells (and not from open pits) is commonly drunk in villages. Tap water is relatively scarce even in cities, where water-carriers distribute water from boreholes. Wells within houses in old cities such as Kano are now often contaminated, and their water at best can be used for washing; its taste precludes use in cooking (Last, 1999). Rarely is water boiled before use, nor is it filtered. Hence soft drinks like Coke and Pepsi are “pure,” as is bottled beer, which, being alcoholic, is not allowed for Muslims. Traditionally, non-Muslim Hausa brewed beer, which was drunk once or twice a week as a social drink, especially by elders; it was cloudy, nutritious, and (when very fresh) not very alcoholic. It was the only boiled liquid available. Today, it is more rarely found, and those who drink it drink to get drunk (if there’s enough for sale); alternative sources of alcohol are distilled spirits, imported from southern Nigeria. But alcoholism is unusual in Hausaland, or is invisible; hard drinking is done in private.

Wells have other uses, too. Deep wells are the most common site for suicide and attempted suicide (the fire brigade is called upon to rescue people from wells). They are also places where the bodies of victims of violence can be hidden. Contamination of wells and water supply is a standard source of panic, and scare stories against a pariah group may accuse them of this crime. Water, then, is dangerous; only children swim for pleasure—no one is taught to swim. Bilharzia is common where children have been tested for it. Defecation in rural areas is traditionally done on waste ground or on fields close by the farmstead. Only in towns are there pit latrines (*salga*) which are emptied periodically by hand by specialists hired by the residents. The night soil is taken to the edge of town where it dries out and solidifies and is eventually sold to farmers for use as manure. While the latrine is partly full, ash from the cooking place is sprinkled on the surface to reduce the smell. The hole, being infested with cockroaches, is often kept covered with a plate. A rising water table (as in Kano city today) causes latrines to fill more rapidly with water than was usual in the past. Where possible, the preferred direction to face when defecating is south (one prays, in contrast, facing east). Most people defecate very early in morning or at night; and if they are defecating outside they often choose a high place or a slope too steep for housing.

Houses are regularly swept clean by the women of the house, though not in the middle of the day when spirits might be playing (you normally say “excuse me” as you sweep, in case a spirit is about to be disturbed). Inside a house the ground is kept very tidy; but outside the house, rubbish tends to accumulate as the public authorities have generally ceased to clean the streets even in relatively wealthy parts of town. There is a good side to this: as spirits like rubbish to play in, heaps in the street keep them occupied there rather than coming over the wall and inside houses. Spirits are coming into towns, cities, and even villages in ever larger numbers from the “bush” because their “homes” are disturbed by people and especially by motor traffic; hence modernity brings mental illness.

MEDICAL PRACTITIONERS

Healers

There is a range of terms for healers. The most traditional are *maye* (“witch,” implying he deals with spirits) and

boka who is more aligned with herbal medicine. *Maita*, the ability to be a witch, is inherited; there are lineages of *mayu*. Itinerant sellers of medicine may call themselves (or be labeled by villagers) *mayu*, and advertise their wares by a particular roar that can be heard from the street. Their witchcraft substance, ideally *kankara* (hailstone or ice), is in my experience a glass marble flecked with red paint ("blood"); this is elaborately coughed up from the stomach and an object of real panic to villagers. A *maye* in serious medical practice does not travel, but runs an asylum for the mentally ill, often deep in the countryside. Patients are brought to him from afar (sometimes from outside Hausaland), and they may stay with him for a year before they are discharged. He gives patients herbal medicines to drink, and shackles them if they are prone to running away. He initiates them eventually into the *bori* cult, but the primary treatment is herbs, incense, and time. A *boka* may do much the same work (Last, 1976, 1981; Wall, 1988).

Other healers include the *masu magani* (skilled in medicines, mainly herbal) and *masu bori* (skilled in the *bori* spirit cult). The *wanzami* is the barber who may also do some surgical procedures such as circumcision on boys (occasionally on baby girls too, when he merely nicks the hypertrophied hymeneal tags) and a uvulectomy; he is likely too to incise the identity marks on babies and the decorative patterns on girls' necks or upper chest at puberty. He usually tours his district, often on horseback, and is quite distinctive with his hat and equipment. The *madori* sets bones that have been broken (now more common with football being such a popular sport), using bandages, herbs, and prayer (plus a chicken bone), with repeated visits to his patient; no anaesthetic is used, and manipulation is minimal. Finally there is the *ungozoma*, who is any woman serving as a midwife at childbirth in a home delivery. With obstructed labor or especially difficult deliveries, women try to get to a hospital; the traditional midwives are not really experienced in turning a fetus and do not use instruments such as forceps. Cases of retained placenta are treated at home, using a log of wood pressed on the abdomen, but again husbands try and take their wives to the nearest hospital. Pregnant women fearing an obstructed labor may take a razorblade and do a kind of episiotomy on the anterior wall of the vagina. Since the area is particularly vascular, considerable blood loss is possible; worse still, the urethra may be cut, resulting in incontinence that is very difficult to repair in hospital. What women are worried about

here is *gishiri*, an infection that "causes" the anterior wall to swell and "block" the birth canal. It is transmitted from woman to woman, via cooking stools (Last, 1979). The cutting of the umbilical cord and using herbs to seal the cut sometimes results in tetanus in the newborn, whose death is attributed to spirits or to witchcraft within the house. Accusations of witchcraft can split the household, leading to divorces or to physical violence against the "witch" (*mai dodo*).

Other specialists include men expert at pulling teeth without an anesthetic; and there are those who specialize in treating livestock. Oxen are castrated, by smashing the testicles with a stone; wounds from fights involving horns have to be sewn up; cattle need de-worming. But small livestock are treated by their owners, using the common wisdom of the house which may include opening up capsules containing antibiotics and applying the powder to wounds. Snakes are relatively rare, and snakebites even rarer. Lancing (*sakiya*) a boil or an infected site is done with a red-hot arrowhead (*kibiya*). It is a procedure done at home, as is the procedure for removing "dead blood" from the back of a man by applying suction through a cow's horn. Cesarean sections were apparently not done traditionally.

The main modes of healing involve (1) spirits and/or ghosts of the dead; and (2) remedies made from plant materials, parts of dead animals and minerals ground down into powders (Etkin, 1979, 1981, 1996; Etkin & Ross, 1991; Ross, Etkin, & Muazzamu, 1991, 1996). Some healers have their own brews, unguents, or powders, whose composition is a secret; others combine these with verses of the Quran, with numerological "squares" or with special prayers and words written on scraps of paper folded into a "charm" (*laya*). "Islamic medicines," sold in bottles, are now gaining popularity in towns. Farmers often bring plants in very early on market day in order to sell them to the medicine seller (*mai magani*). Although herbs are collected from forested areas, in practice most useful plants grow on farmland or around settlements. In demand are the various incense woods that are burnt at night in people's rooms; Muslim spirits especially are associated with particular scents.

The cult of spirits known as *bori* has been the subject of much study (Besmer, 1983; Last, 1991a; Lewis, 1991; Nicolas, 1972). *Bori* divides into two kinds, one public and the other private. The first, accessible to visiting Europeans and others, is run by public healers competing in the bigger towns for the prestige of being the leading

traditional practitioner. Many of these healers are from out of town; in Kano they are often men and have come from the Niger Republic. Equally public used to be the *bori* performances put on occasionally by the women in brothels (*gidan karuwai*; *gidan mata*), where they danced late into the night to the specific tunes of their spirits. The second kind of *bori* is usually private (if not secret), performed within a *purdah'd* house with women guests invited; it is usually run by women and is focused on a specific problem, such as illness or a misfortune in the family. In a crisis, a mother may go into possession-trance in the middle of the night to identify what is killing her daughter; desperate to find a remedy, she'll have awakened a co-wife or a neighboring woman to help in posing the questions and hearing the answers.

A dead person's soul (*kurwa*) may possess a kinswoman or descendant, and speak through her; curing requires acceding to the soul's demands and then exorcising the patient who might then go on to be initiated (*girka*) into the spirit possession cult (*bori*). A spirit (*iska*) can trouble a person (usually a woman), either through illness or dreams or loss of children, and "call" her, so that her kin then finance her initiation into the spirit cult (cf. Erlman & Magagi, 1989). At its end, one or more spirits have been identified as linked to the initiate, and they are escorted to her room in her husband's house, where they will act as guardians or helpers. A particular kind of hen, goat, or sheep will then be kept by the initiate, as symbol of the spirit's readiness to help. That spirit may on occasions possess her and, speaking through her, express the initiate's complaints and her wants. These wants may include perfume, new clothes, or some luxury, or more prosaically the rightful share of some property or a special ritual (mobilizing her kin to carry out a sacrifice of an animal on her behalf). If a marriage is in difficulty, spirit possession may be a means of negotiating a better relationship with the husband or a co-wife.

The work of healers is to mediate between spirits and patients. The healer supervises initiations (which can be done for more than one initiate at a time, thus reducing the costs of hiring a musician, his assistant, and the healer), and helps to identify the particular spirit that is to act as long-term guardian of the patient. But the healer, who has a spirit of her own, can herself become possessed by that spirit and offer answers to questions posed by the women coming to seek her advice. This consultation is normally done in the healer's room in her house, and is more or less private. Questions are usually about the

underlying causes of illnesses, or how to prevent a child's ill health or some other misfortune, but may also be about a pending move to another house, or re-building a house, or even about the consequences of converting to Islam. As spirits do not always speak "normal" Hausa but disguise it by switching sounds, their pronouncements are not always clear, and can lead to discussion afterward and reinterpretation.

While women are common as *masu bori*, the major asylums where the mentally ill live (in the healer's compound) are run by men, with the help of wives. Such asylums are usually found in the midst of farmland, not far from villages or even towns where inmates on the mend can find odd jobs or extra food. Inmates may come from non-Hausa backgrounds and include both men and women, adolescents and adults. They may stay up to a year in an asylum, being treated with medicines to drink (which may include pills acquired by the healer from a government mental hospital).

Hospitals

Government hospitals, whether run by university medical schools or by state ministries of health, exist in the major cities, but in recent years their services have been marred by lack of drugs and by basic equipment being out of operation. Electricity has also been intermittent. Shortages of running water have made hygiene difficult for in-patients, whose relations are expected to bring in food and drinking water and do the washing of bed linen and patients' clothes. Private clinics have provided good services for the rich. Mentally ill patients are treated in special units (Last, 1991c). In rural areas medical services vary enormously, from a well-staffed and managed hospital to dispensaries or "cottage hospitals" where the few staff can offer little or nothing beyond advice; private clinics now compete for patients too. Drugs may be out-of-date, dumped by first-world suppliers; or they may even be "fake," sold by unscrupulous local "manufacturers" in plausible packaging. Where blood transfusions are possible, blood may be supplied by a relative; if not, a person waiting by the hospital may be hired to supply blood. This is screened, and if all right, added to the blood bank; if not, it is disposed of.

Ambulance services are almost non-existent, in towns or in rural areas, so in an emergency adult patients are carried to the roadside and put in a bus. But cases of obstructed labor, for example, pose a real problem, as they cannot be carried using a bed as a stretcher; that is taken

to be a bier and to presage death. Since hospitals are often seen as places where the sick die, there is a reluctance to be taken to hospital. Taking a body back means specially hiring a vehicle (given the reluctance of public vehicles to carry corpses). Furthermore, a post-mortem in the hospital can leave a body mutilated, giving rise to fears that hospital staff have robbed the body of significant parts for magical use (or for sale). In short, those considered near death are not necessarily rushed to hospital; a decent death at home is preferable. A hospital can ameliorate pain or cure illness but it cannot of itself prevent death, though some of its staff may believe they can delay it.

CLASSIFICATION OF ILLNESS, THEORIES OF ILLNESS, AND TREATMENT OF ILLNESS

Biomedical ideas about disease and about human anatomy and physiology are quite widespread, being taught in schools. But the older generation as well as many young also know the “traditional” ideas, especially about mental illness. Some illnesses are caused by spirits or sorcery: that is, illness originates outside the individual and involves malice. The idiom is that of someone “shooting” you as with an arrow; the “wound” (and the pain) is in the outer layer of the body. In Hausa thought, the body is composed, broadly speaking, of two layers: an outer layer (*jiki*) and an inner core (*ciki*). The outer layer is essentially fluid, with breath, blood, sweat, saliva, and semen, as well as sounds, smells, and sights. Entry points into the outer layer include the throat, ears, nose, eyes; the penis and the vagina are exits. The inner layer contains solids, brought inside via a separate throat and expelled through the anus.

Post-mortems on humans are not part of traditional Hausa mortuary culture, so that there is no formal anatomical knowledge of what is inside the human body. Parts of the body are, of course, given names—heart, lungs, kidney, liver, stomach—and as butchery of livestock is commonly witnessed, the innards of goats and sheep are well known. But people are reluctant to equate human with animal anatomy; to do so would presume acquaintance with the inside of a human, and that is knowledge that only witches have.

The outer layer of the body is not just the site for illness-as-injury, but for all social interactions. Popularity

and pleasures occur on the outer layer, whereas innate characteristics are “solid” and located “inside.” So too is witchcraft substance and a propensity for evil. Life is there too; in death, the solids within liquefy and pour out. Ageing is the gradual drying out of the outer layer, leaving the elderly almost all “solids” and scarcely mobile. The young are predominantly “fluid” and mobile. One symptom of illness is for the fluids of the outer layer to get blocked, and form a swelling that may need to be lanced. Liquids, like semen or urine or “dead” blood (“dead” because of exertion in a hot sun), must be eliminated, or else they back up and go bad (for example, in the small of the back). Too much sweat is a bad sign; liquids should not pour out through the skin.

Medicines enter the outer layer as fluids, whether drunk or (nowadays) through injections. The outer layer can also be massaged with unguents and scarified; it is accessible through incense as well as music and words. It can be terrified by a horrible sight or soothed by what’s pleasing. Mental illness is an affliction of the outer layer; spirits, ghosts can enter that layer, just as a person’s self can go out in dreams, without depriving the person of life.

Many illnesses afflicting people are seasonal and caused not by spirits or sorcery; they are God-given. Seasonal variations affect the outer layer, too: cold and rain, mosquitoes, biting flies and insects, guinea-worms (in the past), as well as the hot sun (noontime is especially dangerous). Night, too, has potential sources of illness, in particular, dew (*raba*) and the full moon, and no one should sleep outside. The countryside is criss-crossed by spirit “highways,” and it is wise not to rest under one of these highways, let alone site a house there. Similarly, paths or cross-roads where people deposit rubbish, old medicines, and any other contaminated article, are sources of “infection”: such items are placed there specifically in order that their “infectiveness” can be carried away by a passerby. It is possible to map sites of danger in a community, and these are usually also sites where extra protection against harm is required (Last, 1988, 1991b). Each adult would expect to have sufficient protection for everyday life. But chance encounters, especially with strangers, carry risks: the marketplace is one such site.

Protective medicine in the form of charms (*laya*; commonly a combination of text in Arabic script plus a few dried leaves and a twig) can be carried on the body. Some special underwear (*bante*) can give magical protection. But the main source of preventive medicine is based in the house, where the ancestors and domesticated spirits are

located, where there are medicines built into the walls of each room and the homestead as a whole, as well as in the structures of the granaries. The regular five prayers a day and the strict practice of Islam ensure well-being, too; the annual rituals are carried out to cleanse the house and sanctify its residents and their kinsfolk. Almost daily the elder men of the household eat together and resolve any conflicts or preempt tensions; senior wives are within earshot, and relay news of problems. The regular succession of illnesses and deaths shows how important prevention is.

SEXUALITY AND REPRODUCTION

Both men and women have “semen” (*maniyi*) that is necessary for reproduction. Without regular expression, the semen can back up, perhaps go bad, and cause illness especially in the lower back. Marriage and regular coition for both men and women are therefore necessary for health. In a polygynous household, wives take turns to cook for their husbands two days at a time, and by implication the two nights are theirs too. (Concubines in the past had one night only; irregular unions occur in the afternoon.) Whereas marriage may take place at a young age (even before puberty) a very young bride is not usually sexually active until she is “strong enough,” that is large enough to bear children safely; this may be a year or two after menarche. Her first child may die in infancy, particularly if the newborn loses maternal immunity at the height of the malaria season (August/September). Given that weddings often occur in March/April, a baby conceived very early in the marriage and born in December/January is at extra risk.

Pregnancies may go to “sleep” (*kwanta*), and not come to term in nine months (Kleiner-Bosaller, 1993). In Maliki (Islamic) law, such sleeping pregnancies can last up to 7 years, so that a divorced woman who conceives out of wedlock can within that period claim her former husband as the father of the fetus; otherwise the formal penalty for fornication outside marriage is death by stoning. But such “sleeping” pregnancies also occur when a wife is having difficulty becoming pregnant and feels threatened by divorce; it can occur too when there is an ectopic pregnancy or a cyst that mimics an early pregnancy. There is no traditional treatment for it. Sleeping pregnancies are not, of course, confined to Hausa culture, but are potentially found wherever the Maliki School of Islamic law is in force, as for example in Morocco.

A further complication of pregnancy occurs when a woman’s uterus has been entered by a spirit, and a changeling child (*dan ruwa*) is later born to her. Spirits are apt to enter women when they bathe or are near water. There are no clear signs of such a compromised pregnancy; and the child only shows his or her changeling status later, for example by sickle-cell anemia or by dying prematurely. A child born to a mother after earlier children have died is known as a *dan wabi*. It is not uncommon for a woman to lose all her children while a co-wife has all hers alive; one assumption is that the repeated deaths are a single child or spirit repeatedly reentering the mother and dying early (Last, 1992). Another assumption is that her breast milk may be bad, or even contain some poison.

A wife who is losing all her children may well decide to leave her husband and “drink other water” in the hope of bearing a child who will survive. While divorce is common and easy, I have known women who have remained with their husband despite having borne him eight or more children all of whom died young. The explanation is that wife and husband both love each other deeply (Last, 1992). Romantic love is not uncommon and may lead to a couple, who were childhood sweethearts, marrying finally in their old age after both have been through other marriages. Some wives concerned over their husband’s apparent infertility may discreetly become pregnant outside the marital home. Similarly, where the husband is from a lineage that only produces daughters, the pressure on a wife to provide him with his only son may result in her taking special measures. There are special sites and rituals (including *bori*) that are supposed to restore fertility, but the most commonly tried cure is a change of husband.

Apparently infertile women may often remarry, and be the third or fourth wife in a large household with many children, one or more of whom she may help to bring up. Such junior wives can be hugely popular, with their stories, songs, and humor bringing fun to the children of the house; they can devote themselves to making snack foods or to petty trading or a craft to earn cash and give presents. They cannot live on their own, nor can they readily return permanently to their father’s house (at least not until old age). Modern conditions may make women-headed households more socially acceptable: for example, where the husband has died of an illness that has been labeled as AIDS (*kanjemau*), his widow may have to live alone, as people fear contact with her and her cooking. Otherwise, every woman has the right to a husband, no matter how disabled she might be (Last, 2000a).

HEALTH THROUGH THE LIFE CYCLE

Pregnancy and Birth

A pregnancy is not considered established until 6 months, when the pregnant mother (*mai ciki*) will cover herself up (e.g., with a cloth over her breasts) and be teased (e.g., asked if she's been eating beans). When spontaneous abortions (*bari*) occur, the fetal matter is disposed of without ceremony. Miscarriages (also known as *bari*) are similarly treated; the dead child is not formally buried in the graveyard. Until recently, women might commonly smoke cigarettes, resulting in babies of low birth-weight. Six pounds was not an uncommon weight, and obstructed labor was relatively rare. Birth is done kneeling down (*nakuda*); another woman (who is then known as *ungozoma*) picks up the child and cuts the umbilical cord. It is she who bathes the cord stump, and washes the baby each morning and evening, in principle until the day for naming. But in practice mothers may take over the care of their babies straightaway, and breast-feed them, despite taboos on letting a neonate suck the colostrum. The placenta (*mahaifa*) and cord (*cibiya*) are both buried behind the mother's room by the *ungozoma*. First births are given this full attention; later births can happen so easily and unexpectedly that the mother may find herself giving birth in a field or in a latrine.

Once delivered, the mother has to be purified and "heated" to remove the damp-cold of birth; the full procedure (*wankan jego*) lasts for 40 days and thereafter continues once a day for 3 or 4 months. If she fails to do this, she will swell and die, or at least become pale and chill. Twice a day she has to wash herself by sprinkling boiling water over herself with special leafed branches (*kunfu* or *cediya*). In Zaria (since at least the 16th century) the mother also lies on a special clay bed under which a fire is kept burning; she is gradually "roasted." Elsewhere she is "steamed" over a pot of boiling water. Finally, she is given a special food made from the feet and head of an ox and medicines (especially potash, but also spices). A consequence of this excessive heat and salt intake is the above-average incidence of periparturient heart failure (*daita*) from which women can die. The local remedy is a plant found in marshy areas similar to foxglove, but it is not always given in sufficient quantity to prevent death. A baby whose mother dies is usually not nursed by a wet-nurse, though if some kinswoman is lactating and is willing to take on the orphan, that is acceptable (but the baby

already on the breast and the orphan cannot later marry; sharing the same breast milk makes them siblings).

In theory, on day three a barber will come and cut the uvula, incise marks on the baby's chest, and also cut marks on the baby's face. But I have known these to be done later, on the occasion when a girl baby has her hypertrophied hymeneal tags nicked as if it was the clitoris that was being cut. The baby's first haircut is on day seven, when it is named in a big ceremony.

Infancy

The baby is solely breast-fed until about 6 or 7 months old. Weaning occurs after 2 years and some months, usually by being sent away on a Friday to the mother's mother; sometimes a bitter substance has earlier been smeared on the nipple to discourage the infant from suckling. A baby may react badly to weaning. If an infant is weakening before it is weaned, it may be a sign that the mother's husband has started touching her, or even that she is pregnant with another baby. Such a woman feels shame. Her infant, in its distress, typically has flies hovering over its face. More routine are the diarrheas associated with teething. A mother watches the fontanel for signs of stress. Another hazard is the fire within the mother's room; babies have occasionally been known to fall into the fire as they sleep with their mother. The baby by day is carried on her mother's back (or by an elder sister), and is therefore very early taught not to urinate or defecate except when told (the baby is held between the mother's ankles, and a "ssss" sound is made). The twinning rate in Hausaland is much lower than among the Yoruba to the south; twins may be unusually bad-tempered.

Childhood

Children work as well as attend school. Punishment is given to those who fail to do their work properly; a child absconding from school may find himself kept in shackles (*mar*). But willingness to punish varies between Hausa communities: Muslims are readier to punish the young than are non-Muslim Hausa (Last, 2000b). Child sexual abuse does occur, if rarely: there are stereotypical stories about sadistic or sexually active teachers who abuse their pupils. So, too, young girls may be sexually abused in cities by adult men on weekends (and need urgent hospital repairs the next day). But sometimes children use their time on the street to experiment sexually with each other.

Circumcision of Muslim boys occurs about 7 to 9 years old, and a group of boys is operated on by the barber at a major ritual in the cold dry season; non-Muslim Hausa boys may be circumcised just before puberty. The operation is done with a knife with the boy sitting on the ground over a small hole; the fraenum, though, is cut not with a blade but with the barber's fingernail (*akaifa*). The wound is then smeared with juice from acacia pods, and bound up. It can take a month before he is fully recovered. Newly circumcised boys usually do not sleep on a mat or wear clothes; and there is traditionally an adult man to keep an eye on them at night, so as to stop anyone from rubbing his penis. Nowadays, bandages are used.

Hausa girls are not excised (nor were they in the 19th century), apart from the nicking of the hypertrophied hymeneal tags shortly after birth, at the time when the uvula is also cut. The object in both cases is to keep open the two orifices (the throat, the vagina), on the assumption that both might otherwise become blocked at maturity; it is not about controlling sexuality or closing the vagina. Confusion arises because the term used, *beli* (cf. *belu* for uvula), implies that it is the clitoris, seen as a parallel organ to the uvula, that is being cut, when observation of the operation clearly shows that it is not cut, and could not be at that age. I have known people worry that their uvula has grown (or re-grown) and is causing them trouble in their throat; I have never heard of the clitoris growing to cause a blockage. Vaginal "blockage" occurs only in late pregnancy and is caused (if at all) by a temporary swelling of the anterior wall of the vagina. This swelling is relieved by using a razorblade to remove the liquid, not by cutting the clitoris.

Adolescence

While menarche may mark the start of adolescence, courtship may precede menarche, with the girl receiving presents from older suitors. The period of courtship in villages may start with girls having decorations (depicting, e.g., drums or even a boxer) incised on the neck and upper chest; pot black darkens the drawings. Ideally in the middle-class urban context, the would-be husband should be 10 or more years older than his bride. In rural areas, the age difference is less pronounced, and adolescents go courting in marketplaces and in the evenings once the harvest is brought in (October to January). Courting involves petting but not coition. The process from betrothal to wedding takes some 3 months, and is a

dry-season activity involving elders as well as the couple's friends and kinswomen. Male adolescents may go to a village brothel if they have the funds after the harvest, but today, with AIDS and the reintroduction of Islamic law, many brothels have been closed down and the women dispersed.

Young men have to work hard to accumulate cash to buy presents for their girlfriend. Many go on dry-season migration (*ci rani*), to farms in the south of Nigeria and even Ghana, or to cities where laboring jobs are to be found. They gain experience by seeing the world and experimenting with different foods, drinks, and social habits; by being away, they also save their parents the costs of feeding them from the family's granary (cf. Last, 1993a). Adolescent girls stay at home, possibly going to school or trading on their mother's behalf. Stricter households, particularly in the towns, may insist on the girl being in purdah by day, and only allowed out with an escort after dark. Ideally, she will be betrothed or married soon after menarche, thus transferring responsibility for her well-being (and her further education) from her parents to her new husband.

Adulthood

An adolescent male becomes an adult when he takes a wife; he is responsible for another person. A woman becomes an adult, not when she marries, but when she has her first child, when she too is responsible for another person. The couple are housed by the husband's parents, with the bride having a room of her own, filled with her bridal goods, and she has her own waterpot as well as food bowls there; she cooks at her own fire in front of her room (unless there is a single family kitchen). She is likely to get pregnant within 2 years; if not, there may be pressure on her to leave her husband, or on him to seek a second wife (if he can afford one). If she does get pregnant and bears a child, it is not unusual for the first child to die young. Although there is pressure on her to "avoid" her baby (and not over-coddle it), in practice mothers are very solicitous of their firstborn. If all goes well, she will be pregnant again some 2 years after the first child is born. And the process will continue for some six to ten births. Women do seek means of restricting the number of conceptions, but there are no formal means of contraception. Were she to divorce her husband, she would conventionally have to leave behind all her weaned children; alternatively, she could declare herself menopausal, and

stop sleeping with her husband. If he had not already done so, he would seek another wife or wives. The first wife may well encourage him to do so, to save her some of the hard labor of being his sole wife; a good polygynous household, run by a competent senior wife and a just husband and filled with children, is more desirable than a small domestic unit. An unhappy polygynous household can be riven by conflict and jealousies, with fears of competitive love-magic and sorcery resulting in mental or other illness; a husband's favoritism adds to the tension. Violence between wives, symbolic or actually physical, may result, and the husband may resort to beating a wife. Divorce is always a possibility, more often initiated by an unhappy wife, but she may just go away awhile to cool off; she would return to her parents' home or seek out a sympathetic brother.

As a divorcee a woman can expect to re-marry as a junior wife. Although a husband has to treat all his wives with strict equality, her status is still subordinate to the senior wife. A woman may move on from husband to husband until she finds a congenial household; some in the period between marriages set themselves up as courtesans, keeping a salon where men come to chat and one or more of these men court her with a view to sleeping with her regularly or marrying her. This is not the same as prostitution based in a brothel; relations of courtesanship are built up over time, and sexuality is controlled and only part of the scenario. Finally a divorcee may decide to marry a farmer, in which case he may give her fields to farm on her own account, and she re-builds a life around her own earnings and new friendships. Although adultery (*zina*) occurs in towns and villages alike, only pregnancy outside marriage is really serious; as noted, it can now result in the woman being sentenced to stoning.

As a married man's household expands, he may section off part of his father's compound, dividing it from his brothers' area; but where a house is crowded (as in an old city), a wash-room may have to be converted into another bedroom, in which case it may still retain the "wrong" aura and give rise to illness. Alternatively he may (especially in rural areas) build himself a new house of his own, choosing a propitious site with the help of an Islamic scholar. The well-being of his household may depend on how carefully the sacred rituals have been carried out at the house building. Repeated illness may force him to move house again, or his wives to leave him. Spiritual well-being can be enhanced by regular religious practice, for example by being part of a Sufi brotherhood

and joining in the extra recitations after the Friday prayer; extra fasting, twice a week, may be done too, as well as regular reading of the Holy Quran. Drinking alcohol or smoking or intemperate behavior generally calls into question not just his own health but that of his whole household.

The Aged

A man starts becoming an elder (*dattijo*) around 40 years old, but can cease to be regarded as an elder once he becomes senile. An elderly woman too, after menopause, acquires a special status, staying on with her grown-up sons who have taken over the house and its land after the death of her husband. Such old women are no longer subject to *purdah*, but they may have little reason to go out except to the life cycle rituals of their children's families and other kin. Elders seldom leave the house and its environs, spending long hours in their dark room with enough of a fire to keep them warm and may be fed by their sons' wives. Often toothless, they need to grind such luxuries as kolanuts or groundnuts on a small tin grinder; other foods require no chewing. Now they may have a radio with its songs to listen to.

Dying and Death

In the 19th century, March/April and October/November saw more deaths than other seasons. Malaria is particularly lethal in August/September, and was attributed traditionally to the newly harvested grains. A study I organized of burials in the old city of Kano showed that more women and children died on a Friday (and Thursday). To die on a Friday is a blessing given by Allah, and it might seem that people "choose," if they can, to die on that day. But the timing of death is Allah's alone, people say. Yet people also report mothers (and fathers) summoning their children to come to them and awaiting their arrival; after speaking to them in front of others (a sure sign of impending death), the dying mother closes her eyes. Foreknowledge of death does not provoke attempts to avoid it, but rather to ensure that what needs to be done right is done. Near-death experiences occur on occasions of very high fever, which may provoke visions of ancestors. The corpse is washed in the ritual Islamic manner. No post-mortem is done. A death in the house is marked by a deep, almost audible silence; no wailing is heard (as it implies impatience with Allah). No work is done that day (two days if the dead person was

important), and visitors come to express condolences. Grief is meant to be restrained.

Burial is done within a few hours; or if the death occurred at night, early the following day. Graves in city cemeteries are dug in advance each day by a gravedigger and on Fridays by volunteers. A head of a house is likely to be buried in the yard behind his room; others are carried out on a bier and buried in a cemetery, with graves unnamed and all aligned toward Mecca (head to the south, facing east). It can soon be difficult to locate a specific grave in a city cemetery where 10 to 15 new graves are dug daily; the body is meant to have anonymity in death. But in recent years gravestones with names have become fashionable. The body is never disinterred, and though graves can in theory be reused after seven years, they seldom are. There is a persistent fear of grave robbers digging up recent corpses at night for body parts to be used in magic or for sale; anyone loitering in a graveyard therefore attracts suspicion.

Some bodies have to be treated differently. Wives brought back dead from the hospital to their husbands' house are buried in a field near where they lived, and not in the family or village graveyard. In the past, slaves who died in town were not necessarily buried; their bodies were thrown into ponds (where crocodiles ate them). War dead were quickly buried, unwashed and in their clothes, on the battlefield, but many such bodies were in fact eaten by hyenas. Nowadays hyenas, crocodiles, and vultures are all so rare that carrion (*mushe*) rots uneaten. Hausa, being Muslim, have no concept of reincarnation.

Hmong in Laos and the United States

Kathleen A. Culhane-Pera, Dia Cha, and Peter Kunstadter

ALTERNATIVE NAMES

Miao or Meo (considered derogatory by Hmong).

LOCATION AND LINGUISTIC AFFILIATION

Hmong are a distinct ethno-linguistic group who originated in China and who migrated into northern Southeast Asia during the 19th century. After the end of the “Secret War in Laos” in 1975, many Hmong fled to Thailand and then were resettled around the world, including the United States. Most Hmong in the United States speak two closely related dialects of the Miao–Yao language: White Hmong (*Hmoob Dawb* or *Moob Dlawb*) and Green Hmong or Blue Hmong (*Hmoob Ntsuab* or *Moob Lees*). These two groups were traditionally distinguished by their dialect, dress, housing style, and other cultural differences.

The Hmong diaspora is extensive, with over seven million in China, one million in Southeast Asia (Schein, 2000), and almost 16,000 in France, Canada, French Guyana, Australia, and Argentina (Rice, 2000). According to the 2002 Census, 169,428 Hmong live in the United States, with most in California, Minnesota, and Wisconsin (Pfeifer, 2002). However, Hmong community leaders feel

the U.S. Census 2000 undercounted the Hmong and estimate that 227,217–268,747 live in the United States (Hmong National Development Links, 2001).

OVERVIEW OF THE CULTURE

History

Hmong myths suggest Hmong lived in northern China and migrated into southern China. Early Chinese historical records indicate that Hmong were lowland irrigated rice farmers. Resisting the political control and population pressures of the Han Chinese, many ended up in the mountainous areas of central and southern China. Some Hmong migrated into the highlands of northern Southeast Asia in the mid-1800s. In the first half of the 20th century, French administrators in Laos granted opium-growing concessions to some but not all of the Hmong in Xieng Khouang province. This was one basis for the split between Hmong who allied themselves with the French and the Americans after 1954 and those who allied themselves with the Pathet Lao and northern Vietnamese.

From the 1960s through 1975, many Hmong were recruited by the United States Central Intelligence Agency

(CIA) to fight on the side of the Royal Lao government against the communist Pathet Lao and Vietnamese in the “Secret War in Laos” (Warner, 1999; Weldon, 1999). Hmong suffered many casualties and great economic disruption during the war. After the collapse of the U.S. side, more than 100,000 Hmong fled to Thailand (Robinson, 1998; Yang D., 1991). Some emigrated to the United States starting in 1975, but some were not resettled until the end of the 1990s. Tens of thousands of Lao Hmong remain in Thailand with unresolved immigration status, and approximately 10,000 Hmong were repatriated to Laos (Cha & Chagnon, 1993; Cha & Small, 1994; Kirton, 2002).

Economy

The 20th century economy of Hmong in Laos was based on subsistence swidden (slash and burn) cultivation of upland dry rice, vegetables, and maize, with opium as a medicine and as a cash crop in some areas. They also raised pigs and chickens for food and horses for transport. Large multi-generational patrilineal extended families cooperated economically in subsistence production. Other than the activities of the CIA and the United States Agency for International Development (USAID), there was no wage labor and no Hmong village-based commerce. Very few Hmong received any formal education or became fluent or literate in Lao, French, or English (Yang D., 1991). Thus few Hmong refugees had skills or basic knowledge that was appropriate for employment in modern Western industrial, market, and service economies and only a small proportion of middle-aged and older adults have been employed in wage work outside the house. In the 1980s to 1990s, some Hmong were self-employed farmers or gardeners, especially in California, but many have depended on welfare programs for income and for health services. Many adults work in menial jobs, such as janitorial and factory work, often working two jobs or interchanging day and night shifts so parents can care for their children. However, many of the younger generation have become educated and have entered the mainstream U.S. economy (Lo, 2001; Mills & Yang, 1997; Yang & Murphy, 1994).

Social and Political Organization

Membership in exogamous patrilineal clans is the major organizing principle of Hmong society. Traditionally Hmong lived in large multigenerational patrilineally extended family households that were economic and

ritual units. Elder or middle-aged men led households and groups of closely-related extended families. Clan members had some obligations to provide each other with support, such as shelter (Cooper, 1984; Tapp, 1986), and had a strong influence in ethnic identity (Leepreecha, 2001). Political organization was limited to the village level. Village leaders were usually the heads of the largest and economically most influential families. French colonial authorities recognized some of these leaders and gave them positions in the local administration, but Hmong villages retained their autonomy. During the war, some Hmong men became high-ranking military officers in the Royal Lao Army (Quincy, 1995).

In the United States, housing and economic conditions preclude forming large household units, but relatives often live in close proximity. Most Hmong still follow rules of clan exogamy, but some do break the traditional taboos. Some clans have expanded the assistance functions of clan membership, to other functions, such as encouraging higher education (Hones & Cha, 1999). Elders still tend to occupy leadership positions, leading important rituals and influencing important decisions including medical care (Cha, 2000; Hones & Cha, 1999; Pfeifer, 2002). Former military leaders often continue to lead, acting as heads of social welfare organizations that are often based on clan or Laotian region affiliation and attempting to serve as spokesmen for an increasingly heterogeneous “Hmong community.” As the younger generation become educated and acquire professional qualifications, they are replacing the elders as political leaders. Some Hmong organizations, including Christian church groups, cut across the traditional kinship or regional lines and serve a variety of social welfare and community development purposes. At a national level, Hmong have several organizations for political lobbying, and for staging conferences to discuss various issues (Hmong National Development Links, 2001).

Religion

Traditional Hmong religion is animistic, with beliefs in spirits (*dab*), ancestor worship (*dab niam txiv pog yawg*), multiple souls (*ntsuj plig*), reincarnation, incantations for blessing, curing, or cursing, and selection of spiritually appropriate locations for houses and graves. The most powerful spirits, including the Master of the Universe, are believed to live in the sky; lesser spirits dwell on earth, or underground (Lemoine, 1986; Morechand, 1968). In Laos, Hmong learned about Buddhism from lowland ethnic

Laotians and learned about Christianity from Catholic and Protestant missionaries (Barney, 1957; Capps, 1994). About 25% of the Hmong in the United States are Christian, having converted in refugee camps or having accepted the religious affiliation of their immigration sponsors (Capps, 1994).

THE CONTEXT OF HEALTH: HMONG HEALTH CONDITIONS IN LAOS AND THE UNITED STATES

There is no systematic record of Hmong health conditions in Laos, but data collected from Hmong refugees in the United States suggests that infections and parasitic diseases predominated in Laos, and that wartime trauma was also a leading cause of injury and death. Reproductive histories collected from Hmong women in Merced, California in 1987 suggest that infant mortality of children born in Laos was around 120 per 1,000 live births, declined to about 90 per 1,000 for children born in refugee camps in Thailand, and fell to about 9 per 1,000 among children born in the United States (approximately the same as the U.S. infant mortality rate) (Kunstadter & Kunstadter, 1990).

Historically, Hmong in Laos had access mostly to their traditional system of healing. Modern preventive or curative health services were not available until USAID established a few hospitals in Laos and trained some Hmong military medics and nurses in the 1960s (Weldon, 1999). Modern health services were provided in refugee camps in Thailand. There were conflicts between Hmong refugees and a fundamentalist Christian organization that provided medical care in Ban Vinai, the largest Hmong refugee camp in Thailand (Bouvier, 1994; Wright, 1986). Thus some Hmong refugees associated modern health care with coercion, an idea that has been reinforced by several notorious cases of court-ordered treatments (Culhane-Pera, 1989; Fadiman, 1998). Occasional major conflicts between Hmong and health care providers have received wide attention in the media, especially related to surgery, chemotherapy, and radiation therapy, and sustained medical treatments for tuberculosis (Arax, 1994; New York Times, 1994; Snyder & Kunstadter, 2001).

Changes in environment, risk behavior, and the availability of modern health services in the United States have resulted in changes in Hmong health and health-seeking behavior. While child mortality has declined dramatically,

health of adults appears to be deteriorating. Comparisons of self-reported survey data from Hmong in Fresno CA with non-refugee Hmong in Thailand (Kunstadter P., unpublished data 1997) indicate the U.S. Hmong adults age 40 and above have three times as much illness including about 20 times as much hypertension, 20 times as much diabetes, 13 times as much depression or mental distress (all differences significant at $p < 0.001$); and similar rates of gastrointestinal ailments. Fresno Hmong parents reported twice as many respiratory ailments, and approximately the same rate of gastrointestinal ailments for their 0–4-year-old children than did Thailand Hmong parents. Analysis of Hmong death certificates in Fresno County between 1980 and 2001 (Kunstadter & Vang, 2002) revealed significant reductions in deaths of all ages from infectious diseases while deaths of adults 40 years and older from degenerative diseases have increased. There were marked reductions in proportions of deaths of young children with increased proportions of deaths in adults 40 years of age and older over this period. Deaths associated with external injuries and violence (motor vehicle accidents, drowning, suicide, and homicide) increased, especially for those aged 10 to 39. There were no significant gender differences in proportions or causes of death.

Improvement of child survival among infants born to Hmong refugee mothers, who are generally poor, have no education, have high fertility, and short birth intervals, is similar to reports of an “epidemiological paradox” among Hispanic migrants to the United States (Markides & Coreil, 1986). The apparent deterioration of the health of older Hmong in the United States is similar to reports of increases in cardiovascular diseases and diabetes among Japanese and Samoan migrants to the United States and some Native American groups (Baker et al., 1986). In all of these populations the increase in degenerative diseases appears to be associated with a decline in physical activity and changes in diet (increases in consumption of fats, sugars, and total calories). The similarity in rates of gastrointestinal ailments reported for all ages among Fresno and Thailand Hmong suggests that despite the availability of protected water supplies and sanitary waste disposal in the United States, hygienic conditions related to spread of these diseases might not have improved. The decline in infectious diseases as causes of death, especially among children, suggests that public health measures (immunizations and environmental sanitation) and modern curative medicine for acute illnesses have had important effects on the U.S. Hmong population.

Unlike some other groups, Hmong in the United States do not seem to have increased their consumption of tobacco greatly as compared with Hmong in Southeast Asia, but they may have increased frequency and amount of alcohol consumption. There is an apparent increase in the amount of violence directed at self or other Hmong (Hmoob Thaj Yeeb, 1998) as well as an increase in gambling addiction (Zander & Xiong, 1996). These socially dysfunctional behaviors are indicators of mental distress probably related to stresses of social adjustment. Depression and post-traumatic stress disorder have impaired people's adjustment to the U.S. (Westermeyer, 1988; Westermeyer, Lyfoung, & Neider, 1989; Westermeyer, Neider, & Vang, 1984). Mental distress and depression contribute to poor physical health, and compound the difficulty in following modern treatments for chronic diseases—along with the lack of traditional knowledge about chronic diseases requiring long-term therapies.

MEDICAL PRACTITIONERS

The Hmong have several traditional healers who continue to influence the community's health beliefs, values, and practices in Southeast Asia and the United States (Cha, 2000; Culhane-Pera & Xiong, 2003; Kirton, 1985; Lemoine, 1986; Spring, 1989; Thao X., 1986).

Shamans

Shamans (*tus ua neeb*) are generally men, but women shamans are also known. There are two main types of shamans: *muag dub* (covered face) and *muag dawb* (uncovered face). The *muag dub* shamans are chosen by the shaman's helper spirits (*dab neeb*), go into trance while wearing a black or red cloth over their face, and enter the spirit world in order to battle the offending spirits, aided by their helping spirits. In contrast, the *muag dawb* shamans are not chosen by spirits, and do not heal while in a trance, so do not cover their faces with cloths (Chindarsi, 1976; Cooper et al., 1996; Lemoine, 1986).

Tus ua neeb perform a wide range of ceremonies for people in need of spiritual healing, as determined by themselves, other healers, or family members. They perform preventive rituals such as soul calling (*hu plig*) at New Year celebration and tying strings on wrists (*khi tes*); diagnostic rituals and therapeutic ceremonies (Bliatout, 1986; Cha, 2000; Cooper, 1996). To ward off spirits in

healing and preventive ceremonies, shamans may attach strings on sick people's wrists (*khi tes*) or ankles (*khi hlua*), or place necklaces, bracelets, or anklets on sick people made of three twisted metals (or three twisted strips of red, white, and black cloth that represent three metals). The shaman's power varies depending on how much they have studied or learned, their innate abilities, and the power of their helping spirits. Additionally, their success is influenced by the match of the shaman's inherent power (*hwj huam*) and the patient. If the shaman's power is stronger than the patient's power, the shaman's healing efforts are more likely to be successful (Cha, 2000).

Herbalists

The *kws tshuaj* are herbalists who diagnose illness and dispense herbal medicines. They are usually women who acquire their knowledge apprenticed to an older female relative. The *kws tshuaj* are guided in diagnosing disease and prescribing medicines by their helping spirits (*dab tshuaj*) whose altar is beside the household altar to a main house spirit (*dab xwm kab*). Sick people or their family members bring spirit paper money and incense for the *dab tshuaj*. Herbalists burn the offerings to inform the spirits that people have come for assistance and to ask for their spiritual guidance when gathering the appropriate healing herbs (Cha, 2000; Cooper et al., 1996; Rice, 2000; Thao X., 1986).

In the United States, herbalists dispense dried herbs (*tshuaj qhuav*) they receive from Southeast Asia or China, fresh herbs (*tshuaj ntsuab*) they cultivate from Asian plants, and medicines they collect in the wild or obtain from botanical gardens. Herbalists also distinguish between "wild" herbs (*tshuaj qus*), which are forest plants and "tame" herbs (*tshuaj nyeg*) which are domestic plants. Additionally, the *kws tshuaj* may know other diagnostic or healing techniques, such as *hu plig*, *zaws hno*, *kav*, *ngus*, *hno koob* that are described below. Some *kws tshuaj* specialize in specific areas, such as fertility or childbirth (Cha, 2000; Cooper et al., 1996; Rice, 2000; Spring, 1989; Thao X., 1986).

"Magical" Healers

The *kws khawv koob* are "magical" healers. They are usually men who learn their skills and obtain their connections with spirits (*dab khawv koob*) as an apprentice to an experienced healer. There are various types of *khawv koob*, each with specific rituals that use metal, water,

incense, and chanting. The *kws khawv koob* diagnose and treat people with ailments such as burns, broken bones, foreign bodies in eyes, vomiting, babies' chronic nocturnal crying, children's febrile illnesses with rash (*ua qoob*), children's fright (*ceeb*), bleeding, and other illnesses caused by evil or wild spirits. Their powers and abilities vary widely and some have extraordinary powers (*muaj leej*) (Cha, 2000; Cooper et al., 1996).

Other Healers

The *tus hu plig* are ordinary men and women (not necessarily healing specialists such as shamans) who have gained the knowledge and skills to return people's wayward souls. They can return souls that have left people's bodies when the person was frightened or when the souls were abducted by spirits and they can secure souls to bodies during preventive ceremonies, such as during New Year's celebrations or prior to a long journey. They help people with soul loss as identified by themselves, other traditional healers, or by a household diagnostician. They have varying power and abilities. Some perform basic ceremonies where they chant, entice the soul with eggs and chickens, tie strings to wrists that secure the soul (*khi tes*), and interpret the soul's return. Others perform additional, more elaborate ceremonies (Cha, 2000; Chindarsi, 1976; Cooper et al., 1996).

Ordinary people have healing knowledge that is not recognized as specialist knowledge. Many women know about herbal medicines, without being an herbalist. Some people know how to divine the presence of spiritual problems (*tsawv qe* and *nchuav qe*). Some people know how to massage the abdomen and extremities, and then to gently pierce the skin with a needle to release illness, built-up wind, or bad blood (*zaws hmo*). Others apply ointment on the skin, then rub with a silver coin (coining or dermabrasion *kav*), or apply suction to the skin with a cup (cupping or moxibustion *ngus*) to bring the illness to the skin's surface in order to release toxins, wind, and stress. Some people massage specific neural pressure points to stimulate blood flow and relieve muscle strain (*xais ceeb*) and others pierce the skin with needles, akin to acupuncture (*hmo koob*) (Cha, 2000).

Changes in the United States

Hmong in the United States continue to conceive of health in a traditional holistic way, which integrates the

body and its souls and perceives natural, supernatural, social, and personal causes of illness. Science classes, advanced studies in nursing and medicine, health care providers, and conversion to Christianity are influencing ideas about sickness such that people have varied concepts of illness and treatment. People continue to seek the assistance of traditional therapies, as well as other healers. However, there are several important factors that impede traditional healers. There are constraints that limit the use of traditional methods, such as difficulty in obtaining medicines; restrictions on fires in hospitals and communities; injunctions against butchering of animals in cities (Arax, 1995); limits on noise; and conflicts between the divergent nature of traditional and modern medical practices. Also, fewer people are learning traditional healing methods. In addition to these constraints, fewer people believe that traditional healing methods are efficacious, due to the influences of formal education, modern medicine, and Christianity. Hmong families also seek assistance from non-traditional healers, such as Christian ministers and priests; traditional healers of Cambodian, Lao, Vietnamese, Chinese, and Thai ancestry; as well as Hmong and non-Hmong licensed health care professionals (Cha, 2000; Culhane-Pera & Xiong, 2003).

CLASSIFICATION OF ILLNESS, THEORIES OF ILLNESS, AND TREATMENT OF ILLNESS

Traditional Hmong classification of illness can be divided into four classes: natural, supernatural, personal, and social (Culhane-Pera & Xiong, 2003; Helman, 2000; Thao, X., 1986).

Natural Etiologies: Illnesses and Treatments

Hmong traditional ideas about natural etiologies include imbalance of metaphysical forces, germs, genetics, behaviors, constitution, and accidents (Culhane-Pera & Xiong, 2003). Metaphysical ideas similar to the Chinese concept of *yin/yang* indicate that the balance of natural elements is essential to health and that an imbalance causes disease. People get sick from hot or cold, dry or wet, windy or calm weather, and particularly from weather changes with increased wind or air pressure. Foods or water that are

thermally hot or cold or that are traditionally classified as hot or cold, can cause illness when people's bodies are thermally or metaphorically out of balance. Small creatures that are observable (lice or parasites) or unobservable (microorganisms) can cause infectious diseases. New "American" germs that cause diseases that Hmong were unaware of in Laos can be particularly worrisome. Hmong traditionally believed that some diseases run in biologically related families and may also affect women who marry into a family. Pregnant women's behaviors can cause congenital birth defects. Susceptibility to disease is related to bodily constitution: people with bad fat and blood, weak immunity, heavy and weak bones rather than light and strong bones, flabby muscles rather than firm muscles, people who are skinny and/or emaciated rather than fat, are more likely to get sick (Xiong & Culhane-Pera, 1995). Hmong also believe that chemicals, including pesticides, fertilizers, horticultural medicines, and Yellow Rain (chemical weapons to which they believe they were exposed to in Laos) can cause a wide range of diseases.

Naturally caused illnesses are diagnosed by physical appearance and symptoms and by history. They are treated by massage, cupping, coining, poking with needles, herbal medicines, and, in America, by physical therapy, chiropractic, or osteopathic manipulation and the whole range of modern medical care, including surgical operations and pharmaceutical preparations (Culhane-Pera & Xiong, 2003).

Supernatural Etiologies: Illnesses and Treatments

Hmong distinguish between five types of supernatural problems (Cha, 2000; Cooper et al., 1996; Culhane-Pera & Xiong P., 2003; Lemoine, 1986).

Souls (*ntsuj plig*). Souls (*ntsuj plig*) can make people sick in many ways, with soul loss (*poob plig*) being the most common. Wandering souls may go off by themselves and not be able to find their ways back; may be caught in dreams; or may leave after an emotional trauma, such as being frightened from a fall, an attack, or seeing someone die. Reincarnated souls may leave if they are enticed by seductive spirits, stolen by evil spirits, or being reincarnated. Other types of problems with souls include a child's soul being unhappy with its parents, clan, or name; or a reincarnated soul wanting a grievance from a previous life remedied or a debt from a previous

life settled. The soul who guards the grave may make family members ill if the grave is disturbed or if non-disintegrating elements are in the body, coffin, or grave.

Shaman's helper spirits (*dab neeg*). People become sick when shaman's helper spirits (*dab neeg*) chose them to become a shaman, and they recover when they accept the responsibility of becoming a shaman. Shamans must maintain good relationships with their helping spirits; if they do not thank their helping spirits or offend the spirits by performing rituals not consistent with spirits wishes, they may get sick.

Tame and wild spirits (*raug dab*). Even though they usually protect people, many types of tame or domestic spirits (*dab nyeg*) and wild spirits (*dab qus*) cause illness. Tame spirits include the ancestral spirits and the seven household spirits that reside in houses. Families honor and feed them with spirit money and food during special ceremonies. In turn, the spirits protect families from evil spirits or warn them of impending doom. However, if families neglect their responsibilities, or if spirits need something from families, then spirits communicate their need by making someone sick.

Wild spirits live outside the house. They can cause illness, seizures, or death by disturbing or stealing people's souls. People may inadvertently disturb the land or water where spirits reside, thus inviting wrath. Evil spirits may purposefully seek out people to cause death and destruction. Some spirits sit atop sleeping people and squeeze the breath out of them. Also, souls of dead who were not properly buried and cannot find their ancestors in the afterworld may cause illness, as a plea for assistance. Souls or ghosts that have not achieved reincarnation because of the suicide or violent death of their previous owners, may entice other people to die in similar ways. In the United States, interactions with wild spirits seem to occur less frequently than in Laos. People speculate that spirits are scared away by electricity. Still, spirits in lakes cause drownings, roaming ghosts cause car accidents, and evil spirits cause suffocation (diagnosed as Sudden Unexpected Nocturnal Death Syndrome).

Sorcery (*raug pob zeb, nyuj ciab*). People who are motivated by hate or revenge to harm others can hire black magic specialists to send stones, bones, or other objects to lodge in others. Sorcery was rare in Laos, and seems to be even less common in the United States.

God and sin (among Christian Hmong).

Christian concepts of supernatural etiologies vary by denomination, but include sinful thoughts, words, and actions, as well as God's displeasure.

Treatments for the above supernatural etiologies include soul-calling ceremonies (*hu plig*), shaman rituals (*ua neeb*), releasing black magic, Christian prayer, as well as modern medicines or operations in addition to specific supernatural treatments. Generally, Christians pray or ministers lay on hands instead of performing traditional ceremonies, although Catholics may be more likely than evangelical Christians to integrate traditional spiritual healing with Christians prayer healing.

Social Etiologies: Illnesses and Treatments

Stress and anxiety of day-to-day life as farmers in the highlands of Laos or as refugees in American society can cause illness. Human conflicts, such as between generations and genders, can cause illness. Mocking a sick person may result in having that same illness, and teasing a handicapped person can result in children being born with that same disability. When people curse each other, the gods can hear the dispute and cause the guilty person to be harmed. Women who do not revere their husband or parents-in-law can have a difficult time at childbirth.

Treatment requires resolving intra-personal stresses, interpersonal conflicts, and ritually removing the strength of the words said in curses. Medication may also ease pain and disability, but the illness may not be completely cured without repairing the rift in social relationships.

Personal Etiologies: Illnesses and Treatments

Personal behaviors can affect one's health. Using tobacco, opium, or alcohol can cause weakness and a range of illness. Accidental injury can cause impairment immediately after the accident, as well as years later. Not following health promotion proscriptions can make people sick (but too much medicine, even if it has been medically prescribed, can also cause illness, and some modern medicines are known to have side-effects). Frying spicy odiferous food when children have fevers may cause children to become sicker. Not following specific restrictions in eating, sex, and physical activity during their postpartum month may cause women to suffer from headaches,

arthritis, infertility, or prolapsed uterus. Treatments are often aimed at the physical ailment, with massage, poultices, Hmong medicines, or pharmaceutical medications bringing relief. Changing underlying behaviors may also be important, such as stopping tobacco or opium consumption.

Medical Decision Making

Traditionally, the sick person is passive, staying in bed and letting family members provide care—feeding, clothing, bathing, and making treatment decisions (Culhane-Pera & Xiong P., 2002). Family members use many sources of information to identify the illness, its cause, the best healer, and best therapy. They may consider the sick person's symptoms, bodily signs, and prior events (such as trauma or conflicts); they may generate ideas about potential causes; they may perform diagnostic divination procedures; and they may consult clan and community members before deciding on which healers to consult or which therapies to employ. The vast majority of illnesses are initially considered to be caused by natural etiologies and are treated accordingly, but if people are chronically ill, seriously ill, or have some significant historical event, then supernatural etiologies are considered, and supernatural prevention or treatments are pursued. Any illness event can have multiple explanations for causation.

While this traditional sick role and family based decision-making persists, in the U.S. there are changes. Some individuals will tell the family what they want to do; some will make medical decisions without the family approval; and some will even take actions without informing the family. Some individuals shun while others embrace modern modalities, including operations, medications, chemotherapy, and radiation therapy. People may still consider the above cultural information, but other issues are also relevant: religious orientation, insurance availability, language services, previous experiences with invasive therapies, and relationships with and reputation of the healer/provider (Cha, 2000; Culhane-Pera et al., 2003).

When considering treatments, family members evaluate both risks and benefits. Often times, people who follow the traditional animist perspective are concerned about the spiritual risks of invasive procedures as well as the physical risks. Souls can be frightened and leave the body during an operation and during anesthesia. People can be reincarnated with physical disabilities related to loss or destruction of tissues from operations performed

on their spiritual ancestor. Also, metal staples or metal prosthesis placed in the body during operations can cause the soul that stays with the grave to make living family members sick. These dangers may influence people to refuse life-saving or reparative surgical operations (Mouacheupao, 1999; Westermeyer & Thao, 1986).

SEXUALITY AND REPRODUCTION

Sexual Identity

In traditional Hmong society, gender was interwoven with the division of labor and considerations of social worth. Both men and women worked in the fields and at home. Women were responsible for child rearing, cooking, weaving, embroidering, and animal husbandry. Men were responsible for clearing land, creating tools, building houses, making decisions, maintaining and overseeing clan rituals, and supervising family matters. Men also took an important part in child rearing. Generally, men had higher social status and more power than women although women gained power as they grew older and had larger households to manage (Cooper, 1984; Donnelly, 1994; Tapp, 1986; Thao C. T., 1986). Also, there was cultural variation, such that some wives had more power than their husbands, related to their recognized intelligence, ability to manage money, treat illnesses, or make decisions. Generally, at marriage, women left their natal family and lived with their husband's family. Marriage had both brideprice and bridewealth components. The groom's family gave money (*nqi mis nqi hno*) to the bride's family, compensating for the family's economic loss and emotional hardship, and illustrating their promise to love and take good care of the bride. The bride's family sent a dowry with the bride, consisting of clothes and silver, for her contribution to her new household. Women were generally considered to be worth less than men (*tsis muaj nqis*), as they were raised always knowing that they would one day leave the family. Changing gender relations and women's increasing power in the household is causing social conflict (Her & Heu, 2003; Lyfoung, 2003).

Women were at a disadvantage with regard to courtship and marriage. Traditionally, girls were expected not to initiate courtship, and they were enjoined not to openly express their preference for a husband. This is changing in the United States, as some women and teenage girls initiate courtship and express their desires about

potential husbands. Newly married daughters-in-law (*tus nyab*) had little power in their husbands' families, performed many chores, and had to adjust to customs and manners of their new families (Cooper, 1984; Donnelly, 1994). Men could discipline their wives physically, in order to teach them and help them conform to familial expectations. If women were mistreated, they could appeal to their male family members for assistance, and if abused, women could ask their male family members to bring civil charges (*ua plaub*) against their husband and his family (Donnelly, 1994; Ovesen, 1995). In the United States, domestic violence continues to occur, and is possibly even escalating, as recently publicized cases of murders and murder-suicides illustrate (Haga & Her, 2001).

Hmong consider marriage a way of life. Traditionally, every individual was expected to marry and raise a family, as Heaven created women and men to love, care for, and help each other (Thao C. T., 1986). Traditional forms of betrothal included marriage by parental arrangement and bride capture, but agreement between groom- and bride-to-be and elopement were more common ways of marrying. Levirate was practiced in a few cases if an older brother died leaving a widow with young children. Most marriages were monogamous, but polygyny occurred (Kunstadter, 2003). In the United States, people are choosing their mates more often, and arranged marriages are becoming rare.

Traditional sanctions against divorce were strong for women (Cooper, 1984; Donnelly, 1994; Lyfoung, 2003). Young couples and couples with problems were repeatedly counseled against divorce. Divorced women brought shame upon their families and were characterized as having moral defects. Divorced women were almost always separated from their children, who belonged to their former husband's clan and stayed with their father. Usually there were strong economic and religious constraints on divorce for women, because they had limited means of independent livelihood. They had already been separated at the time of marriage from their parents' ancestral and household spirits, and the divorce separated them from their husbands' ancestral and household spirits. Those who did not re-marry often returned to live with their natal families, but they could not sleep in the same room with their father's household and ancestor spirits, and could not be included in the clan rituals. If they were seriously ill, they were not allowed to die inside their father's house, and could not receive funeral rituals that connected them with ancestral spirits. In the United States, divorced women may become Christians, or their families

may ask Christians to conduct the funeral. While the divorce rate is low in traditional society (Thao C. T., 1986), current literature indicates an increase in the United States (Strohl, 2000).

Reproduction

In traditional society, the purpose of sex was for reproduction, and reproduction is for both economic reasons and for continuation of the patrilineal links with ancestral spirits. Hmong traditionally prefer large numbers of children for economic and social reasons (Kunstadter, 2002). Additional hands in agricultural fields result in enhanced family income and needed assistance in times of trouble and old age. In Thailand, the total fertility rate was 8 in 1987, which may have been similar to the number in Laos. Fertility rates remained high in California in the 1990s (Kunstadter et al., 1993).

Contraception

Traditionally, most couples did not use deliberate methods of contraception but accepted children as fate (*hmoov*) determined. It was believed that if a woman did not deliver the pre-determined number of babies, she would be reborn as a woman to deliver these infants. Birth spacing was increased by near universal and prolonged breast-feeding. If contraception was used, women secretly obtained herbal medicines that could cause sterility from herbalists. Herbalists were familiar with abortifacients, although the extent of their use in Southeast Asia and the United States is not known. It seems that abortifacients were used sparingly, given the danger of hemorrhage and death; women and their husbands had to agree about taking the medicine.

In the United States, some people are choosing to limit the number of children although many people are concerned about side-effects of Western methods of contraception, from changing normal hormonal cycles to increased weight to cancer. Most people prefer *caiv*, which has multiple meanings: natural family planning, or withdrawal, or abstinence. Decision-making about contraception varies, influenced by people's acculturation and education levels; most men decide alone, many men and women decide together, and some single or married women make the decision alone (Kunstadter, 2003; Spring, 2001; Spring & Luchongvu, 2003). Over the past 25 years in the United States, surgical abortions have increased, as people have found the procedure more acceptable over

time. Some people voice concerns about consequences of denying the infant soul's desire for life, and of performing multiple abortions on women's health.

Sexual Pleasure

In traditional society only heterosexuality was approved, as reproduction was the purpose of sexual intimacy (Thao C. T., 1986). Homosexual relationships were generally unknown, although in the United States some homosexual relations are being recognized. However they are apparently still very strongly disapproved of, as witnessed by the recent suicide of a lesbian couple in Fresno California. Generally, intercourse in the "missionary position" took place with clothes on, in a bed that contained sleeping children. No kissing, foreplay, oral sex, or verbal sexual expression occurred during love-making. Men initiated sexual advances and took the lead in sexual intercourse, and women were not to display any sexual eagerness. Men and women did not discuss sexual pleasure with each other, but men would discuss with men, and women with women (Symonds, 2003).

Sexual modesty was the traditional cultural norm especially for women. Sanctions against public displays of affection—such as extended conversation and any physical contact, even shaking hands—were implicit. While premarital sex was strongly discouraged especially for young women, it happened often, with ensuing pressures for marriage. Extra-marital affairs were permissible for men, but prohibited for women (Donnelly, 1994; Trueba, Jacobs, & Kirton, 1990). In the United States, social sanctions are more relaxed; couples can hold hands and otherwise openly express their feelings in public. Premarital sex and ensuing marriage is still common. Men's accusations of their spouses' sexual affairs are a common reason cited for marital discord, divorce, and domestic violence (Haga & Her, 2001; Strohl, 2000).

HEALTH THROUGH THE LIFE CYCLE

Pregnancy and Birth

Traditionally, pregnant women followed their usual work activities. Modest, they did not inform anyone about the pregnancy until people noticed. They were instructed to avoid some activities (*caiv*) for the well-being of their pregnancy (reaching above their heads could cause

a miscarriage), health of their baby (cutting cloth in their bedrooms could cause a cleft palate), and easy deliveries (being disrespectful to in-laws could cause a difficult labor). There were no traditional midwives who followed women through their pregnancies. If abnormal events occurred—such as vaginal bleeding or premature labor—then herbalists, message therapists, or shamans were consulted (Spring et al., 1995; Rice, 1997, 2000).

In Southeast Asia, women gave birth at home, attended by their mothers-in-law and husbands. Women pushed while squatting, with their husbands supporting them. If problems occurred, families sought assistance from elderly experienced women or men for medication to ease the delivery, massage to turn the baby, chanting to call the baby's soul, or appealing for spiritual assistance. After delivery, the placenta (or baby's shirt *lub tsho menyuam*) was buried under the earthen floor (by the ancestral post for a boy and under the bed for a girl). If the couple preferred a specific gender for the next baby, a ritual could be performed on the placenta before burial (Symonds, 2003).

Traditional proscriptions (*caiv*) during the postpartum month assured the mother's immediate and long-term health as well as her breastmilk supply. Women ate only thermally and metaphysically "hot" foods (rice, eggs, and chicken cooked with herbs). For the first three days after delivery, women sat by fires on beds of grass wearing hemp skirts. For the first month, women did not perform household duties; were not sexually active; did not visit other people's houses; and covered their heads and bodies so the wind would not enter their joints. These healthy proscriptions ensured the flow of lochia, restored their metaphysical "balance," and protected them from spirits (Symonds, 2003). Since women had lost "hot" blood, they must only eat hot foods; cold foods could make their blood clot inside and make them infertile; and cold wind could enter their joints and cause old-age pains, such as arthritis. Also, if they ventured outside, evil spirits could visit them and cause hemorrhage and death, or if they visited other people's houses, the spirits accompanying them could cause other people to hemorrhage.

In the United States, women usually obtain prenatal care from physicians or midwives in the second trimester. Women's motivation may be more for ease of entering the hospital for deliveries in order to obtain needed birth certificates, or for assistance after birth such as from the WIC program than for desire for a healthy pregnancy. Some women refuse to have blood drawn, have pelvic exams, or take prenatal vitamins as a result of modesty and traditional

prohibitions on anyone except a husband touching a woman's genitals, for fear of harming themselves, their fetus, or having large babies, and difficult deliveries. Many women want fetal ultrasounds for reassurance about the baby's well-being, and for knowledge of the baby's sex (Bruce & Xiong, 2003; Spring et al., 1995).

Most women deliver in hospitals in the United States, but some women deliver at home either because the labor and delivery occurred too quickly to get to the hospital or because they stayed home to avoid conflicts with hospital personnel. While most women lie down, some may squat if labor is difficult. For decades, many women have resisted obstetrical interventions, such as rupture of membranes, internal monitors, medicine for induction, medicines for pain relief, or Cesarean sections. Recently use of pain medications is on the increase, as is acceptance of interventions. Placentas have been taken home for burial, but this practice is virtually abandoned, due to difficulty of burying placentas under floors in modern dwellings (Symonds, 2003).

Most women follow some of the traditional postpartum proscriptions. Women eat "hot" foods, wear hats, cover their bodies, and refrain from sexual intercourse in order to ensure that the blood flows out of the uterus so they will not become infertile or crippled with arthritic pains. Families object to nurses and doctors vigorously massaging the postpartum uterus, as women fear resulting problems will occur, such as infertility, pelvic pains, abdominal pains, and cancer (Culhane-Pera, 2003; Spring, 2001; Spring et al., 1995). Other proscriptions are not followed strictly. As breast-feeding is no longer the norm, proscriptions to insure breastmilk are no longer important. And nearly universal bottle-feeding has ended the biological influence of breast-feeding on birth spacing and fertility rates.

Infancy

Traditionally, at three days of life family members welcomed a newborn infant by calling the soul (*hu plig*) and bestowing a name (*tis npe*) (Symonds, 2003). Today, animists continue these practices while Christian families have altered or abandoned this ceremony, depending upon their denomination. Traditionally, breast-feeding mothers cared for their infants, with their families' assistance. In the United States, the vast majority of infants bottle-feed so family members can care for babies while mothers return to school or work (Culhane-Pera, Naftali, Jacobsen, & Xiong, 2002; Tuttle & Dewey, 1994, 1996).

Multiple births are a blessing. Birth defects are caused by fate (related to events in infants' or parents' previous lives) or by mothers' actions while pregnant, or by a curse. While the ideal is to have equal numbers of boys and girls, people prefer boys, since boys stay with the family and girls marry outside of the clan. Mortality risk is equal for girls and boys, indicating that boys are not given preference over girls such that girls are at risk of increased mortality (Kunstadter et al., 1993).

There were many traditional health promotion and disease prevention activities. Infants fed on-demand; they wore silver necklaces, ornately decorated hats, and bright bracelets with bells to please their souls; and wore amulets to ward off frightening spirits. Parents refrained from unpleasant words that could upset the infant souls and from praising children, a practice believed to attract evil spirits. Parents did not wash fontanelles, the location of a soul; and they cut infants' hair to protect from fright of thunder (Culhane-Pera, unpublished ethnographic research). Many of these activities persist today, except some Christians who refrain from engaging in all animist practices. Some adults are concerned about childhood vaccinations causing pain, fever, illness, and disability, and refuse vaccines until children are older and less vulnerable to side-effects (Xiong & Culhane-Pera, 1995). Several Hmong children died in measles epidemics in California and Minnesota in 1990 from inadequate vaccinations (Henry R., 1999).

Traditional Hmong practices for sick children included *khawv koob* for fevers with rashes; *ua ceeb* for fright or startle; *nqus qe nyiaj* to reduce fevers; herbal medicines (solutions and poultices) for various illnesses; and pharmaceutical preparations from the United States and Asia. In the United States, parents also take children to see physicians. While desiring medications, and accepting intravenous fluids, families have concerns about adverse effects of venipunctures, lumbar punctures, and operations on their children's health. Conflicts between families and physicians have sometimes resulted in court-ordered treatments for diagnostic and therapeutic procedures (Brunnquell & Kuracheck, 2003; Culhane-Pera, 1989; Culhane-Pera & Thao, 2003; Fadiman, 1998; New York Times, 1994; Plotnikoff, 2003; Snyder & Kunstadter, 2001).

Childhood

A general philosophical orientation toward childrearing is characterized by *hlub*, a loving permissive attitude

(Culhane-Pera, Naftali, Jacobsen, & Xiong, 2002; Xiong Z. B., 2000). As children become older and gain more responsibilities, parents are more likely to discipline them, which can include physical punishment. The perception is that sexual abuse was rare in traditional society and that child abuse occurred more often for orphans and step-children. Social workers in the United States note that probably more child protection orders have been brought against parents for neglect (allowing children to have too much independence) than for abuse.

Some diseases are especially significant in Hmong children: (1) Hepatitis B: all infants need Hepatitis B vaccines, and infants of carrier mothers need to be tested for immunity (Franks et al., 1989; Gjerdingen & Lor, 1997; Poss, 1989). (2) Measles: a 1990 measles epidemic in Minnesota hit Hmong children, as they had a low immunization rate (Henry R. R., 1999). (3) Milk anemia: a high rate of iron-deficiency anemia in toddlers is related to a diet heavy in cow's milk and low in solid foods (Culhane-Pera, Naftali, Jacobsen, & Xiong, 2002). (4) Thalassemia: a genetic disorder of hemoglobin, thalassemia can be fatal (Choy et al., 2000; Yang P., 2000). (5) Baby bottle tooth decay: prolonged and frequent sucking of milk in a bottle leads to tooth decay as well as ear infections (Tuttle & Dewey, 1994, 1996). (6) Lead toxicity: Exposure to lead results from ingesting lead paint chips in older homes, and when given a Chinese red powder as medicine (MMWR, 1993). (7) Obesity: obesity in Hmong children is increasing, probably due to over-bottlefeeding, over-eating, and under-exercising (Gjerdingen et al., 1996).

Adolescence

Traditionally, teenagers had much work responsibility and little freedom beyond the household and extended family (Xiong Z. B., 2000). While there were no traditional "rites of passage," teenagers were encouraged to marry when they had accomplished agricultural and domestic life skills. The expectation to assume adult responsibilities was high, and discipline tended to be strict. While premarital intercourse was tolerated, sexually active teenagers were expected to marry. Conflicts in the United States are resulting from tensions between parental demands for conforming to traditional values and youth's desires for increased freedom. Parents feel their traditional values are being disrespected, and teenagers feel parents are not realistic in U.S. society (Wheeler, 1998). Parental concerns are compounded by the high rates of

pre-marital intercourse, sexually transmitted diseases, gangs, and use of tobacco and drugs. External injuries and violence are leading causes of death for adolescents and young adults in Fresno California, and the rate is increasing (Kunstadter & Vang, 2002).

Adulthood

In Laos and the United States, middle-aged adults have the most responsibility for children, aging parents, and society at large. Men are active in leading society, and increasingly gain respect as they become elders. Women also have increased status, with increased influence over family matters, and may have some community influence especially if their husbands are clan leaders (Donnelly, 1994).

In Southeast Asia, adults suffered from infectious diseases, accidents, and other ailments. In the United States, the “modern” diseases of diabetes, hypertension, strokes, heart attacks, and cancers are on the rise. Many suffer from these ailments, and are challenged to respond to these chronic and life-threatening conditions.

The Aged

Traditionally, elders—people older than 50 years of age—were respected for their opinions and life experiences, and enjoyed a reduced work load. Usually youngest sons and their wives were responsible for the aged, including providing care as they became infirm. This continues in the United States, although elders’ opinions and life experiences may be less relevant to their children and grandchildren than in Southeast Asia, and more elders live alone or in nursing homes. Their health issues include the modern diseases, as well as degenerative diseases (arthritis, osteoporosis, blindness, and deafness).

Dying and Death

Death is understood as a transition from the world of the living to the world of the spirits and as a preparation for the next reincarnation (Symonds, 2003). Living family members continue to revere, remember, and appease ancestral spirits with offerings. Nonetheless, family members will engage in many actions to heal sick family members, including traditional and modern healing options. A “good death” occurs without pain and at home, surrounded by the loving family who attend to physical needs and visited by friends and relatives who give them encouraging words

about their long life. In addition, a good death occurs in the company of ancestral spirits while wearing traditional clothes, and with the chance to impart their last words to the family (Vawter & Babbitt, 1997).

Traditionally, at death family members wailed their grief and washed the body before dressing it in multiple layers of ancestral clothes. Funerals of un-embalmed bodies lasted up to 9 days, depending on the deceased’s social importance, with many rituals. Burial occurred in a place chosen by geomancy rules for good luck. Rituals continued at the gravesite every day for 3 days, with a final ritual to release the soul at 13 days. In the United States, animists still wail and conduct traditional funeral ceremonies, whose details have changed to adapt to current social, economic, and political realities. Christians conduct prayer services with songs and sermons, and do not wail (Bliatout, 1993).

Iroquois

Barbara W. Lex and Thomas S. Abler

ALTERNATIVE NAMES

The Iroquois were and are a confederacy of several Native North American nations. The original five members of the confederacy were the Mohawk, Oneida, Onondaga, Cayuga, and Seneca. Accordingly, they were known to English colonial officials as the Five Nations. When the Tuscarora joined them early in the 18th century, they became the Six Nations. The Iroquois saw their confederacy as a metaphorical longhouse, the multi-family dwelling which housed them in settlements at the time of contact with Europeans. Hence they referred to themselves as the Hodénosaunee, meaning, roughly, People of the Longhouse. French colonists in Canada used the term Iroquois, a name they probably learned from a 16th century Basque–Algonquian pidgin used in the St. Lawrence valley (see Bakker, 1990; Goddard, 1978).

LOCATION AND LINGUISTIC AFFILIATION

Iroquois territory stretched through what is now upstate New York from the Mohawk River valley to that of the Genesee. The Mohawks lived in the Mohawk valley; the Oneidas lived near Oneida Lake; Onondaga territory was lands surrounding present-day Syracuse, New York; the Cayugas lived near Lake Cayuga; and the Senecas occupied lands to the west. In historic times there was an expansion westward and the Iroquois claimed as hunting territories lands now in Pennsylvania, Ohio, and Ontario. In the late 17th century Mohawks who had been converted

to Christianity by French Jesuits moved north to the St. Lawrence valley where they remain in communities in Quebec, New York, and Ontario.

Following the American Revolution, a large portion of those Iroquois who had fought as allies to the Crown moved to lands in Ontario. Others remained in New York, the Onondagas with a reservation near Syracuse and the Senecas currently living on three reservations in western New York. The Oneidas, who had fought as allies to the rebellious Americans, initially remained in their homeland, but in the early 19th century emigrated in large numbers to both Wisconsin (near Green Bay) and Ontario (near London). The Tuscaroras moved northward from South Carolina to reside in the Iroquois country about 1720, and now occupy a reservation near Niagara Falls, New York. Some Iroquois who had settled in Ohio eventually were established on a reservation in Oklahoma (Campisi, 1978; Fenton & Tooker, 1978; Sturtevant, 1978; Tooker, 1978a). Table 1 lists the many contemporary Iroquois reservations and reserves and their enrolled memberships. However, a large portion of those enrolled live off-reservation or off-reserve and the residents of a reservation or reserve include many not officially enrolled as tribal or band members.

The nations of the Iroquois Confederacy, as well as neighboring, politically independent groups such as the Huron, spoke languages of the northern branch of the Iroquoian language family. A single language, Cherokee, survives in the Iroquoian language family's southern branch. Of northern Iroquoian languages, Tuscarora is the most divergent. Mohawk and Oneida are the most closely

Table 1. Contemporary Iroquois Reservations and Reserves

Reservation or reserve	Enrolled population
<i>New York</i>	
Seneca Nation (Allegany and Cattaraugus)	6,241
Tonawanda Band of the Senecas	1,050
Oneida	1,100
Onondaga	1,600
Tuscarora	1,200
Akwesasne (St. Regis)	5,638
<i>Ontario</i>	
Akwesasne (St. Regis)	9,500
Tyendinaga	7,046
Six Nations	20,876
Wahta Mohawk (Gibson)	659
Oneida of the Thames	4,776
<i>Quebec</i>	
Kahnawake (Caughnawaga)	8,888
Kanesatake (Oka)	1,943
<i>Wisconsin</i>	
Oneida	11,000
<i>Oklahoma</i>	
Seneca-Cayuga	2,460

These figures reflect the enrolled or registered membership of the above communities in or about 1990 for the United States and 2000 for Canada. Many enrolled members live off-reservation or off-reserve. The reserves and reservations also are home to many non-enrolled individuals, Indian and non-Indian, who have married into or otherwise have a right to reside on the reserve or reservation.

related of northern Iroquoian languages still spoken while Mohawk itself has distinct dialects (Bonvillain, 1984; Lounsbury, 1978).

OVERVIEW OF THE CULTURE

The Iroquois lived in compact villages usually located in defensible positions near water sources, ranging in size from approximately 500 persons up to 3,000 or possibly even more. Typically surrounded by palisades, a village consisted of parallel rows of longhouses, each elm-bark and pole structure housing a number of

matrilineally related women with their spouses and unmarried children. Open hearths were spaced about 8 m apart in the central aisle running the length of the house. Each was shared by two families, and the usual longhouse at time of contact had three or four hearths, hence housing six to eight families (Abler, 1970).

Surrounding the village were its agricultural fields that provided the larger portion of the Iroquois diet. Here grew what the Iroquois referred to as the “life-supporters” or the “three sisters”—maize (corn), beans, and squash. Men cleared the fields that the women planted, cultivated, and harvested. Nearby, women gathered firewood, necessary for cooking and heating, and collected edible wild green plants, nuts, and fruits to supplement cultigens. When local sources of firewood were exhausted and fields drained of their fertility by repeated crops of maize, a new village would be established at some distance from the old settlement. Males were frequently away, hunting, trading, or waging war. Deer was the most important mammal that was hunted, both for its meat and its hide. Large quantities of fish were also harvested at semipermanent fishing stations. With the coming of Europeans, the harvesting of beaver pelts, to exchange for goods of European manufacture, became important. Wallace (1952) has contrasted the “village” and the “forest” in Iroquois life with the former being the women’s domain while the latter was the sphere of male activities.

The dog was the only native domesticated animal, although captured bear cubs were raised in pens until of sufficient size to warrant slaughter for food. From their European neighbors the Iroquois obtained pigs that thrived in the temperate forest of North America and were found in large numbers in Seneca villages by the last quarter of the 17th century. Other European animal and plant domesticates were adopted, and through the 18th century the multi-family longhouse was used with lessening frequency, being replaced by single-family dwellings. As threats of outside invaders subsided, large villages fragmented into smaller hamlets that did not exhaust local resources.

Iroquois communities were divided into exogamous matrilineal clans. The number varied from nation to nation, with the Mohawk and Oneida having only three clans each while the other nations had from eight to ten matrilineal clans. A smaller clan might have just one lineage, but larger clans were divided into two or more lineages, each lineage headed by a senior woman or matron often referred to as a “clan mother.” This woman had considerable responsibility in organizing the activities of her sisters,

daughters, and nieces (sisters' daughters) in the lineage and in choosing from among her brothers, sons, and nephews (sisters' sons) in the lineage one qualified to hold a position as a political leader in the community (Fenton, 1978; Tooker, 1978b).

Marriage was monogamous. Men upon marriage left the home of their own clan and lineage to reside in houses belonging to their wives' lineage. As is often the case in matrilineal societies, divorce was relatively easy and common, with the children remaining in the home of their mother. Bonvillain (1980, pp. 52–53) notes the role of women in initiating pre-marital and extramarital sexual encounters which "occurred easily." She also notes that in the "ideal pattern" the lineage matron of an eligible male would arrange a marriage with the senior women of the lineage of a prospective bride. Extramarital affairs were among the behaviors condemned by the prophet Handsome Lake and he also condemned those who gossiped about such activities leading to the breakup of a marriage (Parker, 1913, pp. 32–33; Wallace, 1971, pp. 370–371). Fenton (1941b) reports infidelity of a husband as a common cause of female suicides.

Extensive documentation of Iroquois religious practices postdates both the revitalization of Iroquois religion by the prophet Handsome Lake, who experienced his first vision in 1799, and the conversion of substantial numbers of Iroquois to Christianity (Wallace, 1970). The yearly cycle of ceremonies was first outlined in Morgan's pioneering ethnography (Morgan, 1851). The major ceremonies, Midwinter and Green Corn, as well as many lesser ceremonies, relate to the agricultural year, but others such as the Strawberry ceremony and Maple ceremony celebrate the wild foods which had been important in the Iroquois diet (Fenton, 1936, 1941a). Another important aspect of religion among the Iroquois involved societies involved in the curing of illness.

THE CONTEXT OF HEALTH: ENVIRONMENTAL, ECONOMIC, SOCIAL, AND POLITICAL FACTORS

Skeletal remains excavated from early historic (late 16th century) sites yield some clues about general health status in several Seneca villages (Wray, Sempowski, & Saunders, 1991; Wray, Sempowski, Saunders, & Cervone, 1987). Lacking information to be gained only from analyses of

soft tissue or body fluids, the fragmentary nature of this record and possible collection bias dictates cautious interpretation. Given their close spatial and temporal proximity, variations among sites and even between cemeteries at a single site are puzzling. Pathologies at the Adams and Culbertson sites suggest many suffered from anemia or iron deficiencies (Wray et al., 1987, pp. 28–29, 188). Over half of the analyzable remains from Cemetery 2 at the Tram site exhibit pathologies, and the greater portion of these exhibit nutritional deficits or growth-disrupting illness (Wray et al., 1991, p. 390). The pathology rate at Cameron was low, but interment of immature individuals was very high, indicating contagious disease either of European origin or the result of poor sanitary conditions resulting from village size increases in the 16th century which could have promoted indigenous dysentery epidemics (Wray et al., 1991, p. 397).

Dobyns (1983, pp. 313–318) argued that European diseases introduced elsewhere in the Americas in the 16th century also swept through Iroquoia. A number of scholars (Henige, 1986; Snow & Lanphear, 1988, 1989) strongly reject that assertion, seeing no evidence of European disease epidemics among Iroquois people before 1634. Ramenofsky (1987), who concurs with Dobyns about the early impact of European disease on Native American populations, found insufficient archaeological evidence indicating that European diseases led to a 16th-century Iroquois population collapse.

None deny, however, the impact of European diseases such as smallpox, measles, and mumps on the Iroquois population during the 17th century. Snow (1994, p. 98) estimates half of the Mohawk population died over fewer than 100 days in 1634. Mortality from periodic epidemics of European diseases continued among Iroquois from that date until well into the 19th century. To maintain their population, the Iroquois adopted large numbers of refugee populations and war captives.

Estimates reporting the number of Iroquois fighting men from the latter half of the 17th century suggest 2,000 to 2,500 warriors (see Table 2), hence a total population of 10,000 to 12,500. A half-century of contact with European diseases had considerably reduced the population. Archaeological and ethnohistoric work with the Mohawk suggests a population in 1633, prior to epidemics of European diseases, of 8,000 to 10,000 for the Mohawk alone (Guldenzopf, 1984; Snow, 1992; Snow & Lanphear, 1988; Snow & Starna, 1989; Starna, 1980). Snow (1992, 1994, p. 100) notes the Mohawk population

Table 2. Estimates of Numbers of Iroquois Warriors

Nation	1660	1665	1677	1689	1698
Mohawk	500	300 to 400	300	270	110
Oneida	100	140	200	180	70
Onondaga	300	300	350	500	250
Cayuga	300	300	300	300	200
Seneca	1,000	1,200	1,000	1,300	600
Total	2,200	2,240 to 2,340	2,150	2,550	1,230

Source: Abler, 1970, p. 21.

had expanded greatly in the previous 50 years with an influx of refugees and/or war captives and speculates that the total Iroquois population was 22,000 in 1633, prior to the first epidemics of European diseases to strike Iroquoia.

Warfare was intensified in historic times (Abler, 1992), and skill in treating wounds was praised by a contemporary observer (Lafitau, 1974–77 (2), pp. 204–206). Accidents were also a danger (traditional Iroquois still pray that dead tree limbs not fall on children playing underneath them) and fire was a constant hazard in villages composed of densely packed bark-covered dwellings.

Suicide has been a continuing pattern in Iroquois communities (Fenton, 1941b, 1986). Abuse or mistreatment can lead one to suicide. Both children abused by parents and middle-aged women abandoned by husbands are prominent among those who commit suicide. Also, a political leader who had lost the support of his followers might take his own life. A typical method for committing suicide was ingesting the root of the water-hemlock, *Cicuta maculata*.

MEDICAL PRACTITIONERS

Recent ethnographic studies of conservative portions of Iroquois communities report that diagnosis of illness occurs separate from its treatment. There are a small number of clairvoyants or traditional diagnosticians who are regularly consulted about the cause of a patient's problem. These practitioners then direct patients to appropriate cures. Advice may be to consult a herbalist for treatment, to have a rite performed by one of the medicine societies, or to consult specialists in western medicine (Blau, 1969, p. 7; Shimony, 1994, pp. 270–274; Isaacs, 1973, p. 77).

Herbalists are specialists who have acquired from an earlier generation knowledge of local flora and the

efficacy of their use (Herrick, 1995). Fenton (1940, p. 793) notes a herbalist of either sex may pass his or her knowledge on to either a son or daughter or even, skipping a generation, to a grandchild. The knowledge of herbalists is often extensive; Fenton reports that knowledgeable herbalists with whom he worked could identify from 200 to 300 species of plants, perhaps a third of the plants available locally (Fenton, 1942, p. 504; see also Isaacs, 1973, pp. 76–79). However, plants in the ethnopharmacopoeia have changed over time (Isaacs, 1976–77, pp. 272–281).

Religious practices and health practices overlap. Specific illnesses may require performance of specific rites by medicine societies with a restricted membership. Some of their rites occur in public ceremonies; others can be witnessed only by the patient and society members. Generally, having been cured by a specific medicine conferred membership, with its obligations, in the society. The nature of the illnesses treated by these societies and the sort of rites performed are briefly discussed below, although it should be recognized many participants are uneasy about public discussion of these matters. Here we summarize only material which has appeared in print.

Fenton reports a ritual pattern followed by the medicine societies in conducting their rites. Invitations are sent out by a headman. A thanksgiving and tobacco invocation begins the meeting. These are followed by the ritual with its cycle of songs. The participants are then thanked and appropriate food is provided for the participants (Fenton, 1979, p. 1607). Medicine societies are the means by which individual illness becomes a group concern because participation involves mutual aid, allays anxieties about health, and increases involvement in traditional Iroquois culture (Lex, 1977, p. 284).

Certainly the best documented among the medicine societies is the Society of Faces, often named the False Face Society. Participants wear wooden masks, usually painted either red or black, with perforated brass plates for eyes and hair made from tails of horses. They carried large rattles made of the shell of the snapping turtle, its long neck reinforced with splints to form the handle. The Society of Faces journeyed through the community in the spring and fall visiting houses to drive out disease (the Traveling Rite). Fenton (1941c, p. 425) described his encounter with the Faces on the Allegany Reservation in the 1930s: "The company afforded a wild spectacle as they sped up the valley road in open Fords with their hair whipping in the chill winds; they grated their rattles on the car body and uttered their terrifying cries whenever they swerved to pass a

stranger.” They also perform publicly at the Midwinter ceremony. Individuals suffering from illnesses which the Faces have the power to cure can also have private rites performed for them in their homes and subsequently become members of the society (Fenton, 1987). Both private and public rites manipulate fire as a source of power for preventing or curing illness (Isaacs & Lex, 1980).

A second masked medicine society is the Husk Faces or Bushy Heads. They wear masks made of braided corn husks. They serve as heralds to announce the arrival of the Society of Faces during the Traveling Rite and at Midwinter. Among the ailments cured by Husk Faces is backache (Fenton, 1987, p. 400).

The third medicine society to use masks has been named by Parker (1913, pp. 122–123) the Society of Mystic Animals (it is also known as the Medicine Company or Shake the Pumpkin). The “blind masks” once used by this society, with which the wearer demonstrated his power to find objects even though the wooden mask had no eye holes, were out of use by 1900 (Fenton, 1987, p. 48). Pig masks carved of wood are also used by this society which performs its rituals in a darkened room, and Speck (1949, p. 104) reports the medicine used by this society to be “extraordinarily powerful.”

The most powerful of the medicines is held by the Little Water Society. Strictly speaking members of this society did not cure, since all their rituals served to maintain the potency of the Little Water medicine. The rites are conducted in the dark, between 11:00 pm and dawn and both gourd rattles and a flute are used to accompany the cycle of songs. Visitors may listen in the next room but only the initiated should witness the renewal of the medicine (Parker, 1913, pp. 116–118). As the most potent of available medicines, the Little Water medicine is also the most dangerous, and one who has custody of such medicine must exhibit exemplary behavior (Shimony, 1994, p. 284).

Other important medicine societies include the Pygmy Society or Dark Dance, the Eagle Society, the Bear Society, the Otter Society, and the Buffalo Society. Speck (1949, pp. 59–60) describes several dissociative illnesses which one or another of these societies were able to cure, such as convulsions in an Oneida woman treated by the Buffalo Society and howling hysteria in a brother and sister treated by the Bear Society.

Not all illnesses require interventions by medicine societies. In some instances a cure necessitates performance of a particular rite or dance with general participation,

for example the war dance. Outcomes of games, such as lacrosse or snow snake or the Bowl Game, could have curative as well as predictive effects (see Blau, 1969, p. 144; Speck, 1949, pp. 115–126).

CLASSIFICATION OF ILLNESS, THEORIES OF ILLNESS, AND TREATMENT OF ILLNESS

Iroquois theory asserted that misfortune and ill health could be caused by several sources. These could be simply physical, as with injury or war wounds. Another source was witchcraft in which illness is caused by foreign objects that have been magically projected into one’s body. A failure to perform obligatory rites or rituals was another. Spirits, including those of the dead, could attack. An additional and significant cause of illness was unfulfilled desires of the soul that were expressed among the Iroquois through dreams. In his evaluation of this last category, Wallace, a psychological anthropologist, considers the Iroquois dream theory as “basically psychoanalytic” and phrased “in language which might have been used by Freud himself.” The Iroquois recognized that the mind possessed both conscious and unconscious desires and “were aware that the frustration of these desires could cause mental and physical (‘psychosomatic’) illness.” They were also aware that the dreams often had latent content which required considerable interpretation to uncover their symbolism (Wallace, 1958). A frequent desire of the soul as expressed in dreams was for the performance of a particular ceremony by one of the medicine societies.

Shimony (1970) reports that witchcraft is universally attributed to “jealousy” but notes this is most often envy of unusual achievement on the part of the bewitched or a past grievance. She reports cases in which auto accidents and the death of a child were attributed to witchcraft. Witches can transform themselves into animals, but they are also sometimes seen at night as flying lights. Shimony points out that those who prove themselves able to cure illnesses caused by witchcraft sometimes come under suspicion of being witches themselves (on witchcraft, see also Herrick, 1995, pp. 37–38, 42–44).

Isaacs (1973, pp. 72–72a) notes external causes in addition to witchcraft which could cause physical distress. These include being attacked by a spirit of a dead individual or because one has offended an animal spirit.

The former is often revealed by the fact that one dreams of the deceased. Affliction by an animal spirit could call for the performance of the rites of one of the medicine societies. Speck (1949, pp. 65–67) cites the case of a woman suffering from St Vitus's dance whose father had mistreated his catch while fishing. Her illness called for a performance of the rites of the Otter society.

Herrick (1995, p. 37) reports "offensive behavioral acts or taboo violations" as a primary cause of disease and misfortune. This includes contact with a menstruating woman or even eating rich foods. Possession of powerful medicines and charms can pose a danger to one and one's family if one fails to treat and "feed" (e.g., perform rituals, burn tobacco) the medicine in the required manner (see Fenton, 1987, pp. 143–144; Shimony, 1970, pp. 250–254, 1994, p. 285). Also, witnessing rites of a medicine society by the uninitiated can lead to hysteria or other mental or physical harm. Initiation into the society is often the cure (Shimony, 1994, p. 282). Herrick (1995, pp. 50–63) presents a list of 287 conditions (with some repetition or overlapping testimony) of illnesses with their causes.

There are specific illnesses that demand the performance of a medicine society for their cure. Fenton (1987, p. 143) lists various symptoms of False Face sickness which can be cured by the Society of Faces. These center on the head, shoulders, and joints and include inflammation and swelling of face, nose bleeding, earache, toothache, other facial pain, and facial paralysis (see also Isaacs & Lex, 1980, p. 8).

SEXUALITY AND REPRODUCTION

Women typically bore four or fewer children and spaced their children by 5- or 6-year intervals. There was a herbal remedy which was believed to induce abortions, but its use was forbidden in the teachings of the Seneca prophet, Handsome Lake (Parker, 1913, p. 30). Contraception was also forbidden by Handsome Lake, but it is reported that it is practiced by his contemporary followers, that boiled sassafras shoots is thought to be an abortifacient, and that they are also convinced that prolonged breast-feeding reduces fertility in women (Shimony, 1994, pp. 208–209). Shimony also observed a gender difference in average duration of breast-feeding, with two years usual for girls but a range of from one year to 1 year and 9 months for boys. Engelbrecht (1987) concludes from evidence

from historic sources discussing the Iroquois and their neighbors and from archaeological sites that the average Iroquois family size was small. Those who have investigated Iroquois culture have ignored the issue of homosexuality. A recent study reports the belief that masturbation leads to insanity (Herrick, 1995, p. 70).

HEALTH THROUGH THE LIFE CYCLE

Pregnancy and Birth

Conception is thought to take place during a new moon. Pregnant women are expected to refrain from certain activities, such as associating with men engaged in hunting or making medicines (Shimony, 1994, p. 207). Pregnant women had to bring their own cup to use when strawberries were distributed as part of the annual Strawberry Ceremony in June (Shimony, 1994, p. 159). Skinning mink was avoided since the odor was thought to cause abortions and certain behaviors (such as sitting in a doorway or sitting upon one's foot) are to be avoided as detrimental to the birth or the fetus. Contact with a menstruating woman would also cause abortion (Shimony, 1994, pp. 208, 217). While geophagy was known among the general population, it "is quite common among pregnant women" (Shimony, 1994, p. 208). Kneeling was the traditional position for delivery, a practice still "found occasionally" a half-century ago (Shimony, 1994, p. 207). Maidenhair fern was prescribed by midwives for labor pains and sassafras was brewed into a tonic for use by women after childbirth (Fenton, 1942, p. 517).

Infancy

Public recognition of the place of an infant in a community came at the Midwinter Ceremony or the Green Corn Ceremony that followed its birth. Today the exact day on which the names are announced as one element within these lengthy ceremonies varies. A speaker announces the name of each new member of the community. Each infant receives a name held or owned by the matriline into which she or he was born (Sturtevant, 1984). Only one living person bears a specific name, and infants thought destined to fulfill important ritual roles in adulthood are given names of deceased ritualists (Blau, 1969, p. 27).

Infants are reported to have been nursed for lengthy periods, 3 years being common with observations nearly

two centuries apart reporting cases of children over 5 years of age still nursing (Engelbrecht, 1987, p. 19). Children were weaned by painting the nipple black to frighten the child, placing a chicken feather on the breast, or coating the nipple with a noxious, non-toxic substance (Shimony, 1994, p. 209). A recent study among the Mohawks of Kahnawake, Quebec, reported that breast-feeding increased from 45% of infants in 1978 to 64% in 1986 (Macaulay, Hanusaik, & Beauvais, 1989).

Traditionally infants would be strapped to a cradle board, a plank approximately 0.5 m long and 0.25 m wide. At the bottom there was a foot-board and the head was protected by a hoop or bow. Morgan (1851, p. 390) reported “the patience and quiet of the Indian child in this close confinement are quite remarkable.”

High infant mortality is indicated by the Iroquois proverb, “an infant’s life is as the thinness of a maple leaf” (Fenton, 1978, p. 314). Engelbrecht (1987, pp. 21–22) argues that the fact that Handsome Lake found it necessary to preach against infanticide indicates its earlier practice. Scattered references found in the historic literature suggest that infants may have met death through conscious actions or neglect in cases in which their mother died or their mother was distraught because of the death of a husband or other social circumstances. Handsome Lake specifically stated that childless women should adopt infants born to their sisters (Parker, 1913, p. 35).

Childhood

Restraint on the actions of children was limited. The preferred form of punishment for bad behavior was to splash the child with cold water. A thorough dousing or the threat of a dunking in a cold stream were used on children who do not reform. A red willow whip, to which tobacco had been burned, was used to strike particularly disobedient children. Traditional values disapproved slapping. Indeed, severely punishing children was thought to bring disease, hysteria, or the vomiting of worms upon the disciplinarian (Shimony, 1994, pp. 209–210). Parents also refrained from disciplining children lest they commit suicide by eating the poisonous root, *Cicuta*, or that they might mature to abuse their elderly parents (Fenton, 1941b, p. 125). Field workers have noted considerable respect for the rights of children to make their own decisions. Shimony (1994, p. 269) records the case of parents accepting the refusal of a 9-year-old to undergo a heart operation deemed necessary by the local hospital.

Adolescence

Oral traditions suggest that vision quests by males at puberty were once a significant element in Iroquois culture, but this does not appear to have been widely practiced in historic times. Similarly, oral tradition suggests the isolation of a girl for up to a year at the time of her first menses, but again this seems to have disappeared as a practice by the time observers were recording Iroquois culture and behavior. The girl did have to observe the prohibitions of behavior observed by any menstruating woman for the first three days of her period (Shimony, 1994, pp. 215–216).

As a mark of maturity, the “baby name” previously held was replaced, each person receiving an adult name from the roster of names of his or her matriline. As was the case with the “baby name,” these names were publicly announced at either the Green Corn Ceremony or the Midwinter Ceremony. One of the boys who had received a new name then led a Great Feather Dance as part of the worship (Fenton, 1963).

Adulthood

Since the time of Morgan (1851, p. 83), clan exogamy has been recognized among the Iroquois. However, this rule has been frequently breached, even among conservative Iroquois. Lineage exogamy is more frequently observed. In addition to these matrilineal relatives, all persons related to one through either parent are forbidden as a spouse or sexual partner (see Shimony, 1994, pp. 30–32).

Adult males, particularly those with ritual obligations, undergo a regimen of purging for three days in the spring. In the past this included baths in a sweat lodge. Various herbal concoctions are used as emetics and laxatives to cleanse the body. An 18th-century observer noted the use for purging of “very strong medicines which clear them out to excess and might well kill a horse” (Lafitau, 1974–77 (2), p. 206). One fasts during the purge but then takes tonics to regain one’s strength. Sassafras is thought to restore the blood following the period of the purge. In addition to this period of “spring cleaning,” men may also purge themselves in preparation for an important ritual (Parker, 1913, p. 77; Shimony, 1994, pp. 265–266). A phobia apparently rare or absent among Iroquois males is fear of heights (Wallace, 1951, p. 64).

Onset of menses was believed to occur at the new moon. Shimony (1994, pp. 216–218) reports that women

were considered “poisonous” or “dangerous” during the first 3 days. They should not attend curing rituals or be in the presence of medicines, nor should they come into close contact with males. They even constitute a danger to themselves, since if they comb their hair it might fall out. They may attend longhouse events, but should drink from their own cup rather than the common dipper. These restrictions are no longer followed, and the timing of the Midwinter Ceremony no longer allows 5 days for completion of menstruation (Blau, 1969, pp. 59–60; Shimony, 1994, p. 174). Contact with a menstruating woman causes bloody diarrhea and bleeding piles. Menstrual blood is also an ingredient in love medicines that can lead to bad luck or even insanity.

The Aged

Morgan (1851, p. 171) recorded the teaching of the Longhouse religion speaker from Tonawanda, Jimmy Johnson: “It is the will of the Great Spirit that you reverence the aged, even though they be as helpless as infants.” The prophet Handsome Lake preached that it was “ordained that people should live to an old age” and that “an old woman should be as a child again and when she becomes so the Creator wishes the grandchildren to help her” (Parker, 1913, p. 35). Despite this, Fenton (1941b, p. 125) feels “that the number of cases where Iroquois adults have maltreated their aged parents is great enough to warrant investigation” and notes that two abused elderly Onondaga males committed suicide. In one of these cases there were factors involved other than simply abuse by adult children.

Randle (1951, p. 171) presents an idyllic view of the role of the aged woman: “Honored as heads of clans and household, the old age of women could be rewarding, surrounded by her offspring.” Although unmarked by a rite of passage, after menopause women can partake in activities involving curing and medicines that previously had been barred to them (Shimony, 1994, p. 218). Wallace (1951, p. 64) notes that the absence of fear of heights continues into old age—“even old men of 60 and 70 will take, and efficiently perform, such jobs as pruning high trees, painting the roofs of buildings, and carpentry work on scaffolds.”

Dying and Death

Several authors have commented upon the excessive grief and intensity of mourning found among the Iroquois.

Wallace (1970, p. 77) noted: “Descriptions of Seneca mourning behavior read like psychoanalytic essays on the dynamics of depressive states, and the paranoia of bereavement, which generated blood feud and fear of witchcraft, was regarded by the Iroquois themselves as a continuing threat to the solidarity of the community.”

Unusual behaviors of birds often foretold deaths (Shimony, 1994, p. 234). People preferred to die at home, and those believed terminally ill had the clothes in which they will be dressed in their coffin placed within their view. Although an innovation of the modern New York Onondaga involved a ritual of lying in state in their Longhouse to show respect for a Confederacy chief (Blau, 1969, p. ix), traditionally the corpse was on view in a coffin in the home. This was a time of much unease, since the dead attract other dead who may take offence at some action among the living—especially inattention to ritual details—and cause illness or bad luck. Children under the age of five were considered particularly vulnerable, and typically a deerskin thong tied around the wrist was used to protect them from the spirit of the dead. Shimony reports that a wake involving special songs and a wake game was conducted on the Six Nations reserve, but this was not practiced by the conservative element in other Iroquois communities. The grave was dug by a member of the moiety opposite to that of the deceased.

The whole community mourned for 10 days, culminating in a tenth-day feast organized by matrilineal kin of the deceased and marked by distribution of his or her property. The spirit of the dead then may depart the community, but would be addressed again during a feast on the first anniversary of death. It is believed that Handsome Lake forbade mourning for an entire year, considering that practice too disruptive to daily life (Shimony, 1994, pp. 228–250). An all-night Feast of the Dead (*Ohgiwe*) is held at least once annually to honor and propitiate potentially restive spirits (Blau, 1969, pp. 245–252; Fenton & Kurath, 1951, pp. 139–166; Lex, 1977, p. 294; Shimony, 1994, pp. 229–233). Certain songs are sung falsetto, and dancers move clockwise as does distribution of special feast foods. At dawn a procession of the living was intermingled with spirits of the dead.

CHANGING HEALTH PATTERNS

In the mid-20th century no strict dichotomy of beliefs and behaviors associated with health and illness distinguished Longhouse adherents from those who eschew traditional

beliefs (Weaver, 1972, p. 33), and acceptance of Western medical services by some Six Nations reserve inhabitants is documented before 1850 (Weaver, 1972, p. 39). Contagious diseases such as smallpox (Weaver, 1971, pp. 361–378) diminished as preventive measures such as vaccination and sanitation improvements became available on reservations and reserves; most prevalent currently are chronic diseases stemming from behavioral risk factors (Lex & Norris, 1994, pp. 193–196).

Among Iroquois in both the United States and Canada, alienation of land, breach of treaty rights, and monetary exploitation—as well as discriminatory attitudes and actions of the dominant societies—have promoted resentment and distrust of governmental authority, and concomitantly reinforced desire to be treated as sovereign nations (Abler, 1997, pp. 27–28; Weaver, 1971, pp. 361–378; Weaver, 1972, pp. 32–37). Prevention and treatment in Canada are provided by Health Canada, and in New York by the American Indian Health Program of the state Department of Health (not the Federal Indian Health Service). Governing bodies on each reserve or reservation would need to grant permission for health-related surveys (Lex & Norris, 1994, p. 195), and some reject enumeration (Department of Health, 1999, p. 32). Given intragroup factionalism, participation could be neither required nor guaranteed despite needs for knowledge to plan appropriate programs.

Some chronic disease data are available from selected samples. Indian populations have high rates of Diabetes mellitus (Type 2 diabetes) linked with obesity, hypertension, anemia, and nutrient deficiencies, as well as complications of pregnancy (Lex & Norris, 1994, pp. 198–199). For 1980 to 1986 in upstate New York, birth certificate data were compared for Indian (predominantly Iroquois), white, black, and other race infants (Buck et al., 1992, pp. 569–575). Mothers of Indian infants not only were younger, had less education, had more children, and took longer to obtain prenatal care than mothers of white infants, but also had more post-term births and excessive-sized (>4,000 g) babies—factors associated with gestational diabetes or diabetes mellitus. Death certificate data for the same interval (Mahoney, Ellrott, & Michalek, 1989, pp. 403–412) showed that Indians died at an average age 9 years younger than others (women 65 versus 74 years; men 58 versus 67 years), with ages 50 to 59 years and 20 to 29 years showing higher rates for females and males, respectively. Diabetes mellitus was the leading cause of death for women, followed by liver cirrhosis,

nephritis, and homicide, and for men major causes were tuberculosis, diabetes mellitus, cirrhosis, and pneumonia.

A tribal survey of the Seneca Nation of Indians during the mid-1970s reported 26% had diabetes mellitus. Epidemiologists assessed mortality causes by analyzing death certificate data for 914 deaths among 3,262 Seneca (391 of 1,690 females and 523 of 1,572 males) listed on the tribal roll January 1, 1955, resident in New York State, and followed until December 31, 1984, in comparison with deaths of other upstate New York inhabitants during that interval (Mahoney, Michalek, Cummings, Nasca, & Emrich, 1989, pp. 816–826). Tuberculosis was the leading cause for Seneca women, followed by diabetes mellitus, pneumonia, liver cirrhosis, nephritis, accidents, and homicide; for Seneca men ranked causes were tuberculosis, diabetes mellitus, atherosclerosis, hernia/intestinal obstruction, cirrhosis, and accidents. Median age at death increased from 55.9 years during the first decade studied to 64.6 years during the last. A similar study analyzed 74 deaths among 3,033 Seneca children (47 of 1,483 females and 27 of 1,550 males) ages 0 to 24 years born between January 1, 1955, and December 31, 1989 (Michalek, Mahoney, Buck, & Snyder, 1993, pp. 403–407). Most deaths before age 5 were from infectious diseases. Between ages 15 and 24 years, accidents, particularly motor vehicle accidents, were predominant causes for both males and females, with males also exhibiting elevated suicide rates.

In a 1985 study, Kahnawake Mohawk adults with and without diabetes mellitus were chosen randomly and matched for age and sex. Data from clinical records, interviews, and body measurements showed male and female diabetics to have 5.51 times more peripheral vascular disease, with ratios of 4.57 for cerebrovascular disease and 3.56 for ischemic heart disease. Among diabetics, 48% had ischemic heart disease (versus 22% of non-diabetics), the highest known rates for North American Indians. Moreover, 86% and 74%, respectively, were obese. Persons with diabetes also had high rates of hypertension, hypercholesterolemia, and diabetic complications. These factors in combination indicated need for community-wide interventions (Macaulay, Montour, & Adelson, 1988, pp. 221–224; Montour, Macaulay, & Adelson, 1989, pp. 549–552).

Children between ages 9 and 10 years exhibited increased weight, height, body mass index, and subscapular skinfold thickness (SSF) associated with increased television viewing and decreased physical fitness. Findings led to a pioneering community-based primary prevention program, the Kahnawake Schools Diabetes

Prevention Project, to change diets and promote physical activity (Macaulay, et al., 1997, pp. 779–790). In 1994, 103 girls and 95 boys attending elementary schools in two Mohawk communities were surveyed for demographic and lifestyle variables, height, weight, and SSF were measured, and children performed a run/walk fitness test, with a follow-up assessment of SSF in 1996.

Despite improvements for some children, risk factors, especially television viewing, were confirmed for Kahnawake girls (Horn, Paradis, Potvin, Macaulay, & Desrosiers, 2001, pp. 274–281). Also, among asthmatics ages 4 through 12 years, Seneca girls were over-represented when compared with pupils from other ethnic groups; their “triggers” were associated with adverse housing conditions (Lwebuga-Mukasa & Dunn-Georgiou, 2000, pp. 745–761). Accordingly, lifestyle factors associated with risk for development of chronic diseases and associated complications need to be discerned and addressed on reserves and reservations, with special emphasis on understanding gender differences

Jamaican Maroons

George Brandon

ALTERNATIVE NAMES

Windward Maroons, Leeward Maroons. Also call themselves Nyankimpong Pickibo (“children of the Creator” in Twi).

LOCATION AND LINGUISTIC AFFILIATION

There are two major centers of Maroon life in Jamaica. The Leeward Maroons are centered in the mountainous Cockpit country of the Western half of Jamaica in the parishes of St. James, St. Elizabeth, and Trelawney. The spiritual and physical center of the Maroons in this area is the village of Accompong with significant Maroon populations in Aberdeen, Maroon Town, and Whitehall. On the eastern half of the island, in the Blue Mountains, is the other center of Maroon culture, the village of Moore town. Other Windward Maroon settlements in this area include Scots Hall and Charlestown. Most of the time Maroons speak a Jamaican patois that derives most of its vocabulary from English but often has syntactical and grammatical features more akin to those common in West African languages. Both Maroon groups also possess

an archaic language they call Kromanti, an African-based tongue that nowadays has no consistent native speakers but survives in ritual songs and in old folktales. In Accompong there is a small but significant Rastafarian community that has added its own distinctive form of Rasta-talk to an already complex linguistic situation.

OVERVIEW OF THE CULTURE

Maroon identity is based more on history, land and sacred charter, and the primacy of certain social values than on cultural or linguistic distinctiveness. Jamaica's Maroons trace their origins to explorers, livestock managers, and militia brought to Jamaica from Africa and the Iberian peninsula by the Spanish in the 1550s when various European colonizers contended for possession of the island. The Africans had been commissioned by Spain to raise livestock, intercede with the remaining Arawak Indians, and protect the island from other European powers should they attack. When slavery became the operative principle of colonization and the British contested Spanish possession of the island, this growing group—who had already intermingled with the remaining

Arawaks to some extent—refused to align themselves with either the Spanish or the British; instead they grabbed their weapons and took to the hills to forge a new life for themselves on their own terms. It was because of this that they came to be referred to as Maroon, a term deriving from the Spanish *cimmaron*, meaning “wild” or “untamed” and referring especially to domesticated animals that escape and return to the wild.

By no means were the Maroons a homogeneous group. Their numbers included people from various ethnic groups of West and Central Africa, Spanish deserters, runaways who had found their way to Jamaica from Barbados, Africans mixed with Arawak, and refugees from shipwrecked slave ships including a few who were native to Madagascar. Out of this heterogeneous collection of peoples they forged a new group that fanned out across the island to form the Leeward Maroons centered in Accompong in the western mountains of Jamaica’s Cockpit country, and the Windward Maroons in the Blue Mountain region on the eastern side of Jamaica. Despite the distance that separates the Leeward and Windward Maroons, the two groups are in contact and have long maintained relations with each other.

Jamaican Maroons possess an abstract conception of history focused on the military and political events of the Maroon Wars and on the 1738 and 1739 treaties that the Leeward and Windward Maroons concluded with the British government. In this conception of history the “first time Maroons”—that is, the original Maroons and those who waged the warfare that led to the treaty—achieve a mythic and heroic status. The “first time Maroons” and the next generation of “Old People” were venerated in rituals after they died and the most important war leaders such as Cudjoe, Nanny, and Accompong were promoted into a spiritual pantheon. Origin myths grew up around them and the oldest Maroon religion was essentially an ancestor cult devoted to the spirits of these people. The treaties ending more than 80 years of intermittent warfare with the British have also achieved a sacred status. The 1738 and 1739 treaties ceded land to each of the Maroon groups as a whole rather than to individual Maroons and the communal ownership of these lands has remained an important anchor of Maroon identity among both Leeward and Windward Maroons up to the present day.

Today Maroons are a part of Jamaica’s rural peasantry and share much of its culture. Most rural Jamaican communities have populations of less than 4,000 and Accompong and Mooretown are probably at the midrange with populations of about 2,500 to 3,000 each if you include

their environs. Men and women both farm but housework is performed mainly by women and children. The influence of orthodox Protestant religious denominations, various heterodox Afro-Jamaican forms such as Revival and Rastafarianism, and survivals of Myal, an early creolized version of African ancestor veneration, are as evident in Maroon communities as they are throughout the rest of rural Jamaica. Maroon family and household structure exhibit the same extreme variability of form, frequent dispersal of children across households, multiple forms of mating, late marriage, and female-headed households that we find all across the rural areas. Still Maroons’ history as rebels against slavery and their self-image as fighters are keys to many of their social and communal values.

Independence, communalism, and self-sufficiency are important Maroon values stemming from their warrior heritage. The peasant’s attachment to land has been given a particular valence by the sacred status of the Maroon treaties and because Maroons anchor their conception of history and some important social and cultural values to specific geographical sites. Maroons have a reputation throughout Jamaica as skillful practitioners of the Jamaican magic tradition of Obeah and as makers of powerful traditional medicines. While Maroons are apt to protest to outsiders that they do not practice Obeah, in fact some of them do. No such stigma or denial attaches to Maroon traditional medicine, though. Traditional medicine is now being seen as an anchor of contemporary Maroon identity and non-Maroon entrepreneurs have appropriated this connection between Maroons and associate it with their own commercial preparations to increase customer appeal. A ceremonial and ritual figure unique to the Jamaican Maroons is the Maroon abeng player. The abeng, a side-blown animal horn producing a narrow range of pitches, once communicated messages across the distances separating Maroon groups. When the first time Maroons were alive the abeng conveyed important military information between camps in coded messages that reflected the tonal features of some African languages. Nowadays, the abeng summons the community to town meetings, announces difficulties and deaths, and plays an important symbolic role in funerals and holidays.

CONTEXT OF HEALTH

Maroons are politically, socially, and economically marginalized within Jamaica. The 1738/39 treaties gave the colonial government the right to appoint Maroon chiefs

(called “Colonels”) and also created a position for “Whites” who fulfilled the twin functions of representing the Maroons to the central government and also representing the interests of the central government to the Maroons. In effect the Colonel became a middleman to a middleman and the colonial government refused to meet with or recognize Maroons. The political situation did not improve substantially after Jamaica gained independence from England in 1962. Both the Peoples’ National Party and the Jamaica Labor Party have attempted to cultivate a broad base of support among Jamaican Maroons from time to time because of the party loyalties of their large extended families. Partisan politics, however, has brought few tangible rewards to Maroons and has even fomented serious divisions within the communities.

Because of the 1738/39 treaties Maroons pay no taxes to the national government and so get little in the way of services in return. Their roads are badly maintained—even by Jamaican standards—and the government contributes meagerly to Maroon educational and health services. Maroon involvement in government-sponsored agricultural initiatives has been a roller coaster affair subject to dramatic market fluctuations, expensive chemical inputs to agriculture, and high transportation costs. At the same time as traditional farming methods are waning and cooperative labor arrangements supplanted by wages, Maroons find themselves vulnerable and dependent upon an external economic system over which they have no control.

All in all, an estimated 100,000 people in Jamaica regard themselves as Maroons or Maroon descendants. Not all of them live in the traditional Maroon areas. Many Maroons now live in nearby cities such as Montego Bay or Port Antonio, or they move to Kingston in search of work and shuttle back and forth between urban life and the rural environment of the Maroon settlements. In the late 1950s, just before Jamaica’s independence, a significant number of Maroons left for England and a steady stream of migration there has continued ever since. This overseas Maroon population sends remittances home and continues to have rights to land in the settlements. More recently a new stream of migration has begun, this time it is elderly and retired Maroons who are returning from England to the communities in which they were born.

MEDICAL PRACTITIONERS

There are no full-time Maroon healers. Every healer practices their particular form of medicine part-time, alongside

farming and sometimes even a third occupation or trade. There are five types of Maroon healers: herbalists, midwives, bonesetters, dancers, and science men.

Herbalists. The training of Maroon herbalists frequently combines apprenticeship and family tradition with self-teaching. Everyone begins learning about the healing properties of plants from an early age but only a few pursue it conscientiously. There is often a religious component in the herbalist’s practice and orientation; many of them use the Christian Bible and see no opposition between prayer and healing by faith, and healing through herbal medicine. Some are community workers with high standing and live in the towns; a few spend much of their time in the forest and are marginal to the community but bring in plants that are difficult to find in the settlements or the fields. A few herbalists have established reputations wide enough to bring in clients from the towns and coastal cities or even overseas. In recent years some herbalists have formed groups to share knowledge, promote their craft, and mount small-scale economic ventures.

Midwives. Midwives are trained by older women through observing and assisting them in births. Midwives form a loose network of cooperation and work as teams with shifting membership assisting the delivery of Maroon babies under the direction of an elder woman, the nana.

Bonesetters. Bonesetters train primarily by observation and the empirical experience of seeing bones set. There is sometimes a family tradition in this work but the role can be assumed by anyone with the requisite experience and skill. The bonesetter needs to be able to fashion splints, do some elementary massage, and administer herbs that help reduce swelling and pain and assist healing. Bonesetters usually work as individuals who gradually establish a reputation within the Maroon community.

Dancers. The dancer was a distinctive ritual and religious figure that was last seen in Mooretown in the 1940s. Dancers specialized in ailments caused by spirits and in severe cases that had not been resolved by other medical means. They conducted public and private rituals in which the dancer, assisted by prayers and drumming, went into spirit possession and then healed from the possessed state.

“Science Men”. The distinctive characteristics of this kind of Maroon healer relate to their role as seers and

diviners, and their use of European magic and occult sciences. Invocations, fashioning charms and talismans, and using oils, candles, and holy water in their rituals are part of their expertise. They may specialize in fortune telling, sexual and love magic, magic related to farming or treating particular health problems with a combination of rituals and herbal medicine. "Science men" or "scientists" are frequently associated or identified with obeah (the Afro-Jamaican sorcery tradition) and herbalism, and may or may not perform any of the other healer roles already mentioned. They are often ambivalently valued figures inspiring both fear and respect. A few science men occasionally have clients coming in from abroad or from distant regions within Jamaica.

CLASSIFICATION OF ILLNESS, THEORIES OF ILLNESS, AND TREATMENT OF ILLNESS

Maroon Disease Theory: Etiology

Cold and Blood. Cold and blood are important concepts in Maroon explanations of the causes of sickness. "Cold" is a fundamental element of Maroon etiology, an explanation for a general type of disease process with wide ramifications. When Maroons speak of "contracting a cold" or "contracting cold" they are referring not to the sickness itself as we might in speaking about a head cold, but to "cold" as a causal factor underlying the symptoms that have developed (Cohen, 1973, p. 69). According to them, "cold" is responsible for the majority of the sicknesses afflicting Maroons. "Cold" is a range on a continuum of judgments that Maroons use in describing bodily sensations related to temperature. While this scheme of explanation tends to focus on the effect of cold, the other extreme is not neglected and a few ailments are traced to the effect of too much heat, the most prominent of these being "belly hot."

"Cold" is a pervasive generalized sensory quality or force that emanates from certain objects or places in the environment. The earth or ground is a source of cold; so is immersion in cold water or getting soaked in the torrential downpours that mark the lives of both Leeward and Windward Maroons day after day for weeks at a time. But encounters with these cold-emanating elements of the environment are common everyday occurrences.

Under certain conditions, however, contact with cold can adversely affect people's health. This contact is even more dangerous if cold is actually able to enter the body and reside there. Cold permeates the whole body once it has made its way inside.

Blood is the most important part of the body, its vital force. Maroons evaluate and describe blood by referring to its ability to flow, its purity, and its strength. Break down and impurity of blood cause the organs to malfunction and fail. For Maroons a warm body is a healthy body. It is the blood and its circulation through the body that keep the body warm. When cold intrudes itself into the body the thickness and stubbornness of cold mix with the blood, rendering it stagnant, obstructing perspiration (itself a cleansing process). If the blood is pure, strong, and flowing it will force the cold back out of the body otherwise the cold mixes with blood and causes it to "sleep" and not flow, and the body becomes vulnerable to disease.

What causes and facilitates the intrusion of cold into the body is the sudden or rapid alternation of extreme states of heat and cold. This is especially true if the rapid/sudden alternation of heat and cold is repetitive and reoccurs over a few months or goes on over years. Cold accumulates in the body because of poor defenses (i.e., impure, stagnant, or weak blood). Cold becomes "rooted" in the body as subsequent intrusions occur, only emerging as an identifiable disease years later. The accumulation and repeated intrusions of cold trigger a gradual development from transient discomfort to chronic disease and pain (arthritis, asthma) or even permanent disability (blindness, deafness) (Cohen, 1973, p. 75.) Some health problems ultimately traced to cold intrusion include: loss of appetite, malaise, asthma, pneumonia, diarrhea, boils, deafness, blindness, arthritis, catarrh, some fevers, blockage of the urine, sore throat, tuberculosis, and earaches.

Germs. Maroons attribute some diseases to entities they call "germs." Germs are little organisms living in the ground (Some people say that they can see them). Germs breed in dust and in dirt and it is from there that they venture out to attack human beings. Once they attack, germs survive by "feeding on the flesh" of their victims. "Cold" in the body provides germs with an environment where they can thrive, but germs will not abide long in "heat" (Cohen, 1973, pp. 79–80). While it can be argued that their conception is an inadequately understood mixture of the antique and the contemporary, nevertheless it does overlap with biomedical understandings in so far as

Maroons think of germs as very small living things capable of causing disease.

Germs provide Maroon etiology with an agent to use in explanations of disease causation that draw on the idea of contagion. This contagion can be between one human being and another, and also between human and nonhuman life forms as in the case of flies and mosquitoes. According to them, germs may be transmitted by food. (The necessity of boiling pork before cooking it any further comes from the need to kill germs as much as anything else.) Coughing in someone's face, putting one's foot in another's boot, and drinking from a sick person's glass are other means of transmitting germs and sickness. Malaria, gonorrhea, "night fever," urinary blockage, tooth decay, grunitch, ringworm, other body itches, and sores are all problems Maroons attribute to germs. Urinary blockage comes from drinking unclear water, that is water contaminated with dirt and therefore, with germs.

Maroons have no direct action they can take against germs and the preventive strategies they employ against germs are mainly prompted by the idea of contagion between human beings. They do not use their germ ideas to explain the upper respiratory infections that are so common among them and which the visiting medical teams treat with antibiotics. Although Maroons appreciate the efficacy of the antibiotics they get from physicians, they do not understand the basis of that efficacy, and they do not relate it to their own indigenous germ theory.

Things People Do or Do Not Do. Maroon's etiological system also implicates behaviors related to food and physical exertion as causes of sickness.

Diet. Mooretown Maroons trace problems such as constipation, diarrhea, stomach pains, chest and gas pains, nausea, vomiting, and high blood pressure (and the headaches and nose bleeds they connect with it) back to an imbalance between "hard" and "soft" foods in the diet. Mooretown Maroons consider yellow and Negro yams to be "hard" foods. (Pumpkin, dasheen, and coco are hard foods, too.) Other yams, though, such as renta and St. Vincent yams, are "soft," as are boiled banana, boiled rice, chocho, and mango (Cohen, 1973, p. 80). The amount of meat a person consumes is also considered important. Too much beef, mutton, or "rich" food injures the body.

There is a small minority of Maroons in Accompong who are Rastafarians and follow that religion's dietary practices. For them even following the dietary strictures

noted above does not ensure good health, either physically or spiritually. The most orthodox of the Rastas are vegetarians, eschewing all meat especially pork. For the most part they either grow their own food or trade for it with other Rastas, and promote a doctrine of "ital" or "natural" eating that bans salt, sugar, alcohol, and the store bought foods that so often contain these substances. Their views have begun to spread but they still constitute a marginal minority group among Maroons. One point where the Rastas and more general Accompong Maroon ideas converge, however, is on the issue of pesticides and chemical fertilizers. Quite a few Accompong Maroons oppose the use of chemical fertilizers and pesticides for growing food crops. They would not use them and say that eating foods grown this way affects people's health and causes disease.

Work, Exercise, and Physical Exertion. We noted the importance Maroons attach to blood and blood circulation when we described their ideas about what happens when "cold" enters and lodges itself within the body. Contrary to the stagnating and contaminating effects that cold has on the blood; work, exercise, and physical exertion cause blood to flow freely hence directly and positively affecting health. Physical work also cleanses the body of internal poisons that adversely affect blood quality. The poisons leave the body through perspiration. Maroons view perspiration itself as a cleansing process.

Hard work has a social value for Maroons and is an important component of how men assess each other as farmers. They also believe that hard work has health consequences. When people are too sedentary, do not work enough, and do not get enough exercise, sometimes they get sick. On the other hand, a person can exert themselves too much or inappropriately and end up with health problems too, especially if they fall or get hit by something. Excessive or inappropriate exertion underlies back pain and pains in the heart, biliousness, stiff neck, cataracts and eye inflammation, hernias, and some instances of urinary bleeding (i.e., those not caused by falls or gonorrhea). Physical exertion also includes sexual intercourse. "Running around with too many women" leads to impotence. Sometimes Maroons use exercise, particularly walking, as a form of self-treatment as when Accompong Maroons with chest colds attempt to treat the cold by "walking it out."

Emotional Reactions. Although emotions are a minor component of their disease theory system, Maroons do believe that emotional reactions can cause health

problems. Too much excitement, for example, or a startling sudden fright can cause pains in the heart (Cohen, 1973, p. 82). If a pregnant woman has a strong emotional response to a particular person or animal, the attributes that ignited the pregnant mother's emotional reaction—a man's deformity or hirsuteness, an animal's crippled limb—get transferred to her unborn child. Later on, though it may stop short of tears, a mother's disappointment or anger at some aspect of her child's behavior can seek vengeance and harm the child on its own without her conscious intention. In the last two instances the mother-child bond provides the social and biological context in which the mother's emotional reaction creates an unusual relationship between the child and an external event.

Spiritual Intervention: Duppies, the Devil, and God. Religious ideology thoroughly permeates the lives of rural Jamaicans and spirit concepts supply a pervasive idiom for explaining misfortune. Although Maroon etiology charts the actions of duppies, the Devil, and God as they relate to the domain of human sickness; the full domain of spiritual interventions in Maroon life is much wider and the true domain being dealt with is not disease and/or sickness but misfortune: road and farming accidents, problems with neighbors, marital tensions, sexual difficulties, economic woes, and personal anxieties. The actions of spirits may underlie all of these problems.

Duppies are ancestral spirits, also called "shadows," "shades," and "wandering spirits." The duppy differs from the soul in that it remains in the grave after death; the soul does not. With the proper rites the shadow reaches the land of the dead where the fact that it has made the transition from being a live person to being a dead one is confirmed. Without the proper funeral rites the "shadow" becomes a duppy, a dispossessed and dissatisfied ghost that brings misfortune and terrorizes the community. When a duppy's attack comes through illness, it is called a spirit illness. The Devil also afflicts humans with sickness and, though the range of sicknesses is no different from those associated with duppies, the Devil is more selective in his choice of victims. These are primarily people who are sinful as opposed to those who are righteous and of strong Christian faith. God can also visit sickness upon a person as a punishment for wrong doing, for someone who has malevolently, intentionally, and knowingly harmed other people.

Spirits can cause any sickness. Whether the sickness results from spiritual intervention is not something Maroons can recognize by the fact that the sickness has

occurred or by the symptoms it presents. In addition, using spiritual intervention to explain the cause of a particular disease does not automatically cancel out other possible explanations for it. Although Maroons may attribute "madness," "fits," leprosy, and stroke to duppies and spiritual interventions, they will acknowledge other causes as well. If the sickness or misfortune has struck suddenly and for no apparent reason, Maroons may suspect that spirits have been involved.

Some Maroons have an idea of how the sicknesses they encounter are supposed to progress and this colors how they explain them. Often this concept of disease progression resembles an S-curve with a gradual mounting of disease symptoms and discomfort that reaches a peak of maximum intensity and is then followed by a less gradual falloff. When the sickness does not follow the progression healers and lay people recognize as normal for that ailment, they may be forced to consider whether there has been some intervention by spirits. In other cases, they are forced to resort to spiritual intervention as an explanation because they have exhausted all the other possibilities their etiological system offers and because the sickness has proved refractory to both folk and biomedical treatments.

Treatments

All of the healer types make use of a wide variety of locally available plants in the forms of infusions of leaf teas, decoctions made from the roots of plants to create "roots tonics" or "bitters," and tinctures using white rum, wine or some other alcohol as a solvent medium. The Maroon herbal pharmacy supplies them vermifuges, cathartics, sedatives, diuretics, emmenagogues, antihypertensives, and medicines serving many other uses. The uses often overlap and are emphasized variously in the practices of the different healer types. For example, many of the same herbs that are used to modulate menstruation, ease, and speed up labor in childbirth, and perform purifying "washouts" of the body also induce abortion, so midwifery requires a sophisticated knowledge of these herbs and their dosage effects. "Bush baths" are another means of using herbs medicinally. The healer ties up bundles of leaves and dips them in a tub or small basin of hot bath water to steep. The patient either submerges himself in the water or sits over the water's steam. Treatment with poultices involves crushing the plants into a pulpy mucilaginous mass, which is then positioned over and wrapped around the affected area. Poultices can be made

from either fresh or dried herbs. If dried herbs are being used a common practice is to mix them with cornmeal or some other starchy substance to bind the dry leaves together and wet them in an effective way. Another use of medicinal plants in healing involves striking or lightly hitting the patient's body with the plants themselves.

Religious ritual is an integral part of the recognition and treatment of some medical problems. Some Maroon healers claim a kind of psychic ability that allows them to diagnose a patient's ailments with no information from them. They may do this through divination with devices such as a chunk of crystal or the Bible, or simply by looking at the patient. Bush baths are thought to have both medicinal and spiritual properties and may be accompanied by songs. Striking the patient's body with healing plants is regarded as a cleansing act and may be accompanied by songs and associated with other rituals. And the midwife augments her knowledge of herbal medicine not only with skills in physically manipulating the fetus and the pregnant woman's body, but also with the ability to perform the ritual procedures needed after the birth.

All three spiritual causes of sickness and misfortune—duppies, the Devil, and God—are resorts when other explanations within the etiological system fail, or the sickness is anomalous, and common therapies do not suffice. As Maroons' ability to predict, explain, and treat specific sicknesses diminishes, spirits' explanatory role increases. Furthermore, as the spiritual actor and the mechanisms involved become more remote from the human and less alterable by human action, they become more and more powerful. There are defenses against sickness-causing duppies (among them obeahmen, science men, and good duppies). If God did not defeat the Devil in the battle for the sinner's heart, in the Mooretown of olden days at least, it was possible to call on the dancer, a healer who could succeed where ordinary healers could not and was able with his spirits' aid to stand and confront the Devil himself. But before the wrath of God even extraordinary healers are helpless. Any sickness that God causes can only be healed by God. The utter helplessness of humans before God testifies to the ultimate power of God over all. This kind of sickness brings Maroons into direct confrontation with that ultimate power and imparts the knowledge that in this situation they have reached the absolute limit of their human and spiritual capabilities.

The national government has provided biomedical training to a small number of Maroons as health aides and these health aides render first aid for minor problems to

people in the community and assist visiting nurses when they come through. Church-sponsored medical teams including physicians are an infrequent presence in the Maroon settlements and may only appear for a few days two or three times a year. Sometimes antibiotics obtained through a doctor's prescription become items of trade, are sold for a few dollars, and get into the hands of people who use them inappropriately and ineffectively. Given the sporadic availability of biomedical care, most Maroons rely on self-treatment with over-the-counter items or the teas they know as a first resort. Vicks Vapo-Rub, the bathing soap sometimes incorporated into poultices, kerosene, and headache and cold remedies such as Comtrex and aspirin are all commercial items available locally and used to self-treat health problems. White rum also figures prominently in self-treatment and in the *materia medica* of herbalists.

SEXUALITY AND REPRODUCTION

Pollution, Purity, and Sexual Experience

In rural Jamaica generally sexuality is closely connected with ideas of pollution, waste, and impurity. The male's semen is viewed as a kind of waste product that women's bodies are only able to tolerate and fully absorb when it fertilizes an egg. Otherwise women's absorption of semen fosters decay, pressure and sickness, things they avoid only because of menstruation, a process that cleanses the body of semen, excess blood and a host of other impurities. Men's bodies do not accumulate impurities as rapidly as women's do; and men also tend to cleanse themselves more rapidly of these impurities through sweating. Maroons do not consider sexual intercourse to be either good or bad in itself. Instead they consider it to be inevitable, but also healthy, for most people. It is denial of the sexual impulse and of sexual gratification that they regard as unhealthy, as it leads, in their thought, to mental instability and "madness" in women and back problems and accumulation of toxic substances in men due to their failure to ejaculate.

Sexual experiences generally begin at mid-adolescence so that 14- and 15-year-olds are often sexually active. Both females and males are likely to have a succession of sexual partners. But males are more likely to have several sexual partners at once. Women are more likely to have a series of

short-lived relationships before settling into a more steady sexually exclusive relationship with one male; over her life there may be a series of these longer lasting unions, which may or may not eventuate in legal marriage. This mating pattern is reflected, albeit negatively in certain ideas about the health effects of multiple mating and multiple sexual partners. These operate differently for females and males. Each man's semen is supposed to be unique, differing from that of all other males. If a woman has more than one sexual partner at a time their semen will mix inside her body after she absorbs them. Mixing different men's semen is both taxing and dangerous to the woman's body and accelerates the process of decay and sickness we described earlier. This belief tends to decrease women's attempts to obtain sex outside of a current relationship. The corresponding belief for men is one that regards excessive intercourse or having too many women as a cause of impotence or erectile dysfunction. In this case men may seek out any of a number of roots tonics that claim to deal with these problems (Cohen, 1973; Sobo 1993, p. 221).

Having a baby automatically sweeps out the impurities in a woman's reproductive system. The new mother becomes clean while the childless woman's level of purity ebbs and flows with her menstrual cycle. Post-menopausal women, however, escape this purity bind altogether. After menopause their wombs are thought to "close up," and a man's discharge cannot lodge within them. They neither generate impurities relevant to sexuality nor can they absorb them from men; nothing accumulates within them. The woman who is childless is pitied rather than stigmatized or derided. In part this is because the cause of childlessness is not thought to lie within her but with her mate or their relationship. Mooretown Maroon males believe men are the most important and powerful element in reproduction; women are just containers. If a couple is infertile, then, the blame falls on the man because his "seed" (semen) must have become sick or weak (Cohen, 1973). Maroons also believe that disharmony between sexual partners may cause infertility.

Contraception and Abortion

There seems to be a high degree of ambivalence about both contraception and abortion among Maroons. Reproduction forges links between males and females that imply a regime of reciprocity and kin connections which—fragile, conflicted, and unreliable as they often are—still have to be dealt with and often channel decisions around

contraceptive practices and abortion. According to some Maroon women indigenous birth control practices have been lost in Accompong, leaving no local alternatives for contraception. Couples in Accompong have become almost totally dependent on outside sources and non-indigenous methods for birth control. Indeed contraception goes against the implicit ideology surrounding both sexual intercourse and social intercourse. Contraception places the power of continuity within the hands of women as opposed to men. Contraception also removes the woman from the round of reciprocity with the network of the partner. On the other hand contraception also allows people to limit the size of their families and strike the balance between what they can invest in the care and rearing of children and what the children can return to the parents in terms of love, care, and labor.

A survey of clinic records of women utilizing family planning in Accompong gives a tentative picture of contraceptive use that differs from the conclusions of the National Survey for the region. Depo-Provera injection is clearly the most common contraceptive method used by women in Accompong. Younger women favor condoms. Condom use peaks between ages 18 and 24 and drops dramatically after 30 years of age. Intrauterine device use is uncommon and is only found in women under the age of 30.

Just under 23% of the women in the Accompong clinic sample had had one or more abortions. Undoubtedly this figure understates the abortion rate for women because it only accounts for the surgical abortions of women referred by clinic physicians. While contraceptive knowledge has been lost in some Maroon communities, knowledge of herbal abortifacients has not. Furthermore, as we noted earlier, herbal abortifacients form part of a continuum of treatments aimed at purifying the blood, regulating menstruation, and managing childbirth. Early abortions, whether spontaneous or accidentally or deliberately induced by natural medicines, might not even be classified as abortions by those experiencing them, nor reported as such to anyone at all.

The abortion rate reflected in clinic records appears to be related to the length of time a woman has been involved in family planning on one hand, and the number of times she has been pregnant on the other. The number of abortions per woman decreases the longer they have been on birth control and is highest for women who have used contraception for a year and a half or less. Elisa Sobo's rural Jamaican informants supported a suggestion put forward by Brody that Jamaican women's use of

abortion increased with successive pregnancies (Brody, 1981, p. 51). Even my very limited quantitative data from Accompong also tend toward this conclusion and implies that Maroons share this correlation of abortion and pregnancy with the wider Jamaican population.

HEALTH THROUGH THE LIFE CYCLE

Pregnancy and Birth

The traditional Maroon birth process involved a team of women headed by an elder midwife called a nana. There are few nanas today. Contemporary Maroon women frequently voice the need to train midwives and revive the practice of midwifery but the remaining midwives are not called on very often except in emergencies. Nowadays most women trek considerable distances to hospitals in neighboring towns to give birth. First I will describe what was the traditional practice until fairly recently.

The mother in labor is taken to a birthing room or some other area where she is prepared to give birth. Typically the nana administers the woman a variety of teas specialized for different purposes: teas to cleanse the bowels; a tea made from fresh cut cerassee to cleanse her uterus and womb. Other teas will have already been given to her—in advance of the labor pains—to prepare her to dilate. The nana “bands” or places a cloth around the mother’s stomach, anoints it with leaf herbs and oil, and massages her throughout the delivery. If the nana comes to believe that the labor is taking too long she will give the mother castor oil, penny royal tea, or a tea made from piabah to speed it up (Crellin et al., 1998, pp. 41–42, 63, 65).

After the baby is born, the nana and birth team have to do a number of things to protect the baby from sickness, and establish the baby’s relationship to the land where it will reside, as well as its relationship to the community of ancestral dead. They lightly wash the newborn child with white rum and massage the bottoms of the baby’s feet, its head, and navel with this liquor to ward off cold. Newborns attract spirits, so the nana uses bluing derived from plant dyes to mark an “X” on the baby’s forehead and also rubs some onto the infant’s eyebrows to prevent spirits from troubling or harming it. Putting asafetida on the baby’s navel discourages playful spirits from even coming around.

The nana and the birthing team burn the placenta under a tree that is dedicated to the baby and bury it there

in a brief ceremony that includes making a nonalcoholic libation to the ancestors and reading psalms from the Bible. The baby’s navel they tie off with a cotton string and burn it and bury it at the same spot as the afterbirth or, failing this, under another tree dedicated to, and thereafter symbolizing, the baby’s link to its ancestors. After the delivery the nana and birthing team also give the new mother a special bush bath. (Some midwives have the mother drink some of this bath mixture before they throw it out.) Mother and baby then spend the next 9 days together in the birthing room where the women will look after them during the subsequent days of “special care and welcoming.”

Infancy

Depending on the number of other children a mother has and the nature of her other responsibilities in the household, babies usually feed at the breast until their first teeth appear. Sometimes women use a commercially prepared formula along with breast-milk. Goat milk is available if there is a problem with feeding but it is used only in emergencies. When infants cease breast-feeding they are weaned onto soft foods, often a preparation composed of seasonal fruits and vegetables in a pulverized form. Mothers may also spoon-feed infants a thick porridge, fruit juice, and mashed fruits. It is not unusual to see a 3-year-old child receiving porridge from a bottle. Infants’ diets may lack variety but malnutrition is uncommon. Sometimes, though, there are problems: When infants’ teeth come in: their gums hurt and they may develop diarrhea. A Maroon remedy for the gum pain is to rub the gums with a young tomato. The diarrhea can be helped with a “rehydration salt” of lime juice, sugar, and soda given by the spoonful.

A not uncommon malady of infants is the “mole cold.” According to Maroons, this infantile malady develops either because the mother takes her infant outside while the rain is falling and the baby’s fontanel becomes wet; or because the mother has not done a good job of drying the baby’s scalp after bathing it. Mole colds are fateful for later life. If the mole cold takes root, Maroons predict the child will become a sickly adult (Cohen, 1973, p. 75).

Childhood and Adolescence

Mothers or grandmothers care for small children by using home remedies and herbs. Within the household there is

a value placed upon listening to parents and elders. While a small percentage of parents beat “bad” children, parental discipline is usually light, consisting of a spank or yelling as well as reasoning. Children assist in household labor and, when they get older and strong enough, they help with farm work in the fields. Children are often dispersed or moved between households. These shifts in residence and between caretakers sometimes make a dramatic difference in the health status of infants and young children.

Children and adolescents quite early take on the dietary patterns of adults: yams, rice and kidney beans, breadfruit, dumplings, bananas, and plantain predominate at meals. Pineapple and papaya, oranges, and apples, neesberry, and ackee go in an out of season. Salt-preserved codfish is a mainstay because fresh fish is expensive and has to be brought in. Maroon diet makes protein deficiency a real problem for adolescents and both young and mature adults. Beef and pork rarely appear at meals and the diet is high in sugar, starches, and salt.

Immunization for common infectious diseases affecting children depends upon the visits of medical teams from non-governmental organizations or the existence of a clinic. Often sponsored by religious groups which dispatch the teams 2 or 3 times a year, the medical teams are conscientious in giving, recording, and maintaining a program of childhood immunizations, and doubtless the disease picture for early childhood in Maroon communities would be very different without them. But immunizations do not take care of everything and there are number of very common health issues for Maroon children.

The most prominent children’s health problems include worms (round worms, pinworms, tapeworms, long worms, etc.), upper respiratory infections, sores, asthma, rashes, “runny belly,” scabies, eczema, “loose bowels,” ear infections, iron and zinc deficiencies (often a result of worm infestation), and pica. Accompong Maroons associate children’s worm infestations with excessive sugar consumption.

A significant part of Maroon childhood is spent in school. These are usually Protestant mission schools that emphasize Christian religious teachings while also giving instruction in secular subjects, mete out harsh discipline, and have corporal punishment as a standard practice. The poorer Maroon children may only wear their shoes—if they possess them at all—to school or church and go barefoot the rest of the time, a situation that predisposes

them to pedal fungal infections. About a quarter of the students drop out at the primary school level, especially boys. Whether they have remained in school or not, by age 12 Maroon children are often able to take care of simple medical problems on their own using traditional medicines, especially teas, and fresh picked leaves.

Adulthood

The two largest age groups in Mooretown and Accompong are the youth and elders. Adults and young adults, particularly the males, are highly mobile and are often away from the villages for long periods. Working away from home forces them to leave their children in the care of grandparents or other relatives. Of the middle aged as many have migrated as have remained in the countryside, gone to England or the coastal cities. Hypertension, back pain, insomnia, arthritis, and epigastric pain bedevil the adult men, as do the injuries and wounds that result from farm work. The health problems of Maroon women are very similar to the males’ except that the women are more likely to suffer from headaches and psychiatric disorders.

Adults use both traditional medicines and the non-prescription commercial medications available at small local stores for self-treatment. Maroons treat themselves for common mild problems or may seek assistance from another adult or a relative. Mild problems that linger may occasion a trip to a town where there is a biomedical practitioner or an older mature Maroon woman who has had much experience with diagnosing or treating similar problems. Severe, painful, or disturbing problems of long duration call for either a biomedical doctor or a more specialized Maroon healer. Sometimes a failure of biomedical diagnosis and treatment confirms the patient’s own self-diagnosis and directs them back to the Maroon folk system where herbal therapies predominate, sometimes supplemented by divination and other rituals.

Menopause is dealt with through dietary prescriptions (such as increase in eating green, leafy vegetables) and a variety of herbs that are said to reduce the symptoms and strengthen the body. Domestic violence (men beating women) flares up because of rumors of female infidelity or men finding out that their women have been with other men. If attacked by men, women are encouraged to fight back. Men’s drunkenness is an important cause of arguments and violence between men and women. Alcohol use also figures prominently in fights

between men. Knives and machetes are the weapons of choice but injuries from using these weapons in fights are much less common than injuries from using the same tools in farm labor. No one I talked to could recall a local incident of murder or rape.

The Aged

Prominent health problems of Maroon elders include chronic pain (hands, feet, stomach, and “all over”), high blood pressure, arthritis, stomach problems, nerves, weakness, and fatigue, also diabetes. Quite a few elderly Maroons continue doing light farm work into their sixties and seventies. Subsistence requires it. With the old cooperative work, labor exchange, and barter arrangements long laid low, elders must either farm or hire wage workers—not a viable option for most elderly Maroons. Instead the elders depend on their adult children who have remained in the Maroon communities to assist and look after them. Often, however, their children have left and gone to the cities or overseas. These children may send money back to elders but they are not there to look after them. In these cases other relatives take care of them.

Death and Burial

Although women usually outlive men, Maroons generally die in their 60s and 70s. The abeng player is the first to be notified after a Maroon dies; his job is to blow the abeng to announce the death of a Maroon to all the Maroon community. Nowadays the body of the deceased is given over to a mortician in a nearby city for 2 or 3 weeks for embalming and to allow relatives across Jamaica or from overseas time to get to the Maroon community for the funeral. In Accompong they used to preserve the body within the village for 3 or 4 days before the funeral. This was done by sinking a zinc lined shaft into the ground, putting the body in it and keeping the shaft continuously filled with ice while draining off the water from the melting ice. The body orifices of the deceased (their ears, anus, nose, and eyes) would be stuffed with native coffee and cotton before placing it in the shaft.

Maroons have always buried their dead in coffins. People used to pitch in spontaneously to dig the grave but now at least some of the diggers have to be paid. Anyone can dig a grave and there is no stigma attached to being a gravedigger. At the graveside libations of white rum bring the ancestors near and give energy to the gravediggers

who sometimes sing Kromanti songs while they work. It takes several days to dig the grave and construct the concrete burial vault. The deceased’s family supplies the diggers with food at the gravesite and hosts a wake the night before the funeral.

After the abeng player has announced the arrival of the body, the funeral begins at a Christian church with a service usually called a “Thanksgiving.” After the service the abeng player leads a procession from the church through the town to the cemetery blowing the abeng to make continuing musical announcement of the key events of the burial up to its final moments. The process of interment in the burial vault is accompanied by the blowing of the abeng and by hymn singing at the graveside.

This burial sequence is the same for men and women. Children who die after reaching school age receive the same kind of funeral and burial as adults, including the blowing of the abeng. Children who die before school age do not receive a funeral. Their mothers bury them without ceremony in a shallow vaultless grave dug behind the house.

The modern public cemeteries near churches supplement much older burial ground, which may or may not have the concrete slabs or raised headstones that are in common use to mark graves now. Some Maroons bury their dead relatives near their homes as opposed to the communal burial sites. They say they do this simply because they want their dead relatives near them.

Japanese

Denise Saint Arnault

ALTERNATIVE NAMES

China referred to the Japanese in ancient writings as “Children of *Wa*,” using the characters of the sun and the tree in script. This name acknowledged the indigenous mythology of the Japanese as ancestors of the sun goddess, and the cultural focus of harmony. From around AD 500, the Japanese referred to themselves as *Yamato*, which was also the name of their central island, created in myth by the eighth son of the sun goddess; they currently pronounce these characters as *Nippon* or *Nihon* (de Bary & Dykstra, 2001).

LOCATION AND LINGUISTIC AFFILIATION

Japan consists of several thousand islands, however most of the population inhabits four major islands, located between the Pacific Ocean and the Sea of Japan, near Korea to the northeast, China to the east, and Russia to the north. Despite the massive urbanization over the last 50 years, the mountainous topography of the islands has helped the people retain regional characteristics, including dialects in at least 21 regions and regional family names. Japanese administration is by prefecture (*ken* or *to*). Within the 47 prefectures, there are cities (*gun* or *shi*),

each of which are subdivided into wards (*ku*), and blocks, or neighborhoods (*chome*).

The linguistic origin of the Japanese language is debated, however the leading theories are either that it is from the Ural-Altai family (Miller, 1972) or that it is related to Korean (Ohno, 1970). The Japanese written language includes a complex collection of characters derived from Chinese, and two native Japanese syllabary, or *kana*, each of which include 39 syllables. The Japanese use *Hiragana* for Japanese words, and certain grammatical elements. The *Katakana* includes the same sounds of the *hiragana* syllabary, but is used to write foreign loan words and words written for emphasis, such as in advertising. Japanese language is flexible, accepting loan words for new and evolving social ideas. Recent trends in Japan include not only the adoption of loan words, but also the adoption of Roman characters in advertising. Despite the liberal sprinkling of Western concepts and Western text, their meanings and pronunciation retain a distinct Japanese flavor.

OVERVIEW OF THE CULTURE

Demographics

There were 127 million Japanese in Japan in 2000 (World Health Organization, 2002a), making it the eighth largest population in the world (see Table 1). The annual growth rate in 2000 was 0.3%, much lower than the 1.1% in the United States. Twenty-three percent of the Japanese population is over 65, higher than the 16.6% in the United States. The fertility rate is below replacement level in Japan, at 1.4 children per woman, while, in the United States, the fertility rate is 2.0. Seventy-five percent of the Japanese live in urban areas. In the 1930s, the Japanese household was primarily multigenerational, with around 70% of the elderly living with their children. In 1955, about half of Japanese households were still three generations, and by 1990, 60% were nuclear family households and only 15% were three generations (Feeney & Mason, 2001). The Japanese citizenry are educated and literate, with 100% of the population completing primary school since 1955, and 95% completing secondary school during the same period. In 1996, estimates were that 31% of the population was enrolled in tertiary education. However, a gender gap persists in higher education, with 27.2 per 1,000 women in third level education, compared with 35.8 per 1,000 men

Table 1. Population Statistics (World Health Organization, 2002a)

WHO member states	Total population (000) 2000	Annual growth rate (%) 1990–2000	Percentage of population aged 60+ years		Total fertility rate	
			1990	2000	1990	2000
Germany	82,017	0.3	20.4	23.2	1.4	1.3
Japan	127,096	0.3	17.4	23.2	1.6	1.4
Sweden	8,842	0.3	22.8	22.4	2.0	1.4
United Kingdom	59,415	0.3	20.9	20.6	1.8	1.7
United States of America	283,230	1.1	16.6	16.1	2.0	2.0

enrolled at the same level in 1996. In addition, only 22% of third level teachers are women (United Nations, 2000).

History

The Japanese migrated to the islands in AD 470, where they were primarily a tribal people, with heterogeneous, regional, cultural, and social patterns. The Empress Suiko reigned from 592–628, and institutionalized several elements of Chinese civilization into Japanese social and political life, including the adoption of the Chinese writing system, rules of rank and etiquette, the Chinese calendar, diplomatic relations with China, a highway system, and a constitution. The Nara period (709–784) institutionalized Buddhist religion and with it, Chinese images, books, ritual devises, astronomy, and architecture. This period also gave rise to the public bath, cremation, maps, and an irrigation system. The Heian period (8th to 12th century) was a period of cultural evolution, including the development of an indigenous Japanese *kana* writing system, poetry, and scroll paintings. Feudal institutions, a militaristic government, and political power struggles resulted in the social disorder and feudal warfare that characterized the Medieval period (12th to 16th century). However, this period also saw the rise of Zen Buddhism, and the development of an indigenous healing system based on Chinese medicine. The Tokugawa period (1603–1868) marked military reunification, and the development of the *bushido*, or the way of the Samurai warrior. Confucian rules of civil order, including rules of

loyalty, social hierarchy, and filial piety, were institutionalized into the society, as well as an aversion to outside cultural influences.

The 700 years of cultural isolation during the Medieval and Tokugawa periods (1185–1853) allowed not only a richly developed cultural identity, but also an intense nationalism. The 1847 Meiji restoration was the official end of this international isolation, as the government centralized, deposing the feudal landholders, as well as modernizing education, the judiciary, the military, and their economic system (de Bary & Dykstra, 2001; Reischauer, 1981; Vogel, 1967; Yoshino, 1992). Japan's late but rapid rise in industry and urbanization has set it apart from other East Asian countries, and its capitalistic economy was based on a Confucian social and political order, creating an industrial organization very different from most other industrialized countries.

Economy and Occupations

Japan had an agricultural economy until the turn of the 20th century, and the percentage of the total labor force in agriculture shifted from 33% in 1960 to 7% in 1990. As of 1990, the percentage of employment for all men and all women over age 15 was 77% and 50%, respectively. A statistical "M" shaped curve characterizes Japanese women's employment since 1965, with the highest rates of employment from 20–24 and 40–49, and lower rates during child-rearing ages (Okunishi, 2001). In 1998, 36% of women were employed part-time, compared with 12% of employed men in the same year (United Nations, 2000). Most women (54%) work in clerical, sales, and service fields, and the wage differential for women was 60% of male wages in 1990 (Bauer, 2001).

Family and Kinship

Japan had a patrilineal kinship system organized around the household, or *ie*. Within this system, the eldest son succeeded the father, and inherited the family property and the responsibilities of the househead. Other sons established stem families (Befu, 1980, 1993; DeNoon, Hudson, McCormack & Morris-Suzuki, 2001). The household was a cooperative unit, and included the parents, eldest son and his wife, and their children, and sometimes workers for the family, as well as adopted sons-in-laws (when there was no oldest son). The *ie* is also a concept, and it refers to the entire lineage of ancestors. Stem families

then were essentially equivalent to nuclear families, as they were established outside the *ie* or household structure. These stem families had a much less important role in the economics of the family. Therefore, this kinship pattern allowed for the mobility of nuclear families, which were free to move to the cities with the coming of urbanization and industrialization, perhaps facilitating the rapid trend toward urbanization of Japan after World War II (Vogel, 1967).

Religious Traditions and Philosophical Underpinnings

Shrines, temples, and doorways draped with folded paper punctuate the seemingly endless urban landscape of Japan. These sights belie the sustained importance of Japanese traditional, philosophical, and religious underpinnings. Japan's first religion, Shinto, continues to influence day to day cultural patterns. Based in earlier animistic and shamanistic spiritual traditions, Shinto shrines honor the gods and goddesses of ancient Japanese mythology. Shinto concepts that are important to Japanese daily life include cleanliness of the body and the dwelling structure, symbolic cleansing required before entering Shinto structures, at important seasonal events, and funerals. Ritual devices include salt for purification, rice and *sake* for offerings, and folded paper, bells and rope as communication with the deities.

Buddhism arrived from China in the 5th century. While Shinto was the people's religion, the elite adopted Buddhism. Japanese Buddhism had numerous sects, which rose and fell with the important families that adopted them. Zen Buddhism is especially important in Japanese culture, with an emphasis on personal effort, personal sacrifice, dedication, exertion, and attunement to the body, as well as meditative activities involving daily activities such as tea, flower arrangement, or gardening.

Neo-Confucian philosophical traditions are embedded in religious and secular institutions today, including loyalty and piety in the five essential human relationships, which are father–son, ruler–son, husband–wife, older brother–younger brother, and between friends (de Bary & Dykstra, 2001).

Sociocultural Norms

Research shows that two opposing dynamics are central in Japanese social interactions. One dynamic is the

perception of relative intimacy between oneself and another. Shared group membership and a commitment to group harmony and solidarity foster intimacy among group members. The opposing dynamic is the hierarchical organization within any given group. This hierarchy arises from differences in age, social status, and social roles. Appropriate behavioral styles and norms about social exchange in a given situation depend on the accurate perception of relative social distance between any given two participants (*kejime*). Interaction between intimates (*uchi*) includes relatively free expression of emotions and needs (*honno*) and by non-verbal, unrestrained exchange of support (*amae*). Social distance decreases intimacy; prompting people to communicate using polite deference (*enryo*) in order to avoid offending the higher-status person. Strict rules of reciprocity between non-intimates include the edict that each favor incurs a reciprocal exchange. Therefore, the social exchange norm in Japanese culture is to ask for help only within one's intimate social group (Bachnik, 1994; Hendry, 1992; Lebra, 1976; Saint Arnault, 2002). Smooth functioning within the group requires a person to sensitively assess each context and one's role within it. One important task for a Japanese person involves appropriate role behavior. Behaviors that foster conflict or indicate deviance are frowned upon, and may result in ostracism (Bestor, 1996; Johnson, 1995; Smith, 1961).

THE CONTEXT OF HEALTH: ENVIRONMENTAL, ECONOMIC, SOCIAL, AND POLITICAL FACTORS

The Japanese Health Care System

In the 1999 fiscal year, the Japanese health government social security expenditures totaling 75.0 trillion yen (Ministry of Public Management, Home Affairs, Posts, and Telecommunications, 2002). According to the WHO, in 1998, Japan's health care expenditure was 7.5% of its GDP (World Health Organization, 2002a) (see Table 2). Like other nations with national health care coverage, Japan pays over 78% of its health care expenditures with public monies; of these monies, over 89% come from social security revenues. Private expenditures are 77% out-of-pocket, as Japan uses virtually no private insurance.

Japan maintains a westernized, technological health care system, and has as many or more physicians and nurses than the industrialized nations selected for this chapter (see Figure 1). Another interesting difference is the higher number of pharmacists per 100,000 in Japan, which may be related to factors such as the heavy use of pharmaceuticals in Japan, the health care payment structure, governmental support of medical technology research

Table 2. Selected Industrialized Countries' Health Care Expenditures for 1998
(World Health Organization, 2002a)

WHO member state	Percentage of GDP Total	Percentage of total expenditures		Percentage of public expenditures		Percentage of private expenditures	
		Public	Private	Social security	Tax funded	Private insurance	Out-of- pocket
Germany	10.3	75.8	24.2	91.6	8.3	29.5	52.8
Japan	7.5	78.1	21.9	89.2	10.8	1.3	77.8
Sweden	7.9	83.8	16.2	0.0	100	—	100

and development and limited cost control monitoring (Steslicke, 1987) (see Figure 2).

Morbidity and Mortality

In 1999, the average life expectancy was 77.10 years for men and 83.99 years for women, the highest level in the world. Infant mortality rate in 1990 fell to 3.4 per 1,000. The three leading causes of mortality in 1999 were malignant neoplasms (cancer), heart disease, and cerebrovascular disease, with 29.6% of all deaths due to cancer (Ministry of Health Labour and Welfare, 2002; World Health Organization, 2002a) (see Figure 3). The rise in cancer, heart disease, and cardiovascular diseases since the 1950 is probably related to an increased exposure to the risks of poor diet, pollution, work related threats, and

stress. A comparison of international disease trends reveals that Japan ranks high among these nations in cardiovascular accidents (strokes), digestive diseases, chronic liver diseases, external causes of death, and suicide. However, Japan ranks lower in diseases of the circulatory system and heart attacks (see Figure 4). The symbolic prominence of the stomach and abdomen as the seat of the self for Japanese plays a role in the perception of somatic distress (Ohnuki-Tierney, 1984). This symbolic seat is different from that seen in the West, where heart and the blood are symbolic centers. For example, interview data reveal a concept of “swallowing sadness,” noting that concealing the true self for the sake of social harmony may create a symbolic, but somatic, abdominal form. In the West, the cultural prominence of syndromes such as type A personality and hostility may be similarly related to cardiovascular disease and heart attacks.

Figure 3. Leading causes of death in Japan 1995-97 (World Health Organization, 2002a).

Figure 4. Selected WHO members death rates (per 100,000): 1996 (World Health Organization, 2002a).

Figure 5. Japanese 1997 suicide rates per 100,000 by sex (World Health Organization, 2002a).

Figure 6. Selected WHO members suicide rates per 100,000 by sex: 1996 (World Health Organization, 2002b).

Mental Illness and Suicide

In 1999, the largest total number of patients in hospitals per 100,000 were tied between mental illnesses and circulatory diseases (259 each) (Health Statistics Division, 1999). However, the Japanese tend not to use outpatient mental health services. Mental illnesses rank second to the lowest number of patients using outpatient services (at 124 per 100,000) compared with digestive disorders (at 1198 per 100,000). Most of the mental hospital beds are occupied by persons diagnosed with schizophrenias (68.6%), then dementia (6.4%), mood disorders (5.5%), and alcohol dependence (5.0%). The incidence of neurosis, depression, psychosomatic disorders, and other mental illnesses can be attributed to urbanization and the related stress

(Ministry of Health, 2002). Suicide is a major source of concern for Japanese men (see Figure 5). The rise in the rates for men aged 35–55 are probably related to the economic downturn in the 1990. While Japan’s suicide rates for men are higher than some nations, they compare favorably with those of the former Soviet Republic and many Eastern block countries (see Figure 6).

MEDICAL PRACTITIONERS

Japan’s primary medical system is western biomedicine. The government sponsored medical scholars to study Dutch medicine and translate German medical texts in the 1700s. In the late 1800s, the Japanese government

formalized the adoption of the German medical system of medical training and medical care delivery (Long, 1987).

The second system, *Kampo*, was formalized in Japan during the Heian period (794–1192). Rooted in Traditional Chinese Medicine, *Kampo* is a uniquely Japanese healing system. Despite periods of decline, in the 1950s the government granted *Kampo* official status and governmental regulation. One aspect of the regulation is that practitioners must have a medical degree before becoming a certified *Kampo* doctor (Ohnuki-Tierney, 1984; Rister, 1999). Almost 77% of Japanese physicians have used *Kampo* medicine, and nearly 60% of physicians surveyed considered *Kampo* to be the best choice for certain diseases (Long, 1987; Rister, 1999). Currently, *Kampo* has educational institutions, journals, a scientific presence and development corporations, as well as national insurance coverage for some types of *Kampo* treatment, including *Kampo* hospitals and clinics.

CLASSIFICATION OF ILLNESS, THEORIES OF ILLNESS, AND TREATMENT OF ILLNESS

The primary concept in *Kampo* is balance in the entire physical, mental, social, and emotional state. *Kampo* practitioners gather information about subtle aspects of personal experience, such as cravings, warm or cold sensations, sweating, eye, nose, and mouth states such as dryness, redness or congestion, digestive changes, energy level, quality of sleep and the like. Causes of imbalances include both internal and external pathogens, such as wind, cold, heat, dampness, improper diet, or overwork. The state or condition is then understood according to three sets of complementary sets of indicators—hot: cold, excess: deficiency, and internal: external. Hot and cold refers to the experience of temperature throughout the body, as well as under or over activity of physiological processes. Excesses and deficiencies refer to the constitutional state of the person, including the degree of vitality, resistance to stress and imbalance, and energy level. Finally, internal: external refers to the location of the pathogenic processes, and attunes the practitioners to the “depth” of the problem. Internal problems indicate that pathogenic situation has existed longer and the problem is more entrenched. In addition to these complementary states of balance, *Kampo* is concerned with blood flow, bodily fluids, and vital energy (*qi*). Bodily fluids and *qi*

need to circulate freely and can become blocked or stagnant, causing states of illness.

Kampo treatment is indicated when multiple organs are affected, such as in immune disorders or in the failing health of the elderly, and when the patient’s condition does not have a ready biomedical diagnosis or effective treatment, such as is the case in psychosomatic illness or idiosyncratic illness expressions. Finally, they are widely used as alternative and complementary treatments to biomedicine (Long, 1987; Ohnuki-Tierney, 1984; Rister, 1999; Tsumura, 1991; Yamamura, 1987).

Sexuality and Reproduction

Japanese women are socially expected to be modest, polite, and deferent to men, consistent with sexual hierarchy and social propriety. The social prescriptions to avoid open display of emotion or private feelings creates a climate that discourages public discussion of sexuality, and schools do not teach family planning or sex education. Despite the ethos of modesty and propriety, sex hotels, prostitution and pornography, including provocative, explicit, and often violent *manga* (comic books) are widely available. As Japanese women have become more assertive about their rights and legal protection, they have complained about sexual advances at work and in public areas, such as trains. During field experiences in the mid 1990s, sexually explicit advertisements were common on trains; in 2002, they were much less present. However, sexually explicit *manga* and advertisements in newspapers are still common. The molestation of women on trains is such a problem that some train lines offer women-only cars during rush hour.

The concept of the “good wife and wise mother” (*ryosai kempo*) historically saw women as productive members of society, with important roles in the family and the community. In the last 40 years, though, the mothering role has become increasingly important in self-definition, and as a foci of resistance among women (Lock, 1987; Rosenberger, 2001). Women in the last few decades are marrying later and having fewer children. Still, most women do have one or two children, and devote substantial amounts of patience, energy, devotion, and personal sacrifice to them.

Methods of birth control have been primarily male condoms in Japan. The availability of the birth control pill was an issue of rancor and concern for the Japanese people and their government. The birth control pill was finally legal for sale in Japan in 1999, however, a survey of over 1,500 women found that only 4% of Japanese women use

Figure 7. Japan fetal death rates per 100,000 by year and cause (Ministry of Health Labour and Welfare, 2002).

this method, compared with 87% in the United States and 93% in Germany (Pharmacia, 2001). A physician must monitor the use of the pill regularly, and it is not covered by the national health insurance. Other forms of birth control have included infanticide and abortion in historical Japan (Cornell, 1996). Figure 7 depicts the prevalence of abortion in Japan since 1940. The highest periods of the practice were in the 1960s, and the practice has decreased somewhat, but remains a means of birth control in modern Japan. Abortion is not taken lightly, but is considered an extreme and painful necessity to provide for the security and health of surviving members, and is often accompanied by ritual and lifelong grief.

The death of an unborn child, whether spontaneous or artificial, is marked by ritual in contemporary Japanese society (Klass & Heath, 1996–97; Namihara, 1987). The *Mizuko Kuyo* is a Buddhist ritual in which parents express regret and gratitude to their aborted children for their sacrifice for the family. Aborted fetuses are believed to have no connection with the living or ancestors. An unconnected spirit remains bound to the world, wandering about and feeling vengeful. These vengeful spirits can cause illness for the parents and the living children. One aspect of the ritual is to form connections with the spirit of the fetus and the *Jizu*, who is the guardian bodhisattva.

HEALTH THROUGH THE LIFE CYCLE

Pregnancy and Birth

Women tend to give birth around 26–32 years, and 99% of women giving birth in 1992 were married

(Miyaji & Lock, 1994). Pregnancy is both a natural act and a technological event in Japan. Pregnancy is considered a natural state in which daily events such as mood changes of the mother, changes in diet, and even the weather have important effects on the health of the child (Ohnuki-Tierney, 1984, 1989). With the advent of modern, westernized medicine, new mothers are encouraged to monitor the pregnancy carefully using the Maternal and Child Health Handbook (*boshitecho*). Women have monthly visits to the physician to monitor the baby's growth, usually with ultrasound. Mothers prefer to either return to their natal home to have the baby delivered, or have their mother or sister come to be with them for the birth and postnatal period. Almost all births happen within a medical facility, and 98% occur under physician supervision, with a full range of medical technology available. The birth tends to be without pain control, and episiotomies are routinely practiced (Miyaji & Lock, 1994; Yeo, Fetters & Maeda, 2000).

Infancy

Mothers tend to stay in the hospital for a week, but may remain confined to the house for as long as a month. About half of all Japanese mothers breast-feed, and women experience a great deal of anxiety about producing enough milk for the infant, fostering the use of therapeutic activities such as breast massage, heat applications, and supportive nursing care. The nursing event is considered a natural, intensely personal time for the mother and infant to connect in a nonverbal, mutually dependent way. Fathers, and Japanese society, believe that childcare is

within the purview of women, and that the only one who can truly love and nurture an infant is its mother (Miyaji & Lock, 1994).

Maternal–infant bonding in Japan has been the subject of numerous international psychological studies (Shwalb & Shwalb, 1996). Japanese mothers quietly and physically reassure and interact with their baby, anticipating needs rather than waiting for the infant to signal needs. The intense bond formed during this period is part of the interdependent relationship pattern that will continue throughout life. This socialization pattern fosters individuation within an interdependent social frame. Throughout their lives, Japanese individuals enjoy periods of “refueling” into the indulgence of the intimate relationship, referred to as *amae* (Freeman, 1998).

Childhood

As the child enters into toddlerhood, gendered differences in the maternal–child relationship have been noted (Freeman, 1998). Boys are rough, active, and vocal, receiving minimal interference from the mother. When the male child is disciplined, it tends to be with a gentle encouragement to be concerned about his role as the older brother (if appropriate) and to recognize that his behavior reflects on his family. Girls are expected to help the mother at a young age, and are encouraged to recognize their role in the home, and their role as a sweet, loving, polite daughter in public.

Children are rarely cared for outside of the home during their first few years. When mothers return to work, it tends to be after their children enter school. The child’s schooldays are similar to that of adolescents, wearing uniforms, and commuting to school by train. Visitors to Japan are often enchanted by groups of well-groomed and well-behaved, eager, and boisterous children on trains and buses. Mothers are expected to prepare balanced, fresh foods for children, be involved in school activities and to devote their evenings to the children’s studies.

Adolescence

The Japanese school year begins in April. The average high school day begins around 8:30 am. Since most people in Japan travel by rail, a teenager in Japan may leave home as early as 6:30 am. At the end of the day students are often involved in club activities. Consistent with the tendency for people in Japanese culture to affiliate with one primary group, Japanese students may join only one club. These clubs may be sports or culture clubs. The Confucian hierarchical relationship pattern of seniors and

juniors is created and maintained during the club activities. It is the responsibility of the seniors (*senpai*) to teach, initiate, and take care of the juniors (*kohai*). It is the duty of the *kohai* to serve and defer to the *senpai*. Most of the interaction the typical adolescent has is with peers at school, on the long rides to and from school, and through phone and e-mail contact.

Japanese students spend as many as 240 days a year at school. In addition to this long school year, it is highly likely that students attend after school “cram schools” where approximately 60% of Japanese high school students go for supplemental lessons. These schools operate after school and extend into the evening, and require extra homework, leaving the Japanese adolescent little free time during the week. Tuition for these schools is expensive and parents may carefully select and pay for the highest level of schools affordable. Parents and adolescents accept this burden on their time, effort and finances because admission to a good university can be a primary factor in the success of a Japanese adult, determining employment opportunities, and future income. Students who fail an entrance examination may feel as though they have failed their family and experience intense worries about their future, making them a highly vulnerable sector of Japanese youth (Johnson & Johnson, 1996; Rohlen, 1983; White, 1993).

The behavioral problems of Japanese adolescents have risen throughout the 1980s and 1990s at an alarming rate. Many of these problems, including truancy, rebelliousness in school and school refusal, can be seen as social reactions to the incredible stress of life in a conformist society, where academic success is held to be the most important social goal. The school-refusal syndrome is characterized by somatic complaints of headaches and stomachaches, followed by refusal to go to school, moodiness, and sometime verbal and physical abuse of parents. The child may then become listless, depressed, withdrawn, and remain secluded in their rooms. These somatic symptoms, passive resistance, and retreatism are consistent with the Japanese forms of resistance in the face of social pressure which cannot be directly changed (Lock, 1987).

Some of these behavioral changes may also be related to the modern ambivalence toward Japanese cultural rules, and the westernization of Japanese cultural expectations. One example is the problem of bullying (*ijime*). One survey found that 31% of third-graders, 25% of fourth-graders, 13% of fifth-graders, 10% of sixth-graders, 17% of seventh-graders, and 8% of eighth-graders are victims of *ijime* (U.S. Department of Education, 2002). One aspect of *ijime* is that students who

participate in it tend not to feel guilty about cruel acts in which they engage. This may be because *ijime* may be a modern distortion of the *senpai–kohai* relationship.

The Aged

The rapidly aging population has created a burden on the health care infrastructure of Japan. Much of the distresses related to the chronic illnesses described above are age related. The most controversial element of the burgeoning health care needs of the elderly is about who should provide their care. Japan has only recently begun to create an institutional infrastructure to accommodate these needs (Health Statistics Division, 1999). Instead, the Japanese government has called upon a reawakening of the traditional structure of the Japanese family and the Confucian ideal of filial piety among the citizenry. This expectation leaves the burden of long term care of the elderly to the women in Japanese society.

Another facet of the burden of care is the cultural expectation of dependency. Japanese patients, especially the chronically ill or elderly, are expected to remain dependent. Western models of rehabilitation for the purpose of self-care are considered inappropriate. The concept that an elder may become bedridden, and be cared for by family, is alive in the Japanese consciousness. Even when an infirmed elderly person is in a facility, or when they live with family members, all present hold no expectation that they will resume self-care (Keifer, 1987; Shibusawa & Mui, 2001). One example of this phenomenon is the average length of stay in Japan's hospitals is 38.3 days, compared with 8 days in the United States (Keifer, 1987; Sonoda, 1988), suggesting an expectation of dependency.

Another aspect of the plight of the elderly and the chronically ill in Japan, as in much of the west, is that these conditions do not respond to technological advances. In Japan, fortunately, there is an alternative health care system, *Kampo*, which specializes in chronicity and quality of life. *Kampo* medicines are often paid for by the national insurance, and it is common for the elderly to seek *Kampo* (Keifer, 1987; Sonoda, 1988).

Dying and Death

The concept of pollution is at the heart of most funeral rituals. Japanese culture has well articulated notions of pollution and rituals devoted to the eventual restoration of purity, particularly within the Shinto religion. Contact

with death, especially in the material realms, such as utensils and clothing, are important places for ritual intervention. One way that people have historically provided protection from pollution is through reversal—that is, object, patterns, furniture, dishes—are placed on the opposite side or in reverse during the funeral period. Spirits of the dead are believed to wander about the earth until they are appeased. Eating and drinking among the living provide protection during this vulnerable, transitional state, and food and drink are available as offerings to the spirits of the newly deceased. There is usually a wake the day of the death, with burial of cremated remains in a family area of the cemetery the day after the death. Rituals may occur as often as weekly until the 49th day. The family member is remembered with a blessed placard bearing their name placed with the other family names in the family gravesite. Families often have a Buddhist altar in the home, with photos of the deceased. Remembrances yearly and at special days throughout the year are marked by rituals including the offering of incense and prayers. The altar also bears other symbolic elements, including salt, *sake*, water, and rice. Some families also practice a Shinto purification ritual of “pouring water,” (*misogi*) at the family gravesite. This might be the responsibility of the wife of the eldest son, but, more generally, the wife of the household nearest to the grave does it.

Jat

Sunil K. Khanna

ALTERNATIVE NAMES

The Jats constitutes one of the largest and diverse communities living in northwestern India and Pakistan. According to Westphal-Hellbusche and Westphal (1964), the Arabic equivalent of Jat is *Zutt*, a generic term used for “men from India.” The word *Jat* also means “bunch of hair” and the Jats themselves claim that they have descended from the hair of lord Shiv. According to Ibbetson (1916), Jats are of Indo-Aryan (or Indo-Scythian) descent. Bowles (1977) argues that the word *Jat* in the Punjabi language means a “grazer” or “herdsman,” but notes Ibbetson’s (1916) suggestion that a shift from the Punjabi soft “t” to a hard “t” in some Muslim areas means an agriculturalist.

LOCATION AND LINGUISTIC AFFILIATION

The Jats are distributed over a wide and diverse geographic area—from the hot and humid regions in northwestern India to the hills and plains in southern Pakistan—presenting extensive cultural, linguistic, and religious diversity. Some Jat groups have also been identified in the Maldives, Russia, and Ukraine. Different Jat groups living in India and Pakistan speak different dialects of Hindi, Urdu, Sindhi, and Punjabi.

OVERVIEW OF THE CULTURE

It is important to note that each Jat community presents certain unique cultural characteristics, which makes it difficult to generalize about the Jats as a culturally homogenous group. Any attempt to generalize about Jat culture and/or its characteristics is therefore problematic. This account does not attempt to represent the vast cultural diversity and regional variation among the Jats. Instead, it presents some of the cultural characteristics shared by the Jat communities inhabiting the northwestern provinces of India and southern Pakistan.

There is considerable disagreement among scholars over the caste ranking of the Hindu Jats. Throughout the 1900s, several scholars and Jat politicians and activists have used three very different labels for Jat identity. While some have identified the Jats as members of the warrior group (*Kshatriya*) (Qanungo, 1982), others have argued that they belong to the “backward castes.” Freed and Freed (1993) argue that until 1958, the Jats were not considered members of the three twice-born *varnas*. Instead, the Jats were ranked as “clean menial workers” (*Shudras*). Some suggest that the Jats rank below the *Rajputs* in the warrior group primarily because of the practice of widow remarriage (Lewis, 1965). Recently, the Jat community has been added to the list of “Other Backward Communities” primarily based on poor economic and education status of the Jats in India.

The Hindu Jats in India generally follow *Arya Samaj*—a reform sect of Hinduism, which originated in the mid 1800s. Generally, the Jats follow the teachings of Swami Dayananda Saraswati, the founder of the *Arya Samaj*. According to Datta (1999), the Jats living in the northwestern plains of India belong to the *Shudra* group. Primarily because of the influence of the *Arya Samaj*, the Jats claimed a *Rajput* descent and a *Kshatriya* status.

Fuchs (1974) defines the Jats as a Central Asian nomadic group that immigrated into northwestern India. Serological and anthropometric studies of the Jats in Haryana—a north Indian state, suggest a close association between the *Rajputs* and the Jats (Khanna, 1995). The Jats in India primarily practice Hindu religion, however, some Jat groups in Punjab embraced Sikh religion around the 17th century. These Jat groups are called Jat Sikhs or Sikh Jats. In western Punjab, now in Pakistan, the Jat community adopted Islam between 8th and 10th centuries AD.

Notwithstanding social, linguistic, and religious and diversity, the Jats are one of the major landowning agriculturalist communities in South Asia. Generally, Jat communities in India primarily engage in agriculture and live in permanent village settlements in rural and urbanizing areas. However, some groups are nomadic herdsman.

As agriculturalists, the Jats grow cereals such as wheat, maize, and millet, and cash crops such as sugarcane, fruits, and vegetables. Typically, Jats live in villages in which their community is in numerical majority and dominates the economic and sociopolitical aspects of the village life. In Haryana as well as in Delhi, Jats are locally referred to as chiefs (*chowdharies*). The title symbolizes their ancestral control over the village land and their socioeconomic dominance in the village (Pradhan, 1966).

The Jats practice subcaste (*gotra*) exogamy in arranging marital alliances. Ideally, subcastes of the father, mother, paternal grandmother, and maternal grandmother are to be avoided. Residence after marriage is patrilocal and the inheritance of property patrilineal. Agrarian needs also forced the practice of widow remarriage among the Jats, especially levirate (Chowdhry, 1994). The practice of levirate is called *Karewa*, *karao*, or *chaddar andazi* among the Jat communities in northwestern India. It involves marriage by the simple ritual of a man throwing a white sheet (or chaddar) over the widow's head, signifying his acceptance of her as his wife (Chowdhry, 1994). Such marriages are described as "wearing bangles in the name of her husband" (*chura pahenana*). Sometimes levirate alliances are primarily symbolic in order to protect the right over property and to avoid a sexual indiscretion on the part of the widow.

THE CONTEXT OF HEALTH: ENVIRONMENTAL, ECONOMIC, SOCIAL, AND POLITICAL FACTORS

Throughout northwestern India and southern Pakistan, state-sponsored health care delivery programs and services as well as efforts by numerous non-governmental organizations have led to significant improvements in health care access for all rural and urbanizing communities. Members of the Jat community in these regions now receive health care from allopathic and non-allopathic physicians. In India, the state sponsored Maternal and Child Health (MCH) programs and the Integrated Child Development Scheme (ICDS) have expanded the public health care system to urbanizing and rural areas. These programs involve recruitment of village-level workers (*Anganvadi*) and their training in prenatal, perinatal, and neonatal care. Most commonly, local midwives are selected as village-level workers and are trained at state sponsored instructional workshops. These trained health

care workforce then serve as crucial links between the community and the government trained health care practitioners.

Most Jat villages in northwestern India are part of one of the Maternal Child and Family Welfare (MCFW) target zones of the regional Primary Health Center (PHC). A recent family planning survey suggests high acceptance of family planning methods among the Jats of New Delhi (Khanna, 1995). Child immunization records in this region indicate that Jat children are immunized in a timely manner. The success of the state sponsored programs among the Jats living in urbanizing villages can be attributed primarily to the easy availability and utilization of state sponsored health care services. Furthermore, the social position and networks of the *Anganvadi* workers in these villages play an important role in this process. They regularly visit and pursue the parents to utilize the available health care services. Khanna (2001) reports that in Shahargaon—an urbanizing Jat village in New Delhi—increasing awareness of health care and close proximity to state-sponsored and privately run health care services, especially those for mothers and children, have led to an overall increase in the utilization of these services and a corresponding decrease in family size among members of the Jat community.

MEDICAL PRACTITIONERS

Traditionally, Jats received health care from traditional doctors (*vaidys*) practicing *Ayurvedic* and/or Greek (*Unani*) medicine, *homeopathic* physicians, midwives, and local self-trained village healers who practice popular medicine. With increasing government support and sponsorship for western medicine, a large number of Jats are now using the services of allopathic doctors at the local dispensaries, primary health centers, hospitals, and private clinics.

For childbirth, Jat women prefer at-home deliveries with the help of a local village midwife. In Shahargaon, just like in many other Jat villages, the village midwife belongs to the low caste of Untouchables (*Balmiki Harijans*). It is important to note that due to increasing urban contact and improvement in state-sponsored health care delivery, most Jat communities now have access to biomedical services (Khanna, 2001). This has brought significant changes in birth practices among the Jats; gradually leading to increased medicalization of pregnancy and childbirth and a corresponding decrease in the roles of the village midwife. Nowadays, Jats have access to trained

midwives and/or biomedical doctors for prenatal, perinatal, and postnatal health care. Notwithstanding these changes, health care during prenatal and perinatal periods is primarily a responsibility of Jat women and Jat men play little or no role in this arena.

CLASSIFICATION OF ILLNESS, THEORIES OF ILLNESS, AND TREATMENT OF ILLNESS

In spite of the increasing use of western medicine and technology among the Jats, traditional ideas of health, illness, and healing, generally associated with *Ayurvedic*, *Homeopathic*, and *Unani* healing systems constitute the core theories of illness. Generally, the Jats use non-biomedical systems of healing for chronic health conditions. The non-biomedical treatments prescribed generally involve herbal and plant medicines, seasonal do's and don'ts, dietary changes, etc. Among the Jats, non-biomedical categories "hot" and "cold" foods are generally associated with seasons and physiologic effects (Freed & Freed, 1993).

The *Ayurvedic* system of medicine adopts a holistic approach through dietary and lifestyle changes, herbal medicine, and exercise to cure chronic disease and maintain individual health. The *Ayurvedic* system of medicine is based on the ancient knowledge contained in *Atharvaveda*. It deals with the totality of individual and social health including preventive and curative aspects. In fact, *Ayurveda* is a way of life based on certain emphasis on diet, lifestyle, and Yoga practices suitable for an individual according to his/her constitution. The constitution, in turn, is determined on the basis of the predominance of or loss of equilibrium in one or more of the humor, viz. Gas (*Vata*), bile (*Pitta*), or phlegm (*Kapha*). Based on the symptoms produced due to excess or deficiency of particular fault (*dosha*), the *Ayurvedic* practitioner selects remedial measures in the form of herbs, plant medicine, and metal salts.

The present health and healing culture among the Jats of northwestern India and Pakistan involves an eclectic use of treatments and therapies from several distinct healing traditions, namely, *Ayurveda*, *Homeopathy*, *Unani*, and biomedicine. In addition, local healers use a combination of ideas related to disease causation and treatment modalities borrowed from a variety of healing traditions and practices.

The Jats in north India continue to believe in numerous mother goddesses, many of whom serve as the names of diseases, especially those of childhood. Most Jat communities identify two mother goddesses namely, *Sitala* and *Khasra* for smallpox and skin rashes, respectively. In order to protect children and family members from illness, evil eyes, and harmful spirits, the Jats tie protective amulets made of iron, gold, silver, copper, beads, cloths, and strings on children's wrists, ankles, and around their necks (Freed & Freed, 1993). Beliefs associated with evil spirits are more common among Jat women than among Jat men. More commonly in rural Jat communities, diseases like tetanus, diarrhea, and measles are often associated with spirit possession and evil eye. Jat women are expected to worship local deities and observe charms (*totkas*) in order to ward off evil spirits and cure diseases among family members, especially children (Chowdhry, 1994).

SEXUALITY AND REPRODUCTION

Before discussing sexuality and reproduction among the Jats, it is important to note that members of this community no longer live in isolated communities. Most Jat communities are currently experiencing rapid social change brought about by urbanization and technological diffusion, especially in terms of increasing access to education, health care, and the mass media. Such changes have perceptibly influenced everyday life among the Jats. Amidst rapidly changing social and economic environments, the Jats are experiencing significant shifts in their health and economic well-being as well as in their traditional cultural ethos.

Among the Jats, culture-bound beliefs and practices associated with gender, conception, prenatal period, childbirth, postpartum care, childhood, puberty, adulthood, and old age are central to perceptions of health, illness, and well-being. Such beliefs and associated practices significantly influence the utilization of health care. Like other agriculturalist communities in South Asia, the Jat patriarchal system constitutes core cultural values, customs, laws, social roles, and metaphors that clearly subscribe to the larger Hindu ideas and ideals of male dominance. Under the Jat peasant patriarchal system, there is little equality or symmetry between men and women. As compared with men, Jat women are generally given little choices, especially with regard to marriage, mobility, education, and employment. Extensive ethnographic evidence suggests gender-specific neglect against women

among the Jats (Das Gupta, 1987; Khanna, 1995). The customs and traditions of a patriarchal society are suggested as underlying causes of the overall neglect of women leading to their poor overall physical health (Jeffery et al., 1989; Khanna, 1997). These studies conclusively demonstrate the adverse effect of the culturally prescribed subordination of Jat women on their reproductive health and survival. Culturally prescribed practices associated with a biased allocation of intrahousehold resources for health care and food have been argued to be responsible for the poor overall health and high morbidity rates among Jat women.

Among the Jats, marriage marks the socially acceptable initiation of reproduction. However, it involves two distinct events—the actual social event associated with marriage and the consummation of marriage. Traditionally, marital alliances are arranged with the help of the village barber who assists Jat parents in finding a suitable match for their children and in finalizing the timing, exchange, and other important details associated with marriage. After a suitable match has been arranged by Jat parents, an elaborate religious ceremony marks the marital bond. The consummation of marriage (*gauna*), however, takes place usually within one or two years of marriage. Before a marriage has been consummated the bride stays at her natal home. The term *liviyao* refers to the time in the *gauna* ceremony when the bridegroom, along with his other relatives, comes to take the bride to her affinal village. Recently, there has been a considerable decrease in the time gap between marriage and its consummation among the Jats. On both occasions, however, the bride's family is expected to arrange for feasts for the marriage party and to provide gifts for the groom's relatives. Some Jat communities have traditionally preferred "double marriages," which involve marital alliances between sets of sisters and sets of brothers. Such marriages are described by Jats as more realistic and suitable to an agricultural way of life and three-generation patrilocal extended family system (Khanna, 1995; Kolenda, 1987).

HEALTH THROUGH THE LIFE CYCLE

Anthropologists have often used events marking life transitions as age categories signifying major divisions of life. Earlier research among the Jat communities in north India provides detailed accounts of the rites of passage, highlighting the importance of rituals and ceremonies associated with birth, marriage, and death (Lewis, 1958). The Jats recognize an individual's life cycle into the three

major stages (*ashram*) as prescribed by the traditional Hindu views. In *brahmacharaya-ashram*, the individual as a student follows a strict code of chastity (*brahmacharaya*) and learns from his teacher (*guru*). In the next stage or *grahastrha-ashram*, the individual is expected to take household responsibilities (*grahastha*) and fulfill his duties toward his family and his *dharma*. *Vanprastha-ashram* marks the third state of life in which the individual begins the hermitage phase of life and returns to contemplation and for guiding family and society. The fourth and final stage, *sannyas-ashram*, marks the beginning of the renunciation phase of life. The individual is expected to renounce all the "outer" goals of life and to begin learning about spirituality away from all social or political concerns (Lewis, 1958).

Among the Jats, specific ceremonies or events are often associated with the transition of an individual through different stages of life and that in each life stage, individuals are expected to perform the social roles prescribed for that life stage. It is, however, important to note that the traditional Hindu views do not separate life stages based on gender. Peasant patriarchal system among the Jats and the corresponding gender stratification place severe constraints upon the activities and roles of Jat women throughout the lifecycle. These constraints directly affect Jat women's ability to access health care.

Pregnancy and Birth

Both pregnancy and childbirth are considered auspicious events among the Jats. Childbearing constitutes an important part of an adult Jat women's life. During the time of a woman's labor, family members gather in the house and women perform important roles associated with childbirth. If the child is a boy, the relatives bang a metal plate (*thali*) or fire in the air to announce his birth. Because of a strong son preference among the Jats, the birth of a son is considered an auspicious occasion of happiness and rejoicing. No such celebrations take place on the birth of a girl. The happiness on the birth of a son is shared by members of the affinal and natal families of the mother as the birth of a son improves the social status of the mother in the affinal patrilineage. The affinal family of the mother receives gifts, special food items, and money from the natal family. These contributions are comparatively smaller in case of the birth of a daughter. This practice, however, is limited to the first-born daughter. For

subsequent daughters the natal family generally does not send gifts and money to the affinal family.

Infancy

A great deal of demographic, ethnographic, and health research among northwestern peasant communities in India, especially among the Jats, indicates sex differentials in health and mortality during infancy and early childhood. While several factors have been identified as causing excessive female mortality during infancy and early childhood, culturally prescribed patterns of son preference and daughter neglect are considered important proximate determinants of gender differentials in morbidity and mortality among the Jats. The mortality patterns among the Jats correspond with the South Asian pattern of sex differentials: males generally have equal or slightly higher mortality rates than females during the first month of life and lower mortality rates than females after the first month of life.

Ethnographic research suggests that Jat parents tend to show preferential treatment for sons, generally investing more household resources toward ensuring their survival. Infant girls are considered relatively more resistant to disease than an infant boy. A daughter is often equated with *kikkar*—a thorny bush that grows wild and does not require much nurturing.

Childhood

Gender role socialization begins very early in the life of a Jat individual, often before children are even aware of their sexual identity. This may happen even before the development of an internal motive for conforming to sex role standards. Jat parents and the community play important roles in reinforcing norms of expected behavior. Jat girls, generally socialized under strict patriarchal control, came to understand their limited sex role options and the rigid patterning of these options.

For the young girl discrimination in terms of nutrition and health care allocation occurs in conjunction with a constant reinforcement of her gender identity.

The individual and additive effects of cultural and biological factors invariably lead to lower survival rates for Jat girls than boys, and negatively influence their overall growth and development patterns, reproductive health, and fertility (Khanna, 1997).

Adolescence

Son preference and daughter neglect has continued among the Jats in spite of increased urban contact as well as access

to and utilization of education and health care services. In the Shahargaon—an urbanizing Jat community located in the outskirts of New Delhi, India, recent shifts in the economy and occupation based on agriculture to urban job-based economy, and improvements in education and health care facilities have not significantly changed traditional patterns of son preference and daughter neglect. Jat sons are viewed as economic and political assets, adding to the strength and prestige of the family, but daughters are perceived as an economic and moral burden. While Jat parents expect their teenage sons to enroll in schools and colleges, for a majority of Jat daughters, adolescence invariably marks the end of their education experience. Rarely are they allowed to study beyond the middle school level available at the village school. Most Jat parents in Shahargaon feel that the daughter should be educated up to a level so that she can write letters to her parents and take care of her children's health and education.

As the development of secondary sexual characteristics and the onset of menarche signal a girl's emerging sexuality, Jat girls are expected to spend more time in the house and take responsibility of the domestic workload. Jat girls are expected to help prepare and serve food and take care of their younger siblings. Culturally mediated concerns for virginity, marriage, and workload expectations lead Jat parents to enforce seclusion and strict parental control of mobility, education, and occupation of Jat daughters. The imposition of a strict conduct of behavior invariably leads to agitation, apprehension, and emotional anxiety among young Jat girls. Although the onset of menstruation is regarded as a natural event, women rarely discuss this issue amongst themselves. Delayed menarche is often considered an indicator of infertility. Irregular menstrual cycles are believed to be associated with a sexual indiscretion on the part of the girl and a source of great anxiety for parents. One of the major parental concerns is the fear of a daughter's emerging sexuality and of any dishonor which sexual activity could bring to the family. Anxiety over menstruation and lack of knowledge adds emotional distress to the psychosocial development of an adolescent girl.

Health care behavior among the Jats also indicates a strong bias favoring sons over daughters. Generally, Jat sons receive "modern" health care at an earlier stage of their illness than Jat girls. In comparison to Jat girls, Jat boys are more likely to be taken to biomedical "specialist" doctors and clinics. An ill son is a matter of great concern and anxiety for the family members while an ill daughter soon becomes the target of insults and parental frustration.

Girls during this stage of their life have little or no control over their health and are dependent on decisions of the elder family members.

An adolescent Jat girl's life in her natal home is often emically described as life in a state of transition, at the threshold, or living inbetween two worlds. She is considered a "commodity" (*paraya dhan*) that belongs to some one else. Life stages like puberty and development of secondary sexual characteristics reinforce the idea of her temporary existence in her natal home.

Adulthood

Jats prefer early marriage, especially in the case of girls. Among the Shahargaon Jats, the average age at marriage is 16 years (Khanna, 1995). Jat parents observe strict patterns of subcaste (*gotra*), village, and at times, regional exogamy while arranging marital alliances for their children. Jats practice patrilocality—a cultural practice that requires the bride to leave her natal home after marriage in order to live with her husband's family. The "adjustment" process for the young Jat bride in her affinal home involves meeting conjugal responsibilities, often from a position of complete ignorance, and dealing with the daily demands of the household chores. She is expected to maintain veil (*purdah* or *ghunghat*) from senior men in the family and the community.

Expectations to produce a son usually result in early pregnancy among the Jats. Early marriage followed by early childbearing increases the risk of obstructed labor and reproductive morbidity. Due to increase availability of health care in most rural and urbanizing areas of north-western India, the Jats generally seek prenatal and perinatal health care from state-sponsored health clinics. Jat women in the household are primarily responsible for health care during and after pregnancy.

Among the Jats, sex and gender are contrasting concepts. Jat parents do not think of their children only in terms of a child's sex because what concerns them most is whether the child is a son (*beta*) or daughter (*beti*). These terms invoke an entire set of cultural values and behavioral norms associated with the sex of the child. While the birth of a son is considered a good gift or an indication of the family's good fortune, that of a daughter is considered a sign of distress and anxiety. Some of the commonly used proverbs expressing strong son preference among the Jats include:

"The number of sons is equal to the number of sticks and the number of sticks determines the amount of land controlled by a family" (*jitney ladke utney lath, jitney lath una kabza*); and "selling milk is equivalent

to selling a son" (*jisney gharka dudh baech diya usne apna puut baech diya*).

On the other hand, common household names for daughters include:

Rambatheri (God, this one is enough) or *Rambheji* (this daughter belongs to God and he will take care of her).

Among the Shahargaon Jats, increasing urban contact and access to health services and reproductive technology, especially prenatal diagnostic technology, have provided Jat parents with a reliable means for reducing family size and limiting the number of daughters in the family. Shahargaon Jats are using temporary methods of contraception for reducing the number of children per family and achieving the desired family composition by using ultrasonography to identify the sex of the fetus and, in some case, aborting female fetuses. In a survey of 127 Shahargaon Jat women in 45 or less age category, 28.3% women used ultrasonography to identify the sex of the fetus and 13.4% women opted for sex-selective abortions between 1989 and 1994. The majority of Shahargaon Jat parents (68%) expressed desire for a small family size, and considered two sons and a daughter to be the ideal family composition (Khanna, 2001).

It is important to note that despite considerable improvements in economic and educational status brought about by urbanization, the use of prenatal diagnostic technology and sex-selective abortion of female fetuses suggests the continuation of the son preference and daughter neglect reminiscent of the Jat agrarian ethos. Notwithstanding the legality of abortion in India, well-equipped and professionally operated screening and abortion facilities are not readily accessible to all rural and urbanizing Jat communities. By seeking repeated ultrasonographic examinations and, at times, abortion services, Jat women are at increasing risk of complications resulting from unsafe and unhygienic abortion procedures, including reproductive tract infection. In the context of the generalized lack of knowledge and social stigma associated with reproductive health problems in the Jat community, Jat women are less likely to seek treatment for reproductive health problems.

The Aged

Older members in the Jat community command considerable social prestige and respect. The Jats prefer to live in joint families with older men as heads of the household. While men enjoy high status and respect in the family primarily by virtue of their gender, Jat women have to

contribute male heirs to the husband's patrilineage in order to gain authority and power in the family. Often older Jat women's primary responsibilities include direct supervision of their children's socialization. Among the Shahargaon Jats, the elderly women lack physiological knowledge associated with menopause and experience a wide range of menopausal symptoms such as tension, headaches, swelling, and loss of appetite. Some informants also reported a feeling of resentment and anger. Although the elderly Jats rarely seek health care for minor health problems, the joint family system among the Jats provides financial security and facilitates timely health care. Even at this stage in life, Jat men have a privileged social status over Jat women.

Dying and Death

The Jats generally observe 13 days of pollution after death. Jat men are expected to show considerable behavioral restraints during the days of pollution, while Jat women are expected to express their grief in public. The dead are cremated by following the traditional Hindu ritual of cremation in which the eldest son plays an important role. At the death of a married woman, rituals and practices reinforce the notion that she does not belong to her husband's patrilineage. Her sister(s) and natal women relatives prepare the body for cremation and funeral rites.

Lijiang Naxi

Sydney Davant White

ALTERNATIVE NAMES

Currently, the “Lijiang Naxi” and the “Yongning Naxi” (or Mosuo) are officially classified by the People's Republic of China government as members of the same Naxi “minority nationality,” with the Mosuo designated as a “branch” of the Naxi; however, both groups see themselves as significantly different peoples. This entry focuses on the Naxi of the Lijiang area, specifically the Naxi of the Lijiang basin. During the Republican Period (1912–49 CE), the contemporary Naxi of the Lijiang area of the People's Republic of

China (PRC—1949–present) were referred to by Joseph Rock (1947) as the Na-khi; the contemporary Mosuo of the Yongning area (officially referred to as the Yongning Naxi, and sometimes also as the Naru, Naze, or Na by various scholars) were referred to by Rock as the Hli-khin.

LOCATION AND LINGUISTIC AFFILIATION

The Lijiang basin has historically been the geographical, political/administrative, economic, and cultural center

of the Naxi. The town of Dayanzhen (referred to by outsiders as Lijiang) is located at the center of the 2,400-meter Lijiang basin at the base of the spectacular 6,300-meter Jade Dragon Snow Mountain. Numerous villages surround Dayanzhen, and the Naxi area extends to the north, northwest, and south of the Lijiang basin. Dayanzhen serves as both the county seat for the Lijiang Naxi Nationality's Autonomous County and as the seat for the larger Lijiang Prefecture (which encompasses a total of four counties). The Lijiang area is located in the northwestern corner of Yunnan Province, adjacent to ethnically Tibetan areas in the province's Himalayan sweep toward Tibet. Yunnan is located in the southwesternmost corner of the contemporary PRC. The first language of most Lijiang basin Naxi residents is *Naxi-hua*, a Tibeto-Burman language, though most basin Naxi who have come of age since 1949 have acquired the western Yunnan dialect of Mandarin through the schools as they have grown up.

OVERVIEW OF THE CULTURE

Naxi are the predominant “nationality” of the Lijiang basin and of the larger county, constituting approximately 250,000 of the county's 300,000 residents. As of 1990, Dayanzhen had a population of approximately 60,000. In order to understand Naxi identities and therapeutic practices both prior to and since 1949, however, it is critical to note that not only has the Lijiang basin been the center of Naxi culture for centuries, but it has also been an arena of longstanding engagement between basin Naxi and the Chinese state—the latter encompassing both state policies and Chinese popular culture practices. Thus, while “Naxi culture” is the hegemonic culture of the Lijiang basin, at the same time it has been shaped in many arenas—including the arena of therapeutic practices—by several centuries of influence from Chinese society.

Historically, Naxi are believed to have originally been a Qiang people from the Qinghai Plateau, who migrated to the Lijiang area approximately 1,400 years ago. Beginning in the Yuan Dynasty (1206–1368 CE), the Naxi “kingdom” entered into a tribute relationship with the Chinese state under the *tusi* system; this marked the formalization of a two-tiered structure of elites and commoners within Naxi society. During the Ming Dynasty (1368–1644 CE) and the Qing Dynasty (1644–1911 CE), basin Naxi sociocultural identities were influenced by the immigration of Han

Chinese soldiers and other Han settlers from areas such as Nanjing, with whom basin Naxi apparently frequently intermarried. The Lijiang area was formally incorporated into the Chinese state under the system of “regular government” in 1723. To a degree under the Republican state, but of special note under the Socialist (i.e., post-1949) state, basin Naxi have been strong adherents to the official/Chinese state status quo.

With respect to economic practices, historically most Naxi were agriculturalists and pastoralists. Wheat, corn, and various legumes have long served as the primary basis of basin Naxi diets, and the raising of horses, oxen, and pigs has also long been central to the village-based Naxi economy. For contemporary basin residents, the primary salient social distinction is along lines of urban versus rural/town versus village residence (as is the case throughout the PRC). Dayanzhen has for centuries been an important stop on the trade route between Lhasa (in Tibet) and Kunming (the provincial capital of Yunnan)—many basin Naxi men historically took part in the muletrain-based, long-distance transport trade as well as in a number of other itinerant trades such as leatherworking, and many Dayanzhen Naxi women controlled the local markets with formidable marketing and business skills.

In the post-Mao period (i.e., post-1979), most Dayanzhen residents have had relatively secure employment in state or collective work units (though this is changing). Additionally, many of the town-based enterprises that are controlled by Dayanzhen residents (as opposed to outsiders) are run by Naxi women. Over the past decade, however, the ethnic tourism that has emerged as a booming industry in the Lijiang area has drawn (primarily male) Han entrepreneurs from a number of different provinces to the area. In the context of post-Mao decollectivization, basin village residents for the most part rely upon their own family labor for their livelihood—primarily in terms of agricultural labor, but also in terms of wage-labor opportunities in village industries and via migration to Dayanzhen and other urban centers throughout Yunnan, Sichuan, and the PRC in general.

Graduates of Dayanzhen high schools compete with top students throughout the PRC for admission to provincial and national level institutions of higher education. Basin Naxi males in particular have historically sought to associate themselves with the Chinese state; since 1949, Communist Party membership has been an important marker of social status for Naxi men.

Patrilineal descent, patrilocal postmarital residence, and (patrilineal) ancestor worship continue to be practiced by both village and town Lijiang basin Naxi residents (in contrast to the system of matrilineal descent and “walking marriage” of the Mosuo). Prior to 1949, arranged marriages were also the norm, and older Naxi women describe their pre-1949 lives as “terribly bitter.” Dayanzhen Naxi women have an advantage over village Naxi women in that they do not “marry out” of their natal villages, and they are able to utilize this advantage to maintain their childhood social networks and enhance their entrepreneurial talents as small business managers.

In addition to the neo-Confucian practices that basin Naxi incorporated in their formal and informal encounters with the Chinese state, basin Naxi culture has historically been influenced (at various historical moments) by Buddhism in both Chinese and Tibetan (Nyingmapa) forms, by Daoism, by Tibetan Bon practices, and by a variety of Chinese popular cultural practices. For ethnographically-based research on the Lijiang Naxi, refer to Chao, 1995, 1996, 1999; Goullart, 1955; Hansen, 1999; McKhann, 1992, 1995; Mueggler, 1991; Rees, 2000; Rock, 1947, 1963, and White, 1993, 1997, 1998a, 1998b, 1999, 2001. For ethnographically based research on the Mosuo, see He, 1994, 1999; Mathieu, 1996, 1998, 2000; Rock, 1947; Shih, 1993, 1998, 2001; Walsh, 2001a, 2001b; Weng, 1993; and Yan, 1982.

THE CONTEXT OF HEALTH: ENVIRONMENTAL, ECONOMIC, SOCIAL, AND POLITICAL FACTORS

Epidemiological Profile

According to official PRC Public Health Bureau representations, infectious diseases of all varieties were of dire proportions in the pre-1949 basin, and poverty insured that much of the population was particularly susceptible to them. The relatively dramatic transformations in the epidemiological profile of the basin over the past several decades are undoubtedly due to the vigilant vaccination system that has been put into place in both urban and rural contexts since 1949, along with the overall increase in the standard of living for the majority of basin residents since 1949. These shifts in the overall epidemiological profile occurred in spite of the large-scale

starvation and malnutrition experienced primarily by basin villagers during the Great Leap Forward (GLF—1958–61). In basin villages, virtually every family lost at least one or two members during the GLF due to starvation and malnutrition—a famine (provoked primarily by Maoist policies) that was far worse than any in villagers’ memories. (See Mueggler, 2001.)

In the contemporary basin, the most common afflictions vary between town and village contexts, but colds, influenza, and stomach problems are common among all ages in both contexts; coughs, pulmonary infections, and both gallstones and kidneystones are common among older basin residents; rheumatoid arthritis, gynecological disorders, high blood pressure, chronic headaches, and “neurasthenia” are particularly common among middle-aged and older Naxi women (see below). During the summer months in the villages, dysentery is common among villagers of all ages, though especially among young children; intestinal worms are also common among young village children during the summer.

Overall, while infectious diseases such as hepatitis A and tuberculosis are common (as elsewhere in the PRC), the epidemiological profile in the Lijiang basin, and throughout most of the PRC, is closer to that of a “developed” rather than a “developing” country. The widespread PRC practice of using only boiled water for drinking and cooking (in addition to improved standard of living and vaccination factors) can be credited for this. However, in basin villages the use of human waste for fertilizer, the lack of physical containment of poultry and livestock, and the lack of screens are important factors influencing the spread of infectious disease by flies and other vectors. Limited access to bathing opportunities in basin villages is also a factor that influences a number of afflictions (including vaginal infections). See below for discussion of risk factors for HIV/AIDS and hepatitis B.

Environment/Global and Local Factors Influencing Health

Environmentally, the Lijiang basin does not suffer from the dramatic increases in air pollution, water pollution, and forms of environmental pollution that plague most contemporary PRC cities. However, as noted above, over the past decade, the Lijiang basin has become a prime national and international tourist destination for an estimated million plus tourists annually, and the considerable economic development in the basin has resulted in

increased environmental degradation. The town/village divide and the gendered division of labor are the key local factors influencing health (see below).

Public Health Infrastructure

Beginning in the 1950s and the 1960s, the Lijiang basin has benefited from being the location of both county-level and prefectural-level public health bureaus, clinics, and hospitals established by the Chinese socialist state. In addition to the County Hospital and the Prefectural Hospital, there are also county-level and prefectural-level Hygiene and Prevention Health Stations, Women and Child Health Protection Stations, and Pharmaceutical Inspection Stations. At the county level there is a specialized Chinese Medicine Hospital and a Schistosomiasis Station; at the prefectural level, there is a Hygiene School and a Pharmaceutical Company (the Lijiang area and Yunnan in general being prime areas engaged in the production of herbal Chinese medicine). Public health bureaus that are under the joint administration of the public health system and other government administrative units include the Patriotic Hygiene Movement Committee, the Birth Planning Committee, and the Leprosy (Hansen's Disease) Hospital.

During the Maoist period, particularly during the Cultural Revolution (1966–76), brigade-based clinics served as the first of three tiers of resort, the second tier being commune-based health centers, and the third tier being town-based hospitals. The average brigade consisted of approximately 500 families or 2,000 individuals. These cooperative medicine clinics were (with a few exceptions) dismantled during decollectivization in the post-Mao period. “Integrated Chinese and Western medicine” (see below) was originally implemented as the lynchpin therapeutic practice for cooperative health care.

Therapeutic Practices

Prior to 1949, the primary therapeutic epistemology informing basin Naxi understandings of affliction was the “medicine of systematic correspondence” following Paul Unschuld's (1985) term—the classical text-based humoral therapeutic practice associated with the Confucian state that serves as the theoretical underpinning of the post-1949 socialist Chinese state's formulation of “traditional Chinese medicine” (TCM). The hegemony of this epistemology reflects both the degree

of influence of the Chinese state in the Lijiang basin and the significance of this epistemology for the “civilizing project” (Harrell, 1995) of the Chinese state. Some other therapeutic practices existed in the basin as well. These practices for the most part were like popular therapeutic practices in other (Han) parts of Yunnan and China in general. They encompassed fortune telling, the exorcism of ghosts or demons, the retrieval of lost souls (Goullart, 1955), and *gu* witchcraft. Rituals associated with Buddhist and Daoist voluntary associations also factored into basin Naxi therapeutic practices. Neither Tibetan medicine, “Western medicine,” nor indigenous Naxi *dongba* or *sanyi* practices played a significant role in pre-1949 basin Naxi therapeutic practices (though *dongba* and *sanyi* practices were influential in other parts of the Naxi area).

In the early 1950s the Chinese Communist Party (CCP) established a distinction between “official” and “unofficial” therapeutic/religious practices. Therapeutic practices designated as official during the Maoist period—in the basin as well as throughout the PRC—included four practices, which were identified as “Chinese medicine,” “Western medicine,” “integrated Chinese and Western medicine,” and “folk medicine.” All other types of therapeutic practices were officially labeled as “unscientific,” “backward,” and reflective of the “feudal superstition” associated with the “old society” prior to 1949.

For basin Naxi, this meant that fortune-telling, exorcism of ghosts and demons, retrieval of lost souls, and *gu* witchcraft were no longer etiologies that could be openly acknowledged or strategies of therapeutic resort in which citizens could be openly engaged. It also meant that other ritual practices of various members of basin Naxi society, such as those associated with Tibetan Buddhism, Chinese Buddhism, Daoism, Confucianism, and/or other aspects of Chinese/Naxi popular culture were banned.

“(Traditional) Chinese medicine” (hereafter referred to as TCM), the official PRC practice of Chinese medicine, reflected a reformulated medical practice whereby the medicine of systematic correspondence, the pharmaceutical canon, and a variety of techniques such as acupuncture, moxibustion, and acupressure were standardized and “scientized” (see Croizier, 1968, 1976; Farquhar, 1998; Hsu, 1992; Kleinman, 1980; Scheid, 1995; Sivin, 1987; Unschuld, 1985; White, 1993, 1999, 2001).

The official PRC practice of biomedicine, designated as “Western medicine” (hereafter referred to as WM), was also a Maoist period creation. In the 1950s,

Mao broke with physicians who had been trained during the Republican era in an elite-focussed, urban-based, hospital-centered practice of biomedicine. It was at this juncture that Mao declared TCM a “national treasure-house,” and that biomedicine was re-envisioned, reformulated, and reorganized to enable the new, more pragmatic, broad-based, public health oriented practice of WM.

The aforementioned “integrated Chinese and Western medicine” (hereafter referred to as integrated medicine) emerged as a consciously formulated hybrid medical practice that was introduced by Mao during the Cultural Revolution as the cornerstone of national health policy (see RHCHP, 1977). Ideally, it was to represent a synthesis of the best of TCM and of WM. And although it was initially implemented in both urban and rural areas, it was in fact geared toward the health care needs of the rural areas in particular.

“Folk medicine” was the official category established during the Maoist period to acknowledge medical practices other than TCM and WM. It came to encompass aspects of folk and popular Chinese therapeutic practices (particularly local herbal medicines) that were perceived as relatively “scientific” and therefore as relatively legitimate. In the Lijiang basin, “Naxi folk herbal medicine” was recognized as a form of folk medicine, albeit one described in basin Naxi and state public health discourses alike as “without (its own) theory” (i.e., no theory distinguishable from TCM theory) informing the pharmaceutical usage of its materia medica.

The Maoist period establishment of these four official practices through public health policies and institutions reshaped the contours of the previously existing Chinese medicine and other therapeutic practices in the basin. In Dayanzhen, where most of the public health bureaus, hospitals, and clinics were established beginning in the 1950s, the newly reformulated practices of TCM and WM were the ones with which town residents engaged when they sought health care. As was the case elsewhere during the 1950s and early 1960s in the PRC, Dayanzhen medical institutions operated according to an institutional division of labor between TCM and WM. The Prefectural Hospital and the County Hospital each maintained separate WM and TCM departments that mutually engaged in cross-referrals, but maintained no other coordination. There was additionally the County Chinese Medicine Hospital that engaged solely in the practice of TCM. For the duration of the Cultural Revolution, all three institutions shifted to the revolutionary practice of

integrated medicine (indeed, it was counterrevolutionary to do otherwise), but returned to their former institutional division of labor arrangement as soon as the Cultural Revolution began to wind down. In contrast, in basin brigades (now “administrative villages”) integrated medicine became thoroughly institutionalized as the prevailing therapeutic practice starting from its implementation in the late 1960s. Rural residents engaged in this new practice that endeavored to combine TCM and WM when they sought out treatment from brigade cooperative health care practitioners.

In the post-Mao period (as was the case during the Maoist period), the four officially recognized therapeutic practices—TCM, WM, integrated medicine, and folk medicine—have continued to be the only therapeutic practices technically regarded as “medicine” in the PRC. While medicine, “hygiene,” and public health have remained centerpieces of ongoing PRC discourses of socialist modernity and “culture,” however, all four official practices have become more professionalized, “scientized” (in a manner different than the Maoist period), and commoditized in the post-Mao period. Additionally, there has been a post-Mao “reemergence” of certain practices formerly banned as unofficial into the officially tolerated (if not sanctioned) arena of “popular culture.” Most prominent among these practices have been fortune-telling and, in basin villages, *gu* witchcraft—both of which reflect long-standing Chinese popular culture legacies.

MEDICAL PRACTITIONERS

Prior to 1949, basin Naxi practitioners of Chinese medicine (namely, the medicine of systematic correspondence combined with Chinese herbal pharmaceuticals, acupuncture, and massage techniques) were virtually all male, and had either acquired their knowledge as apprentices of their fathers or other older male relatives, or through an apprenticeship with a non-related practitioner usually arranged by their parents. They started as young boys and gradually developed expertise over the years through learning from their masters, reading the classic texts of Chinese medicine, and learning through personal experience.

During the Cultural Revolution, the practitioners in the basin who were recruited to staff the brigade clinics and to carry out the practice of integrated medicine were generally from one of three backgrounds. Middle-aged and younger doctors and medical technicians trained in

“Western medicine” (sometimes via state medical training schools or universities and sometimes via People’s Liberation Army training programs) were “sent down” to the countryside from town and city hospitals and clinics for at least the early years of the Cultural Revolution. Older Chinese medicine practitioners were selected from the brigade itself. They usually came from families that had a multigenerational legacy of practicing Chinese medicine or that at least had a repertoire of secret medical (usually herbal) remedies. The “barefoot doctors,” the majority of whom were male, in their twenties, and of “good” political background, were selected at the brigade level as well. It was the barefoot doctors in particular who were targeted to learn the newly minted practice of integrated medicine, but practitioners from all three backgrounds agreed that what they collectively strove to practice was integrated medicine.

By the early 1980s, most of the “Western medicine” practitioners who had been sent down to the villages of the basin at the beginning of the Cultural Revolution had returned to their original town- or city-based clinics and hospitals, and the dissolution of cooperative health care did have an impact on the lives of rural practitioners. Former cooperative health care practitioners were officially re-designated as “village doctors,” and they became independent, private practitioners. A national examination system for village doctors was implemented in 1982 and 1983, whereby doctors were to choose and ideally pass either the TCM exam or the WM exam. In the Lijiang basin, while all village doctors eventually took one of these exams, not all of them passed their respective exams. Of the village doctors I interviewed, approximately half had passed one of the exams (basic literacy usually being a problem for many of those who did not). While passing one of the exams generally added to the prestige of a given doctor among villagers, those doctors who did not pass an exam were not stigmatized or prevented from practicing.

As a result of the exams, most basin village doctors presently categorize themselves as either TCM or WM specialists. However, they virtually all refer to the type of medicine that they practice as integrated medicine, just as was the case during cooperative health care. While there have been changes in the rural health care infrastructure, the practitioners for the most part are still the same individuals. And they identify integrated medicine as the prevailing epistemology that informs their therapeutic practice.

In the hospital contexts of Dayanzhen (and other cities in China), there is more of a clear-cut division of labor carved out between TCM and WM. Both the Lijiang Prefectural Hospital and the Lijiang County Hospital concentrate most of their space and staff on the practice of WM, and have a relatively small space and staff focused on the practice of TCM (TCM is one department among the rest). In this context, the practice of integrated medicine is restricted to those patients who choose to visit both WM and TCM doctors of their own volition, and to pursue both kinds of diagnoses and treatments simultaneously; although there is a mutual referral system, there is no formal consultation between the concerned TCM and WM doctors who share the same patients.

CLASSIFICATION OF ILLNESS, THEORIES OF ILLNESS, AND TREATMENT OF ILLNESS

In the contemporary basin, the options open to residents with respect to strategies of therapeutic resort are for the most part determined by whether or not they have state jobs. This division breaks down primarily along urban and rural lines: the vast majority of village residents in the Lijiang basin (as throughout the PRC) are not state employees and consequently have no health insurance. Since most villagers also have limited access to cash income, this socioeconomic distinction means that they tend to avoid visits to the clinics and hospitals located in Dayanzhen. Villagers who have average or higher than average incomes will attend the latter clinics only in the event that they have a major illness, or for the birth of a first child. Villagers who have lower than average incomes just let the disease take its course, or have their babies in the village.

For most afflictions in both town and village contexts, depending on the illness, the first resort is usually either to use herbal medicine which one collects oneself, to purchase some medicine (either WM, TCM, or integrated medicine) at the local pharmacy, or to go to the nearest local clinic for an injection (usually of antibiotics) depending on one’s resources. While visits to village clinics are on average at least 50% less expensive than visits to town clinics, villagers must use their own hard-to-obtain cash, whereas town residents generally pay very little of the cost themselves.

Additionally, there is a pecking order among the therapeutic institutions that villagers tend to frequent as opposed to those that members of work units tend to frequent. Most villagers in Lijiang County go to the somewhat less expensive county level institutions, whereas it is primarily members of state work units or those who can afford to pay out of their own pockets who tend to frequent the prefectural hospital. Most villagers complain bitterly about the fact that, since decollectivization, city hospitals and clinics demand payments up front before admitting anyone without health insurance. For most villagers, then, the primary form of medical care available (aside from self-treatment) is from village doctors.

The most common afflictions in basin villages, by the accounts of village practitioners and non-practitioner village residents alike, included colds, influenza, dysentery, parasites, stomach afflictions, gallstones and kidneystones, arthritis, heart disease, tracheitis, and gynecological disorders. The etiologies of these afflictions—according to basin village practitioners and lay villagers—are rooted in a variety of factors, including inattention to properties of heat and cold, dryness and wetness, and “wind,” and/or inattention to “water–earth relationships,” seasonal weather cycles, basin microclimates, one’s diet, one’s body type, one’s emotions, one’s gender, and/or one’s position in the life cycle. For example, colds are caused by one’s inappropriate response to excessive heat or cold in the weather in terms of one’s choice of clothing (especially failure to wear enough clothing), or the “hot” or “cold” properties of the food one chooses to eat without consideration for the weather. Influenza is an especially potent form of a cold, which is “infectious” (i.e., defined as being more widespread) during the spring and fall seasons when the weather is particularly prone to changeability. Stomachaches are caused by eating irregularly, exposing oneself to excess cold through work, eating cold food, and drinking cold water, and/or by harboring unhappy feelings. Dysentery is primarily caused by exposure to too much heat, which is the explanation for its prevalence during the period of the Chinese solar calendar known as *san fu tian* (the hottest period of summer); dysentery is also caused by eating too many chili peppers, eating too many kinds of food with oppositional “qualities” (e.g., sour versus sweet, etc.), eating unpeeled fruit, or by eating cold food and drinking cold water. Gallstones and kidneystones are frequently also attributed to excess cold, and/or seen as resulting from many years of stomach problems. Heart

disease is caused by chronic illnesses in other parts of the body that spread to the heart. Arthritis is a “wind” affliction caused by exposure to too much dampness, cold, and wind, as well as by exposure to sudden shifts in temperature and by working to exhaustion. Tracheitis and bronchitis are caused initially by exposure to cold and then continual exhaustion from work. Gynecological disorders are generally due to the intrinsically depleted nature ascribed to women’s (reproductive) bodies (see below).

The etiologies of these afflictions overwhelmingly reflect a view of disease and illness causality that has been called the “medicine of systematic correspondence” (Unschuld, 1985). The medicine of systematic correspondence has evolved over the past two millennia and has integral links to Confucianism and the official culture of the Chinese state. Yin/yang dualisms in physiological, humoral (e.g., hot/cold, wet/dry, etc.) and other arenas parallel the dyadic relationships upon which Confucianism is premised. “Five phase” (*wu xing*) relationships between bodily organs and a variety of other substances parallel the emphasis on the complex network of relationships intrinsic to the bureaucratic structures of the Chinese state. These dyadic and quinary relationships are replicated at the levels of the individual body/self, the local level society/environment, and the state/cosmos. The goal for the maintenance of order/health and the avoidance of disorder/affliction is proper behavior/health care and balance. This discourse of proper behavior and the maintenance of balance reflects, among other things, an emphasis on prevention. Once out of balance, the medicine of systematic correspondence body is in a state of depletion and in need of some “bolstering” to renew its balance.

In addition to medicine of systematic correspondence references, informants sometimes also use germ theory references in their etiological definitions (i.e., in terms of concepts such as bacteria, viruses, and hygiene), but neither are these concepts used in keeping with their strict WM sense, nor are they viewed as primary agents in the cause of the afflictions just described (e.g., as would be particularly notable from a WM perspective in the cases of colds, influenza, dysentery, parasites, or stomach problems).

Many of the afflictions just outlined are treated by Lijiang basin village practitioners primarily with injections of antibiotics, intravenous infusions of glucose water, vitamins, and/or antibiotics, or tablets of WM pharmaceuticals. Some of the afflictions are treated primarily with Chinese medicine pharmaceuticals (which

are administered through injections or IV infusions as well as in ways more conventional to Chinese medicine). And some of the afflictions are treated with a combination of both WM and TCM pharmaceuticals and techniques.

In all PRC official medical practices, an analytical distinction is made between the theory associated with a given practice, and the materia medica—or pharmaceuticals—associated with a practice. Techniques and substances associated with one practice (e.g., WM) can thus be “detached” and incorporated into another practice (e.g., TCM) without there being a perception that the integrity of a given practice has been violated. This logic also informs the local practice of integrated medicine in the Lijiang basin.

Additionally, when basin village practitioners and lay villagers are asked why they frequently utilize injections and IV infusions (of antibiotics or other substances), they explain that it is important to “bolster one’s health.” Both injections (usually of antibiotics—or, in other instances, of vaccines) and IV infusions (usually of glucose water combined with supplements such as vitamin C or iron or Chinese medicine infusions) are used to bolster the health of depleted bodies. Thus, with respect to the most common afflictions in the basin, WM treatment techniques and pharmaceuticals are being appropriated into an explanatory model primarily informed by a medicine of systematic correspondence discourse.

In addition to the much more prevalent medicine of systematic correspondence afflictions just addressed, village practitioners and lay villagers alike also refer to a number of afflictions that are much less common but that are highly stigmatized and consequently imbued with great symbolic importance. These afflictions include epilepsy, “madness,” “leprosy,” and *gu* witchcraft. The explanatory models used to talk about these afflictions reflect the discourses of two therapeutic practices. The first is the longstanding Chinese therapeutic practice of demonic medicine (Unschuld, 1985), in which are rooted concepts of “dirt,” “pollution,” and the need for the exorcism of malevolent and usually invisible agents. The other influence is WM, from which discourses of germ theory, hygiene, infectiousness, and genetic inheritability have been appropriated. Informants use these same discourses to talk about individuals with non-normative bodies as well.

Epilepsy, for example, is seen as both directly genetically transmitted and infectious. WM notions of germ theory and infectiousness, however, are appropriated into

basin Naxi explanatory models of infectiousness that are rooted in both humoral concepts of “bad air” and demonic medicine concepts of malevolent agents. “Madness” is seen as potentially (although not necessarily) both hereditary and infectious. “Leprosy” (Hansen’s disease) is regarded, again by basin village practitioners and patients alike, as both genetically transmitted and extremely infectious. “Leprosy” has a long historical record as one of the most stigmatized afflictions in China, and continues to be extremely stigmatized. *Gu* “poisoning” a form of witchcraft that was prevalent in the rural basin prior to 1949, was banned as feudal superstition during the Cultural Revolution, and has undergone a gradual resurgence in the villages of the basin since the beginning of the post-Mao period. *Gu* is an affliction that is first described in the demonological literature of the late Zhou dynasty (770–221 BCE) (Unschuld, 1985). *Gu* transmissibility is thus talked about in a discourse of “infectiousness.” It is also talked about in a discourse of genetic inheritability since *gu* cultivation was seen as passed through family lines (usually from mother-in-law to daughter-in-law—Diamond, 1988). Finally, as is the case in clinical and popular contexts elsewhere throughout the PRC, basin villagers with bodies that fall outside cultural definitions of “normality” are highly stigmatized. Should they choose to marry and have children, these individuals are generally criticized by their fellow villagers (including practitioners) and sometimes their own immediate families. The stigma draws upon fears of the inheritability of their disabilities.

While this analysis has been based primarily upon research in the village contexts of the Lijiang basin where the practice of integrated medicine is the prevailing epistemology informing therapeutic practices, it is reasonable to assume that this analysis is also reflective of therapeutic practices throughout much of the rural PRC; it is reasonable to make this assumption given the powerful influence of state policies (including cooperative health care and integrated medicine policies) during the Maoist period, and given that no new health epistemologies have been introduced to replace integrated medicine—notwithstanding the dissolution of cooperative health care as a brigade-based system. Additionally, it is important to note that in the town context of Dayanzhen and in the urban context of Kunming (the provincial capital), there is also a hegemony of Chinese medical epistemologies—most specifically TCM—that prevails in popular culture contexts, despite the institutional division of labor between WM and TCM

that exists in urban contexts; this analysis is probably also generalizable to much of the urban PRC.

Implications for the Spread of HIV/AIDS and Hepatitis B in the PRC

The implications for these findings with respect to the spread of infectious diseases such as HIV/AIDS and hepatitis B are significant. As is the case everywhere in the world, popular culture and medical culture understandings of affliction and of treatment have profound effects on medical and lay responses to epidemics, and this is certainly the case with the emerging HIV/AIDS epidemic in the PRC. The frequent use of needles for injections of antibiotics that are a routine form of treatment in the basin (and elsewhere in the PRC) for many of the common afflictions described above can be a significant risk factor in the spread of both HIV/AIDS and hepatitis B. In the villages of the Lijiang basin as of 1990 (as was likely the case throughout much of the rural PRC at that time), needles were re-used multiple times for injections, with a ceremonious swish of a cleaning solution employed by village doctors between injections. Disposable needles have gradually become common in urban contexts over the past decade and a half, but the sterility of these needles has been compromised by the quality control issues that plague the contemporary PRC (see, e.g., Kristof, 1993).

SEXUALITY AND REPRODUCTION

It is taken for granted throughout the Lijiang basin, in keeping with the rest of the PRC, that the normative practice is to get married and then produce one or more offspring (depending on whether one is an urban or rural resident). In contrast to the dramatically pro-natalist policies of the Maoist period (Potter & Potter, 1990), since the early 1980s in Dayanzhen (as in other urban PRC contexts) the norm that has been strongly enforced by the government is the one-child policy—notwithstanding the fact that the majority of the population in Dayanzhen are classified as “minority nationalities” (a class of individuals who are theoretically exempted from the one-child policy). In the village contexts of the basin, as in other rural PRC contexts (where 80% of the population resides), there has never been a one-child policy. In basin villages that consider themselves more “cultured” and “advanced,” most village families have two children, with

the second child usually spaced two to three years after the first child (fines—sometimes considerable—are levied against those who exceed the two-child maximum or have their second child earlier than stipulated by the birth planning policy). In villages that are farther from the reach of the state, more than two children per family is the norm, and birth spacing is ignored.

In some contrast to other parts of the (Han Chinese) rural PRC—most notably southeastern China—not having male offspring to perpetuate the name of the lineage and to provide insurance of care in one’s old age (as daughters generally marry out) is not considered to be completely devastating to basin families. Both in basin villages and especially in Dayanzhen, young men are frequently sought to marry into a son-less family and have at least one of their children take the surname of their wife’s patrilineage. Nonetheless, the longstanding neo-Confucian ethos of “placing greater emphasis on males than females” does considerably influence the lives of both girls and boys as they grow up in the basin.

Young married women who do not become pregnant are stigmatized (in notable contrast to their husbands) as “without children.” Of particular note in both town and village contexts of the Lijiang basin, the “stopping of menses” (i.e., among pre-menopausal women) is a much-cited causal factor cited by medical practitioners in their diagnoses of (female) infertility. How the basin compares statistically with other parts of the PRC is not clear, but basin practitioners attributed the frequency of amenorrhea to the ethos of hard physical labor and to the limited nutrition of most basin Naxi women.

One of the distinctive characteristics of the Naxi of the Lijiang basin—that is, in contrast to most other parts of the PRC—is the division of labor along gender lines. Even before the post-Mao feminization of agricultural labor in the PRC (Bossen, 2002), village basin Naxi women carried out most of the field labor, and both village and town basin women tend to do virtually all of the physical labor for their families. A Naxi woman’s prestige is based on her ability to labor for her household, as well as to save and manage money for the household.

It is this ethos of ceaseless work that points to a major faultline between Naxi constructions of gender and the normative constructions of deficient female bodies reflected in pre-1949 neo-Confucian informed Chinese medical notions (Furth, 1986, 1987, 1999) as well as in the public health policies of the socialist Chinese state (including both WM and TCM paradigms). On one hand,

Naxi women work in their fields and in their homes everyday regardless of the rain or cold, blatantly ignoring the proscriptions of public health policy. On the other hand, there is nearly universal observance of postpartum “confinement” and special dietary practices among Naxi women in both town and village contexts of the basin (see below). The form and the spirit of Han-derived postpartum practices are observed, but the model of female physiological deficiency upon which this practice is based does not apparently carry over into any of the other practices proscribed by Chinese medical and public health policy.

The model of gender in Naxi society is one in which women are associated with production and men are associated with consumption. Epidemiologically, this dynamic is played out in the basin in the sense that the major chronic afflictions of women are those associated with activities of production. Naxi women, both rural and urban, suffer in highly disproportionate numbers (compared to Naxi men) from rheumatoid arthritis, chronic headaches and other pain, and a condition which they and local practitioners refer to as *shengjing shuairuo*, or neurasthenia (Kleinman, 1986). Naxi men, on the other hand, are plagued by diseases associated with consumption: liver and gallstone or kidneystone ailments from excessive consumption of grain alcohol, heart disease and strokes from excessive consumption of pork fat and meat in general (of which men get choice portions), and lung cancer and chronic bronchitis from excessive smoking. There is also a popular pun according to which the term for “vascular heart disease” is recast as “(government) official heart disease.” This relatively new epidemic is ascribed to the consumption of too much rich food and too much grain alcohol among government officials at state-sponsored banquets (the overwhelming majority of whom are Naxi men).

This gendered division of labor also informs birth planning practices in the basin. As is also the case throughout the PRC, in the Lijiang basin, women’s bodies are the primary objects of state birth planning policies and the objects of the Women’s Federation representatives who monitor them; consequently women in both urban and rural contexts bear the primary responsibility for contraception. Intrauterine devices (IUDs) are the most common birth control technique utilized (approximately 40% of basin women), but many users and practitioners complain of often serious side effects (e.g., infections, bleeding) from these devices. Birth control

pills and Depo-Provera type injections are popular methods in the basin (approximately 30% of basin women); condoms are not. Tubal ligation is also a strategy employed by some basin village women (approximately 20%) after their second child, if they have a hospital birth for this child (hospital obstetricians regularly recommend to their clients that they undergo this procedure during their hospital stays following their second birth). This latter strategy is not a popular one, however, as it is believed to weaken a woman’s health, and vasectomies are rarely considered as a viable strategy for men for the same reason (see Potter & Potter, 1990). Abortion (which is free) is a common strategy of last resort for contraception.

HEALTH THROUGH THE LIFE CYCLE

In keeping with a medicine of systematic correspondence approach, basin residents and practitioners refer to their own body types as either “fire bodies” (intrinsically “hot”), or “water bodies,” (intrinsically “cool”). Additionally, people who are plump are considered to be healthier than people who are thin. Babies’ bodies up until their first birthday are considered to be particularly weak, as are women’s bodies during the first month after having given birth.

Afflictions are seen as seasonal not only in terms of the annual cycle, but also in terms of the life cycle and gender. Village practitioners and lay informants alike usually present afflictions as “children’s diseases,” “elderly person’s diseases,” or “women’s diseases.” These categories of persons (children, the elderly, and women) are considered to be particularly vulnerable to affliction. In the neo-Confucianism-influenced medicine of systematic correspondence, female bodies are constructed as normatively out-of-balance and depleted (not unlike Victorian era women’s bodies). Children in general are considered to be vulnerable, since they “eat too diversely,” are always playing in water (therefore exposing themselves to cold), and do not have a regulated lifestyle. The elderly are presumed to be in a vulnerable state because of their advancing age. These divisions along lines of age and gender would seem to imply, by default, that the teen-aged to middle-aged male represents the normative body, at least in terms of lower inherent vulnerability to affliction. As noted earlier, children’s diseases include colds, coughs, fevers, stomach aches, diarrhea, dysentery, and parasites. Elderly people’s diseases usually include colds, tracheitis and chronic coughs, and rheumatoid arthritis. Older

women in particular tend to be afflicted by rheumatoid arthritis, and post-menarche women of all ages seem to be afflicted with gynecological diseases, headaches, and neurasthenia.

Most babies in the basin are born between October and March, and health practitioners estimate that 80% of births are between November and February. This is because most young people get married during the Spring Festival (the lunar new year), and get pregnant during the first few months of marriage. Virtually all basin women—town and village alike—observe the longstanding Han Chinese tradition of a postpartum period lasting 30 to 40 days (and sometimes as long as 100 days) during which they rest under very proscribed conditions, and are supposed to consume specific “rich” foods.

Malagasy

Janice Harper

ALTERNATIVE NAMES

The people of Madagascar are known collectively as the Malagasy. This chapter is based on fieldwork conducted among the Malagasy living in the southeastern forests of Madagascar who are ethnically identified as both Tanala and Betsileo. Although treated as comparative and mutually exclusive ethnic groups, such social groupings are misleading. Tanala (“People of the Forests”) is a performative identity; those who live in the forests and engage in the forest economy are “Tanala,” whereas Betsileo is an administrative division of the pre-colonial Merina autocracy. Hence, for many living in the southeastern forests of Madagascar, Betsileo represents one’s ancestry, while Tanala represents one’s contemporary social identity. Moreover, ethnic identification is problematic because those so labeled do not necessarily think of

themselves in terms of ethnicity, as much as they do in terms of ancestry or lineage. For further discussions on ethnicity in Madagascar in general, see Astuti (1995), Bloch (1989), Kottak (1971a), and Larson (1996, 2000). For further discussion of the Betsileo, see Dubois (1938) and Kottak (1971b, 1980), and on the Tanala see Beaujard (1983). For further discussion on lineage and ethnicity among the Tanala and Betsileo of the Ranomafana region, see Hanson (1997) and Harper (2002).

LOCATION AND LINGUISTIC AFFILIATION

Madagascar is the fourth largest island of the world, lying like a teardrop in the Indian Ocean, just off the coast of southeast Africa, approximately 400 km from

Mozambique. This geographical isolation from the main continent has contributed to its unique ecological biodiversity, as the island's flora and fauna have evolved independently from the rest of Africa. Despite its ecological diversity, the country is notable for its relative linguistic and cultural uniformity. The official language is Malagasy, originating from a Malayo-Polynesian language, and most, but not all, dialects are mutually understandable, despite significant grammatical differences. Many educated Malagasy also speak French, although this language is rarely spoken or understood in rural villages.

OVERVIEW OF THE CULTURE

Madagascar was first settled by Indonesian and Bantu seafarers in approximately AD 600. Although this human habitation is frequently noted as the chief cause of environmental degradation, less noted is the rich human diversity that has evolved from this settlement. There are now over 15 million Malagasy living on the island, half of whom are under the age of 18, and most of whom live in extreme poverty.

This poverty is related, in part, to the island's geography. A long mountainous terrain extends vertically down the center of the island, making agriculture and transportation particularly difficult in many parts of the island. Thus, agricultural lands, transportation of goods to and from major markets, and access to urban social services, are limited for many of the residents.

Pryor (1990) estimates that due to this topography, along with soil degradation, only 4% of the island is under cultivation. Nonetheless, agriculture comprises up to a third of the country's GDP, employs over three quarters of its labor force, and is the major source of its exports. The principal crops include rice, coffee, vanilla, sugar, spices, cotton, and tobacco. Up to half of the land is irrigated, although swidden agriculture (known as "tavy") is practiced extensively, particularly in the forests of the southeast, where *tavy* rice production is regarded by many as the principal cause of deforestation.

In addition to crop production, livestock and seafood contribute to important sources of domestic and international trade. The industrial sector includes food processing, clothing, textiles, soap-making, mining, petroleum refining, paper production, and tanning. More recently, efforts have been made to expand the island's service economy, most notably in ecotourism, but this objective

is constrained by poor infrastructure, limited public transport and, in more remote areas, few hotels.

Despite its rich resource base, GNP per capita is approximately \$250.00 annually; many have incomes far below this figure, although non-formal economic strategies are practiced widely to augment incomes. This poverty is related not only to the geographical constraints limiting agricultural production and transport, but also to a history of domination and exploitation that have contributed to present social divisions and marginalization.

Madagascar was colonized by the French from 1896 to 1960. Prior to colonization, however, a pre-colonial highland autocracy was established in the late 18th century, known as the Merina Empire. During the reign of the Merina, land was appropriated by the state, forced-labor of men was instituted, taxes imposed, and debtors or their families sold into domestic slavery. These objectives were facilitated by bestowing gifts, titles, and lands on indigenous leaders or others who would promote allegiance to the empire, a policy that furthered state aims to forge ethnic identities. Although the forging of a Merina ethnic identity was effective in the highlands (see Larson, 2000), the empire was never to gain authority over more than a third of the island. Nonetheless, a complex social hierarchy emerged (in varying respects) throughout the island, in which people were categorized not only in terms of ethnic affiliations, but in terms of caste as well, as they became identified as *andriana* (noble), *hova* (free), and *andevo* (slave). Moreover, within these categories there existed a range of social status. These social identities are no longer formally recognized, but they remain as significant markers of identity and status, contributing to contemporary social relations which Campbell (1985) suggests are best understood as impermeable categories of caste (see Bloch [1989] for further discussion on social rank).

Thus, ancestry and lineage are prominent in Malagasy culture as a means of establishing one's history and place in society. Kinship is generally bilateral, with one's ancestry traced through both the mother and the father. In most rural areas, where indigenous cultural practices are strongest, patrilocal residence patterns are the rule, though individual exceptions are common. Women have rights to land, including constitutional provisions (based on indigenous practice) of one-third inheritance. Women are active in decision-making, and men take an active part in child rearing (some areas, such as the southern Antandroy, are more patriarchal than others).

Throughout the 19th century, Lutheran and Catholic missionaries were active in the industrialization of the island, as well as the education of children, becoming exceptionally successful at converting Malagasy to Christianity. Thus, Protestantism, Catholicism, and indigenous belief systems continue to coexist and have fostered pluralistic belief systems that are particularly notable in the indigenous medical system.

By the end of the 19th century, the Merina Empire was replaced by French colonial rule, which replicated in many respects the strategies of the precolonial autocracy, including continued forced labor, taxation, land appropriation, and indirect rule through indigenous power structures. In addition, the French promoted a shift from subsistence agriculture to cash crop production, most notably in coffee, vanilla, and pineapple, with uneven success temporally and geographically. Although French occupation was noted for its intrusive control over the land and people of Madagascar, some practices had favorable results. For example, in an effort to augment the labor pool, maternal and neonatal hospitals were introduced in the early 20th century, which provided biomedical health services to women and infants. In order to limit the spread of infectious disease, manufactured pharmaceuticals were provided, in many cases, gratuitously. These and other health services contributed to improved health status and declining mortality rates, while compulsory education in the French language enabled many people to compete for administrative positions.

The oppressive nature of the colonial government, which was most characterized by its forceful rule over agricultural production and cultural practices, culminated in a peaceful transition to independence in 1960, followed by a period known as The First Republic, led by Philippe Tsiranana. Covell (1987) indicates that this period was effectively rule by a government of minority elites selected and supported by the colonial government, which continued to exert its influence throughout the decade. By 1975, however, the Second Republic was instituted when Didier Ratsiraka took power through a military coup, and promoted nationalist ideals including educating children in the public schools exclusively in the Malagasy language, banning foreign ownership of property, and drastically limiting foreign trade. Ratsiraka's rule was based on a Marxist-Leninist economic philosophy, advocating public ownership of the primary means of production, and conversion of expropriated lands to agricultural co-operatives. At the same time, he borrowed

heavily from the world market to finance poorly conceived national industries that failed to succeed, including soy and flour mills, despite the fact that the Malagasy do not produce soy or wheat. Consequently, notwithstanding his proclaimed resistance to foreign influence, Madagascar became the first socialist country to accept the economic liberalization criteria of the IMF. Structural adjustment policies included the continual devaluation of the Malagasy franc (including by nearly half in 1987), drastic cuts in the social sector such as health care and education, and privatization of industry, banking, and other financial institutions. These policies were aimed at expanding foreign economic investment in the country, but caused rapid inflation, severely limited access to biomedical health care, and contributed to the decline of educational standards in the rural areas (see Hewitt, 1992 on structural adjustment in Madagascar).

Ratsiraka's reign over the people collapsed following the massacre of peaceful demonstrators outside his palace in 1991. In 1993 physician Albert Zafy was democratically elected as president, but by 1996 he was impeached for abuse of power and Ratsiraka elected to return to office, this time as a "humanist ecologist," calling for international investment in the country's ecological resources. The island's species diversity has led it to be regarded as one of the world's "biodiversity hotspots," drawing considerable international aid and attention to its endangered flora and fauna, most notably the many species of lemur that exist no place else on earth.

In 2001, Ratsiraka lost a bid for re-election when the self-made millionaire mayor of Antananarivo, Marc Ravalomanana, narrowly defeated him. When Ratsiraka refused to concede defeat and declared martial law, mass protests ensued, leading to an economic paralysis of the country. A recount of the electoral results was ordered, and Ravalomanana was sworn in as president in May of 2002. The African Union refused to accept the presidency as legitimate and suspended Madagascar from the African Union, leading to a new election in December of 2002. When Ravalomanana clearly won a majority of the votes in the second election, Madagascar was reinstated into the African Union. Ravalomanana has made reducing poverty and inequalities in the distribution of wealth priorities of his presidency, and has continued to endorse the goals of environmental conservation. Toward these efforts, he has called for increasing attention to ecological tourism as a strategy toward economic self-sufficiency among the Malagasy.

THE CONTEXT OF HEALTH: ENVIRONMENTAL, ECONOMIC, SOCIAL, AND POLITICAL FACTORS

While the health of the island's lemurs and other endangered species receive frequent attention in the media and scientific literature, UNICEF (2002) reports that more than half of the population does not have access to safe water (including 15% in urban areas and 69% in rural areas), 40% of infants are moderately to severely underweight, and the infant mortality rate is 95 per 1,000 births, or nearly 10% (with far higher rates in rural areas). For every 100 children born who do live, more than 15 will die before their fifth birthday. For those who survive, life is likely to be short, for life expectancy at birth is a mere 54 years (New Africa 2001).

Illnesses include malaria, which is particularly prevalent in the rural areas, and has been increasing over the last two decades. This increase followed a 20-year decline in malaria, when an eradication campaign begun in 1948 proved to be very effective. Unfortunately, the effectiveness of the campaign led to decreased resistance to the disease. Hence, its return has been particularly devastating, as many Malagasy who cannot withstand the disease die. The United States Library of Congress (2001) reports that in 1985, 6,500 Malagasy died of malaria, increasing to 11,000 by 1987. The decreased resistance to the disease is further exacerbated by increasing malnutrition and parasitical disease.

Parasitical diseases include schistosomiasis (associated with the lack of safe drinking water and inadequate sewage), and chronic infestations of a variety of worms. Kightlinger (1993) found that 97% of residents of the Ranomafana National Park region in the southeastern region of the island were infested with multiple parasites. Other illnesses of concern in Madagascar include tuberculosis, leprosy, cholera, brucellosis, yellow fever, and bubonic plague. Of even greater concern was the prevalence of respiratory disorders and what appeared to be hepatitis. Respiratory disorders prevailed among children and women, and were probably related to both the rapid transmission of infectious disease in the closed quarters of local housing (with five to ten people sharing one to two bedroom houses no bigger than 10 by 20 ft), and the common practice of women cooking over wood burning fires inside their homes with only a tiny window and door for ventilation. In the village where I resided, several adults, both men and women, died following short

illnesses that were locally diagnosed as *fefy*, *tazovony*, or *albumen*. Though having subtle differential diagnostic criteria, each of these illnesses included dark urine, yellowed skin, and swollen abdomens, suggesting that they were probably associated with hepatitis.

Malagasy are the world's greatest rice lovers, consuming more rice per capita than any other population in the world. *Tavy* rice is particularly nutritious, providing substantial protein and vitamins. The typical diet in the rice-growing regions includes two to three meals of rice per day, usually with some form of sauce (*laoka*), typically made of boiled greens. On occasion, rice is consumed with beans and, rarely, beef, pork, or chicken. Protein is also obtained from small fish caught in the irrigated fields, grubs and insects from the forest, and crayfish and eels caught in the rivers. Endangered species, such as tenrec, are also eaten, though consumption of these animals is not common, and more a matter of necessity than choice. Wild boar are also hunted and consumed occasionally. Manioc, cassava, boiled green bananas, and pineapple are additional staples of the forest diet. Beverages include coffee, rice tea, and *toaka gasy*, a locally distilled rum. Tobacco is chewed, primarily by women, as a means of curbing the appetite.

Malnutrition, however, is chronic, and exacerbates other health concerns such as malaria and respiratory problems. During my 14-month residency in a village adjacent to the Ranomafana National Park (1995–96), I witnessed the deaths of 18 men, women, and children (from a population of approximately 180). Of these, several were of small children who were extremely underweight for their ages (see Harper, 2002 for a detailed account of the death of a malnourished child). Villagers reported that in the ambiguously defined past, greater cooperation and exchange enabled less fortunate residents to remain well fed. As economic security declined, there was less willingness to provide food and cash to others, including close relatives. As a result, it was not uncommon to find weakened infants fed only breast-milk and watery rice while their healthier age mates received more substantial diets. Adults, as well, suffered from malnutrition, undoubtedly exacerbated by parasitical diseases, affecting both men and women.

MEDICAL PRACTITIONERS

A wide spectrum of medical practitioners can be found in Madagascar, but access to western biomedical practitioners,

medicines, facilities, and technologies remains extremely limited to most Malagasy, particularly in the rural areas. Indigenous medical practitioners include *ombiasa* (shamans), who may generalize or specialize (in single illnesses, types of illness, or certain diagnostic or divination techniques), birthing specialists, herbalists, bonesetters, and veterinarians.

Ombiasa may be either men or women, though men are more common. The *ombiasa* may be trained from childhood, often learning the craft from his/her parent, or may assume the profession in adulthood. In the case of the latter, it is not uncommon that one's failure to have become an *ombiasa* as intended by the ancestors leads to illness. Upon diagnosis, the *marary* (sick person) accepts the mantle of *ombiasa*, learns the craft through spirit possession ceremonies and the assistance of an elder *ombiasa*, and becomes healed. More common, however, is the apprenticeship of the children or grandchildren of *ombiasa*. From childhood on, the apprentice is taught local medicines, diagnostic techniques, and ceremonial customs.

Diagnostic techniques may be limited to evaluation of physical symptoms, such as skin eruptions, and the prescription and preparation of local plant medicines. When such treatment fails, or the symptom constellation does not conform to a known illness category, or to an illness category regarded as originating in the environment, then other diagnostic techniques are employed to determine the source and treatment of the illness. Such techniques may include divination by mirror, water, seed, or sand. Linton (1933) indicated that divination by water was rare among the Tanala; my own fieldwork indicated that it was very common, perhaps because it was more easily learned by younger *ombiasa* than the more elaborate form of divination by seed, *sikidy* (see Linton, 1933 for a detailed account of *sikidy*). Less common is divination by sand, which involves pouring sand on a wooden tray and making marks in it with a stick.

Ombiasa also consult the ancestors through spirit possession ceremonies. They may either invite the ancestor to possess them, and thus, serve as a conduit through which the ancestor communicates to the living, or they may direct the possession of others. It is common for non-*ombiasa* to become possessed of spirits during such ceremonies, in which large numbers of participants may become possessed. (For ethnographic detail and analysis on spirit possession, see Sharp, 1993, 1994.)

More commonly, individuals with no particular professional standing may specialize in the treatment of a single disease or type of illness, such as an elder woman

noted for being *mahay fanafody zazakely* (knowledgeable about children's medicines). Knowledge of a particular indigenous medicine may also be passed from generation to generation, such as a famed recipe for a measles vaccine made from local plants and chicken parts that I witnessed dispensed to children annually in the Ranomafana region. In many cases, men are the guardians of such knowledge, while women bring with them a more pluralistic medical strategy. This may be because the great variety of ecological niches in Madagascar have created differing native pharmacopoeia. In patrilocal settings, men are able to pass on to their sons the knowledge of their local indigenous medicines, while women, coming from other ecological zones, may bring with them broader knowledge of treating common health concerns. Thus, women's knowledge may be more generalized and innovative, while men's knowledge may reflect greater depth of the local pharmacopoeia available to them.

CLASSIFICATION OF ILLNESS, THEORIES OF ILLNESS, AND TREATMENT OF ILLNESS

While there is a wide range of understandings about illness classification and causation, illnesses tend to be classified as illnesses of God (*Zanahary*), illnesses of the environment, illnesses sent by the ancestors, those caused by witchcraft, and ghost or spirit illnesses. These categories are not mutually exclusive. For example, an ancestor can be displeased, and so send an illness of the environment, such as malaria (*tazo*—fever). It is understood that some illnesses are caused through infection, others through contagion, and still others through interactions with the environment. Nonetheless, if the illness is believed caused by acts of the ancestors, ghosts (*biby*), spirits (of which there are a variety), or witchcraft (*mosavy*), treatment of the symptoms will only lead to the recurrence of the disorder, or the onset of another health problem.

Malaria is prevalent and understood to be brought by mosquitoes. As an illness of the environment, treatment through pharmaceutical medication is preferable, but if not available, teas made from bitter plants are administered. *Hazomafaika* is the tea of choice in this case, but if it is not available, other bitter substances will be substituted. The concept of bitter is clearly associated with fevers, and in some cases over-consumption of bitter substances (such as unsweetened coffee) may be believed to *cause* the fever. When a child falls ill with malaria and

dies, it is generally believed to be the cause of an illness of the environment or of God; if an adult falls seriously ill, it is more likely that other origins of the disease will be considered, such as witchcraft. If several family members fall ill or meet with misfortune, ancestral displeasure or witchcraft may be suspected, in which case, an *ombiasa* will determine the appropriate treatment.

Tazo vony (literally, “yellow fever”), *albumin*, and *fetsy* are diagnostic categories for illnesses associated with yellow palms, yellow eyes, dark urine, and swollen abdomens. Widespread disagreement exists among both *ombiasa* and lay people as to the causation and differential diagnoses of these three illness categories that probably represent hepatitis or other liver dysfunctions. Nonetheless, it was agreed that they were usually illnesses of God, and could not be cured by either indigenous medicines or by *fanafody vazaha* (medicine of foreigners).

Retina biby (“ghost sickness”) is often diagnosed when an illness is sudden, severe, and its symptom constellation does not correspond to any recognized illness category. Diagnosis is made by an *ombiasa*, and treatment, if successful, will require appeasing the offended ghost. *Biby* are considered so powerful, however, that treatment is often unsuccessful and the illness leads to death.

A classic example of an illness of the environment is *hantana* or scabies. *Hantana* is believed to be caused by poor hygiene and is very contagious; the prevalence of *hantana* in the village where I resided was so widespread that it was not even mentioned as a health concern, except when serious infections ensued. The treatment of choice is lindane, which is usually too expensive for most people. When unavailable, a number of plant medicines are used to make herbal infusions that are applied to the skin.

Mental illness is recognized, and the mentally ill are cared for and respected. In most cases I observed, mental illness was attributed to violation of a custom (*fomba*) on the part of the impaired person or his/her mother during pregnancy or while nursing. Ingestion of too much alcohol is believed to cause temporary madness, while smoking marijuana is believed to cause a person to become violent. It is also recognized that addiction to alcohol can occur, in which case the addicted ought never to drink again, corresponding in many ways to generalized views of alcoholism in the United States.

SEXUALITY AND REPRODUCTION

Sexuality is accepted as a natural experience for both men and women, although the consequences of sex, such as

pregnancy at a young age or vulnerability to sexually transmitted diseases, is taken seriously. Single mothers are not stigmatized, although recognition of their economic vulnerability discourages women from being single mothers if they can avoid it. Adultery of both men and women is common, though probably no more so than in the United States, and responses range from passive acceptance to divorce. Women are more likely to be stigmatized for adultery, and may lose their children due to it, while men may be required by local elders (the *fokonolona*—village-level council) to make restitution to their wives (such as providing her with cash or livestock). Homosexuality is practiced with discretion.

The ideal family size has varied throughout Madagascar’s history. Prior to colonization, marriage was often in the mid to late-twenties, and family size relatively small (see Harper, 2002). Colonial policies aimed at increasing the labor-pool included taxing unmarried people and waiving forced labor for fathers of seven or more children. In addition, maternal hospitals were introduced to improve women’s reproductive fitness. All but one of the elder women with whom I lived had given birth in the colonial hospitals; their daughters all gave birth on dirt floors in the home, as access to safe and hygienic biomedical care was very limited (the local hospital lacked both running water and electricity).

Infertility is a grave concern to both men and women, in large part due to the shortage of labor and social support that one would suffer if he or she had no children. An elaborate system of fosterage has developed in response to infertility, and it is not uncommon for Malagasy to adopt the children of their neighbors or kin.

Sexually transmitted diseases are common and have been increasing, and include gonorrhea, syphilis, trichomoniasis, and candidiasis (U.S. Library of Congress, 2001). While the World Health Organization reported that HIV/AIDS cases were so rare in 1993 that it ranked the country as having a 0.0 case rate, by 1997 this rate of HIV had increased to 0.12%, an estimate that USAID reports is probably due to underreporting. Moreover, the rate is expected to accelerate, due to the high rate of other STDs, which include a 35% rate among sex workers and 15% among pregnant women. USAID researchers have found that up to 82% of all women have had at least one sexually transmitted disease, and that in rural areas, 21% of pregnant women had active syphilis. In my own research in the southeastern forest region near the Ranomafana National Park, I found that women were commonly not informed of their husband’s STD infections,

due to a belief that it was a “man’s disease,” that women without symptoms were not infected, and that men taking medication could not infect women.

HEALTH THROUGH THE LIFE CYCLE

Pregnancy and Birth

Birth control is commonly desired by both men and women, although birth spacing is regarded as more critical than curbing the number of children. Nonetheless, ineffective family planning campaigns which have provided only short-term supplies of birth control pills and/or no follow-up care, have led to resistance among Malagasy to participate in family planning campaigns. Concerns that have been expressed include the many side-effects associated with the pills, side-effects which people indicated were particularly aggravating to undernourished and chronically ill women. The use of contraceptive implants is of even greater concern, as follow up care is difficult to access, if it is provided at all.

Abortion is practiced, often with indigenous medicines, but it is highly stigmatized, particularly among those who have converted to Catholicism. Women have been known to accept birth-control pills from family planning agencies, which are then saved and dispensed discretely to women in need of abortions, who take several pills to induce spontaneous abortions.

Women often withhold public disclosure of their pregnancy, letting their swelling bellies announce the coming child. They continue to work up until they give birth if necessary, particularly if farming obligations find the woman hoping that she not go into labor until the harvest is in. When they are no longer able to work, their female friends and kin will assist them. When in labor, a woman is not expected to cry in pain. To do so would indicate weakness. Births usually take place in the home, on grass mats laid on dirt floors, with a fire burning in the home. Elder women assist, generally someone specialized in midwifery skills. When the child is born, it is washed and dressed, its head covered in a knit cap to protect it from entry of malevolent spirits (believed to enter through the fontanel). After it is dressed, it is shown to the crowd gathered outside the door, and quickly brought back inside. The birth of a girl is as joyously celebrated as the birth of a boy.

Infancy

The new mother will stay with the child in the confines of the home for up to 2 months, venturing outside only to relieve herself. This period of confinement has been growing shorter and shorter, as women’s agricultural work must be resumed and the heat of the home may become unbearable (with little or no ventilation or light). I heard several stories of new mothers becoming ill from ghost sickness, requiring them to terminate their confinement early, in order to appease the ghosts.

Women try, if possible, to give birth in their natal home. When this occurs, there will be a celebration to mark the departure of the child and mother from the village, before their return to the woman’s marital residence.

Children are nursed into their second year. They are toilet trained at a young age, often less than a year when diapers are not available. The urine of a baby is considered benign and laughter is the usual response to a child urinating in the home or on an adult. Although women are the primary caretakers of children, brothers, fathers, and grandfathers are very active caregivers, and do not hesitate to hold or watch young infants or children when the mother is unavailable.

Children who are seriously ill or handicapped are loved and cared for, although I did witness several instances of serious neglect of very ill children, with considerable disagreement as to why they were neglected (see Harper, 2002).

Measles are a grave concern for young infants, as is possession by ghosts. *Ombiasa* prepare special amulets for protection. Chronic disorders, such as scabies and respiratory problems, are so ubiquitous that they do not cause much alarm. Indigenous medicines may or may not be used. When pharmaceutical medicines are available, they are used.

Childhood

Children are well loved and cared for in Malagasy societies. Among the forest farmers of the southeastern region, childhood was a time of great joy, imaginative play, and hard work. Children learn at an early age to care for younger siblings, to help their parents with household chores, to labor in the fields, and to go to school. Learning the responsibilities and skills associated with rural living begins early. Children are taught to use large knives in many cases before they can even walk, and once

walking, are quickly taught to master a multitude of household tasks. Gender distinctions are clear. Girls are taught to carry items on their heads and backs, building up their back muscles by carrying blocks of wood or small dolls, with the weight gradually increasing until they are able to carry an infant sibling by the age of 5 or 6. Girls also have small “tea parties,” making small bowls and cups from leaves fastened together with bits of twig, and filled with various seeds, flowers, and leaves. And importantly, girls learn to help their mothers sort beans, and shake and pound rice, before the age of 3.

Boys’ play includes various sporting activities such as fashioning a game of soccer from a grapefruit, or hunting for insects from the forest. Boys chop wood, harvest rice, and learn carpentry skills. They also assist in the care of their younger siblings and cooking if there are no older girls in the home.

Both boys and girls contribute to the household income when necessary by assisting in the rice fields (girls plant, weed, and harvest swidden rice, boys harvest both swidden and irrigated rice, and older boys may help prepare the rice fields). One very common way for children to earn extra income for the household or meals for themselves is by using their slingshots to scare away birds eating the rice fields. Boys use the typical y-shaped sling-shot, while girls use a long macraméd type of slingshot.

Both boys and girls go to school starting at about the age of 6. Education is highly valued, but not always completed beyond the fourth or fifth grades for a number of reasons. The schools in the rural areas are virtually unfunded. What little funding they have goes to such costs as teacher salaries and building repair. Consequently, there are virtually no schoolbooks, and parents must purchase pencils, papers, and any other supplies. Teachers have decades’ old texts to work with, chalkboards without chalk or erasers, and limited educations of their own. In addition, the agricultural needs of a farming community contribute to frequent absences. Schools close for harvest seasons, in many cases children’s labor is needed on the fields for planting season, schools must be closed three days for funerals (during my fieldwork, this meant that the school was closed 18 times in a period of 14 months), and when teachers must hike to the provincial center for their monthly paychecks, schools may have to close. (Another factor contributing to the closing of the school in the village where I worked was the simultaneous birth of both teachers’ babies, leaving the school closed for nearly 2 months while the teachers convalesced.)

The period of childhood generally lasts until the early teens, when an adolescents’ growing independence and sexuality take hold.

Adolescence

Boys are circumcised from the ages of about 4 to 14. Circumcision is based more on availability of the circumciser than any culturally ascribed time period, although this may have been otherwise in the past, or may differ in other regions. I witnessed one circumcision ceremony, in which all uncircumcised boys over the age of about 4 were publicly circumcised in an unannounced ceremony. Following circumcision, they were given *toaka gasy* to drink and set down on the ground. Every boy thus circumcised developed serious infections, requiring the use of antibiotic creams and, in some cases, oral antibiotics (requiring the father and the infected boy to hike an hour and a half over the hilly terrain to the nearest hospital to get a prescription for antibiotics requiring a substantial portion of the household income).

Adolescence is a period of increasing responsibility and preoccupation with the opposite sex. Girls go to the market every week, in hopes of meeting a boy from another village. Boys also attend markets, and in many cases, begin drinking. Alcohol use and abuse can become a serious problem at this stage. Drinking, and sexual promiscuity, is a concern among a number of parents who regard these habits as new and potentially destructive to both the family and the culture, although it is unclear how new such habits are.

Many girls are mothers by their mid- to late-teens, and if they are unmarried, they remain in their natal household and receive considerable support from their families. Nonetheless, economic hardships are common, and adults recognize early pregnancy as increasing a daughter’s economic vulnerability.

Adulthood

Domestic abuse does occur, but a woman is not expected to endure it. Should her husband abuse her, the community will support her and the *fokonolona* (village-level council) may intervene. Nonetheless, divorce may well have significant economic repercussions, leading a woman to endure an unhappy or abusive marriage despite its unacceptability. Divorce means that a woman is expected to return to her natal village. Although she will theoretically have rights to one third of her parents’ land,

the reality is that land shortages have led most farming families to intensifying production on lands they hold. Thus, a woman may well return home to find that “her” land is being farmed by her brothers, themselves likely to have limited land, and she cannot just reclaim it. Many women protect themselves from just such an event, by continuing to farm their land after marriage, returning frequently to their natal villages and enlisting the help of family members in agricultural production in exchange for giving them a share of the crops. In this way, a woman is able to augment the income of her own household income, and maintain her rights to her land in the event of divorce or the death of her husband.

For a woman to divorce, she must also accept the loss of custodial rights to her children in many cases. Although most groups in Madagascar recognize bilateral kinship, acknowledging one’s ancestry through both the mother and the father, because children are important sources of labor, their custodial care remains with the father upon divorce, regardless of cause. A woman may take a nursing infant, but she is expected to return him or her to the custody of the father upon weaning. Visitation rights are generous and accorded both parents. In cases of child abandonment by a father (frequent with fathers, but rare in the case of mothers), a mother will retain custodial rights.

While access to medical care does not prioritize one gender over another, both men and women face limited health care options. Thus, chronic illnesses often become naturalized and suffered without complaint or treatment. Women are more likely to suffer respiratory disorders, which may well be related to cooking over wood fires in homes with little ventilation. Women also suffer serious back problems, related to the planting and weeding of rice that requires them to be bent over for several hours a day. In terms of nutrition, men may well eat more, but their rights to food are not considered a priority over women’s. Women will be the first to wake in the morning, however, to prepare the morning meal and fetch water from the river, and the last to end work after washing the dinner dishes in the river.

The Aged

Age is regarded with considerable respect, and is considered a time when one’s work in the fields is expected to give way to domestic responsibilities. Older people are important to the household economy by caring for children, cooking, cleaning the home and compound, and

providing important medical care, such as finding and preparing indigenous medicines. More recently, elder people have often had to continue working in the fields for wages, if their children have died or left the village, or otherwise failed to care for them.

Elders are also important to the community as members of the *fokonolona* or otherwise contributing to important community decisions. Their views and wishes are regarded with respect and to defy the wishes of an elder is highly stigmatized. More recently, economic stratification has increasingly replaced the stratification that comes with age, as elders complain of having little voice in community matters that more prosperous but younger adults rule on.

Although it is not uncommon to hear of people living to be 115, 120 years (age often being a guess), as people age their health problems increase significantly. Unfortunately, with their increasing health needs, they also face decreasing access to health care. The older they become the more difficult it becomes to cross rugged terrain to reach public health facilities. Thus, elders living in rural areas must rely on traveling health professionals, if there are any (which are rare), indigenous medicine, or the pharmaceutical medicines younger adults bring to them.

While one’s eyesight fades, in villages with only candles to light the night, there are no eyeglasses. Hearing aids are available only to those with the money, and who live or have access to larger cities. As arthritis sets in, it becomes more difficult to squat to urinate or defecate, or to cook over an open fire or get up from the floor where one eats and sleeps. As teeth are lost, there are no dentures to replace them. Thus, aging may bring greater respect, but it is also likely to bring greater pain and discomfort in carrying out the days’ activities. It is also likely to bring economic hardship, particularly with the death of a spouse (elder women are not expected to leave the community upon the death of a spouse, but are more likely to remain in the household of a son).

Dying and Death

When a person is dying, the extended family is notified and the family prepares for their arrival. They will sit with the *marary* (sick person), caring for them, and visiting with kin. Women provide greater care, but if the dying is a man, male relatives will assist with personal needs. Upon death, the community will gather outside the home, and women will wail loudly, a wailing that continues for several hours.

A child's death is regarded as a great tragedy. In many cases, however, the likelihood of a child dying is so great, that it is met with dignity and stoicism, but little outward grief (aside from the wailing that announces the death). The older a child is, or the younger an adult, the more profound the grief.

Upon death, a body will be cleaned by the same-sex kin of the deceased, and then wrapped in clean *lamba* (cloths). If a married woman, her body will be wrapped in grass mats and carried by men to her natal village, where her kin will carry out the remaining preparations for burial. Men will go to the forest and chop down a tree, which will then be stripped of its bark and hollowed out. While this is being done, the *maty* (deceased; the term also means "dead") is wrapped in grass mats and taken to the *trano-be* (literally, "big house" used for ceremonial and communal purposes). Women will attend the corpse throughout its rest in the *trano-be*, fanning flies from its face and guarding its soul. Both men and women, girls and boys, will visit to pay their respects. All non-essential work duties cease for three days.

(Cows are sometimes sacrificed at this point, if affordable, but economic hardships, at least in the village where I conducted my research, have made such sacrifices rare.)

When the coffin is prepared, the *maty* is wrapped in clean cloths again (the body fluids having soiled the corpse), and placed in the coffin. On the third day (or longer if the family has not yet arrived from other villages, although the decay of the corpse is rapid and its internment encouraged), a funeral is held. The village gathers outside the *trano-be*, a *kabary* (public speech) is recited in honor of the dead, and the offerings made from the various households are publicly listed. The coffin is then brought out of the *trano-be*, and placed over burning embers, in which vines have been smoking. The vines are then wrapped around the coffin and tightly tied, the *kabary* continues, and the coffin is then carried into the forests, along with a burning ember (to provide warmth to the *maty* in its afterlife) where it will be interred in caves (based on lineage). As the coffin is taken away, the crowd follows, while the embers are stamped out, placed onto a grass mat, and all the soiled mats and *lamba* added. They are then wrapped up and tightly bound with the vines, and taken away to a sacred spot. Failure to follow this custom may lead to death from ghost sickness (see Harper, 2002 for an account of such a death).

As the coffin leaves the village boundaries, it is carried high overhead where it passes over the crouching

figures of the children (if any) of the deceased. In this way, it blesses their lives before departing.

Grief is expressed with loud displays of sobbing and fainting among the children and women at this point. In some cases, the tears immediately give way to festive partying, in other cases, a deep sadness permeates the village which then prepares to feed the mourners and visiting families.

Malays

Ronald Provencher

ALTERNATIVE NAMES

There are no alternative names for Malays, but many Malays have sub-ethnic and regional identities based primarily on descent, dialect, customary ritual, and typical foods. Such identities are prefaced in conversation by the word *orang* (person), for example: *orang bugis*, *jawa*, *johor*, *kedah*, *kelantan*, *minang*, *patani*, or *selangor*. *Melayu* means “Malay” in the Malay language, the paramount trade language of Southeast Asia for centuries. It was the name of a seventh century AD trading state on the Jambi river in Sumatra, near the Straits of Melaka. The royal family of the port city of Melaka, which claimed descent from the Jambi monarchy, was among the first to convert to Islam, an effective foil against conversion of common people to the Christianity of European colonial regimes. From that time, converts to Islam who could speak Malay, whatever their natal ethnic identity, were said to have become Malays (*masuk Melayu*).

Who are the Malays? In Malaysia, according to federal law and everyday usage, the term “Malay” applies to anyone who habitually speaks Malay language and is a Muslim. Malay has been the primary language of commerce and the lingua franca of the Malayan Archipelago (modern Indonesia, Malaysia, southern Thailand, and Brunei) for many centuries because of the dominance of Malay speakers in trade.

LOCATION AND LINGUISTIC AFFILIATION

There are large populations of Malays in Malaysia, Singapore, the independent Malay nation of Brunei in northern Borneo, and in the southernmost provinces of the nation of Thailand (Pattani, etc). Other significant populations of Malay speakers live in many areas of Indonesia (especially in Sumatra, north coastal cities of Java, and Indonesian Borneo). Malay is the official national language of Malaysia, Indonesia, and Brunei; and one of the official languages of Singapore.

Malay language belongs to the Western Malayo-Polynesian sub-group of the Austronesian family of languages, which includes closely related languages spoken in Madagascar, Vietnam, the Malayan peninsula, island Southeast Asia, and western Micronesia (Bellwood, 1985, pp. 107–108). Most scholars believe that present-day Indonesia (particularly Sumatra) was the original homeland of speakers of Malay language.

Malay language has several registers (levels of sophistication of vocabulary and grammar) and a number of regional dialects. Regional dialects of the everyday register of Malay commonly coincide with sub-ethnic identities, and other languages and cultures closely related to Malay have been strongly influenced by it. For example, the everyday language of the Minangkabau of western Sumatra (in Indonesia) and of the Minangkabau

in the state of Negeri Sembilan in Malaysia are dialects of Malay.¹

OVERVIEW OF THE CULTURE

Modern Malay culture, like other complex cultures of the present, has absorbed much from neighboring civilizations, which in turn borrowed from Malay culture. As a particular civilization, it is at least as old as existing European cultures. Malay traders were probably involved in the maritime trade between East Asia and South Asia by the first century AD. Four centuries later they were described as long distance traders in Persian court literature. Malays may have sailed as far as the East African coast by that time. They traded luxury goods and ordinary commodities. Through a period of twenty centuries, as they interacted with other Southeast Asian, South Asian, East Asian, Middle Eastern, African, and European peoples (especially Portuguese, Dutch, and British) involved in long distance trade, they borrowed and adapted aspects of these other cultures. The result is a very complex culture and society that has long included urban as well as rural elements.

Probably, the beginnings of this civilization were based on the cultivation of irrigated taro (*keladi*) and rice (*padi*) combined with river and coastal fishing and trade, economic activities still pursued by many. Chiefdoms developed at junctures of large rivers with the ocean, and strong chiefdoms conquered weaker, leading to the development of small states. As Malay kingdoms came into contact, through trade and warfare, with states of greater scale they absorbed knowledge of “world religions” such as Hinduism, Buddhism, and later Islam. Traditional Malay medical knowledge bears the imprints of all three of these world religions (especially in representations of spirits, curing rituals, word charms, healing prayers, sacred numbers, and therapeutic objects). Traditional medical knowledge also retains older, aboriginal elements such as the concepts of soul substance (*semangat*), and of intrusion of a foreign soul (*badi*), or loss of one’s own soul (*jiwa*) as causes of illness and death.

At the beginning of the 16th century AD, first the Portuguese and then the Dutch and English colonial regimes pressed European ideas about health upon the Malays. Those ideas, of course, were not clearly superior to those of traditional Malay medicine of that time. European medicine was still based largely on the humoral

concepts of Greco-Islamic medicine (itself previously introduced to Malays by Arab traders) and certainly not those of modern cosmopolitan medicine, which was barely in its infancy. Cosmopolitan medicine came into being gradually, not becoming nearly what it is today until the beginning of the 20th century AD. It became available to colonial subjects in the Malayan Peninsula and the Indonesian Archipelago in small steps, about the same time that it became available to Europeans.

Colonial regimes promoted the continuation of Malay as the language of commerce and public communication. Many different kinds of people, with different languages and variations in medical beliefs, had become Malays by the beginning of the 20th century. Descendants of Indonesian immigrants to the Malayan Peninsula, such as the closely related Minangkabau as well as the more distinctive Bugis and Javanese, eventually accepted being members of that broader ethnic category used by colonial officials—“Malay”. They took advantage of economic prerogatives, such as privileged access to land reserved for Malays. As members of the Malay communities they had joined, they contributed stories of health, illness, and curing appreciated by their Malay neighbors, adding to and reinforcing present-day Malay traditional medicine, which coexists with cosmopolitan medicine.

One result of the intensity and duration of relations with many other civilizations over a period of many centuries was the development of a traditional medical pharmacology, comparable to traditional Chinese pharmacology, too extensive and complex to begin to describe in an article of this length (Gimlette, 1971, p. 207).

THE CONTEXT OF HEALTH: CULTURAL, ENVIRONMENTAL, ECONOMIC, SOCIAL, AND POLITICAL FACTORS

The natural environment is not well reflected in traditional Malay medicine. Traditional Malay folklore does not glorify human settlement in the rainforest or jungle.² Very few houses in rural communities are isolated. They are usually within voice distance of neighboring houses, clustered in a hamlet, itself one of several hamlets connected by roads or broad trails to a central mosque (*masjid*) and school (*madrasah*). And/or the houses are within sight and hearing of their neighbors and clustered along highways, riverbanks or seacoast. Rural Malays

prefer to be in their houses by nightfall. And given a choice, many prefer to live near or in market towns and cities. A young man should travel (*merantau*), usually to urban places, in order to gain experience before beginning a family. And if possible, every Malay should travel to Mecca at least once in their lifetime. Malays have been deeply involved in trade and urban places for centuries.

Basic concepts of health and illness in Malay culture have many origins. Some are clearly aboriginal and ancient. The concept of *semangat* ("soul substance"), for example, is clearly related to *mana*, *mano*, *manu*, etc. in many other Malayo-Polynesian languages of Southeast Asia and the islands of the Pacific Ocean. In these cultures, absence or loss of soul substance and intrusion of soul substance of another being are believed to be major causes of illness, especially mental illness.

Humoral and sensual concepts relevant to health have native Malay terms (*angin*, "air" or "wind"; *panas*, "heat"; *sejuk*, "cool"; *kotor*, "dirty"; *bersih*, "clean"; *manis*, "sweet"; *asam*, "sour"; *pahit*, "bitter"). These conceptual foci have been reinforced through early and continuous contact with other societies participating in the ancient long-distance sea trade involving China, South Asia, the Middle East, and the West. Some pre-modern aspects of medical knowledge systems, especially humoral concepts, from these other culture areas have merely reinforced native concepts.

Major themes in Malay culture are strongly reflected in traditional medicine. These themes include profound enjoyment of the details of: (1) food and drink; (2) registers (vocabulary and grammatical levels) and dialects of Malay and related languages; (3) systems and levels of courtesy in their own and other social systems; and (4) one's own social rank compared to others. One's rank vis-a-vis others depends upon such factors as relative age, ancestry, wealth, and authority in the community. This emphasis on expressing differences in rank has become more complex as Malays have become part of the modern industrial world. Basic consciousness of rank is embedded in sibling kinship terminology, in which gender is not noted in the term for younger siblings, but is noted in the terms for older siblings: *adik* for younger brothers and sisters; but *abang* for older brothers, and *kakak* for older sisters. Age is respected through use of a gender-specific term. Respect is good, but being the eldest of one's siblings often involves serious psychological trauma. Generally, a Malay baby is born into a world of adoring adults, and is spoiled by adults until entering

school, where the child first meets serious discipline from adults. Male children are more spoiled than females, who by the time they enter school are already involved in responsibilities for the whole household. Also, the first-born baby (*si long*) is fussed over and spoiled in ways that subsequent children are not. Nonetheless, the firstborn is, at a tender age, given responsibility for the younger siblings who have replaced him or her in the immediate affections of adults in the family. These family lessons concerning rank and its problems mark the lives of most Malays, because kinship terms are used in the everyday register of Malay language as seniority terms to address and refer to non-relatives in the community and workplace. Symbols of social rank are commonly important parts of curing rituals, where they are combined with symbols of "inappropriate" or "contaminated" food and social relationships.

Food and drink are connected to social relationships in all societies, of course. But the connection in Malay society is especially strong. Malays have an intense interest in food and drink. Their cuisine is enriched with fresh spices and many kinds of tasty vegetables and fruits. Rice is served not by the cup but by the plate. Malays routinely eat Hindu vegetarian and Muslim Indian foods, and they occupy most of the tables in Chinese Muslim restaurants. At the same time, an overwhelming majority of Chinese Malaysians are not Muslim, their food and drink are not *halal* (ritually pure), and they are viewed by many Malays as economic and political competitors. Malays love Western "junk" food, and eat at franchise restaurants that serve *halal* (ritually pure) versions of burgers and fried chicken. But more important are the traditional feasts (*kenduri*), which mark the major social events in everyday life: birth, coming of age, marriage, death, economic and social advancement, and the many Islamic holidays.

The greatest feasting occurs at the end of the Fasting Month (*Ramadan*) which is the annual celebration of God's greatest gift, the Holy Koran. Most individuals visit the homes of their parents, other relatives, neighbors, and friends. There, they feast on arrays of the great delicacies of Malay cuisine. They, too, in their own homes, must host relatives, friends, and neighbors. Hours are spent preparing and consuming food and drink. The monthlong fast that precedes this ceremonial weeklong feast is not absolute, of course. It is a fast (*puasa*) that begins with the first daily prayer (just at first light in the morning) and ends just after sundown each day of the

month of Ramadan. Evenings, into the early morning hours, are spent drinking iced sweet drinks, eating especially tasty foods, and performing and listening to the message and beauty of Koranic verses. Very few people lose and many gain weight during the fasting month.

Social rank, ritual, manners, and food are closely linked every day of the year. Traditional houses have formal “front regions” where guests are received and where rank behavior is celebrated. When a guest enters the front region (a verandah or front room), something should be offered, even if only water. The higher the rank of the visitor relative to that of the householder, the more elaborate the offering. Verbal greetings, gestures, and postures signal degrees of difference in social rank. The more formal the occasion or circumstance the more likely appropriate gestures and postures will be displayed by junior persons. The highest-ranking persons in social situations are not really required to perform the gestures and postures of rank courtesy, which is the work of persons of lower rank. Close friends and relatives come to the back door, the kitchen, a place of incredible informality.

Formal occasions are accompanied by formal serving of drink and food, by servers of low rank. Such feasts, although occasions of immense pleasure, are fraught with danger, because as a celebration of rank differences as well as a celebration of food, it is a “natural” setting for crimes of sorcery and affection magic through food (*santau*). Usually, the actual purpose is to make people incredibly fond of you, not to harm them.

Food and drink can be used to control individual behavior. A woman can force a man to be sexually attracted to her by adding word charms and her vaginal fluids to the rice that she cooks for him (*nasi uap*, “perfumed rice”), and a merchant can influence a customer to buy from him, even though his goods are bad and costly, by slipping a chemically potent and be-spelled concoction (*santau*) into his meal or drink. Illness or even death may result, but the intention is simply control over the customer.³ It is the responsibility of the host of a ritual feast (*kenduri*) to be certain that the cooks are clean (*bersih*), which includes the notion of good intentions toward guests. Guests routinely ask who the cooks are.

The Islamic requirement of religiously pure (*halal*) food and drink is a common and deep concern, which is strengthened by the presence of a large population of non-Islamic Chinese that is economically dominant and politically competitive in Malaysia, and simply dominant in Singapore.

There are other concerns about food and drink. Children’s illnesses, for example, are often attributed to their excessive appetite for “cooling” (*sejuk*) foods, especially soft fruits, and slightly sweet and weakly acidic iced drinks. Western friends are routinely warned not to eat durian, a “heating” (*panas*) fruit, while consuming alcoholic beverages, which are not only “heating,” but also forbidden (*haram*) by Islamic law.
